A trial is under way in Toronto comparing interpersonal psychotherapy with the short-term psychodynamic therapy of Lester Luborsky in 72 patients with dysthymic disorder with or without major depressive disorder (double depression) for 12 weekly sessions followed by 4-month monthly sessions. Initial results of interpersonal psychotherapy indicate that most patients reported a reduction of symptoms. The authors found that dysthymic disorder patients responded to interpersonal psychotherapy just as did patients with major depressive disorder, but that because of the longstanding nature of their illness, patients with dysthymic disorder were more difficult to treat.

Bipolar Disorder E. Frank and colleagues in Pittsburgh are assessing the benefits for patients with bipolar disorders of adjunctive interpersonal psychotherapy modified by social zeitgeber theory—behavioral scheduling of daily sleep patterns—as maintenance treatment of lithium-stabilized bipolar disorder patients. Comparing bipolar disorder interpersonal psychotherapy with medication alone, the 3-year maintenance treatment study will initially include biweekly interpersonal psychotherapy visits, tapering to monthly sessions in the final 2 years.

Substance Abuse and Dependence Interpersonal psychotherapy has not been shown to be effective in two clinical trials with substance abuse patients. One study, complicated by high attrition, found no benefit in reducing psychopathology for adjunctive interpersonal psychotherapy added to standard treatment, compared with the standard program alone, for 72 methadone (Dolophine) maintained opioid abusers. The same team in a separate trial found 12 weeks of interpersonal psychotherapy ineffective and marginally worse than behavioral treatment for 42 cocaine abusers attempting to achieve abstinence. The two negative studies suggest limits to the utility of interpersonal psychotherapy but do not necessarily doom its use for substance abuse. For example, interpersonal psychotherapy might be useful for newly abstinent, recovering alcohol-dependent patients, who face numerous psychosocial stressors that precipitate relapse.

Bulimia Nervosa Christopher Fairburn and coworkers altered interpersonal psychotherapy for two studies of bulimia nervosa patients. They used fewer, differently scheduled sessions, primarily to allow comparison with cognitive-behavioral therapy. Except during the assessment phase, when a history of the eating disorder is taken, the content of the interpersonal psychotherapy approach resembles that for depression. Discussion of the patient's eating disorder is avoided during the course of treatment. In fact, interpersonal psychotherapy therapists were instructed not to let talk of bulimia nervosa continue for more than 10 seconds before refocusing the patient on interpersonal issues.

Thus unlike interpersonal psychotherapy for depression, which emphasizes a medical model of depression as illness, interpersonal psychotherapy for bulimia nervosa

actively avoids the diagnosis. This makes clinical sense; depressed patients tend not to focus on depression as an illness, typically confusing it with their personal failings, whereas bulimia nervosa patients are all too symptomatically aware and tend to talk of nothing else. It may help bulimia nervosa patients to shift focus from their symptoms to address their current life situation, stressors, and interpersonal interactions.

The initial study randomized 24 patients to 19 sessions of either cognitive-behavioral therapy or interpersonal psychotherapy over 18 weeks and demonstrated the comparability of the treatments. In a second study, 75 patients with bulimia nervosa were randomly assigned to cognitive-behavioral therapy, interpersonal psychotherapy, or behavioral treatment for 19 sessions over 18 weeks, with a 1-year follow-up. Few patients in behavioral treatment ceased binge eating and purging. Patients in cognitive-behavioral therapy and interpersonal psychotherapy made equivalent, substantial changes across all symptom domains, with interpersonal psychotherapy taking longer to achieve its effects.

A 6-year follow-up study was conducted of 99 patients from both trials. Patients who received behavioral treatment did poorly (86 percent still had an eating disorder), whereas those who received either interpersonal psychotherapy or cognitive-behavioral therapy had better prognoses: 28 to 37 percent met eating disorder criteria. The authors are now experimenting with interpersonal psychotherapy supplemented by a cognitive-behavioral therapy self-help program for bulimia nervosa. A replication study is comparing cognitive-behavioral therapy and interpersonal psychotherapy in bulimia nervosa at Stanford and Columbia in collaboration with investigators at Oxford University and Rutgers University.

Group Format for Bulimia Nervosa Drawing on the work of Christopher Fairburn, Denice Wilfley and coworkers modified interpersonal psychotherapy in a 16-weekly session group format and compared it with group cognitive-behavioral therapy and a waiting list control for 56 women with nonpurging bulimia nervosa. At termination, both group interpersonal psychotherapy and cognitive-behavioral therapy significantly reduced binge eating, but the waiting list did not. These results persisted at 1-year follow-up. A randomized clinical trial of 162 women is now comparing group interpersonal psychotherapy and cognitive-behavioral therapy for 20 sessions over 20 weeks. The initial phase of interpersonal psychotherapy, in which the problem area is identified and the interpersonal psychotherapy concepts and contract presented, is conducted individually. Groups meet for 90 minutes.

Anxiety Disorders The interpersonal aspects of social phobia make it a natural starting place for testing interpersonal psychotherapy as a treatment of anxiety disorders. Interpersonal psychotherapy is being modified for social phobia independently by Joshua Lipsitz at Columbia University and Stuart and O'Hara at the University of Iowa. Open trials are in progress at both sites. Lipsitz, having completed 9 pilot cases, reports that the standard interpersonal psychotherapy ingredients, including the medical model, provision of the sick role, and the supportive therapeutic stance, clearly appear to benefit most patients. The interpersonal formulation, linking anxiety symptoms to interpersonal context, appeals more to some patients than others. For example, a patient with prominent blushing insisted her social anxiety was due to the blushing and unrelated to her interactions with other people or her ability to express emotion freely. Interpersonal psychotherapy seemed to help, nonetheless.

Many social phobic patients present in role transitions: geographic moves, career changes, change in family constellation due to separation from significant others, or the onset of a major illness. Social anxiety may increase in intensity or may simply pose a greater problem in the context of these transitions.

Because social phobia often has an early onset and chronic course, lacking acute precipitants, Lipsitz borrowed an approach from the work of the second author on interpersonal psychotherapy for dysthymic disorder. Providing the medical model of social phobia, offering reassurance that the patient has a disorder that is treatable, and instilling hope for change, the therapist initiates a therapeutic role transition. Patients recognize shyness, passivity, and social awkwardness as symptoms of a disorder, rather than their true personality. This formulation creates a positive stressor that serves as a frame for exploring current interpersonal experiences (“It sounds like you can be quite assertive with your staff now that you're not letting the social phobia get in the way”).

Lipsitz has categorized as “role insecurity” subtler role difficulties than those defined by role deficit—lack of assertiveness, conflict avoidance, difficulty expressing anger, rejection sensitivity—often seen in social phobic patients. This formulation emphasizes the patient's potential for more-competent behavior once social phobia is mitigated. Role playing may be helpful in teaching or reinforcing social skills.

Stuart notes two groups of socially phobic patients: those with avoidant features who desire relationships but have difficulty maintaining them and those with schizoid traits who want to minimize social interactions. The latter seek treatment only when circumstance requires them to interact more frequently; for example, a librarian with no psychiatric history who sought treatment upon receiving a promotion. Her new job required supervising other employees, whereas before she had contentedly shelved and catalogued books with minimal social contacts. Addressing this as a role transition helped her through the acute stress, although Stuart was skeptical of the long-term benefit of treatment.

Social Phobia in a Group Format Weissman and Bonnie Jacobson have adapted interpersonal psychotherapy in a group format for patients with shyness. The patients had social phobia in unstructured interpersonal situations (e.g., parties, intimate discussions with significant others) but not in defined work situations. Most patients were highly successful in professional or business careers despite their phobias.

The 10-session, time-limited group focused on defining and describing the diagnosis, giving the patient the sick role, and finding practical strategies for dealing with shyness in specific situations (e.g., developing scripts to initiate a more personal conversation with an estranged father, or a discussion with a spouse about having a baby). As noted by Lipsitz, the chronicity of the disorder led to a focus on a therapeutic role transition from an impaired to a less-impaired state. The group format seemed to provide a safe haven in which patients could interact with others who had similar symptoms.

Panic Disorder A manual for interpersonal psychotherapy in panic disorder is being developed by Arzt and Meriam van Rijsoort in Maastricht, the Netherlands.

Other Axis I Disorders David Veale in London is conducting a 15-week clinical trial comparing cognitive-behavioral therapy with interpersonal psychotherapy for patients with body dysmorphic disorder and a preoccupation with an imagined defect in appearance that causes distress in social functioning.

George Ikkos has modified interpersonal psychotherapy to manage patients with chronic somatization in primary care. This adaptation adds a fifth problem area, the patient's relationship with health professionals and the pursuit of medical care. The interpersonal psychotherapy medical model works readily with these patients because of their inappropriate use of the health care system. Treatment seeking is reconceived as an interpersonal issue. These patients are easily recruited for interpersonal psychotherapy treatment; however, 12 sessions may be insufficient to engage patients and develop a working alliance. Therapists emphasize that they are not trying to modify the patient's experience of pain, but to help the patient deal more effectively with the problem. An open trial of 20 to 30 patients is planned.

Borderline Personality Disorder Interpersonal psychotherapy has been adapted for patients with borderline personality disorder. The focus in the initial phase is on assessment of symptom patterns related to the disorder, such as anger and impulsivity in interpersonal relations. A fifth problem area, self-image, has been added to address the identity disturbance that is central to borderline personality disorder. Telephone contact is used during crises but not encouraged in lieu of regular scheduled sessions. A pilot randomized trial on 24 patients is under way comparing 12 weekly sessions of interpersonal psychotherapy with relationship management therapy, with monthly follow-up for 6 months. The trial uses a sequential treatment/therapist crossover design to control for therapist effects.

Initial results show lower attrition in interpersonal psychotherapy (10 percent) than in the control group (50 percent). Comparison of prescores and postscores of patients in interpersonal psychotherapy with borderline personality and those with dysthymia or double depression found similar and significant symptomatic improvement on self-report scales across diagnostic groups. It will be interesting to see whether time-limited psychotherapy alleviates a time-resistant disorder such as borderline personality.

Other Disorders

Insomnia A modification for interpersonal psychotherapy for patients with insomnia has been developed by Elizabeth Schramm in Hamburg, Germany. This research arose from the observation that insomnia is often associated with stressful interpersonal life events. The approach emphasizes management of insomnia and regularizing social rhythms adapted from work with bipolar disorder patients. The initial phase presents information on sleep hygiene and rhythm, and patients keep a sleep diary.

Metastatic Breast Cancer Interpersonal psychotherapy is being delivered over the telephone to housebound patients who have metastatic breast cancer by the group at Memorial Sloan-Kettering Cancer Center in New York (see below). A similar study is under way at Clarke Institute, Toronto.

Post-Myocardial Infarction S. Stuart has modified interpersonal psychotherapy for patients with depression after myocardial infarction. The adaptation includes careful initial medical evaluation to ensure that symptoms of insomnia, anergia, and other vegetative symptoms represent clinical depression rather than cardiac illness. Stuart notes that care must be taken to ensure that the physical symptoms exceed those expected during this time period. Medication monitoring must ensure both that cardiac medications are not producing adverse psychiatric effects and that psychotropic medications do not have adverse cardiac effects.

Interpersonal psychotherapy confronts grief over loss of the healthy state, struggles with mortality, remorse over past unhealthy behavior, and the effects of the illness on marital relations and work. Another theme is being forced into the role of receiving care after a life of independence. The authors note that no other trials of counseling with post-myocardial infarction patients have focused on depression. They report that although these patients acknowledge depression, they often politely refuse psychological intervention, even if treatment is labeled “stress reduction” or “coping skills.”

Interpersonal Counseling Many patients presenting to primary care practices report psychiatric symptoms but do not meet full criteria for a psychiatric disorder. These symptoms can be debilitating and result in fruitless, expensive workups and high utilization of medical procedures. Interpersonal counseling based on interpersonal psychotherapy was designed for distressed primary care patients who do not meet syndromal criteria for psychiatric disorders. Interpersonal counseling is administered by health care professionals, usually nurse practitioners without formal psychiatric training, for a maximum of six sessions. The first session can last as long as 30 minutes; subsequent sessions are briefer.

Interpersonal counseling therapists assess the patient's current functioning, recent life events, occupational and familial stress, and changes in interpersonal relationships. They assume that such events may provide the context in which emotional and bodily symptoms occur. Some 128 patients presenting to a primary care clinic and scoring 6 or higher on the Goldberg General Health Questionnaire (GHQ) were randomized either to interpersonal counseling or to usual care without psychological treatment. Over an average of 3 months, often involving only one to two sessions, interpersonal counseling subjects showed significantly greater symptom relief than controls on the GHQ, particularly improvement in depressed mood. Interpersonal counseling led to greater use of mental health services by patients newly attuned to the psychological source of their symptoms.

Subsyndromally Depressed Hospitalized Elderly Patients Observing that depressive symptoms that did not reach criteria for major depressive episode nonetheless impeded the recovery of hospitalized elderly patients, Jana Mossey and coworkers conducted a 10-session trial of interpersonal counseling with elderly hospitalized medical patients who had depressive symptoms. They modified the technique by increasing the number of sessions from 6 to 10, their duration from 30 to 60 minutes, and increasing the flexibility of scheduling from once weekly to a schedule that reflected the patient's medical status. They randomized 76 hospitalized patients over age 60 who did not meet criteria for major depression but had depressive symptoms on two consecutive assessments, to receive either interpersonal counseling administered by clinical nurse specialists or usual care. A nondepressed control group was also followed. Patients found interpersonal counseling feasible and acceptable. Assessment at 3 months showed a nonsignificantly greater reduction in depressive symptoms and greater improvement on all outcome variables for interpersonal counseling than for usual care, versus a slight symptomatic increase among controls. Rehospitalization in the interpersonal counseling and nondepressed control groups was virtually identical (11 to 15 percent), and significantly below that in the subsyndromally depressed group receiving usual care (50 percent). At 6 months, differences between the treatment groups reached statistical significance in reduction of depressive symptoms and self-rated health but not in physical or social functioning. A 1-year evaluation is pending. The investigators felt that 10 sessions were insufficient for some patients and that a maintenance phase might have been useful. They judged the clinical nurse specialists acceptable therapists.

Interpersonal Psychotherapy by Telephone Because many patients avoid or have difficulty reaching an office for face-to-face treatment, interpersonal counseling is being tested as a telephone treatment. An open trial under way at Memorial Sloan-Kettering Cancer Center in New York offers interpersonal psychotherapy to severely medically, but not psychiatrically, ill patients with metastatic breast cancer who are receiving high-dosage chemotherapy. Both the patient and partner receive weekly 30-minute sessions for approximately 15 weeks. All patients have metastatic breast cancer considered incurable by standard treatments. Their chemotherapy regimen is unusually disabling, and patients must move to within minutes of the hospital for the 2 to 3 months of treatment, causing major disruptions for themselves and their families. They must take extended leaves from jobs and leave children and spouses at home. The purpose of the study was to adapt interpersonal psychotherapy to relieve cancer-related stress rather than depression, but prevalence of depression and depressive symptoms is high. The investigators report that interpersonal psychotherapy fits a wide range of the patients' needs well.

The first author and Lisa Miller at Columbia University have a pilot telephone trial under way comparing interpersonal psychotherapy with no treatment in 30 patients who have had recurrent depression but have not received regular treatment.

Interpersonal Psychotherapy Patient Guide The first author has developed a user-friendly interpersonal psychotherapy patient guide with accompanying worksheets. The guide is designed for patients who want to learn about or are receiving interpersonal psychotherapy. It leads the patient through treatment in simple language. Worksheets can be used to facilitate sessions or to monitor problem areas after treatment. Formal testing to determine whether the patient book facilitates treatment has not been done. Informal reports by Gillies and the second author note that patient response has been positive, and that some therapists have found the patient guide useful during training in interpersonal psychotherapy.

Training in Interpersonal Psychotherapy Until recently, interpersonal psychotherapy practitioners were few and almost exclusively limited to participants in research studies. Interpersonal psychotherapy training is now increasingly included in professional workshops and conferences, with training courses conducted at university centers in Canada, Europe, Asia, and New Zealand. A training videotape (Kingsley Communications, Houston, Texas) describes interpersonal psychotherapy and demonstrates the initial assessment phase of treatment.

Training workshops for mental health professionals from a variety of disciplines have been held at Cornell Medical School, New York; the University of Pittsburgh; and in Toronto. Interpersonal psychotherapy is taught in some (but not most) residency training programs and has been included in family practice and primary care training. Interpersonal psychotherapy clinics have been established at the Clarke Institute in Toronto and at New York Hospital-Cornell Medical Center in New York City.

Although the principles of interpersonal psychotherapy are straightforward, training requires more than reading the manual. Candidates should have a graduate clinical degree (M.D., Ph.D., M.S.W., R.N.) and several years of experience conducting psychotherapy. Interpersonal psychotherapy training programs are designed to help experienced therapists refocus their treatment by learning new techniques, not to teach novices psychotherapy. The model program includes a brief didactic phase in which the manual is reviewed, and a longer practicum during which the therapist treats two to three patients under close supervision, monitored by videotapes of the sessions. Therapists who performed well on a first supervised case often did not require further intensive supervision, and experienced therapists committed to the approach required less supervision.

Future Directions Evidence from controlled clinical trials suggests that interpersonal psychotherapy is a reasonable alternative or adjunct to medication as an acute, continuation, or maintenance treatment for patients with major depression; for acutely depressed HIV-positive patients, and for patients with bulimia nervosa. It is a promising, but still not fully tested, treatment for depressed adolescent and geriatric patients, patients with dysthymic disorder, and primary care patients with mild depression and a couples treatment for depressed patients with marital disputes. More efficacy data are needed before stronger claims can be made. Open trials are encouraging but cannot be considered evidence of efficacy. Interpersonal psychotherapy is not effective (compared with standard treatment) for opioid- and cocaine-dependent patients. Several interpersonal psychotherapy clinical trials based on modified treatment manuals are under way or planned, and several manuals are under development. The manuals differ in the depth of their modifications, and some adaptations for particular disorders have not been formalized. There is little agreement on what a manualized interpersonal psychotherapy adaptation should include.

The development of psychotherapy manuals represents progress. They will meet growing requests from third-party payers, managed care, and patients for accountability and specification of treatment. Manuals are a necessary first step in testing efficacy. In the authors' opinion psychiatric and other mental health treatment training programs should include clinical instruction in time-limited, manual-defined psychotherapies in addition to exposing trainees to long-term psychotherapy.

Even for experienced therapists, interpersonal psychotherapy training programs are still not widely available, but access is growing. The established training criteria for research have produced reliable therapists for clinical trials. Yet the educational process for interpersonal psychotherapy in clinical practice requires further study. What educational level and experience does a clinician require to learn interpersonal psychotherapy? How much supervision does an experienced therapist require? Will reading the manual suffice?

Interpersonal psychotherapy research to date has focused largely on outcome. With some effective outcomes now demonstrated, process research is worthwhile to determine specific ingredients of the treatment. Dismantling studies might be useful. For example, the initial diagnostic and assessment phase of interpersonal psychotherapy is essential to the clinical management of all depressed patients. The efficacy of using only the initial interpersonal psychotherapy phase might be compared with the full treatment. Data from the study by Frank and coworkers: showed the value of monthly maintenance interpersonal psychotherapy for patients with recurrent depression, but a series of studies might compare weekly, biweekly, and monthly frequency of sessions. Such studies would be comparable to phase II or III pharmacotherapy trials.

It is unclear how efficacy data for psychotherapies like interpersonal psychotherapy will be used in managed care reimbursement decisions. Will standardization of treatment, training credentials, and evidence of effectiveness and cost offset be required? Since clinical trials usually exclude the patients with complex comorbidity seen in clinical practice, reimbursement policy based on data from clinical trials should adjust for this contingency. It will be important to learn how the efficacy of interpersonal psychotherapy in clinical research translates into effectiveness when used by general clinicians. It is unclear whether untested psychotherapies will be reimbursed, whether psychotherapy will be reimbursed at all, and if so with what limits on intensity and duration of treatment. Strict limits on psychotherapy reimbursement would harm many patients (e.g., recurrent depressive patients unresponsive to medication, or depressed pregnant or nursing women). The efficacy of antidepressant pharmacotherapy is unequivocal, yet medicating depressed patients without psychological management risks poor compliance and persistent unresolved social stressors. The best interests of all psychiatric patients are ensured by access to a range of treatment modalities whose efficacy has been established in controlled clinical trials.

SUGGESTED CROSS-REFERENCES

Substance-related disorders are covered in Chapter 11, mood disorders in Chapter 14, anxiety disorders in Chapter 15, somatoform disorders in Chapter 16, eating disorders in Chapter 20, personality disorders in Chapter 24, and relational problems in Chapter 26. Evaluation of psychotherapies is discussed in Section 30.11. Combined psychotherapy and pharmacotherapy is covered in Section 30.12. Tricyclic drugs are discussed in Section 31.30.

30.8 BRIEF PSYCHOTHERAPY

ROBERT J. URSANO, M.D., AND ANN E. NORWOOD, M.D.

Psychotherapy is the generic term for a large number of treatment techniques that are designed to change behavior through verbal interchange (talking). The psychodynamic psychotherapies—the brief psychodynamic psychotherapies, interpersonal psychotherapy and cognitive psychotherapy—aim to change behavior through the reorganization of mental structures and processes. These changes result from new understandings and the new recognition of old patterns of behavior that have been long enacted but not observed. Through this process an individual's perception, expectation, and behavior can change.

In the past, the terms “brief psychotherapy” and “long-term psychotherapy” were frequently used synonymously with *supportive* and *explorative* psychotherapy, respectively. However, this is no longer accurate. *Brief* and *long-term* describe only the duration, not the technique, focus, or goal. The brief psychotherapies have developed their own theory of technique and goals. Brief psychotherapy is primarily distinguished from longer-term treatments by the time limits placed upon it. These time limits give the brief psychotherapies unique characteristics and distinguish them from long-term psychotherapy and psychoanalysis. The time limits also mean that brief psychotherapists must confront their own ambitiousness and perfectionism as well as any exaggerated ideal of personality structure and function.

Interest in brief psychotherapy has flourished in recent years. Psychotherapy is a verbal interchange between two individuals, one an expert and the other a help-seeker, in this case, the patient. The goal of their work together is to identify the patient's characteristic problems in living so they could be changed. As in all of medicine, both nonspecific and specific factors related to the treatment affect the outcome of this work. The nonspecific curative factors of abreaction, the provision of new information, and maximizing success experiences, guide all forms of medical treatment including the brief psychotherapies. These principles increase the probability that patients will experience relief of pain and suffering. The individual psychotherapies also have specific technical interventions and procedures above and beyond the nonspecific curative factors. As in other medical treatments, there are contraindications and dangers in the use of psychotherapy.

It is not sufficient in the present-day era of managed care and closely watched outcome measures to state that psychotherapy was a success but no change occurred. Although the therapist in the individual psychodynamically derived brief psychotherapies does not require behavioral change, the end result of the therapist's technical expertise is to achieve behavioral change, including changes in well-being, physical health, social supports, and societal productivity as well as symptomatic relief.

HISTORY

Following World War II, interest in psychoanalysis resulted in a rapid growth in the demand for psychotherapy. This considerably increased the pressure on psychiatrists to develop briefer forms of psychotherapy. In the mid 1940s, Franz Alexander and Thomas French made important contributions to the development of brief dynamic psychotherapy. In their report on the Chicago Institute of Psychoanalysis's research project, they advocated shortening treatment and seeing patients less frequently to minimize regression. They proposed focusing treatment on the present rather than the past, using historical conflicts to inform the therapist in providing the best corrective emotional experience for the patient in the present. The goal of the treatment was to provide a complete psychoanalysis in a shorter period of time. Alexander's work, in particular, has been perhaps the most influential in the development of brief psychodynamic psychotherapy.

More recently, the community mental health movement of the 1960s, the increasing cost of mental health care, and the current rise of managed care have stimulated efforts to find briefer forms of psychotherapy. Brief psychotherapy is a necessary part of the modern psychiatrist's armamentarium. The brief psychodynamic psychotherapies of the past three decades have not attempted a complete analysis but concentrate on the analysis of a focal conflict to the exclusion of others. Contemporary brief psychodynamic psychotherapy was heavily influenced by the British School's development of brief focal psychotherapy. Michael Balint sponsored a workshop of experienced psychoanalytic psychotherapists that initially focused on clinical evaluation and attempted to determine which patients might be suitable for deviations from the standard psychotherapy of the time toward a briefer treatment. After Balint's death, David Malan carried on the work of the group. Malan developed and applied the principles of psychodynamic treatment to brief treatment, delineating methods for evaluating process and outcome variables. He emphasized the importance of therapeutic planning and the identification of a focal conflict.

At the same time David Malan was undertaking his research at the Tavistock Clinic, Peter Sifneos was studying brief psychotherapy at the Massachusetts General Hospital in Boston. Many of his conclusions are similar to Malan's. However, there are some differences. Sifneos developed what he called short-term anxiety-provoking psychotherapy as a technique and theory. He emphasized strict inclusion and exclusion criteria for choosing patients. Habib Davanloo broadened the focus of the brief psychodynamic psychotherapies to include more than one conflict. He also advocated the use of psychodynamic psychotherapy, actively confronting resistances, and including other patient populations such as individuals who suffered from character pathology and chronic phobic and obsessional neuroses. As in the other psychodynamic psychotherapies, James Mann's time-limited psychotherapy developed a central issue as the focus of the treatment. However, he introduced the unique contribution of focusing on the meaning of time. Mann related this to the patient's difficulties in confronting loss and separation—the reality of time and death.

In the last two decades, brief psychotherapy has been increasingly research based. Hans Strupp, Lester Luborsky, and Mardi Horowitz have all introduced manualized psychodynamic treatments with substantial contributions to our research understanding of this treatment modality.

Additionally, cognitive therapy and interpersonal psychotherapy represent brief psychotherapeutic techniques greatly influenced by psychoanalysis but with distinctly different approaches. They share many common elements. Both originally were developed as short-term individual psychotherapies for the treatment of depression but have evolved significantly from this initial focus. They have been termed *reeducative psychotherapies* because they emphasize model-specific case formulations, procedurally guided interventions, and education. They also differ from psychodynamic psychotherapy in that they do not center work on transference, favoring an active, collaborative role.

Cognitive Therapy Cognitive therapy was developed by Aaron Beck and colleagues. Cognitive psychotherapy is a brief method of psychotherapy developed over the last two decades by Beck and his colleagues at the University of Pennsylvania. It is similar to behavior therapy in that it aims at direct removal of symptoms rather than resolution of underlying conflicts, as in psychodynamic psychotherapies. Unlike traditional behavioral approaches, however, the subjective experience of the patient is a major focus of attention in cognitive psychotherapy, as in the psychoanalytically oriented treatments. Beck traces his interest in the topic to 1956, when he became curious about unpredicted findings in his empirical studies of the relationship between specific psychodynamic factors and depression. When psychodynamic concepts did not adequately explain his clinical findings about depression, he explored alternative hypotheses. Beck was struck by the distortions of depressed patients in their negative views of themselves and the world. Based on his observations and research by others, Beck set out to develop a treatment to diminish depressive symptoms by correcting patient distortions. Behavior therapy substantially influenced the development of cognitive therapy. In particular, methodological behaviorism's focus on specifying discrete goals and the steps needed to attain them accompanied by prompt feedback were incorporated into cognitive therapy. Beck developed the concept of “collaborative empiricism,” a method of correcting cognitive distortions by testing the patient's negative beliefs in real life situations.

Interpersonal Psychotherapy Interpersonal psychotherapy is a focused, short-term therapy developed by Gerald Klerman and colleagues. Originally, interpersonal psychotherapy was developed as a time-limited (generally 16 sessions), focused individual psychotherapy for nonpsychotic, unipolar depression. Interpersonal psychotherapy's focus is on interpersonal events rather than intrapsychic or cognitive events. Its theoretical underpinnings are based on interpersonal psychiatry, which, in turn, was heavily influenced by the sociological and philosophical views of the time. The first psychiatrist to articulate the importance of psychosocial factors in the development of mental illness was Adolph Meyer. Harry Stack Sullivan expanded the emphasis on psychosocial factors, defining psychiatry as the field of

interpersonal relations. The use of interpersonal theory in treating patients with depression, as distinguished from an exclusively psychodynamic or biological approach, began with Sullivan and Frieda Fromm-Reichmann's work in the 1930s and 1940s. Interpersonal psychotherapy for depression grew out of the work of the New Haven-Boston Collaborative Depression Research Project on outpatient psychotherapy of patients with nonpsychotic unipolar depression, which began in the late 1960s. The research project's work involved testing psychotherapy with depressed patients either alone or in conjunction with pharmacotherapy. In the early phase of the research, the major interest was in pharmacotherapy as a maintenance treatment for depression. When it was included as a treatment to be examined under the National Institute of Mental Health (NIMH) Collaborative Study on the Treatment of Depression, interpersonal psychotherapy was refined further and training was developed. Interpersonal psychotherapy has since been adapted for use with couples and groups, has been used for a broader group of psychiatric disorders, and can be a longer-term treatment.

THEORETICAL ISSUES

Although at times we speak of psychotherapy as beginning as soon as the physician sees the patient, this hyperbole is used primarily to underscore the importance of interpersonal and transferential elements in the initial meeting with the patient. It is extremely important to distinguish the diagnostic interviews from the ongoing treatment. The evaluation process is distinct from, although related to, psychotherapeutic technique. The evaluation is particularly important in brief psychotherapy because of the need for rapid and accurate assessment without the luxury of time to reevaluate and correct mistakes afforded in the longer-term treatments. The interventions and technical procedures performed during the evaluation phase differ substantially from the technical aspects of psychotherapy itself. The necessity for diagnosis, treatment recommendation, and consideration of the interaction among the patient's ego strength, physical health, and selection variables and the different treatment options (including “no treatment indicated”) is a primary part of the physician's responsibility during the evaluation phase for brief psychotherapy, as in any treatment decision.

Through negotiation with the patient, a treatment decision is reached, and the psychotherapy begins. Many patients do not make it through the evaluation phase of seeking help. Repeatedly, it has been shown that more than 50 percent of patients drop out by five sessions. Setting a time limit appears to decrease the dropout rate. It is inappropriate to consider those who drop out as having been in psychotherapy. Clearly, some of these patients benefit during their short contact with mental health professionals, some through the nonspecific curative factors of help seeking and others through guidance and crisis intervention. However, many may drop out because they did not receive what they were looking for. Despite the therapist's interest in targets of treatment, what is dealt with in treatment is what patients can bring into focus, what patients can tolerate talking about, and what they can tolerate the therapist talking about.

Brief Psychodynamic Psychotherapy Theory Primary to the brief psychodynamic treatments is having the patient rapidly feel engaged and involved in the work. The brief psychodynamic psychotherapies are more focused than the extensive reworking of personality undertaken in longer-term psychotherapies and more here-and-now oriented, with less attempt to reconstruct the developmental origins of conflicts. Through the exploration of the patient's metaphors and symbols, defensive patterns and disturbances in present interpersonal relations can be identified in both the treatment setting and in the patient's life. Being able to hear what the patient has to say and understand its meaning remains central to all psychoanalytically oriented treatments. The therapist's task is to identify the continuity present, but hidden, between each session. The therapist operates on the hypothesis that each session is related to the previous one. The establishment of the therapeutic alliance through identification of the patient's initial anxieties related to beginning therapy remains an important technique in the early phases of the psychodynamic treatments. The therapist must establish conditions under which the patient can favorably hear and deal with the interpretations that the therapist plans to give.

The psychodynamic psychotherapies share an emphasis on understanding (1) the mechanisms of defense used by the patient to decrease anxiety and other uncomfortable feelings associated with areas of conflict which are out of awareness and (2) the characteristic transference relationships that distort the patients' response to their adult world. Typically these two areas, defense and transference, create the world of meaning in which the patient lives. The techniques of the brief psychodynamic psychotherapies are directed toward clarifying these areas and presenting them to the patient to increase understanding and thus change symptoms and behavior.

The goal of treatment is to clarify defenses and the transference in the patient's present life, but particularly as they present in the treatment setting itself, where they can be most clearly seen and are available for the patient to learn from immediately. Participating in this process requires certain capacities in the patient. As in all of medicine, medical treatments are given to patients not to diseases, so patients must be evaluated to determine whether or not they can successfully use the treatment. All medical treatments, including psychoanalysis, make certain requirements upon the patient, which must be taken into account when the treatment is prescribed. The psychodynamic psychotherapies generally require individuals who can access their fantasy life in an active and experiencing manner (i.e., psychological mindedness) and can get up and leave it behind at the end of a session. This does not necessarily mean high intelligence quotient (I.Q.) which, as is often true, when accompanied with rigidity, intellectualization and rumination, can be a contraindication to a brief psychodynamic treatment, since these defenses can be quite formidable. The availability of interpersonal support in the patient's real environment and the patient's ability to experience and simultaneously observe highly charged affective states are also necessary for successful treatment.

The brief psychodynamic psychotherapies focus on the recovery of childhood experiences as they appear in the relationship with the analyst and defense analysis. The re-creation in the doctor-patient relationship of a conflicted relationship with a childhood figure is called the *transference neurosis*. Frequently, the transference is paternal or maternal, but it need not be. Sibling, aunt, uncle, and grandparent transferences are all important parts of psychoanalytic work. When transference neurosis is present, the patient experiences the therapist in a very alive manner as the significant figure from the past. Frequently, other elements of the past are simultaneously experienced in the patient's life. Usually in brief psychotherapy the transference is not as intense as in a longer-term treatment or a psychoanalysis. However, a recent precipitant to the patient's problems (as is usually the case in beginning brief psychodynamic psychotherapy) can intensify any transference responses considerably.

The structure of the psychodynamic therapies is directed toward setting up the therapeutic situation and the patient's observing capacity so that the transference can be interpreted. The hope is to be able to interpret both the triangle of anxiety (wish–defense–anxiety) and the triangle of insight (transference figure–relationship in the present to which it relates–the transference element evident in the therapeutic relationship). Interpretations rarely reach the ideal of being given in one sentence in one session. More frequently, interpretations occur over a period of time during which past, present, and transference experiences are linked together. Individuals in an emergent crisis (e.g., imminently suicidal, psychotic, recent major life trauma) and, therefore, very concerned and focused on the real events in their life cannot enter into a brief psychodynamic psychotherapy without first having supportive treatment. A true life crisis does not allow the patient the opportunity to explore fantasies.

Part of the specific treatment effects of the brief psychodynamic psychotherapies result from the interpretation of the transference situation. The transference is best understood as a reawakening of clusters of effects, cognitions, and behaviors that are linked to significant individuals in the patient's past. Behavioral change occurs in the context of the arousal associated with these figures and the simultaneous understanding of the experience. The patient's ability to perceive previously hidden feelings and relationships and the view of the future and the past can change.

Countertransference is an important element in brief psychodynamic psychotherapy as in other psychodynamic treatments. *Countertransference* is narrowly defined as the analyst's transference responses to the patient. More broadly defined, it is the total emotional reaction to the patient, including feelings unconsciously induced in the analyst by the interpersonal pressure of the patient in the clinical setting. In other words, the analyst will respond to the patient as many other persons in the patient's life respond. In this regard, countertransference provides valuable information about the patient's internal world and the patient's characteristic problems in interpersonal relationships. Countertransference is an ubiquitous occurrence that is increased by life stress and unresolved conflicts in the analyst. It can appear as either an identification with, or a reaction to, the patient's conscious and unconscious fantasies, feelings, and behaviors. Analysis of countertransference reactions may help the therapist recognize subtle aspects of the transference relationship and better understand the patient's experience. Because of the more active stance, the brief psychodynamic psychotherapist can be particularly prone to countertransferences that show up as overinvolvement or aggression. In addition, the brief time available for treatment can make recovery from countertransference errors quite difficult.

Free association is part of the technique of treatment. However, the brief psychotherapist also asks questions, directs the patient's attention, and uses benign neglect; that is the therapist avoids some areas of conflict that cannot be dealt with at this time or in a short period of time. Freud described free association by analogy with a train ride. He suggested that if the doctor and the patient were riding together on a train and the doctor was blind, the patient would not forget to describe the beautiful mountains or the ugly coal slags. This analogy is meant to convey the sense of the patient reporting all thoughts that come to mind without censorship and without thinking them too trivial. In point of fact, free association is difficult to attain. The therapist's task is to identify the spots at which free association breaks down (the occurrence of a defense, clinically experienced by the therapist as resistance). Often when patients can talk freely, with a coherent narrative about their conflicts, the work of the treatment is completed.

Early in treatment, the therapist establishes a therapeutic alliance with the patient that allows reality-based consideration of the demands of the treatment and a working collaboration between analyst and analysand directed to understanding the patient. The therapist focuses on analyzing the defenses the patient uses to minimize conflict and disturbing affects. Defenses such as intellectualization, reaction formation, denial, repression, and other neurotic cognitive mechanisms are identified and repeatedly interpreted to the patient. Through the analysis of defense, the transference grows in a manner that can be analyzed. Dreams, as well as slips of the tongue and symptoms, provide an avenue to the understanding of unconscious conflict. Often a given brief treatment concentrates on only one or two defenses. As these are clarified, the transference relationship may clarify.

Medications are frequently used in conjunction with brief psychodynamic psychotherapy. This can complicate the treatment and its progress as well as aid in symptom recovery. The therapist must explore the meaning of the medication and its role in the patients' view of their self and interpersonal strengths and vulnerabilities. The brief psychodynamic psychotherapies can also serve as an alternative to medication treatment for less severe symptoms or when medication is contraindicated.

The brief psychodynamic psychotherapist operates under several rules. These include the rule of neutrality, by which the therapist favors neither the patient's wishes (id) nor the condemnations of these wishes (superego), and the rule of abstinence, whereby the analyst does not provide gratification to the patient similar to that of the wished-for object. Transference has also been described as the role pressure placed upon the analyst to conform to the behaviors of the significant individual in the past. Therefore, transference is experienced by the therapist as an expectation from the patient that the therapist will behave in a certain manner. This interpersonal pressure is sometimes referred to as *projective identification,* or *role responsiveness. Abstinence* is the avoidance of becoming this figure in reality and gratifying these wishes. However, the therapist may frequently be drawn in by the patient to behave in a manner that is reminiscent of the transference figure, and this enactment of the transference wish may provide valuable information about what others experience with the patient.

Interpersonal Psychotherapy Theory Interpersonal psychotherapy (IPT) is a short-term psychotherapy developed by Klerman and colleagues. Interpersonal psychotherapy is brief—12 to 16 weeks in duration—and focuses on current interpersonal problems in outpatient nonbipolar, nonpsychotic, depressed patients. Interpersonal psychotherapy has often been used in combined psychotherapy and pharmacological treatment studies. Interpersonal psychotherapy has also been used in treating drug abuse; however, it did not significantly improve outcome when patients were already in a well-run treatment program that included weekly group psychotherapy. Interpersonal psychotherapy derives from the interpersonal school of psychiatry that originated with Meyer and Sullivan. The understanding of social supports and of attachment provides further theoretical underpinning for this form of psychotherapy. IPT focuses on reassurance, clarification of feeling states, improvement in interpersonal communication, perception testing, and interpersonal skills rather than personality reconstruction.

Interpersonal psychotherapy is a focused individual psychotherapy. The therapist focuses on the current social functioning. A complete inventory of current and past significant interpersonal relationships, including the family of origin, friendships, and relations in the community, is a part of the evaluation phase. Patterns of authority, dominance and submission, dependency and autonomy, intimacy, affection, and activities are observed. Cognitions are generally seen as beliefs and attitudes about norms, expectations, roles, and role performance. Defense mechanisms may be recognized, but they are explored in terms of interpersonal relations. Similarly, dreams may be examined as a reflection of current interpersonal problems. The interpersonal therapist may explore distorted thinking by comparing what patients say with what they do or by defining their view of an interpersonal relationship.

Interpersonal psychotherapy has been primarily used in the treatment of depressed patients. In its opening phase, a detailed symptom history is taken, usually with a structured interview. The symptoms are reviewed with the patient and the patient receives explicit information about the natural course of depression as a clinical condition. There is an emphasis on legitimizing the patient in the sick role. A second major task of this phase is the assessment of interpersonal problem areas. There is an attempt to identify one or more of four problem areas: grief reactions, interpersonal role disputes, role transition, or interpersonal deficits. Each of these areas is considered to be related to depression. The middle phase of treatment is directed toward resolving the problem area or areas. Clarifying positive and negative feeling states, identifying past models for relationships, and guiding and encouraging the patient in examining and choosing alternative courses of action are the basic techniques for handling each problem area. The focus is kept on current dilemmas, not past interpersonal relationships. Interpersonal events rather than intrapsychic or cognitive events are the focus of interpersonal psychotherapy.

Cognitive Psychotherapy Theory Cognitive psychotherapy was first developed for the treatment of depression, and this remains its most fully developed theoretical area. The central principle of the cognitive theory of depression is that symptoms result from characteristic distortions in thinking. The individual's reports of conscious ideas, feelings, and wishes are taken as data. This position contrasts with that of classical behaviorists, who might view them as indicating deeper meanings.

To the cognitive therapist, depressed persons interpret life differently from those who are not depressed. Depressed people have negative interpretations of the world, themselves, and the future (the negative cognitive triad). To depressed individuals, events reflect defeat, deprivation, or disparagement, and their lives are filled with obstacles and burdens. They view themselves as unworthy, deficient, undesirable, or worthless and expect the future to continue the miseries of the present. These evaluations are products of the negative biases inherent in depressive thinking and are applied regardless of the objective nature of the individual's circumstances. For example, a depressed man might think that the checkout person at the grocery store said “Hello” to be nice to him because the person felt sorry for him and knew he was ill. On the other hand, failure to say “Hello” might be interpreted as showing that the checkout person disliked the patient.

In cognitive theory, the affective and motivational aspects of depression are secondary to the negative interpretations of events; that is, how one views an experience determines one's emotional (affective) response to it. For example, a man traveling in a strange city finds himself sitting alone at a conference. If he interprets the experience as a loss of companionship, he is likely to report that he feels sad; if instead he interprets the empty row next to him to mean he is unattractive to people, he may feel shame; if he sees himself sitting alone because the local attendees are unfriendly, he may experience anger. Conversely, a man who sees the same situation as evidence of his independence may feel proud and strong. Persons who anticipate failure, opposition, or humiliation as a result of their efforts may respond with decreased motivation and active avoidance or escapist wishes. Beck has speculated that the physical symptoms of depression may also reflect one's thought processes. For example, psychomotor retardation may be the physical expression of a patient's passive, helpless attitude.

Other psychiatric conditions have their own characteristic cognitive patterns that determine the nature of the symptoms. Anxious persons continually anticipate personal danger or impending disaster, but since this is potential rather than actual (as in depression), their self-esteem remains intact. Paranoid individuals view the world as responding negatively to them, but unlike depressive individuals, they place the blame with the world rather than with themselves.

The thinking disorder of depression as seen in cognitive theory includes arbitrary inference, selective overgeneralization, magnification and minimization, and inexact labeling. These cognitions (verbal thoughts) often feel involuntary and automatic. This thinking is so automatic and the resultant cognitions so fleeting that persons are virtually unaware of them. Such automatic thoughts differ from unconscious thoughts in that they can easily be made fully conscious if the person's attention is directed to them. (Thoughts of this type would be described as “preconscious” in traditional psychoanalytic theory.) A large portion of the work of cognitive psychotherapy deals with training patients to observe and record their automatic thoughts in response to the events of daily life.

Cognitive theory postulates a chronic state of depression proneness that may precede the actual illness and remain after the symptoms have abated. Depression-prone individuals have relatively permanent depressive cognitive structures that determine how new stimuli are perceived and conceptualized. Such structures are called *cognitive schemas.* The schemas of depression may include ideas such as “I am stupid” or “I cannot exist without the love of a strong person.”

Unlike with automatic thoughts, patients are not typically aware of their underlying general assumptions. Rather, they must be deduced from many specific examples of distorted thinking. Schemas such as “I am stupid” may lie dormant much of the time only to be reactivated by a specific event such as difficulty in accomplishing a task. These enduring self-concepts and attitudes are assumed to have been learned in childhood on the basis of the child's experiences and reactions of important family members. Once formed, such attitudes can be self-perpetuating.

Just as depressive thoughts can be triggered by events, episodes of depressive illness may, from the cognitive perspective, be triggered by sufficient stress. Such stresses may be specific to individuals and the particular sensitivities they developed in childhood. Alternatively, sufficient nonspecific stress may precipitate depression in vulnerable individuals. Loss, a setback in a major goal, a rejection, or an unsolvable dilemma are especially common precipitants of depression. The onset of medical illness, with its attendant limitations and associated meanings, is also seen as likely to trigger depression in many people.

TECHNIQUES

Brief Psychodynamic Psychotherapy

Malan and the Tavistock Group: Focal Psychotherapy Focal psychotherapy, which developed from the workshops of Balint and Malan, is an example of applied psychoanalysis. Malan has carried on Balint's earlier work. Previous attempts to develop brief forms of psychoanalytic psychotherapy primarily involved the use of “activity.” However, Malan emphasized the importance of choosing and maintaining a narrow focal area to be dealt with in a brief period of time. Rather than increasing activity, which was frequently equated with manipulation, Malan stresses the importance of finding the appropriate focus in the patient's story and consistently interpreting the focal problem area. Through selective attention and neglect, the therapist maintains the focus and completes a brief psychotherapy. The importance of determining the focus underscores the value of the diagnostic process prior to the initiation of psychotherapy, including the psychodynamic assessment of the patient.

Malan identifies the following factors as leading to the lengthening of treatment: resistance, overdetermination, a need for working through the roots of conflict in early childhood, transference, dependence, negative transference connected with termination, and the transference neurosis. In addition, some therapist characteristics may lengthen treatment, including a tendency toward passivity, a sense of timelessness conveyed to the patient, therapeutic perfectionism, and a preoccupation with deeper earlier experiences. All of these factors must be dealt with to maintain a brief therapy. For Malan, identifying a focal conflict acceptable to the patient is critical to a successful outcome (Table 30.8-1). In addition, the patient must be able to think in feeling terms, demonstrate high motivation, and exhibit a good response to trial interpretations made during the evaluation phase. Patients who have had serious suicidal attempts, drug addiction, long-term hospitalization, more than one course of electroconvulsive therapy, chronic alcoholism, incapacitating severe chronic obsessional symptoms, severe chronic phobic symptoms, or gross destructive or self-destructive acting out are excluded from treatment. The patient is also excluded from focal psychotherapy if the therapist anticipates any of the items listed in Table 30.8-2.

Goal	Identify the defense, the anxiety, and the impulse Link the present, the past, and the transference
Focus	Internal conflict present since childhood Link the present, the past, and the transference
Selection criteria	Patient can think in feeling terms Highly motivated Good response to trial interpretation
Duration	Up to 1 year Mean, 20 sessions
Termination	Set definite termination date at beginning of treatment

Table 30.8-1 Key Elements of Malan and the Tavistock Group's Brief Focal Psychotherapy

1. Therapist cannot make affective contact with the patient during the evaluation
2. Therapist anticipates needing extended work
   - To generate motivation
   - To decrease rigid defenses
   - To reach complex or deep-seated issues
   - To resolve unfavorable, intense transference, or dependence that may develop
3. Depressive or psychotic disturbance may intensify and place the patient at risk

Table 30.8-2 Exclusion Criteria for Malan's and the Tavistock Group's Brief Focal Psychotherapy

For Malan, the criteria in Table 30.8-2 represent specific dangers. If the therapist cannot make contact with the patient or the patient exhibits low motivation or rigid defenses, forming an effective therapeutic working alliance within a short time will be difficult. Complex or deep-seated issues that must be dealt with to resolve a conflict area require longer treatment. Difficult transference relationships may also prevent timely termination or lead to premature termination. Severe depressive or psychotic episodes during treatment can endanger the patient and require adjunctive treatments. Thus, Malan takes the time limitation in brief therapy seriously, which requires rapid establishment of a therapeutic alliance and the ability to terminate therapy without the development of unexpected serious symptoms.

Malan, in contrast to other practitioners, does not necessarily exclude patients with serious psychopathology. In fact, several patients that he presents exhibit significant pathology. Rather, he sees the balance between motivation and focality as of primary importance. A patient with only moderate motivation but a highly focal conflict might be accepted into treatment. Similarly, a patient with high motivation but not as focal a conflict might also be accepted into treatment with the hope that the focus would clarify in a short period of time.

Identifying the precipitating factors, early traumatic experiences, or repetitive patterns can indicate the area of internal conflict present since childhood and the focus for treatment. The therapist should assess the congruence between the current conflict and the nuclear, or childhood, conflict during the evaluation phase. The patient's response to interpretations about aspects of this conflict may lead to acceptance into treatment. According to Malan, the greater the probability that the conflict area will manifest itself in the transference, the more positive the outcome will be. Furthermore, he reported that transference interpretations correlated with character change and that character change endured 2 to 10 years later.

Malan is less concerned with technique than with the importance of choosing the focus. He uses all the usual technical procedures of psychoanalytic psychotherapy and emphasizes the importance of interpreting the transference and connecting it to current and past relationships. This triangle of insight (the transference, the current relationship, and the past relationship) leads to the patient's cure. Overall, the goal is to clarify the nature of the defense, the anxiety, and the impulse that the patient is experiencing and to link these to the present, the past, and the transference. Once the defense and the anxiety are clarified, the link to the past can be made. The interpretation that links to the past may be reassuring to the patient because it emphasizes that the conflict belongs to the world of fantasy rather than the world of the present. Malan emphasizes transference interpretations as the most therapeutically effective interpretations because of their here-and-now character.

In the brief therapy unit at the Tavistock Clinic, a time limit was almost always given when treatment began. For trainees this was usually 30 sessions. However, in his publications, Malan indicates a mean of 20 sessions for patients with favorable outcomes. The longer time for trainees gives an opportunity to correct mistakes that might occur. In some published cases, therapy was extended up to 1 year (46 sessions). In general, Malan advocates the importance of a definite date rather than a number of sessions. Practically speaking, this eliminates the need for the patient and therapist to keep count of the number of sessions and deviates concern about whether or not to make up missed sessions. Such a time limit gives a definite beginning, middle, and end to the therapy; helps to concentrate the patient's material and the therapist's work; maintains the focus; and decreases diffuseness that might lead into long-term work.

Sifneos: Short-Term Anxiety-Provoking Psychotherapy Sifneos emphasizes the importance of patient selection because of the anxiety-provoking nature of his brief psychotherapy techniques (Table 30.8-3). He distinguishes anxiety-provoking therapy from anxiety-suppressing therapy, commonly referred to as *supportive psychotherapy*. For short-term anxiety-provoking psychotherapy (STAP), patients must have above average intelligence and have had at least one meaningful relationship with another person. Patients who have had such a relationship will be able to withstand the anxiety produced by the therapy and rapidly develop a mature collaborative relationship with the therapist. This criterion tends to exclude narcissistic disorders. In addition, the patient must be highly motivated for change, not only for symptom relief. Sifneos also identifies several criteria for patient selection on the basis of the presentation of the patient during the evaluation. Patients must have a specific chief complaint. If the patient has a number of complaints, Sifneos asks the patient which complaint is of top priority. The patients' ability to identify one conflict area and to postpone work on others is considered an indication of their ability to tolerate anxiety. Sifneos looks for patients with anxiety,

depression, phobias, conversion, and mild obsessive-compulsive features or personality disorders involving clear-cut interpersonal difficulties. During the evaluation, patients must show an ability to interact with the evaluating psychiatrist, to express feelings, and to show some flexibility.

Goal	Resolution of oedipal conflict
Focus	Oedipal (triangular) conflict/competition
Selection criteria	Above-average intelligence At least one past meaningful relationship High motivation Specific chief complaint Able to interact with evaluator Able to express feelings Flexible
Duration	A few months Average, 12–16 sessions
Termination	No specific date given

Table 30.8-3 Key Elements of Sifneos' Short-Term Anxiety-Provoking Psychotherapy (STAP)

Sifneos is one of the few authors who clarifies his assessment of motivation. He defines *motivation* as including the patient's ability to recognize symptoms as psychological, a tendency to be introspective and honest about emotional difficulties, and a willingness to participate in the treatment situation. In addition, motivation includes curiosity, a willingness to change and to make reasonable sacrifices, and a realistic expectation of the results of psychotherapy.

Sifneos focuses on the oedipal conflict and does not expect a good outcome in dealing with other than oedipal conflict areas. Most failures using STAP have occurred in patients who complained of reactive depression following the loss of a loved one. He believes that this failure is due to the nontriangular (nonoedipal) origins of the ambivalent feelings in some patients. In such cases, when the issue of termination arises, the patient regresses and an impasse is reached.

During the initial phase of psychotherapy, the therapist must establish good rapport with the patient to create a therapeutic alliance. The therapist uses anxiety-provoking confrontations to clarify issues around the patient's early life situation and present-day conflict. The therapist avoids areas such as passivity, dependence, and acting out, which might lead to extensive regression. The use of anxiety-provoking confrontations in a direct attack on the patient's defenses distinguishes STAP from other brief psychotherapies. Although it is made clear to patients during their evaluation that the psychotherapy is expected to last only a few months, no specific number of sessions or termination date is given. Interviews are held weekly and are 45 minutes long. The vast majority of treatments last from 12 to 16 sessions, and none go beyond 20 sessions. The aggressive, confrontational style of this treatment underscores the importance of excluding preoedipal problems and the importance of countertransference reactions in the therapist related to being too aggressive.

Mann: Time-Limited Psychotherapy Mann has focused on the specific limitation of time in brief psychotherapy. He sees the time variable as a specific operative factor in psychotherapy as well as an element in its curative effect. The experience of the timelessness of treatment and of the treatment's termination are significant elements in Mann's view of the psychotherapeutic process.

Usually two to four evaluation meetings occur before psychotherapy begins. Mann limits psychotherapy to a total of 12 treatment hours, distributed according to patient need. This may result in weekly half-hour sessions for 24 weeks or twice-weekly hour sessions for 6 weeks. In practice, however, nearly all patients are seen in once-weekly, 45- or 50-minute sessions for 12 weeks. Mann admits having chosen the number 12 somewhat arbitrarily; however, his clinical experience indicates that between 10 and 14 sessions suffice. He emphasizes the importance of using a uniform number of sessions in evaluating the psychotherapeutic process among different therapists. This facilitates study of the relation between the patient's presenting problems and psychotherapeutic technique. Also, the patient accepts provision of a specific number of sessions as a typical medical “prescription.” Finally, the setting of a specific last session in the initial contract with the patient allows the therapy to have a clear beginning, middle, and end (Table 30.8-4).

Goal	Resolution of the present and chronically endured pain Change in the patient's negative self-image
Focus	Present and chronically endured pain Particular image of the self Loss, time, and termination
Selection criteria	High ego strength Able to engage and disengage Therapist quickly able to identify a central issue Excludes serious depression, acute psychosis, and borderline personality organization
Duration	12 Treatment hours Usually 12 sessions
Termination	Set date of last session at beginning of treatment

Table 30.8-4 Key Elements of Mann's Time-Limited Psychotherapy

Mann, to some extent, minimizes selection as a central issue for brief psychotherapy. He does indicate a number of exclusionary criteria: serious depression, acute psychosis, borderline personality organization, and the inability to identify a central issue. Mann sees Sifneos' criteria as primarily excluding borderline patients. He does not agree with Sifneos' emphasis on superior academic or work performance.

More recently Mann has expanded his selection criteria by emphasizing the importance of the patient's ego strength as measured by prior work performance and past relationships. Patients who may have difficulty engaging and disengaging rapidly from treatment are excluded. This group includes schizoid patients, certain obsessional patients, patients with strong dependency needs, some narcissistic patients, some depressive patients who will not be able to form a rapid therapeutic alliance, and some patients with psychosomatic disorders who do not tolerate loss well.

According to Mann, selecting the central issue for the psychotherapy is a critical event. It is the vehicle for engaging the patient in the work of therapy and the basis for a successful outcome. Mann looks for a central issue that is developmentally and adaptively relevant and has recurred over time. He describes this issue as the patient's “present and chronically endured pain” and characterizes it as preconscious. Mann has further described the central issue as including a particular image of the self. The central issue formulated in terms of time, affect, and an image of the self is the “paradigm of the transference” expected to emerge in treatment. The therapist's statement of the central issue is a clarification that can be readily recognized, felt, and held onto by the patient. Time-limited psychotherapy is intended to resolve this present and chronically endured pain and the patient's “negative self-image.” The therapist frames the central issue to the patient in terms of a general statement about feelings.

In their volume *A Casebook in Time Limited Psychotherapy* Mann and Robert Goldman described in detail the phrasing of the central issue to the patient. It is the central issue that specifies the therapeutic contract and the goal of the therapy. For a 41-year-old depressed woman who was preoccupied with her husband and children being even 1 minute late, Mann suggested the central issue “You've encountered extreme life situations and have managed them remarkably well... yet you fear and have always feared that despite your best efforts you will lose everything.” For a 31-year-old married man attempting to get a college degree who was consumed with a fear of failing, Mann suggested the central issue. “Because there have been a number of sudden and very painful events in your life, things always seem uncertain, and you are excessively nervous because you do not expect anything to go along well. Things are always uncertain for you.”

Mann uses the usual psychoanalytic psychotherapy techniques: defense analysis, transference interpretation, and genetic reconstruction. Transference is interpreted from within the central identified conflict area and in terms of the adaptive processes of the patient. However, Mann does not confront the patient. In general, his

interventions are very close to the conscious material provided by the patient. Mann identifies specific dynamic events that unfold during the 12 sessions. The opening sessions are understood as filled with the unconscious magical expectation that past pain will now be resolved. During the initial phase, the therapist makes few comments and accepts the positive transference of the patient. Important aspects of the current problem, defense mechanisms, coping styles, and genetic roots of the central issue become clearer during this phase. In the middle four sessions, resistance is likely to appear, as well as the negative transference. The patient experiences the frustration that all of the wished for changes may not occur. In the ending phase of treatment, termination and the patient's resistances to termination in the face of unresolved problems in other areas of life are prominent. Mann sees confronting separation and termination issues as critical to the success of brief psychotherapy. Frequently, patients unconsciously reveal an awareness that the midpoint of treatment has come. They experience separation from the transference-invested therapist as a separation from an ambivalently experienced person from the past, without having achieved the fantasized magical resolution. The goal is to enable patients to separate from the transference-invested therapist less ambivalently than they did from this earlier important figure. Consequently, both the resolution of the central issue and the unfolding of an attachment/separation process in the 12-session treatment contract are intimately related through the development and interpretation of the transference.

Davanloo: Broad-Focus Short-Term Dynamic Psychotherapy Davanloo writes about broad-focus, short-term dynamic psychotherapy. His selection criteria include patients with an oedipal focus, those with a loss focus, and those with multiple foci. Davanloo is particularly interested in patients suffering from long-standing obsessional and phobic character styles presently called mild-to-moderate obsessive-compulsive personality disorder, avoidant personality disorder, and dependent personality disorder. His research data indicate that 30 to 35 percent of the psychiatric outpatient population can benefit from this mode of therapy. Most information about his technique is derived from the publication of cases, presentations, and brief descriptions of his research that accompany case presentations.

The initial evaluation is a specific, focused interview in which the patient's defenses against true feelings are gently but consistently confronted. Davanloo says that this is not a universal technique for the initial interview and cautions on its use with patients with severe psychopathology. Selection is based on psychological-mindedness, the quality of the patient's interpersonal relations, and, in particular, the presence of at least one meaningful relationship in the patient's past. The patient's ability to tolerate and experience anxiety, guilt, and depression are important (Table 30.8-5). Patients must be motivated to complete the treatment process and to resolve neurotic problems. Their ability to respond to interpretation is an important selection criteria. In particular, response to transference interpretations that link the transference with the present and the past is a critical feature in the assessment for broad-focus, short-term dynamic psychotherapy. Davanloo finds no value in criteria based on severity and duration of illness. Finally, the presence of flexibility in the ego's defensive pattern and a lack of use of the primitive defenses of projection, splitting, and denial are important factors in selecting patients.

Goal	Resolution of oedipal conflict,
Focus	Loss focus or multiple foci
Selection criteria	Psychological mindedness At least one past meaningful relationship Able to tolerate affect Good response to trial transference interpretation High motivation Flexible defenses Lack of projection, splitting, and denial
Duration	5 to 40 Sessions, usually 5 to 25 sessions Longer duration for more seriously ill patients
Termination	No specific termination date set Patient is told the treatment will be "short"

Table 30.8-5 Key Elements of Davanloo's Broad-Focus Short-Term Dynamic Psychotherapy

The technique Davanloo uses in therapy is a continuation of that used in the initial interview. The emotional experience of the patient in the transference is emphasized. Patients are "gently but relentlessly" confronted about their defenses against feelings in the transference relationship and in the past. All the usual techniques of psychoanalytic psychotherapy are used: defense analysis, transference interpretations, and genetic reconstruction. Dreams and fantasy material are also used. Transference interpretations tend to be made early. Because of the confrontative style, a strong therapeutic alliance is necessary. Patients frequently experience hostile, angry feelings toward the therapist because of being confronted. Davanloo actively pursues the patient's defenses against recognizing the anger and its transference elements. He warns therapists that passive dependent and obsessional characters may develop a symbiotic transference relationship. This may be avoided through active confrontation and selection of patients. The active confrontation of defenses and early transference interpretations tend to mobilize powerful affects and memories early in treatment.

Davanloo recommends 5 to 40 sessions, depending on the patient's conflict area (oedipal versus multiple foci) and other selection criteria. In general, his treatments fall between 15 and 25 sessions. He does not recommend setting a specific termination date but rather makes clear to the patient that treatment will be short. Shorter time periods (5 to 15 sessions) are chosen for patients with a predominantly oedipal focus, longer durations (20 to 40 sessions) for the more seriously ill group.

COMPARISON OF THE BRIEF PSYCHODYNAMIC PSYCHOTHERAPIES

The work of Malan, Sifneos, Mann, and Davanloo shows substantial overlap in each author's goals, selection criteria, technique, and duration of treatment. These authors would agree that the goals of brief psychotherapy include facilitating health-seeking behaviors and mitigating obstacles to normal growth. From this perspective, brief psychotherapy focuses on the patient's continuous development throughout adult life and the context-dependent appearance of conflict, depending on environment, interpersonal relationships, biological health, and developmental stage. This picture of brief psychotherapy supports modest goals that require the therapist to refrain from perfectionism. Malan, Sifneos, Mann, and Davanloo also seem to agree that brief psychotherapy uses the propitious moment and long-term treatment primarily uses the shared past of the therapist and patient. Both the propitious moment and the shared past carry psychotherapeutic advantages and disadvantages, emphasizing certain technical possibilities and limiting others.

Many of the selection criteria emphasized by Malan, Sifneos, Mann, and Davanloo are common to all kinds of psychodynamic psychotherapy. However, unique selection criteria are necessitated by the brief duration of treatment. Patients in brief psychodynamic psychotherapy must be able to engage quickly with the therapist, to terminate in a short period of time, and to carry on much of the working through and generalizing of the treatment effects on their own.

The necessity for greater independent action by the patient mandates high levels of ego strength, motivation, and responsiveness to interpretation. Sifneos's rather unique emphasis on intelligence as a criterion may be related to his anxiety-provoking interpretations, which require a broader educational context to be understood. The importance of rapid establishment of the therapeutic alliance underlies a substantial number of the selection and exclusion criteria.

The central importance of a focus in brief psychotherapy is mentioned by all authors. They also emphasize the importance of the evaluation sessions to determine this focus. Mann formulates the focus to the patient in terms of the patient's fears and pain. However, he would probably agree with Malan, Davanloo, and Sifneos on the importance of constructing the psychodynamic focus at a deeper level in one's own understanding of the work being done. Maintaining the focus is the primary task of the therapist. This enables the therapist to deal with complicated personality structures in a brief period of time. Resistance is limited through benign neglect of potentially troublesome but nonfocal areas of the personality. The elaboration of techniques of establishing and maintaining the focus of treatment is critical to all brief individual psychodynamic psychotherapies.

The authors also discuss the importance of transference interpretations. However, the manner and rapidity of dealing with transference vary considerably. Malan takes a more typical psychoanalytic approach of waiting for transference to become resistance before it is interpreted. Sifneos, in his emphasis on the oedipal relationship, is more aggressive in handling the deep conflictual areas of transference material. Davanloo is confrontational in developing a transference experience. This confrontational style may at times confuse the patient's experience of the real and the transferential therapist. However, Davanloo's focus on the treatment of severe obsessional disorders, in which the need to increase affective awareness is high, may be where this particular technique is most useful. Aggressive, competitive, and hostile feelings that might otherwise remain firmly defended may thus become available to these patients.

The role of countertransference in brief psychotherapy is as complicated as it is in long-term treatment. Countertransference issues related to the aggressive techniques used by Sifneos and Davanloo have been observed. Countertransference experiences related to termination and loss can also be prominent. The

goal-directed techniques of brief psychotherapy limit the development of regressive countertransference responses.

There is remarkable agreement on the duration of brief psychotherapy. Although the duration ranges from 5 to 40 sessions, authors generally favor 10 to 20 sessions. The duration of treatment is critically related to maintaining the focus within the brief psychotherapy. In Rogerian therapy a positive correlation was found between the number of sessions and recovery. In general, an increasingly successful outcome (measured by the patient's self-concept) is seen up to about 20 sessions. In meta-analyses of a number of brief psychotherapies, 75 percent of patients show some improvement by 26 sessions. However, this study included a wide range of types of treatment. When treatment extends beyond 20 sessions, therapists may frequently find themselves enmeshed in a broad character analysis without a focal conflict. Change after 20 sessions may be quite slow. Clinical experience generally supports the idea that brief individual psychodynamic psychotherapy should involve 10 to 20 sessions, although more complicated cases will require longer treatment. Often, extending treatment beyond 20 sessions is recognition that treatment will involve 40 or 50 sessions.

Brief psychodynamic psychotherapy for depression and narcissistic disturbances has been described. These authors perform an important role by describing the techniques most effective for specific diagnostic categories. Horowitz has described brief psychotherapy focused on the stress responses evidenced by various personality styles. He emphasizes that this psychotherapy is directed toward dealing with the process of the stress response and not character change. However, his outcomes indicate that selected character changes are possible in some areas. The distinction between recovery from a disruption in homeostatic balance, reconstitution of self-esteem and self-concept, and changes in character structure requires further exploration.

The identification of critical points during brief psychotherapy, when the danger of becoming a long-term treatment is most acute, will further clarify the technical handling of brief psychodynamic psychotherapy. Characteristic phenomena have been identified in the interlude between a short- and a long-term treatment: an increasing vagueness with respect to the goals of the treatment, decreased activity by the therapist, and emergence of the transference as a central element. These variables indicate the potential for a short-term psychotherapy to become a long-term treatment. The fourth to sixth hours of once-a-week therapy are when incipient or potential regression may suddenly appear. At this time the patient is testing the boundaries of the treatment. Action by the therapist is required if a brief psychotherapy is to remain exactly that—brief. The study of technical interventions that occur at these critical moments will further elucidate the technical handling of limited regression in brief psychodynamic psychotherapy.

Interpersonal Psychotherapy In interpersonal psychotherapy the therapist's attitude is one of exploration, similar to that in other insight-oriented psychotherapies when applied in a medical model. Applying the dictum of working “from the surface to the depths” results in much of psychodynamic psychotherapy resembling interpersonal psychotherapy. However, Klerman and colleagues have found it useful to highlight the differences between these approaches to standardize a psychotherapeutic technique.

Interpersonal psychotherapy focuses on the patient's interpersonal relationships at the time that psychiatric symptoms began to develop. It emphasizes current rather than past interpersonal relationships and makes no assumption about the cause of the disorder. Interpersonal psychotherapy draws heavily upon psychodynamic theory. In contrast to psychodynamic psychotherapy, the therapist's role is one of active advocacy and the therapeutic relationship is not interpreted as transference. Its goals are to diminish symptoms and maximize social function, rather than to alter personality structure (Table 30.8-6).

Goal	Improvement in current interpersonal skills
Focus	Four problem areas: grief, interpersonal role disputes, role transitions, and interpersonal deficits
Selection criteria	Outpatient, nonbipolar, nonpsychotic depression
Duration	12 to 16 Weeks, usually once weekly
	Three phases: diagnostic evaluation, implement strategies related to one of the four problem areas, consolidate gains
Technique	Education
	Reassurance
	Clarification of feeling states
	Remediation of interpersonal communication
	Testing perceptions
	Development of interpersonal skills
	Medication

Table 30.8-6 Key Elements of Interpersonal Psychotherapy

As short-term treatment for depression, interpersonal psychotherapy consists of three phases. The first phase generally consists of the first one to three sessions. Its goals are to gather psychiatric history, establish a diagnosis, and introduce the framework for treatment. The psychiatric history explores current social functioning. Particular attention is paid to gathering extensive information about interpersonal events that may have precipitated the depressive episode. The patient's current and past significant interpersonal relationships, including the family of origin, friendships, and community relations, are also reviewed during this first phase. The data gleaned from this review are used to identify one of four problem areas that will guide the therapy: unresolved grief, social role disputes, social role transitions, and interpersonal deficits. Psychiatric diagnosis is informed by standard criteria. Decisions about the concomitant use of medication are based on the severity of the symptoms, past response to interventions, and patient preference. The patient is placed in the sick role; the therapist explicitly discusses the diagnosis of depression and its attendant symptoms as well as explaining what the patient can expect from treatment. The depressive syndrome is then related to the patient's main interpersonal theme, which related to the syndrome's onset.

The middle phase of treatment is directed toward resolving the problem area. Specific goals and strategies are used for each of the four areas. For a patient whose main problem area is unresolved grief, the goals of treatment are to facilitate the mourning process and assist the patient in finding new activities and relationships to offset the loss. In the treatment of interpersonal role disputes, the dispute is identified, a plan of action is chosen, and a satisfactory resolution is sought through the modification of expectations or improved communication. If resolution proves impossible, clients are encouraged to consider terminating that plan of action in favor of finding better ones. For depression associated with role transitions, the patient is helped to mourn and accept the loss of the old role. Efforts are directed to helping the patient regard the new role as more positive than the old one. Self-esteem is enhanced by focusing on the new skills that are mastered in learning the new role. Finally, when interpersonal deficits are the core theme, the therapist encourages the patient to establish relationships and diminish social isolation.

Each session begins with the question “How have things been since we last met?” to focus on current mood states and their association with recent interactions. The basic techniques for handling each problem area are clarifying positive and negative feeling states, identifying past models for relationships, and guiding and encouraging the patient in examining and choosing alternative courses of action.

Interpersonal psychotherapy has been used across a variety of depressed populations: geriatric, adolescent, HIV-infected, dysthymic disorder, bipolar disorder, and depressed patients with marital problems. It has also been used for nonmood psychiatric conditions such as substance abuse and bulimia nervosa.

Cognitive Psychotherapy Cognitive therapy aims to correct habitual patterns of distorted thinking. It uses both behavioral modification techniques and verbal interventions geared at empirically testing erroneous beliefs. At inception it was a brief, individual treatment for depression. It has been used for a wide variety of psychiatric conditions and has been adapted for marital and group formats (Table 30.8-7).

Goal	Identify and correct cognitive distortions and dysfunctional beliefs that maintain symptoms
Focus	Beliefs about oneself, the world, and the future
Selection criteria	Primarily used in unipolar, nonpsychotic depression Nonendogenous depression Symptoms not sustained by pathological family
Duration	Time limited, usually 15 to 25 weeks, once-weekly meetings
Techniques	Collaborative empiricism Identification of irrational beliefs and automatic thoughts Identification of attitudes and assumptions underlying negatively biased thoughts Education Structured and directive Assigned readings Homework and behavioral techniques

Table 30.8-7 Key Elements of Cognitive Psychotherapy

Cognitive therapy as it is applied in the treatment of outpatient depression is a brief psychotherapy. Generally, marked improvement is seen between 5 and 7 weeks of once-weekly or twice-weekly therapy. If patients haven't achieved a 50 percent reduction in depressive symptoms using a standard rating scale for depression within 14 sessions, the patient's diagnosis and treatment plan should be reevaluated. After the primary therapeutic course is completed, once- or twice-monthly booster treatments are often given for the next 6 to 12 months.

Cognitive psychotherapy is a directive, time-limited, multidimensional psychological treatment that derives from the cognitive theory of psychiatric disorders. Cognitive theory posits that negative biased thoughts predispose to depression. These thoughts are often unconscious but can become conscious, and if the patient can be induced to become more logical and realistic, the depressed mood can be alleviated.

This cognitive reorientation is accomplished with a collaborative empirical approach. Together patients and therapist discover the irrational beliefs and illogical thinking patterns associated with the patients' depressive affects. They then devise methods patients can use to test the validity of their thinking. The therapist helps patients become aware of their irrational beliefs and distorted thinking (“automatic thoughts”) and to see, indeed, whether their ideas are objectively true or logical.

Cognitive psychotherapy is generally conducted over 15 to 25 weeks in once-weekly meetings. With more severely depressed patients, two or three meetings per week are recommended for the first several weeks. Although cognitive psychotherapy was developed, and is usually administered, as an individual treatment, its principles have been successfully applied to group settings.

Cognitive psychotherapy was developed for unipolar, nonpsychotic, depressed outpatients and has been shown effective in this subcategory of depression. The presence of bipolar illness, delusions or hallucinations, or extremely severe depression are contraindications for cognitive psychotherapy as the sole or primary treatment modality. Other contraindications include the presence of medical illness or use of a medication that may cause depression, the presence of an organic brain syndrome, or an ongoing problem of substance abuse. In addition, cognitive psychotherapy may not be indicated for endogenous depression, which may be accompanied by endocrine, sleep, or other biological abnormalities, or for patients who are enmeshed in a family system that maintains a fixed view of them as helpless and dependent. Cognitive psychotherapy may also be useful in patients who refuse to take, fail to respond to, or are unable to tolerate, medication as well as those who prefer a psychological approach in the hope of greater long-term benefits.

Cognitive psychotherapy proceeds in a succession of regular stages. The first stage is devoted to introducing the patient to the procedures and rationale of the therapy and setting goals for the treatment. The therapist may assign reading material on the cognitive theory of depression. The therapist devotes particular attention to eliciting a full description of the presenting problems and difficulties from the patient. With the patient, the therapist decides on the immediate goals of treatment based on the patient's priorities and the amenability of the symptoms to treatment. These procedures foster the therapeutic alliance by establishing a collaborative tone and socialize the patient to some of the basic therapeutic procedures, such as homework assignments.

In the next stage, the therapist begins to demonstrate to the patient that cognitions and emotions are connected. Patients are taught to become more aware of their negatively biased automatic thoughts and to recognize, both during and outside the psychotherapy hours, that negative affects are generally preceded by such thoughts. In addition, in this stage of cognitive psychotherapy, therapists attempt to find areas in which patients can be helped to demonstrate to themselves rather quickly that they are not as helpless or hopeless as they had thought, often accomplished by graded behavioral assignments (see below), especially with more severely depressed patients. This serves to help break the cycle of hopelessness and passivity.

In the next phase, which normally comprises most of the work, the emphasis shifts to a detailed exploration of the patient's cognitions and their role in perpetuating depressive feelings. The therapist helps patients clarify their beliefs and find ways of empirically testing their validity. Together the therapist and patient explore the content of the patient's automatic thoughts, pointing out instances of illogic and helping the patient consider alternative points of view that are not negatively biased.

In the final stage of psychotherapy, patients have had a great deal of experience in recognizing their habitual thought patterns, testing their validity, and modifying them when appropriate with resultant substantial symptomatic relief. Psychotherapy then focuses on the attitudes and assumptions that underlie the patient's negatively biased thinking. Generally, patients are not immediately conscious of such attitudes, as they would be of automatic thoughts, and they must be identified by careful examination of specific cognitions. An example of such an underlying assumption is the idea “If I'm nice, bad things won't happen to me.” A logically equivalent assumption is then “If bad things happen to me, it is my fault because I am not nice.” Specific automatic thoughts might result from such an assumption: “I caused my husband to treat me badly” or “I never have good times because I'm not nice.” In helping the patient successfully challenge and modify such assumptions, the therapist hopes to diminish the long-term frequency and intensity of negatively biased automatic thoughts and their concomitant negative affects. Cognitive therapists consider an increased understanding of the underlying assumptions about oneself and one's life to be an important element in increasing the patient's own ability to recognize and correct illogical, negatively biased thinking.

At all stages, cognitive psychotherapy is structured and directive. Each session follows a plan that is jointly formulated by the patient and therapist. Typically, a session begins with a review of the patient's reactions to the previous psychotherapy session, homework assignments, and the patient's salient experiences in the interim. Patient and therapist may then discuss possible topics and goals for the current session. Often, depressed patients feel overwhelmed and need help breaking down their problems into individual target symptoms that can be prioritized and dealt with one at a time. Target symptoms that might be the focus of a session include intense sadness, pervasive self-criticism, passivity and avoidance, sleep disturbance, or other affective, motivational, or cognitive manifestations of depression. The therapist repeatedly formulates the patient's beliefs and attitudes as testable hypotheses and helps the patient devise and implement ways of verifying them. The therapist maintains an inquiring attitude toward the patient's reactions to the therapist and the therapeutic procedures. Such reactions are explored for evidence of misunderstanding and distortion, which are then dealt with in the same way as the patient's other cognitions.

Comparison of Psychodynamic, Cognitive, and Interpersonal Brief Psychotherapies Because cognitive and interpersonal psychotherapies derive from the psychodynamic model, there is a high degree of overlap in the problem areas identified in any given patient. The conceptualization of the problem, however, differs. In many ways it is complementary rather than mutually exclusive. The psychoanalytic, interpersonal, and cognitive psychotherapies share explorative and change-oriented goals. Cognitive psychotherapy focuses on the patient's thinking; interpersonal psychotherapy, on the patient's interpersonal relations and social supports; psychoanalytically oriented treatments, on the internal experience of the patient and its relationship to past experience. Cognitive and interpersonal psychotherapies are most frequently used to treat depression rather than to treat an entire range of psychopathology. No studies using well-defined psychodynamic psychotherapies and medication have been performed. In this area, interpersonal psychotherapy and cognitive psychotherapy have been more closely studied.

Interpersonal psychotherapy cognitive psychotherapy, and the more traditional psychodynamic psychotherapies can be compared and contrasted. All three modalities are complex methods of treatment that must be tailored to the individual patient. All demand a high degree of clinical judgment, and the therapist needs a considerable amount of time to acquire competency. The relationship between the therapist and patient and establishment of a therapeutic alliance are essential in interpersonal psychotherapy, cognitive psychotherapy, and the psychoanalytically oriented treatments. Extensive exploration of the patient's thoughts and feelings, including those involving the therapist, are a major portion of the work. In addition, in all three, the therapist attempts to maintain an investigative, collaborative, and nonjudgmental stance (Table 30.8-8).

Time limited
Based on theoretical models derived from psychodynamic models: Recognize defenses (schema and cognitive distortions), transference (interpersonal patterns) and feelings and behaviors out of awareness
Published manuals specify the treatment
Can be used concurrently with medication
Empirical research indicates efficacy

Table 30.8-8 Common Features of the Brief Psychodynamic, Cognitive and Interpersonal Psychotherapies

In practice, cognitive psychotherapy is similar to the analysis of defense in the psychodynamic approaches. Understanding defenses focuses the patient and therapist on the hidden cognitive distortions that result in the patient's faulty perception of both the internal and external world. In the dynamic model, defense mechanisms are directed toward the control of anxiety resulting from conflict. The defenses, however, distort perception and cognition—similar to the distortions that are the focus of cognitive psychotherapy. In cognitive psychotherapy, cognitions are seen as causing the patient's distress. Much of the work in identifying these cognitions and alerting the patient to them is similar to the understanding and interpretation of defenses in the psychodynamic psychotherapies. The schemata underlying the faulty cognitions of cognitive psychotherapy are unconscious assumptions, which the psychodynamic model sees as derived from earlier experience. Both treatments share the importance of identifying these unconscious patterns of behavior and revealing them to the patient. To the extent that a psychodynamic psychotherapy focuses on the here-and-now experience of the patient rather than on the reconstruction of past experience, the similarity to cognitive psychotherapy increases. Frequently understanding a defensive pattern used by a patient to handle an ongoing conflict can be the endpoint of a well-conducted psychodynamic psychotherapy. In such a case, the outcome for cognitive and psychodynamic individual psychotherapy might be quite similar.

In the degrees of structure and directiveness, however, the two types of psychotherapy are different. In psychodynamic psychotherapy, the structure of the session is largely determined by the flow of the patient's thoughts and their interaction with the therapist's interpretive comments. In contrast, cognitive psychotherapy sessions are structured by an agenda that focuses the patient's thoughts and activities. In psychodynamic psychotherapy, the role of the therapist is limited to that of an empathic interpreter and sharer of the patient's experiences; in cognitive psychotherapy, the therapist may direct, prescribe, enjoin, educate, train, or role play as well. Furthermore, cognitive psychotherapy places much more emphasis on directly altering psychopathology rather than facilitating its alleviation through insight and resolution of inferred underlying conflicts.

Interpersonal psychotherapy is most closely related to the psychodynamic object relations' perspective; understanding internal objects rests upon understanding the actual interpersonal relationships of the patient, including the relationship with the physician. Both interpersonal and psychodynamic psychotherapy share a focus on identifications and transference, although IPT does not interpret transference. (Interpersonal psychotherapy defines a *paradigm* similar to *transference* as “past models for relationships.”) In addition, interpersonal psychotherapy pays particular attention to withdrawal and detachment, areas related to defenses in the psychodynamic model and faulty cognitions in the cognitive model. Interpersonal psychotherapy identifies interpersonal, rather than intrapsychic or cognitive, events. This frequently means that the interpersonal psychotherapy therapist's attention is directed to the same area of disturbance as the cognitive or psychodynamic psychotherapist's. However, the identified problem—interpersonal deficits, faulty cognitions, or intrapsychic conflict—is different.

Differences among the interventions of these psychotherapies are more striking than the differences in their goals or identified problem areas. To what extent it is the differences in psychotherapeutic treatments and to what extent it is their similarities that produce behavioral change is less clear. Both cognitive and interpersonal psychotherapy use more directive and behavioral interventions than psychodynamic approaches. Interpersonal psychotherapy and cognitive psychotherapy make more use of teaching new behavioral skills. More than the cognitive and interpersonal treatments, the psychodynamic psychotherapies rely on the patient to activate and practice new behaviors without direction. The briefer psychotherapies interpersonal psychotherapy, cognitive psychotherapy, and brief psychodynamic psychotherapy lack the extended working-through and application period of psychoanalysis and intensive (long-term) psychodynamic psychotherapy.

EFFICACY: RESEARCH AND EVALUATION

The brief psychodynamic treatments have a small empirical database, but much further research is needed. In general, these studies have supported the efficacy of this treatment approach. However, methodological issues are prominent in most research in this area. The development of handbooks for treatment has gone far in improving research in the psychoanalytically oriented brief treatments.

The effectiveness of psychotherapy is not argued as in the past. The brief psychodynamic psychotherapies have an effect size similar to many other medical treatments. However, which psychotherapy should be used for which patient by which therapist is still unclear. The cost-effectiveness of psychotherapeutic treatment remains hotly debated and is a focus of much current research. Individual psychotherapy results in fewer days of hospitalization for patients on medical or surgical services of a general hospital. In health clinics or health maintenance organizations, brief psychotherapy decreases the number of visits to primary health care providers, reduces the number of laboratory and X-ray studies, decreases the number of prescriptions given, and overall reduces direct health care costs. Recent summaries of the cost-offset effects of outpatient mental health treatment, most of which was short term, are hopeful but not unambiguous. One study found that outpatient psychotherapy reduced medical care utilization by an average of 33 percent. Furthermore, these reductions occurred mostly in the more expensive, inpatient medical services. In another study, 72 patients with significant emotional problems, treated only by internists in a general medical clinic, were compared with 62 patients who, in addition to being treated by internists for medical problems, received 10 weekly psychotherapy visits. The groups had approximately the same degree of emotional disturbance. At 4-month and 1-year follow-ups, the brief psychotherapy group reported significantly more global improvement than did the nonpsychotherapy group. Also, more patients in the brief psychotherapy group were employed at 1-year follow-up than in the nonpsychotherapy group. This study suggests specific beneficial effects of brief psychotherapy used in a medical setting by skilled psychotherapists.

Malan's finding of the importance of making the transference/parent link for successful outcome of treatment is significant and requires further exploration. Recently, a replication of his finding has been published, although others have found that too often interpretation of the transference may be related to a negative outcome. More recently, studies have also shown that overuse of transference interpretations may lead to poorer outcome. Measures of the therapeutic alliance, particularly from the patient's perspective, contribute to outcome, usually modestly. In another study attempting to replicate Malan's work, a patient's ability to relate to another person correlated with outcome 2 and 5 years after completion of treatment. Dynamic changes evident at 2 years were also present after 5 years.

Strupp's studies of college students in brief psychotherapy tend to confirm the importance of interactional variables. He found that the quality of the therapeutic interaction and the handling of the transference and countertransference were critical to success or failure in treatment. Strupp's studies indicate that patients treated by nonprofessionally trained therapists, on average, are as much improved as patients treated by professional therapists. However, they also show that such nonexperienced therapists run out of relevant material and soon become unwilling to continue to treat patients over an extended period of time. One of the important tasks of training in psychotherapy may be developing the ability to endure with the patient and, over time, with numbers of patients. Technical training and a theoretical framework may allow the therapist to maintain a sense of competence, direction, and interest in the work that the nonprofessional therapist cannot maintain.

IPT combined with pharmacotherapy is more effective than IPT or amitriptyline (Elavil) given alone. As single therapeutic modalities, IPT and antidepressant therapy are roughly comparable in appropriate mild-to-moderate depression. Maintenance IPT without active medication has resulted in a significantly greater time without relapse than supportive care and placebo.

Beck's cognitive psychotherapy model has been studied the most extensively of any of the psychotherapeutic modalities. Cognitive therapy is more efficacious for acute-phase treatment than waiting-list control conditions. In combination with antidepressant medication, cognitive therapy has proved superior to low-contact medication control groups. In general, cognitive therapy has been comparable to other active psychotherapies (e.g., behavior therapy, brief dynamic therapy, pastoral counseling). It is the only individual psychotherapy that has been formally adapted for treatment of depressed psychiatric inpatients. Cognitive therapy has not yet

been adequately tested for use as a continuation, or maintenance-phase, therapy.

In contrast to most other psychotherapies, there is a small, growing literature on the efficacy of cognitive psychotherapy. Although the number is still relatively small, all studies examining the outcome of cognitive psychotherapy have found it an effective treatment. Cognitive psychotherapy is more effective than no psychotherapy in treating both depressed volunteers and psychiatric patients with diagnoses of depression. The results are somewhat more mixed when cognitive psychotherapy is compared with other forms of treatment. For example, cognitive psychotherapy has been found superior to relaxation training, traditional insight-oriented psychotherapy, behavioral therapy, and client-centered therapy, whereas social skills' training, scheduled pleasant activities, and behavior therapy have been found to be just as effective.

The pattern of results is similar when cognitive psychotherapy is compared with standard antidepressant treatment. Some studies have found that depressed patients do better with cognitive psychotherapy than antidepressants, while others have found the two types of treatment to be equally effective. Although patients may not have been receiving adequate doses of medication in some of the studies that found cognitive psychotherapy to be superior, no study has yet found cognitive psychotherapy less effective than medications in unipolar, depressed outpatients. In these studies, depression (mild to moderate) was diagnosed by standard criteria. Therapy was carried on for 12 weeks (20 sessions of cognitive psychotherapy). Whether some patients benefit more from cognitive therapy or from medication treatment is unclear. Two studies compared patients with endogenous or nonendogenous depression and found no difference in response to cognitive psychotherapy or antidepressants. Older patients with nonendogenous depression respond better to cognitive (or behavioral) psychotherapy than do those with endogenous depression. Private practice patients have responded better to cognitive psychotherapy than to antidepressants, while hospital clinic patients fared equally well with the two treatments. The reasons for this difference are not apparent.

Some evidence indicates that when cognitive psychotherapy is found superior to tricyclic drug treatment, the advantage is in the speed of recovery rather than the eventual outcome. Patients given imipramine (Tofranil) or cognitive psychotherapy improved to about the same extent by 1 year after treatment, although the cognitive psychotherapy group was less symptomatic immediately following treatment. Similarly, patients who received cognitive psychotherapy did about as well 3 months after treatment as those who received treatment as usual (variable doses of antidepressants plus supportive psychotherapy), although those in the cognitive group were more improved at the end of treatment. Since depression is generally a self-limited disease, it is not surprising to see recovery rates equalizing after longer periods of follow-up. The more interesting question of whether cognitive psychotherapy protects against recurrences of depression over longer periods of follow-up has not been addressed in the literature.

Cognitive techniques and perspectives have been applied to conditions including (but not limited to) eating disorders, alcohol abuse, control of smoking, pain management, panic disorder, and tolerance of invasive hospital procedures. Data on the efficacy of such treatments are more scattered than for depression, but the pattern of findings is similar.

In summary, research to date has demonstrated that cognitive psychotherapy is about as effective as antidepressants in unipolar, depressed outpatients. As with antidepressants, however, not all patients respond well, and there are no reliable predictors of treatment response. Similarly, it is not clear that there are any target symptoms or behaviors that are specifically affected by cognitive therapy compared with other treatments. The active ingredients of cognitive psychotherapy in the treatment of depression remain to be identified. Focal, directive psychotherapies, in general, appear to be more effective than traditional, unstructured psychodynamic psychotherapy for depressed patients, but no clear superiority of cognitive psychotherapy over other directive therapies has been demonstrated.

FUTURE DIRECTIONS

The brief psychotherapies are an important component in the treatment of numerous disorders, primarily the adjustment, anxiety, and mood disorders. Both alone and in combination with medication they are an effective part of the treatment armamentarium. Clinicians should be trained in both brief and longer-term treatments and their use in brief, intermittent, and maintenance therapy. Skill in the longer-term psychotherapies is important to developing skill in the brief psychotherapies, in which rapid establishment of the therapeutic alliance and the accurate assessment of transference and defense patterns are important.

Empirical studies comparing well-defined brief psychodynamic psychotherapy with cognitive and interpersonal psychotherapies are limited. Future research must address which form of psychotherapy may be most helpful for which patient. In developing research strategies, it would be helpful to relate this question to the mode or modes through which any particular patient can most effectively learn new behaviors. An individual's available learning path (e.g., through the study of cognitions, interpersonal relations, or subjective experience) is influenced by state, trait, and contextual variables. The process of learning in the psychotherapies and the brief psychotherapies in particular, a process of altering neuronal organization through behavioral (primarily verbal) means, may be influenced by the patient's diagnosis, medications, past history, cognitive style, developmental stage, affective availability, doctor-patient match, and other variables. The effectiveness of the therapist in any given modality is certainly a critical variable. The differences and similarities in the outcomes of the various brief psychotherapies also require study.

SUGGESTED CROSS-REFERENCES

Learning theory is discussed in Section 3.3, and cognitive therapy in Section 30.6. Interpersonal therapy is covered in Section 30.7.

30.9 ERIKSONIAN CLINICAL THEORY AND PSYCHIATRIC TREATMENT

EDWARD R. SHAPIRO, M.D., AND M. GERARD FROMM, PH.D.

Erik Erikson (Fig. 30.9-1) made significant contributions to a broad range of disciplines, but the application of his theories to clinical practice has not received proper recognition. Although considered among the group of ego psychologists that transformed psychoanalytic theory in the 1950s and 1960s, Erikson's emphasis on how the individual is inextricably bound to sociocultural and historical forces has broad and largely underdeveloped clinical significance.

FIGURE 30.9-1 Painting of Erik Erikson (by Norman Rockwell, Courtesy of Edward R. Shapiro, M.D.).

David Rapaport described Erikson's work as the culmination of ego psychology, the first psychoanalytic theory of the person's relationship to social reality with which the ego is always engaged. Rapaport noted, “[Erikson's] concept of mutuality specifies that the crucial coordination is between the developing individual and his human (social) environment.” This concept extends clinical work beyond the boundaries of the individual and opens it to larger scrutiny. From his clinical study of patients, Erikson recognized how the pathology and recovery of patients are linked to how they engage and are engaged by their world.

THEORETICAL ISSUES

Erikson noted that people get as invested in ideas as they do in people. His clinical and theoretical approach included questions of commitment, engagement, and integrity. Integrity was central to psychological health. He defined it as “man's obligation to the most mature meaning available to him, even if this should bring discomfort to himself, deprivation to his mate and offspring, and the loss of friends, all of which must be imagined and endured in order not to be exposed to a final sense of disgust and despair.” Integrity transcends the pair, or dyad, and requires discovery of larger social tasks to which the individual can become committed. This formulation illuminates Erikson's clinical perspective of humans as social beings, linked to larger historical and cultural developments. Integrity and psychological health require discovering this connection.

Erikson had a broad view of the task of psychoanalysis. He considered it a tool for examining “that aspect of man which in a given historical period was being neglected, exploited, suppressed by prevailing technology and ideology.” Given the immediate dependency on the human environment in early life, he considered the study of children and adolescents a crucial window for developing psychoanalytic theory. Erikson conceptualized the identity crisis that occurred during adolescence as a necessary integration of the adolescents' social reality with their history and new biological capacities. Identity formation is an activity of the ego that derives from the relation of individuals' self-definition to developing social definitions of those individuals as they mature. This notion opened the study of interaction, family process, and social change as mediators of clinical phenomena.

TECHNIQUE

According to Erikson, the ability of the patient's ego to mediate between the demands of unconscious internal pressures (i.e., instincts and affects) and the pressures of the external world (i.e., relationships, social reality) was a primary focus of treatment. In Erikson's thinking, the surface (i.e., the ego) revealed the depth. When he listened to patients, he listened with an artist's ear—he heard the words, saw the spatial relationships, and made temporal links between the somatic, affective, and interpersonal parts of the personality. He listened to texture and saw configuration. He paid attention to the whole life context of any immediate situation. He asked a number of questions. What is the immediate stimulus for the patient's reaction? What is the acute life conflict, the current developmental stage, the issues that are manifest? In what developmental context did the patient's reaction first occur? Is it now manifest in the relationship to the therapist, in a repetitive conflict, in a characteristic way that the individual solved earlier developmental struggles? In what social context is the individual embedded, what roles are available? What are the typical stereotypes, particular opportunities, and barriers? What are the characteristic ways in which the individual takes in information? What defenses does the individual use? Where are the individual's deepest psychological investments?

Like his contemporary, Donald W. Winnicott, Erikson had a family perspective. He recognized that children react to the shared family unconscious, reading their parents' vulnerabilities and unexpressed wishes with clarity. Studying seriously disturbed patients, he saw that their breakdowns occurred at times of developmental separation or individuation (e.g., physical intimacy, occupational choice, or identity formation). Erikson's study of identity revealed the consistently accruing social value of increasing commitment to and from others. He saw social recognition as providing defenses against impulses, and he saw work as a means to consolidate conflict-free achievements. Work provided an opportunity to resynthesize childhood identifications in new ways in accord with available roles.

Role of the Therapist Erikson felt that, in the consulting room, therapists had to be aware of both their own and the patient's obligations to others. Therapists have methodological responsibilities and must understand both their role and their motivations. Self-observational vigilance is essential, and Erikson believed that therapists cannot see in another what they have not discovered in themselves. For Erikson, the therapeutic contract with the patient is the essence of study. As new data emerge from the patient, the therapist must be committed to continuous conceptual revision. Establishing a state of trust between doctor and patient is a basic requirement. Erikson felt that the therapist needed a sense of personal trustworthiness that could be transmitted to the patient.

CLINICAL ISSUES

Although no independent Eriksonian psychoanalytic school exists in the same way as the Freudian and Jungian schools, Erikson made many important contributions to the therapeutic process, many of which can be gleaned from examining his rare reports of patients he treated. One such case was reported in his seminal paper “The Nature of Clinical Evidence,” published in 1957. In that paper, Erikson writes that the concepts of “repression,” “regression,” “transference,” and “libido” are essential to his clinical way of thinking. He adds that he tries “to keep each linked with the observation and experience of the clinical encounter as a new event in the patient's life history.” Examination of unpublished aspects of this case (available to the authors) reveals a complex clinical theory that was ahead of its time.

The patient, a seminarian in his 20s, presented with anxiety, hopelessness, “psychic pain” in his body, and suicidal thoughts. He was distressed by impulses to hurt others and obsessively turned to prayer for help, feeling increasingly alone and that his impulses were terribly incompatible with his religious aspirations. These symptoms were the latest attack in a series of such symptoms, beginning when the patient was a senior in high school, following his maternal grandfather's death.

The oldest of five children, the patient was unusually close to his mother who raised him according to the rigid schedule then in vogue. He idealized his father, who was largely absent from the home and “unable to deal with feelings.” He had significant separation problems in kindergarten. Throughout his childhood, he found his mother to be alternatively happy and depressed, loving and withdrawn, nagging and martyred. The patient was uncomfortable with her physical attention to him and her overprotectiveness. Most of the patient's comments concerning family discord centered around his mother's changing moods and his feeling of impotent rebellion against her. The patient felt he was a great deal more like his mother in personality than his father, which was a source of concern to him. He was very close to his mother's father, with whom he spent summers in a rural community. Mother was very supportive of their relationship. Shortly before grandfather's death during his adolescence, the patient was rebellious to him. Grandfather's death led to a significant depression in the mother. Shy and a good student, the patient was preoccupied with issues of power, prestige, and acceptance by others.

Psychological testing confirmed borderline psychotic features in an inhibited, obsessive-compulsive personality, struggling to maintain control over aggressive impulses but also able to distance himself from these feelings well enough to manage them and examine them in therapy.

Erikson's published summary of this case reports one of the patient's dreams and the clinical crisis it suggested: “There was a big face sitting in a horse and buggy. The face was completely empty, and there was horrible, slimy, snaky hair all around it.” The patient stated anxiously, “I'm not sure it wasn't my mother.”

The patient's associations indicated that the “horse and buggy” referred to his beloved grandfather. In the patient's history, he had shown delinquent tendencies, defying his grandfather just before his death. Erikson wondered whether the patient felt that his anger had destroyed his identity supports. His mother had been frightened by his rebelliousness, and he had come to feel controlled by her overprotectiveness. Erikson thought of the Medusa-like image in the dream as the “female void” and considered the meanings of “loss of face” and lack of identity. The general theme of the dream seemed to Erikson to be “when I have faith in another's love and strength, angry feelings come up and I end up mistrusting, empty and full of despair.”

Dreams and Free Association Like Freud, Erikson worked with the patient's associations to the dream as the “best leads” to understanding its meaning. He valued the first association to the dream, which he believed to be powerful and important. Ultimately, Erikson listened for “a central theme which, once found, gives added meaning to all the associated material.”

Erikson believed interpretation to be the primary therapeutic agent, sought as much by the patient as by the therapist. He emphasized free-floating attention as the method that enabled discovery to occur. Erikson once described this attentional stance by commenting that in clinical work, “You need a history and you need a theory, and then you must forget them both and let each hour stand for itself.” This frees both parties from counterproductive pressures to advance in the therapy and allows them both to notice the gaps in the patient's narrative that signal the unconscious.

In relation to the patient described above, Erikson noted “the seemingly paradoxical fact that during his prior hour [before the dream] the patient had spoken of an increased well-being” or again, “Although the patient acted as if he were close to a breakdown, I had the impression that, in fact, there was a challenge in all of this, and a rather angry one.” Beside the central dream image of a horrifying empty face, Erikson notes “omission of important items present in most dreams: motion, action, people, spoken words.” He surveys this surface of the dream as a way of placing it in context; each omission or inclusion has potential significance.

Repression Erikson wrote of his patient: “I have to assume that the patient is (to varying degrees) unconscious of the meaning which I discern in his communications, and that I am helping him by making fully conscious what may be totally repressed, barely conscious, or simply cut off from communication.” He described his patient—and by extension all patients—as a split or conflicted subject, whose self-esteem, stability, and relationships were precariously maintained by an enduring, unconscious obliteration of some core emotional experience. For Erikson, “the traumatic past is of course a present frontier, perceived as an acute conflict.” He saw the ego as an integrative force directed toward overcoming repression.

Regression and the Setting Erikson also described a “regressive trend, a going back to earlier failures in order to solve the past along with the present.” This point of view locates Erikson among the developmental psychoanalysts, like Winnicott, who view regression as a persistent, unconscious effort toward reintegration. They thus follow and extend Freud's later theoretical revisions that explore the compulsion to repeat as an effort to master trauma.

In this positive and optimistic view of regression, Erikson does not neglect his clinical responsibility to the patient's functional regression. “Our patient's behavior and report confront me with a therapeutic crisis, and it is my first task to perceive where the patient stands as a client, and what I must do next.” Erikson felt the patient's panic in and about his dream. He wrote that “even in the hour of reporting, the dream-state seemed still vivid enough to threaten the patient's sense of reality.”

His assessment of the patient's regression not only took into account the emotional tone of the patient's narrative in the session, but “first and last depends, of course, on the *setting* of his work.” Since Erikson's patient was in an open residential treatment center (i.e., the Austen Riggs Center), he was already familiar with the setting and its “calculated risks” and “special opportunities.” He knew that the patient's adaptation to Riggs had been assessed and established. He could thus conclude that “a dream-report of the kind just mentioned, in a setting of this kind, will first of all impress the clinical observer as a diagnostic sign. This is an ‘anxiety dream'.” This statement requires emphasis because along with a number of other comments, Erikson pointed to the setting as a “third” element to the patient-therapist dyad. The setting has symbolic meaning that influences the psychotherapeutic work and gives it special meaning. Context organizes meaning, and Erikson expanded the notion of the relevant context to include multiple levels: environment, family, society. Regarding the patient's dream reported on above, Erikson stated: “whether this dream is the sign of an impending collapse, or. . . a potentially beneficial clinical crisis” depends on its context. In this case, the patient's successful adaptation to the environment pointed Erikson toward the latter interpretation (i.e., potential benefit).

Erikson believed that emotional conflicts of childhood were played out again as part of current developmental tasks. Dream analysis led Erikson to recognize that “these patients [i.e., borderline patients] are deeply, if unconsciously, convinced that they have caused a basic disturbance in their mothers.” The “violated' mother” and the associated “images of guilt” become “an obstacle in the resolution of adolescence—as if a fundamental and yet quite impossible restitution were a condition for adulthood.” To move forward, Erikson's patient must first move backward; this is regression in the service of the ego.

Erikson elaborated a clinical point of view that considered depending on the analytic setting and the relationship to the therapist central to change. Describing the patient above, he wrote:

> [H]e had taken a real chance with himself and with me. Under my protection and the hospital's he had hit bottom by chancing a repetition of his original breakdown. He had gone to the very border of unreality and had gleaned from it a highly condensed and seemingly anarchic image. Yet the image, while experienced as a symptom, was in fact a kind of creation, or at any rate a condensed and highly meaningful communication and challenge, to which my particular clinical theory had made me receptive.

Erikson's view of regression was ultimately an optimistic one. He says, “I would not give the past a kind of fatalistic dominance over the present.” He believed that “we all relive earlier and earliest stages of our existence in dreams, in artistic experience, and in religious devotion, only to emerge refreshed and invigorated.”

Libido Erikson considered libidinal attachments and experiences of dependence and abandonment of paramount importance. Erikson's concept “specifies that the crucial coordination is between the developing individual and his human (social) environment, and that this coordination is mutual.” His theory is not one of quanta of energy but of relationships. Erikson focused on the power of abandonment and dependence. He emphasized and examined attachment, separation, and mutuality in the multiperson system.

Erikson's patient associated the horse and buggy on which the horrifying empty dream-face was seated with his beloved maternal grandfather and, by extension, with the loss of the rural caretaking culture of his childhood. The nostalgia for his grandfather turned out to be the prevailing mood of his mother and the pervasive, unnamed emotional communication from her to her son. Simultaneously, she unconsciously communicated that anything aggressively individuating in him would prove deadly, or at least crushingly disappointing to her. This is a familiar shared fantasy in families of borderline patients, in which the child's separation represents and requires a hateful devaluation of the family. In Erikson's patient, the mother's traumatic loss of her father pushed her unconsciously toward an irrational claim on

her son; his necessary developmental process threatened to reopen her repressed grief. Erikson described this as missed mutuality. Although Erikson did not develop a family group formulation, he did highlight the absent father who might have provided both concretely and symbolically some “third” perspective on this conflicted dyad.

In his 1950 paper “The Theory of Infantile Sexuality,” Erikson outlined his thinking about “libidinal disbalance” along with a hint of his clinical approach. His crucial leap beyond Freud was to give full recognition to the idea that erogenous zones are the sites of highly charged exchanges and interactions with the environment, another aspect of mutuality. Anality thus represents not only a particular site of stimulation, but the action modes of holding onto or letting go and the relational modes of submission or defiance. Erikson thus described a rudimentary action language that is embedded in the body and that helps structure the psyche. His therapeutic approach requires that clinicians pay attention to the patient's actions, particularly those that have not yet been put into words (e.g., the affects surrounding the dream).

Transference Erikson described transference as an important part of treatment. “I would also acknowledge the power of *transference*, that is, the patient's transfer to me of significant problems in his past dealings with the central people in his life; but I would know that only by playing my role as a new person in his present stage of life can I clarify the inappropriateness of his transferences from the past.” He suggests that the context in which transference can be interpreted is the real therapeutic role in the relationship between doctor and patient. Inquiry and care, not indulgence or exploitation, is a new experience for these patients, which contributes to therapeutic change.

Erikson felt that clinical psychoanalysis relied methodologically on “disciplined subjectivity.” By that he meant that he not only attended to what patients said about their dreams and how they behaved in the telling, but he attended also to what he himself thought and felt as he sat with the patient. In focusing on the transference, Erikson considered whether the patient was breaking down or trying to communicate. He noted that “the first would mean that he is slipping away from me. . . the second, that he is reaching out for me with an important message which I must try to understand and answer.” Erikson was completely attentive to the patient's actions in relation to him, and he believed that the therapist had a role-related responsibility for answering or interpreting.

Erikson considered his own reactions to the horrifying empty face of his patient's dream. As the patient reported the dream, Erikson wrote that his “facial and tonal expression reminded me of a series of critical moments during his treatment when he was obviously not quite sure that I was ‘all there' and apprehensive that I might disapprove of him and disappear in anger.” In analyzing dreams, Erikson believed that the therapist “does well to raise discreetly the masks of the various dream persons to see whether he can find his own face or person or role represented.” By so doing, Erikson finds not only transference as distortion but transference as the actual current version of an earlier, but still powerful issue. Indeed, Erikson considers how the patient's transference may be “right” in some aspects. His patient's dream, for example, included both the recent sense that the patient trusted him and an earlier tenuousness in their relationship in response to Erikson's going off for an emergency operation months before. He described that experience as “inflicting his mortality” on the patient. “At the time of this dream-report I still was. . . mildly uncomfortable.” Thus the patient experienced “conflict between his sympathy, which makes him want to take care of me, and his rightful claim that I should take care of him.” Like the dream figure, Erikson had wavy hair.

Erikson comes to a partial interpretation that translates the dream event into a sentence:

> I concluded that the empty face had something to do with a certain tenuousness in our relationship, and that one message of the dream might be something like this: “If I never know whether and when you think of yourself rather than attending to me, or when you will absent yourself, maybe die, how can I have or gain what I need most—a coherent personality, an identity, a face?”

Whatever other meanings there might be to the dream, whatever other central life figures might eventually show through the empty face, Erikson emphasized transference analysis. “I put first (the patient's) fear that he may yet lose himself by losing me too suddenly or too early.”

Countertransference Erikson did not explicitly name countertransference, yet he was aware of it and used it technically. Recognizing the protection given by his professional role, Erikson noted, “The clinician. . . finds himself part of another man's most intimate life history. Luckily he also remains the functionary of a healing profession.” With regard to using the countertransference or, as Erikson puts it, “the disposition of the clinician's ‘mixed' feelings,” Erikson believed that “the therapist must use his own emotional responses during a clinical encounter as an evidential source and as a guide in intervention. . . Patients of the type of our young man, still smarting in his 20s under what he considered his mother's strange emotions in his infancy, can learn to delineate social reality and to tolerate emotional tension only if the therapist can juxtapose his own emotional reactions to the patient's emotions.”

Erikson concluded about countertransference that [a]ny psychotherapist. . . who throws out his ethical sentiments with his irrational moral anger, deprives himself of a principal tool of his clinical perception. . . [O]ur indignation, admitted and scrutinized for flaws of sulkiness and self-indulgence, is, in fact, an important tool both of therapy and of theory.” The therapist's reaction represents, for Erikson, an important aspect of “available emotion and responsive thought.” The therapist must maintain a “disciplined subjectivity.” He must also, “while facing most intimate and emotional matters. . . maintain intellectual inner contact with. . . conceptual models.”

For Erikson, countertransference is used to make sense of the transference and also help the patient consolidate reality testing. Erikson described the previous hours and the way in which the patient presented the dream as feeling like an angry challenge. He noted that “the patient's main resistance consisted of testing me by a whining tone of voice, a child's voice saying, ‘I don't want you to go away, but I know I will make you go away by my not wanting you to.' “He associated the patient's reaction to his operation and the psychological testing that had revealed the patient's precarious control over his aggression. He communicated this reaction to the patient in the form of an interpretation.

Interpretation Erikson told his patient “without anger, but not without some honest indignation, that my response to his account included a feeling of being attacked.” He suggested that the patient was protesting, “Why are you not doing for me what my grandfather did? Why is my father not like my grandfather? Why do all of you father figures abandon me to my mother's masochistic rage? Why is there death, mutilation and rage in the world? How can I sustain love, i.e., *keep your face alive in me*, when my mother's face always disintegrated, making me feel that I had destroyed her?” Erikson goes on to describe feeling worry and pity. He said that he had been touched by the patient but also challenged to prove something. He felt imposed upon with the “burden” of the patient's “future which (the patient) could well learn to manage.” Erikson's final interpretation went something like this: “I feel attacked, worried, pitying, touched, and challenged to prove the goodness of mothers, the immortality of grandfathers, my own perfection, and God's grace.”

This interpretation, a playful tour de force, took into account the manifest dream, the patient's affective presentation and associations, the transference repetition of the patient's rage at the mother and at the grandfather's death, the narcissistic wishes for an idealized figure around whom to build an identity, and Erikson's countertransference irritation. Erikson says, “By relating the fact that his underlying anger aroused mine, and that I could say so without endangering either myself or him, I could show him that in his dream he had also confronted anger.” This is a way of facing the patient. Erikson is describing the therapist surviving the patient's aggression, without retaliation or capitulation, a capacity now considered essential in work with patients with personality disorders. Erikson says of his patient, “[W]hile accepting his transferences as meaningful, I had refused to become drawn into them.” Instead, he compensates for this therapeutic refusal by “offer[ing] him my help as defined by my professional status in attempting to understand what was behind his helplessness.”

“Clinical evidence,” Erikson writes, “is characterized by an immediacy which transcends formulations.” Erikson's patient was “amused, delighted and encouraged” by his confrontative interpretation. Erikson points out that “[t]he patient left the hour—to which he had come with a sense of dire disaster—with a broad smile.” He concludes that the “proof (of an interpretation) lies in the way in which the communication between the therapist and patient ‘keeps moving,' leading to new and surprising insights and to the patient's greater assumption of responsibility for himself.”

The interpretation condensed Erikson's irritation at the patient's “whining” demand and his “desperate insistence on finding security,” while overcoming his countertransference wish to take care of the patient. The interpretation revealed Erikson's confidence in his patient's capacity to deal with confrontation. It affirmed the patient's inner resources to continue his development, and indicated Erikson's appreciation of the risk his patient had taken by symbolically repeating the original trauma in the dream. The “new relationship” captured by the interpretation is between the patient and an adult in a therapeutic role, in which understanding is possible.

Action and Actuality Not only did Erikson pay attention to action as communication, he also supported it as potentially important engagement. He affirmed the healing role of play and its derivative, work. Erikson defined *actuality* as “the world of participation, shared with a minimum of defensive maneuvers and a maximum of mutual activation.” He emphasized how an individual's maturing capacities evoke cooperative responses from others that are needed for joint survival.

Erikson's formulation about actuality derived from his study of Freud's Dora case, during which the treatment foundered on Freud's uncertainty about what Dora needed from him. Erikson argued that Dora needed to have Freud recognize the historical truth of her family's infidelities. Recognition of potential historical truth is not the same as the practice of “validating” historical truth (e.g., childhood abuse). Erikson knew that the therapist could not know the truth in some objective way. That kind of presumed validation can represent a defensive collusion between patient and therapist to ward off the patient's current aggression. To suggest that patient and therapist can know the whole truth collapses the space for inquiry, for not yet understanding, and for perspective. Erikson means to hold onto perspective. The recognition of potential historical truth has to do with the young person's need to have an adult affirm the reality of family dynamics and the possible accuracy of her interpretation of those dynamics. This testing of reality could be approached another way. The therapist could conduct a family meeting in which the patient's interpretation of her family could be explored and tested. Erikson suggests that Dora required an external affirmation of reality. Only then could Dora consider the role of her own impulses in these events. Dora's family was an example of failed mutuality. Erikson grasped the way adolescents need help in recognizing and coming to terms with this shared failure before daring to venture beyond.

In the informal clinical notes on his patient, Erikson explored the world of action in some detail. Because his patient felt unconsciously that he had damaged his mother, he found himself preoccupied with sexuality as a means of both separation and reparation. Successful sexual intercourse, he felt, would “break through to reality, establish himself as a man, [and develop] a lasting ability to think clearly.” There were certainly women patients at Austen Riggs willing to help him, but in line with his commitment to the patient as embedded in the larger community with its values, this evoked in Erikson the need to “firmly insist on some. . . precautions for the protection of Riggs, of the lady (who might become) involved, and of himself.” Erikson described these potential partners as “uprooted.” They could not be expected to keep faith with the patient nor he with them. He stated, “Neither damnation nor salvation will result from these experiences.”

This prohibition served two purposes: it provided a frame within which the patient's anxieties could be contained, and it evoked the patient's transference fantasies that Erikson wanted all the women for himself or, as mother figure, that he would tear out his hair in response to the patient's exploration. When the patient developed sexual fantasies about these women, who were older, Erikson felt he “should not shy away from such material but should rather delineate its reality in an infantile context and its symptomatic nature in the present adult context.” By this, he was referring to incestuous fantasies. Erikson encouraged therapists not to avoid guiding patients; he believed that therapists must offer patients both prohibitions and permissions.

Work In his clinical notes, Erikson added to his ideas about identity the relationship to work and the development of a professional role. He noted that the patient's breakdown occurred in the context of an urgent professional dilemma: wanting to become a monk was “the last step in a series of attempts at becoming somebody who was ‘to help weak people,' while recanting all competition.”

Joan Erikson, Erik's wife, developed an activities program at the Austen Riggs Center as an “interpretation-free zone” where patients could take up work roles or function as students with artists and craftspeople, without the burden of the patient role. This work space encouraged the play and creativity required for the patients' work development to parallel the process of their therapy. This patient moved from pottery in the program, to musician, to bartender in a local inn, to laborer with a construction business, to his professional career. Erikson notes that the pottery preserved the patient's capacity to function as a “good worker,” though he felt the patient was in danger of “becoming a slave” to the clay. As a musician, to his surprise, Erikson's patient felt the fusion of his mother's loving voice with his own noisy infantile one, allowing him to feel a safe connection to her and to realize he had not destroyed her. Once he took a real-world job, he found himself struggling with what Erikson called, “the boss problem. . . the co-worker problem and. . . the work-role problem,” all of which held him safely in a role but pushed him to face his fear of loss of ego boundaries, for example, by reacting to work problems in an all-or-nothing way and ragefully ruining his work in the process. Erikson noted that:

> Impulse control is different in a bartender than in a minister, and so are the small social crises—or so it seems, until one tries it out. Then it becomes apparent that positions of trust, intermediary positions between owner and employees, positions highly susceptible to the weaknesses (and confessions) of others, have a lot in common. . . . It is such recognition of the *principles* of a work situation which. . . gives the patient eventually the freedom to choose his career not on the basis of role-appearance, but on that of inner compatibility of activity, role and personality.

Erikson's patient eventually became a doctor. Erikson commented:

> The patient's medical identity was not the sum of all his identifications with doctors, but. . . the inner coherence of his gifts and trends quite independently pointed in this direction:. . . the wish to help, now relatively freer from soul-saving fervor; the technical gifts of using his hands, now relatively freer from masturbation guilt, and tried on machines; psychological empathy, now relatively freer from over-identification, and tried in an industrial work-situation; an excellent mind for study;. . . liking for being depended on and for wearing a halo, now relatively freer from megalomanic and despotic trends; a freer wish to compete, even with his father for whom he felt a new respect; and behind it all, I assume, the age-old (unconscious) wish of doctors: wanting to cure mother, who seemed so incurable when he was a baby.

Further Clinical Considerations Erikson did not see himself as founding his own school of psychoanalytic psychotherapy nor indeed as departing from Freud in his clinical approach. Though his developmental road map enriches the Freudian psychosexual categories enormously—and offers the possibility of facilitating understanding and change throughout the life cycle—Erikson's clinical theory remained grounded in core psychoanalytic concepts creatively adapted to work with more severely disturbed patients.

Erikson considered the wish to get well, the synthesizing capacity of the ego, and a capacity for mutuality to be important indications that a successful treatment might be possible. He saw developmental trauma and conflicts associated with dependency, separation, and aggression as indications that such treatment might be needed.

APPLICATION TO PSYCHOPATHOLOGY

Erikson described sequential stages of the life cycle, each representing a success or failure of the mutual coordination between the child's development and the responses of the human environment. He related failures of each stage to particular pathological outcomes.

Basic trust versus mistrust—This stage marked the developmental struggle of early infancy. Failures contribute to depression, hopelessness, difficulties in engaging others, suspiciousness, and withdrawal (characteristics seen in disorders in the schizotypal and major depressive spectrum).

Autonomy versus shame or doubt—This characterized the period of separation-individuation and toilet training. Failures in this negotiation contributed to narcissistic vulnerability, delinquency, and obsessive behavior.

Initiative versus guilt—This struggle characterized the outcome of the oedipal conflict. Erikson saw failures here contributing to generalized anxiety, phobias, inhibitions, impotence, or psychosomatic illness.

Industry versus inferiority—Failures in this negotiation during the ages 7 to 11 contributed to work inhibitions, feelings of inadequacy, or a compensatory and defensive drive for money, power, and prestige.

Identity versus identity diffusion—Characterizing the adolescent struggle, failures here contribute to difficulties leaving home, prolonged dependence, the resurgence of borderline and narcissistic phenomena, and manifestations of role diffusion in work or career.

Intimacy versus isolation—Erikson saw the formation of healthy adult relationships as manifesting successful resolution of this stage.

Generativity versus stagnation—This dimension of mature adult life, which involves ongoing growth and commitment to what one has created, Erikson related to midlife crises.

Integrity versus despair—This late-life phase, having to do with the fulfillment of identity, Erikson connected to the depression-related episodes of old age.

Though Erikson's stage theory was revolutionary in the 1960s, subsequent study of parent-child relations have revealed that these phenomena are infinitely more complex. These stages repeat throughout the life cycle. Residues of earlier difficulties recur, and development has a much less linear shape, as do the influences of

the environment. Eriksonian diagnosis reflects this complexity. Rather than insisting on a one-to-one correspondence between developmental phase failure and a specific disorder, Erikson thought that a true developmental diagnosis would describe the range between the initial fixation and the later developmental arrest. In other words, diagnosis has to do with when the trouble started and how far the patient got in development before breaking down.

Goals of Treatment Erikson underlined missed mutuality as a quieter, yet equally traumatic warping of development and considered the restoration of mutuality to be a goal of treatment, as both a way of working and as an outcome. Additional goals included both the developmental advance that follows the resolution of particular life crises (e.g., a restored capacity for trust, the development of more-flexible autonomy, or the discovery of less-inhibited initiative), and the integration of self-awareness and relatedness to the world that combines to make up a coherent and recognizable identity. Erikson's treatment was aimed at helping the patient's ego become stronger and heal itself. A goal of therapy is to recognize how patients have passed or not passed through the various stages of the life cycle and how the various crises have or have not been met. He believed that psychological growth and development can occur throughout the life cycle.

Future Directions Erikson's clinical concepts suggest that learning is a two-way street. Crucial information is gained by “listening” therapeutically to how the younger generation responds to its interpersonal environment. Erikson adds that “it is in this mutuality of the development of the older and younger generations that certain and universal values such as love, faith, truth, justice, order, work, etc. in all of their defensive strength, compensatory power, and independent creativity become and remain important joint achievements of the individual ego development and of the social process.”

Drawing again on the clinical context, Erikson believed that “if ‘psychoanalyzed' man learns to recognize the fact that even his previously repudiated or denied impulses may be ‘right' in their refusal to be submerged without a trace (the trace being his symptoms), so he must also learn that his strongest ethical judgments are right in being persistent even if modern life may not consider it intelligent or advantageous to feel strongly about such matters.” This brings Erikson to an important conclusion: “this means that we somehow harbor a model of man which could serve as a scientific basis for the postulation of an ethical relationship of the generations to each other.”

Erikson's gift was to take the psychoanalytic lens, initially developed to look inward, and use it to look outward as well—to play, creativity, the lived and examined life, the social playground, adult development, collective conflicts, and organizational structures. His grasp of the inextricable links between the individual and the context, his recognition of “the interdependence of individual aspiration and social striving,” and his ability to hold the interests of community and society while strengthening the individual remain as challenges to the future development of clinical work.

SUGGESTED CROSS-REFERENCES

Erik Erikson's life and ideas are further discussed in Section 6.3, and Sigmund Freud's ideas are discussed most fully in Section 6.1. Other theories of personality and psychopathology are discussed in Section 6.3 and Section 6.4. Schizophrenia is discussed in Chapter 12, mood disorders in Chapter 14, personality disorders in Chapter 24, and psychosomatic disorders in Chapter 25. Normal child development and adolescent development are discussed in Section 32.2 and Section 32.3, respectively; adulthood is discussed in Chapter 50, normal human sexuality in Section 19.1, and normal aging in Section 51.2c. Psychoanalysis and psychoanalytic psychotherapy are discussed in Section 30.1.

30.10 OTHER METHODS OF PSYCHOTHERAPY

KENNETH Z. ALTSHULER, M.D.

This section reviews several psychotherapies, some with a particular political slant or dealing with a special population, and some older therapies that continue to have discrete followings. New therapies usually begin with charismatic therapists attracting disciples to their particular theories and teachings. The group so formed refines and promulgates the master's principles and tactics. As the word is spread, a school and often a movement is formed. Proponents of the treatment undertake research and generally show the therapy to be powerful in its scope and effectiveness.

When the founder leaves the scene, the group continues to augment the therapy's principles of practice and extend its range. As generations of adherents follow, what is useful or novel in the original tends to become incorporated into the mainstream. The movement may continue as a splinter group, shrink, or disappear, or have another incarnation and extension as it is rediscovered by a different discipline with a therapeutic aim.

Over the years the parent disciplines of dynamic and behavioral therapy have drawn closer and blurred their boundaries, sharing certain characteristics that form the basis of all psychotherapies. Such common elements include: a healer-patient relationship, with the different roles carrying different expectations and a differential balance of power; a nonjudgmental, supportive acceptance of the patient; and a comforting opportunity for emotional catharsis and the owning up to unpleasant wishes. All also have rituals, that is, things to do together that maintain a focus and keep the parties interested, and a theory that informs the therapist and patient and is a tool with which to reframe experience and enable behavioral change.

The universality and considerable power of these common elements are factors to bear in mind when claims of distinction and unique effectiveness are offered under the banner of any therapy, new or old.

PARADOXICAL AND STRATEGIC THERAPIES

History According to the principle of paradoxical intention fighting the symptoms of performance anxiety increases their severity, but invoking them deliberately may yield the opposite. Milton Erickson elaborated these ideas into paradoxical therapy, and the method was further refined and promulgated widely by Jay Haley.

Erickson was a hypnotherapist whose prowess in the use of paradoxical techniques was reputed to be extraordinary. While working on the double-bind theory of schizophrenia, Haley became interested in the possibility of therapeutic double binds as well as pathological double binds. Haley attended one of Erickson's hypnosis workshops in 1953 and, with John Weakland, began a regular series of visits that lasted for 20 years. Haley and his colleagues observed and learned from Erickson and published what they had learned. Others made similar visits or were attracted by the ideas or the stories they heard, and they added to the reputation and the literature of the growing movement. Haley later developed strategic therapy, essentially a method that applied Ericksonian paradoxical principles, along with other directive techniques, to family therapy.

Interest in paradoxical therapy grew over the years and reached its height in the late 1970s and early 1980s. By this time the method claimed success in treating individuals, couples, and families and for a range of problems, including phobias, compulsions, insomnia, schizophrenia, Tourette's disorder, urinary retention, transvestic fetishism, anorexia nervosa, agoraphobia, childhood fecal incontinence, alcohol use disorders, depressive disorders, fire setting, asthma, constipation, truancy, and a variety of sexual performance and relationship difficulties.

Erickson died in 1980 and a foundation was formed to continue the work he started. He was one of the first to show that brief therapy can be an effective and primary approach. He advocated that therapists should be not just passive listeners but active interventionists guiding the therapy; focusing on symptoms, rather than on dynamics, and on action, rather than on understanding; prescribing as part of the treatment the very resistances and symptoms the patient brought to it; and using indirection and metaphor to achieve the goals of therapy.

Theoretical Issues The overarching idea in paradoxical therapy is to embrace and amplify the notion of paradoxical intention and thereby reduce performance anxiety or destabilize a fixed internal or social system. The paradox and the destabilization may be effective in themselves or may cause secondary reverberations, such as increased self-awareness and the evocation of new behavior or emotions, which lead to helpful change.

Paradoxical therapy is relatively atheoretical about cause and not much concerned with it. Behavioral prescription is emphasized, with the idea that altering internal and social feedback loops can alter the system. Symptoms that block change can be made vehicles for it if they are embraced and prescribed or altered in their timing or the function they serve and if change is restrained. Instructing an impotent patient under no circumstances to try intercourse, for example, may dissipate anxiety and allow him to do so; telling an insomniac to get up and polish the floors for the rest of the night may similarly invite sleep. Paradoxical therapy also recommends defining the problem clearly, establishing clear goals for the treatment, offering a plan, and enlisting the collaboration of the patient or the family in the suggested strategy.

Techniques Some of the principles of paradoxical therapy can be directly translated into techniques: using patients' tendencies toward compliance or defiance—for example, by overtly expecting a relapse and being surprised about improvement; reframing (i.e., relabeling behavior and emotions so that their experience is changed from negative to positive or vice versa); using metaphor, indirect directives, and cryptic paradox; and distancing patients from their symptoms or challenging patients by humor or sarcasm. These techniques and the extent of the therapist activity encouraged in paradoxical therapy are illustrated in the following cases of Erickson and his followers.

Making the Activity Deliberate

An alcoholic wife would secretly hide her bottles and her husband would search for them with increasing anger. The relationship was at a breaking point. Erickson prescribed that she deliberately hide the bottles and that he search for them. If he found one, he would keep it. If it eluded him, she would be allowed to drink in peace. He also suggested that they buy a trailer and go fishing, an activity that they both disliked. The reported results were that the drinking abated and the couple later happily used the trailer to go camping. This conscious game apparently subverted the purpose of the prior secret activity, and forcing the couple to share a disliked recreation brought them into close contact (with alcohol unavailable) and pressured them to communicate, enjoy each other, and make pleasant vacation plans.

Prescribing the Symptom

Instead of telling her husband what she felt, a woman would unconsciously start a fight with him when she wanted affection. She was instructed to do so on purpose and intensely the next time she felt empty or unloved. Doing so, she noted the connection and realized that the attack was so forceful that her partner could not possibly respond in a supportive way. She also felt ashamed, and the experience helped her acknowledge and express her wishes more directly than in the past.

Aversive Conditioning

A woman consulted Erickson about her son who had schizophrenia, who did nothing but sit around the house and moan. Erickson recommended taking him for a drive; she was to drop him off, drive 3 miles farther, then sit and read while she waited for him. After doing that a few times, the son volunteered to walk and later asked if he could go bowling while she read, since he liked bowling more than walking.

A second patient told Erickson that he could drive only on certain streets and that he would become nauseated, vomit, and faint if he tried to drive outside the city limits. Erickson required him to drive to the edge of town in his best clothes, park and lie down in a sandy ditch at the roadside, and lie there for at least 15 minutes. After that, he was to drive one or two car lengths farther and repeat the procedure. He was to do that until he could drive from one telephone pole to the next. He was also told to stop immediately and get into the ditch at the first sign of any symptoms. The patient tried but reported: “The more I did it the madder I got. So I just quit and began to enjoy driving.” Thirteen years later, Erickson reports, the former patient still had no trouble driving. Anger and defiance allegedly brought about a cure.

Flooding

A young male patient of Erickson's avoided a particular restaurant because of his fear of fainting; he also avoided socializing and women. Erickson asked how he would feel about going to dinner at the restaurant; Erickson also described various types of attractive women. The young man said that he would inevitably faint in the restaurant and that he was afraid of women, particularly of attractive divorcèes. Erickson arranged for an attractive divorcee to join them and said that they would go to dinner; he would drive, so as not to worry if the patient should faint. As they parked the car and approached the restaurant, Erickson suggested various places to faint on and discussed the relative merits and dangers of each place. At the restaurant Erickson ignored the young man in conversation and, alerting the management that it was a joke, made an unpleasant scene. The waitress joined in, slamming dishes, and the divorcee added to the discomfort of the scene by urging the patient: “Clean your plate. The fat is good for you!” According to the report, the patient called a friend of his the next night and took him out to the same place without incident, and the therapeutic dinner laid the groundwork for getting him over other fears. Apparently, the flooding experience showed him he could survive the worst, and Erickson's half-mocking concern about his fainting was supportive.

In another example of flooding, a married couple who were both enuretic came to Erickson with great anxiety. He prescribed deliberately wetting the bed together, then sleeping in it; the enuresis disappeared in 2 weeks.

Indirection and Metaphor

A young man feared the open streets but was really afraid of women. Erickson talked to him about his manly biceps and his brains and about improving both. He also suggested that the patient move away from his mother. Erickson labels the technique the use of metaphor and reports that the young man moved, dated, and was soon married.

A more likely use of metaphor is a case in which Erickson, treating a couple with a sexual problem, addressed them in terms of food and preparing dinner. He spoke of how different people have different tastes, how dallying over appetizers can be as pleasant as diving quickly into the main course, how some like soft candles and others like bright light to see by, how a wife can show her appetite, and how a husband can dine in a way that pleases her. Presumably influenced outside the range of consciousness, the couple went home and had a pleasant dinner and successful sex.

In a cryptic use of metaphor, Erickson hypnotized a man who suffered from impotence and talked of large buildings built on a firm structure and fully functional. That patient too apparently overcame his problem.

A man who was hypochondriacally concerned about his heart was seen as heartsick about his job and his wife. He stayed home, never raised his voice, and avoided the exertion of sex because he worried about having a heart attack. The therapist told the wife to take her husband's symptoms seriously and each time he had a pain to offer to call an ambulance, get literature about funeral costs, and inquire about burial plots. The husband became angry. Expressing his anger started a dialogue with his wife about the true nature of his complaints, which allowed his depression to lift and the problems between them to be resolved.

Destabilization

A 10-year-old boy engaged in compulsive, public masturbation; the compulsion had endured for years, despite many treatment efforts. Taking the behavior seriously the therapist asked the boy to keep a list of when he masturbated and to note when he found it most pleasurable. With the idea that he should do it when he found it most pleasurable (on weekends), he was assigned to do it eight times on Sunday but not on Monday. When the boy failed and masturbated on Monday, the disappointed therapist prescribed that he do it 12 times the next Sunday. When the boy was not up to the task, the therapist suggested that, as punishment, the boy masturbate once daily in public and eight times on Sunday. Masturbation was also prescribed as a punishment for thumb sucking and as an alternative to homework. Gradually, the boy stopped and even enjoyed his homework.

Examples reported as successful include telling a woman with headaches that were symptomatic of family relationship problems, that the headaches were probably incurable, and that therapy should aim at helping her live with them; asking the parents of a child with severe and long-standing encopresis whether they could tolerate being normal and being better parents than their mothers (the father then threatened the child with laxatives and the problem disappeared); in a combination of reframing and negative emphasis or challenge, telling a family with a school-phobic child: “Maybe it's better she stay at home. It keeps the family from being normal, and being normal may not be tolerable.” (The therapist reported that the family did not get insulted and leave, but changed spontaneously to prove him wrong.)

Clinical and Ethical Issues Paradoxical therapy is clearly not a psychotherapy itself but a set of techniques usable in therapy. Making explicit the assumptions that underlie the techniques reveals their range of usefulness and their pitfalls. In addition to the idea that prescribing or restraining the symptoms can reduce performance anxiety, the assumptions are that symptoms always reflect a problem in a social context or relationships; that they are somehow and ultimately volitional, even if unconsciously motivated; and that they will therefore respond to being emphasized or manipulated.

Such assumptions are probably acceptable in selected cases in which emphasizing the symptom amounts to flooding, an accepted and well-demonstrated technique of behavioral therapy, and in relationship problems in which prescribing the symptom or altering the context of its appearance may help the participants recognize their inappropriate emotions or behavior patterns.

Using paradoxical therapy in illnesses in which a biological element has been recognized is more of a problem. Expecting a patient with Tourette's disorder to respond to such techniques alone suggests a volitional element greater than what is present. The biologically driven symptoms of schizophrenia are unlikely to respond to paradoxical therapy, and although behaviorally conditioned symptoms may respond, the case histories show the difficulty of distinguishing such boundaries. Most of the literature about paradoxical therapy is anecdotal, and the rare research study is less enthusiastic than authors who suggest that success is the norm.

Most importantly, many of the case histories in the literature include manipulations of the patient or the families that may cover or even invite aggressive acting-out behavior by the therapist, and some case histories suggest a simplistic conception of illness in which punishment is curative. When the operating field permits behavior that is less than open and straightforward, therapists need even more vigilance and self-awareness than when procedural safeguards protect the patient.

CLIENT-CENTERED THERAPY

History Client-centered therapy was created in 1940 by Carl Rogers, a psychologist. Believing that diagnosis, planning, and interpretation manipulate the patient to conform to the therapist's ideas. Rogers tried only to listen, understand, and reflect what he perceived the patient to feel. When Rogers did so, he found that the patient often responded with a deep feeling of personal involvement and the production of new and important material. That passive or nondirective therapy was later

named *client-centered therapy* and was published as such in 1951. Rogers' ideas found wide acceptance, and a movement around the principles of the therapy gathered momentum and grew over the next three decades. Rogers himself continued to develop the method and its applications at the University of Wisconsin, University of Chicago, and Ohio State University and in La Jolla, where he died in 1987.

Client-centered therapy is based on the ideas that each person has the ability to solve psychological problems and that feeling understood and highly valued aid the forces within to do so. Ideas like an instinct toward self-realization and limitless inner powers had enormous appeal to the humanistic idealism that was developing about the time the method was published. A focus on the value of the individual and Rogers' later precept that long and particular training was not necessary for becoming a good therapist were similar rallying points for the antiestablishment, antiauthority emotions of the 1960s and the 1970s.

Rogers played a major role in wresting the practice of psychotherapy from psychiatry alone and distributing it into the hands of psychology and other disciplines. He is also credited with being the first to research his results, the first to record sessions word by word in movies and on videotape, the first to publish transcripts of his failures to encourage the study of what goes wrong, and the first to put forward the thesis that one does not need academic degrees to become a therapist. All but the last idea have become well-accepted elements in the fields.

Client-centered therapy has been reported to be useful for children and adults, problems of neuroses, situational problems, speech difficulties, psychosomatic problems (e.g., allergies), and to some extent psychosis. It has been practiced with individuals and groups, and its principles have been applied in industry, education, child rearing, and intensive encounter groups. Just before his death in 1987 Rogers was training policymakers and leading communication groups in South Africa and workshops in Hungary and the Soviet Union.

Theoretical Issues The overarching presupposition of client-centered psychotherapy is that a basic forward-moving force exists within, a tendency to grow, actualize, and integrate. A number of other principles flow from that idea: all people are believed to have the capacity to understand what factors cause them unhappiness and to overcome those factors; to do so, they must bring what is going on inside into awareness; and to effectuate the circumstances that make awareness possible, the therapist must establish a relationship that is warm and accepting.

Rogers believed that human beings immediately attach meaning to whatever is perceived, so that perception becomes reality. A group of perceptions are organized as the self-concept—people's perceptions of their own characteristics, their relationships with others, and the value they place on those perceptions. Experiences contradicting the preferred perceptions of that organization cause anxiety or maladjustment and must be shut out. In therapy the structure of the self is relaxed so that the patient can drop the barrier and admit, “Yes, I do have those parts of myself that are unacceptable.” When this happens, the previously denied parts are accepted and then integrated, and the result is a better-functioning person, one less tied up in denial and conflict, more effective, and more tolerant of others than in the past.

The aim of the therapy is to create an interpersonal environment in which the self-structure can relax and material can come into consciousness. The therapist sets the three conditions that foster relaxation and the personal growth that follows. The three conditions are *congruence* (or *genuineness*), the ability to be present as a person, to be real in the relationship with the client; *unconditional positive regard*, which conveys to the client, “I accept you as you are, without making judgments or evaluations”; and real *empathic understanding*, a sense of standing in the client's shoes, seeing the world from that vantage point, and then communicating what is understood from that view to the client. When these conditions are met, the client feels released and understood and is able to accept and integrate, view the world differently, and continue the process by bringing out new material.

Client-centered therapy was first practiced in a course of 5 or 6 hours, then 15 or 20 hours, and still later 100 or more hours. Whether the shift was caused by clients' seeking greater levels of change, the enlistment in treatment of more difficult cases, an evolution in technique, or a fall-off in results after the initial enthusiasm is unclear.

Techniques The techniques of client-centered psychotherapy serve the goal of having the therapist convey a sense of the worth and significance of the client, and the idea that the therapist is trying to understand. Far from being laissez-faire, the therapist needs to actively and empathetically help clarify what the patient feels. To be entirely nondirective, the therapist restates and reflects a close approximation of the client's feelings. When this is done correctly, clients feel as if the therapist were almost a part of them, working on their problems as they want to work on them; they feel accepted warmly, without any judgmental overtones. The acceptance and empathy are themselves therapeutic.

Rogers cited an example of an explosive 13-year-old boy who was changed and calmed by sessions in which he and the therapist played tic-tac-toe or in which the therapist allowed silence while the patient sat at the window with his back to the therapist, quietly counting cars. The therapist conveyed respect and belief in the child and the idea that the hour belonged to the child, and that the adult would not be shocked by anything he did. The only limitation was that anger was allowed no physical expression, only symbolic and verbal expression.

The therapy aims not to interpret the client's unconscious motivations or conflicts but to reflect what the client feels. As the counselor and the client progressively clarify their feelings within the warm and accepting relationship, denied feelings come to light and can be dealt with and integrated.

Rogers cited a male patient who had considerable anger. As the therapist accepted the client's feelings and clarified at whom they were aimed, the client came to see which parts were rational and which were not. He was able to say, “If you are like my father or I only see you that way, I hate you as I hated him.” When the unrealistic aspects were expressed openly, they dissolved, leaving the real relationship in place.

The theory also claims that resistance is overcome rather than interpreted. This is accomplished by the consistent acceptance and valuing of the client, the thoroughly undemanding nature of the relationship, and the empathic effort to clarify the client's feelings.

A woman with denied anger at her husband embarrassed him with dizziness and faintness at gatherings that were important to him. The therapist consistently reflected her feelings to her with such questions as, “You seem to feel ...,” “You're confused by...,” and “It seems to you that...” This clarification helped her to move from affirmations of a good relationship with her husband to recollections of old resentments and the recognition of present ill will. Keeping the focus on her also aborted any tendencies for her to project or to accuse the therapist of anything but interest.

Transference is allegedly avoided in a similar fashion. Rogers gave examples of an angry client:

Client:	Am I supposed to tell you everything?
Therapist:	It's up to you; you can talk about anything you want to.
Client:	I had a big fight with you in my mind as I came here. I thought the whole thing was a fraud—I'm being very frank—you can talk like we do down here almost anywhere if you get someone to listen.
Therapist:	It seemed it was kind of a cheat, something you could get anywhere.
Client:	It's like advertisements you see where for a few dollars people will sit and listen to you.
Therapist:	Just listen to your troubles.
Client:	Of course, they don't have your extensive background, but they do the same thing. Then after I talked it out with myself, I realized that the reason I was mad at you is because I feel nervous and jittery coming here (pause) because I'm facing something I don't like to, talking things out myself.
Therapist:	So the feelings about someone listening to you being a fraud you recognize as being connected with your fear and irritation at having to face things in yourself?
Client:	That's right. That's the real logic.

In another case with intense and chaotic sexual and angry feelings, the patient said that she felt the doctor was the most wonderful person she had ever known and that the feeling was more than merely sexual. The therapist reflected back, “You really feel deeply attached to me.” A few sessions later, the dialogue went like this:

Client:	The thing I want is to have sexual intercourse with you. I don't dare ask; I'm afraid you'll be nondirective.

Therapist: You have this awful tension, and want so much to have relations with me.

Client: [after a bit more] Can't we do something about it? Will you relieve the tension... give me a direct answer?

At that point the therapist gently said that the answer was “No,” and the client was relieved. In a subsequent session the client was angry, and the following dialogue took place:

Client: I hate you! I wish you never were born!

Therapist: You just hate me bitterly.

Client: I think I'll throw you in the lake. I'll cut you up! You think people like you, but they don't. I wish you were dead!

Therapist: You detest me, and you'd like to get rid of me.

Client: You think my father did bad things with me, but he didn't! You think he wasn't good, but he was! You think I want intercourse, but I don't.

Therapist: You feel I absolutely misrepresent all your thoughts.

Through this type of work the client later confessed a hallucination and later said: “I had to get rid of this somewhere. I knew you'd understand. It's true I hate myself, but I couldn't say it, so I thought of all the ugly things I could say to you instead.”

Rogers wrote that these interviews showed how feelings of transference were dealt with in the same way as other feelings, and how a consistent reflection of the client's feelings essentially dissolved a transference issue by helping the client to recognize her irrational emotions, after which she could deal with them and what they hid.

Indications The general indications for therapy are when clients feel that their organized self-structures are no longer effective in meeting their needs in the reality situation or when they perceive discrepancies in themselves or see that their behavior is out of control. The description generally covers problems in the neurotic range, but a client-centered approach has been used with 2-year-olds and adults of 65, with people who have mild adjustment problems and disorders diagnosed as psychotic, and with persons of all social classes and levels of intelligence. The theory affirms that a trial of the therapy is unlikely to do harm.

Early in the development of the method, Rogers believed that diagnosis was inadequate and prejudicial. Placing the locus of evaluation in the hands of the therapist rather than the client had undesirable consequences, undermining the client's power of self-determination and raising the specter of misuse for social control. Nosological limitations may have supported this early position, and the social circumstances of the 1960s may have lent it credence, but Rogers' followers believed in it as late as 1987.

Ethical Issues, Research, and Evaluation Rogers' ideas sparked and rode the crest of the humanistic movement in psychology. His emphasis on the value of clients and on the need to accept and respect them in therapeutic relationships were timely and have had a refreshing influence on child rearing, education, and group relations as well as on psychotherapy. His attempts to train nonprofessionals were less well advised and the attempts foundered; the method became so simplified that blank verbal repetitions too easily replaced a true empathic congruence and effort to understand.

Practitioners of client-centered psychotherapy did not believe that diagnosis was particularly useful and did not follow the medical model of illness. That a warm and genuine relationship is sufficient to dissolve resistances that are dynamically motivated and tenaciously held is another tenet open to question. Reflecting what the client feels without interpreting where it comes from or the purposes it may serve is uninformative and could drive the client to action as a further defense. Rogers admitted as much when he noted that the method is frequently unsuccessful with clients who feel incapable of managing themselves and who insist that the therapist take over; a different approach interprets the client's insistence and resentment, rather than just reflecting them. Similarly, reflection in the face of other intense transferences seems to be less effective than a focus on the fantasies that lend force to the transference.

In its contributions to psychotherapy research, client-centered therapy has been outstanding. Rogers and his followers were the first to record and review transcripts of sessions, the first to document the process of treatment, and the first to do follow-up studies of results. They developed such innovations as the Q-sort and scales to objectify the Rorschach test. They showed that in successful therapy negative attitudes about the self are replaced by positive attitudes, that acceptance of others occurs in parallel, that psychological tension decreases, and that plans take the place of old complaints. Although initial claims about success in treating schizophrenia patients had to be dropped, and although Rogers and his colleagues did not do controlled comparisons of their method with others, they were able to document that client-centered therapy is effective. By clearly delineating that a successful outcome is associated with genuine acceptance and an empathic congruence that facilitates the identification and the expression of emotion, they recognized two of the features that empower psychotherapy generically. Perhaps most importantly their emphasis on progressive clarification of the client's feelings sounded an insistent cautionary note about the need for clear understanding instead of a facile interpretation based on the assumptions of one's theory.

TRANSACTIONAL PSYCHOTHERAPY

History Transactional analysis or psychotherapy was the creation of Eric Berne, a psychiatrist with psychoanalytic training who parted with the Freudian movement to focus on social interaction as the unit of analysis. *Transactional Analysis in Psychotherapy* was published in 1961 and *Games People Play* in 1964; *Games People Play* became a record bestseller, with sales of more than 2.5 million copies. Berne's thesis was that in social interactions people seek intimacy, comfort, or recognition, which they get through a series of mutual exchanges or *strokes*. If the ego states of the participants are adult and appropriate, the transaction is harmonious and realistic. Ulterior motives, sponsored by other than an adult ego state, cause discomfort in the transaction, and transactions habitually colored by such motives may become ritualized and predictable.

Written with wit and humor, Berne's books inspired considerable controversy. Some accused them of being facile psychologizing better left to cocktail parties rather than true contributions to psychotherapeutic theory and practice. The fact that the movement has endured, inspiring a journal and an accrediting body and an occasional article in the psychiatric literature, suggests that a number of its ideas have merit.

Theoretical Issues Transactional analysis rests first on the principle that human beings have a hunger for stimulation and contact in the infantile style. When such strivings are blocked, efforts are made to regain the intimate contact. Compromises and sublimations are made in that pursuit so that a hint of the original intimacy may suffice, and the stimulus hunger may be satisfied symbolically. Thus, the original physical strokes of caress and comfort are replaceable by metaphorical stroking by which the person is recognized, flattered, or supported and even by acknowledgments that may appear to bring discomfort. A stroke is a fundamental unit of interaction. An exchange of strokes is a *transaction*, the unit of social intercourse; a stimulus from one person produces a corresponding response in another person. Because social stroking satisfies the original infantile need, it follows that any social intercourse is better than none.

In addition, social interactions fill time, provide structure, and avoid boredom. Interactional programs, all of which contain stroking opportunities, may be *material*, dealing with reality issues; *social*, which constitutes the norms and manners of a social order; or *individual*, by which incidents are sneaked into the other programs in order to get extra, personalized strokes. The sequences of a person's program are developed in line with that person's *life script*, a set of overall goals and patterns, and these sequences are the individual *games*. The games range from harmless and pleasantly satisfying to dangerous and destructive. What develops in a game is assumed to be the purpose of the game and what eventuates as its end result are the strokes that constitute the aim and the satisfaction.

To understand and diagram the interactions in a game, the theory posits three ego states, the parent, the child, and the adult. In the parental ego state, the person reacts either as the parent or as the parent would have directed. In the child state, one may be adaptively compliant or whiny and withdrawing or, as the natural child, rebellious, creative, or impulsive. The adult state appraises reality and acts in tune with it; the adult also moderates between the parent and the child. All three states are present and potentially active at all times.

When the adult in one person addresses the adult in another and is responded to in adult terms, the stimulus and the response are complementary and the transaction is smooth. The same is true if the child addresses the parent and the parent responds appropriately—for example: Child (to parent): “Water!” and parent (to child): “Here, baby.” Such transactions are normal, two-stroke harmonious social interactions.

But if one partner in a couple asks, “Where are my cuff links?” and the other responds, “You're always losing things!” the lines of communication are crossed; the query may be Adult to Adult, but the response is Parent to Child, and the situation gets sticky. A comparable Child-to-Parent cross in response to an Adult-to-Adult

stimulus may occur when one notes to a person driving, “You missed the turnoff,” and the driver responds, “You're always criticizing me!”

Such ulterior transactions are the basis of games, which are ongoing series of complementary ulterior transactions progressing to a predictable defined outcome that satisfies some aspect of the person's life-script strivings. On the surface the interactions may appear plausible, but their recurrent nature, concealed snares, and predictable payoffs define them as parts of a neurotic game.

The test of a game is that a respondent's refusal to play causes increasingly intense efforts to force its continuation; continued refusal may elicit despair or bewilderment. The cure for a game is recognition of its presence, its rules of play, and its motivation. A cure is signified when the initiator can note with a laugh, “There I go again,” and desist volitionally.

Techniques Because games generally involve at least two parties they reveal themselves and are best treated in couples or groups. Transactional analysis has therefore had its most widespread application in couples and group therapies, although it has also been useful in individual treatment. The techniques aim to illustrate the game, dissect the transactions, and frustrate players in their pursuit of strokes. In so doing, the players may learn a considerable amount about their life scripts and how they evolved, although that is not necessarily the goal of treatment.

Games are named for convenience of recognition, with the name usually connoting something about the ends sought. Thus, in “If it weren't for you,” a woman (usually) picks a domineering man to marry, who then forbids her to do things she allegedly wants. She blames him for her unhappiness; they quarrel; their sex life deteriorates; he gives her gifts to make up; and the cycle goes on. In reality, the woman fears the activities she says she longs for, has a sexual inhibition (which the husband may share), and is pleased by the opportunity to prove that men are tyrannical. In the game of “Schlemiel,” a man (usually) messes up or breaks things in order to be castigated and then forgiven.

Other life games include “Debtor,” “Alcoholic,” and “See what you made me do.” The aim of each is to obtain one or several ulterior satisfactions without accepting conscious responsibility. In “Alcoholic” the players may include the alcoholic, a persecutor (usually a spouse), a rescuer (often a health professional), a patsy (who gives money or sympathy), and sometimes a connection (who may tempt the alcoholic to drink). Each player may also be in the game for idiosyncratic reasons, games, or strokes. For the alcoholic person the payoff is the hangover and its chance to indulge in psychological torment and suffering; for the rescuer it is an opportunity to play “I'm only trying to help you”; for the persecutor, it is “Look what you've done to me.” The antithesis, the goal of treatment, is to have each one recognize the role played and to frustrate the primary player (and the other persons addressed as well) by giving up the role assigned.

Groups may be randomly selected or homogeneous. In treatment sessions the theory of transactional analysis is taught assiduously and with blackboard illustrations, the aims of treatment are outlined in operational terms, and contracts are made about individual large goals and are redrawn for small, particular steps in the course of therapy. The therapist's role is active and confrontational but egalitarian.

Research and Ethical Issues Interest in transactional analysis peaked long before the advent of criterion-based diagnosis and controlled clinical trials, and little research on it can stand up to today's critical scrutiny. It was claimed to be effective for persons with neuroses, psychoses, personality disorders, sexual disorders, and mental retardation; for individuals and groups; and as a means of self-help for young children and teenagers. Like most therapies, however, its usefulness rests on clinical lore and a certain common-sense validity. What seems sensible includes an emphasis that is typical of later cognitive-based treatments—namely, identifying elements of behavior that reflect neurotic problems so that their maladaptiveness can be acknowledged, their driving emotions and underlying assumptions recognized, and the pattern of behavior altered. Psychoanalytic therapies share the same aims but include the additional goal of genetic uncovering. More like cognitive therapies also are transactional analysis' emphases on confrontation, contracts, homework, active diagramming of conflict, and teaching about behavior.

The weakness in the system and the potential it has for abuse in work with patients lie in its theoretical assumptions. Neurotic behavior by definition is not realistically aimed and is often maladaptive. To assume that all bad consequences are deliberately sought is incorrect and unfair. To the extent that such a view is held, important motivations may be missed and therapy tainted by a tendency to level accusations. If this position is avoided and complaints are not trivialized by being seen routinely as goals, the dissection of social transactions and the focus on personal responsibility offered by transactional therapy conform to what is generally considered to be of therapeutic value.

GUIDED IMAGERY THERAPY

History The use of guided imagery or guided affective imagery as a form of therapy was systematized by Hanscarl Leuner in 1954. Leuner considered himself an analyst, and he was influenced by Carl Gustav Jung's interest in active imagination and Johannes Heinrich Schultze's autogenic training. Having confronted himself with disturbing emotions and images during his self-analysis, Jung thought that spontaneous, inner, dreamlike images were translations of unconscious emotions and that observing and interpreting them could bring unconscious contents to consciousness. He called the technique *active imagination*, and he made it a part of what clinicians following his analytical tradition would use. Schultze framed the principles of *autogenic training* as a form of self-hypnosis and relaxation training, a mind- and organ-strengthening system based on expansive powers alleged to reside in the mind.

Leuner found that resting comfortably with the eyes closed for some time led to the appearance of images and that an exploration of the images with a guide was a pleasant and beneficial experience. He induced the images actively to shorten the interval before their appearance, added analytic insight to the guided exploration, and so framed *guided affective imagery*.

The ideas of guided affective imagery caught on in the United States and other Western countries, and was reported to be useful in treating in chronic neuroses, personality disorders, depression, phobias, obsessive-compulsive disorders, sexual disorders, hyperhidrosis, substance abuse, anorexia nervosa, ulcerative colitis, and hives. The niche it filled in organized psychiatry, however, was never more than a small one. The ancillary disciplines of medicine, particularly nursing, embraced it with more enthusiasm than did psychiatry, and positive claims have been made regarding its use in postsurgical pain control, in general adaptation to illness, and particularly in coping and dealing with incurable, progressive disease.

Theoretical Issues Guided affective imagery attempts systematically and psychotherapeutically to use the human ability to create images. It holds that so-called *catathymic images*, images appearing before one's closed eyes as if on a screen and ultimately coming together and taking on movement to tell a story, represent a person's interpersonal world in autosymbolic imaginal form. The images include color, plasticity, and action, and the more one is absorbed in them the richer, more colorful, and more subtle they become. The symbols and the stories project the person's conflicts. Psychoanalytically informed guidance as the person recounts the experience can materially enhance conflict resolution by manipulating the symbols or assisting the story toward a successful outcome. The crucial idea is that influencing the symbols and the story influences the conflict.

Techniques The patient is placed in a comfortable chair and taught to practice relaxation, with suggestions of warmth, heaviness, and regular breathing. The patient is then invited to imagine a harmless, pleasant image, like a flower and is asked to describe it in detail, to look in its center, or to touch or smell it. Involvement in the images heightens the relaxation and vice versa; the patient soon becomes able to induce a readiness for imagery quickly. The hypnoidal state is ended with a command, such as, “Clench your fists, bend your arms, open your eyes, and you are back, awake and refreshed.”

When such learning is well established, the therapist relaxes the patient once more and suggests an image to be used in the therapy—for example, a meadow. The patient is told to nod when it comes into view and then to describe the scene.

Specific images used in the therapy are classified as basic, intermediate, or advanced, according to the level of conflict they are likely to involve and the skill and training required by the therapist. Basic images include a meadow, a brook, a mountain, a house, and a wood; intermediate images include a car ride and a rosebush (representing women's and men's sexual feelings toward the opposite sex); and advanced images involve such things as a swamp, a volcano, and a lion.

Descriptions of a meadow or a brook (the patient may see a brook in a meadow spontaneously or be invited to imagine one) reflect current psychological issues. The meadow may be rich and green or scorched to stubble; the brook may be cool and inviting or a raging torrent. The therapist follows and guides, with such questions as, “Can you describe that?” “What do you think of it?” or “What do you see as you follow the brook?”

The therapist's understanding is informed by knowledge and theory and determines whether the therapist interprets to patients or leads them to helpful activity. The therapist may suggest, for example, that a darkening scene reflects the patient's inner mood or that too perfect a picture shows an effort to mask distress. If patients

encounter a fence in the meadow or steep rocks as they follow the brook, the therapist may suggest that the patient climb over or find a way around the obstacle.

A young male patient saw a mountain from which rose another mountain and an observation tower. The young man had problems with authority and would stutter in the presence of his father or his boss. The therapist interpreted the scene to himself to mean that the young man felt watched and that too much was expected of him. The therapist guided him to ascend the tower, which the patient did successfully but amid images of fearful wandering and threats of thunder; the symptoms resolved.

The suggested motifs represent different aspects of the patient's psychology: the house and the edge of the wood—one's own person; the brook—vitality and energy; the mountain and its panorama—the patient's view of the past, present, and future. The therapist looks to see whether supplies and a warm fire are in the house, what comes out of the wood, and whether the brook is cool and refreshing or an icy harbor of dangerous creatures. The management principle is to resolve the conflict symbolically.

One young student got over a block about taking an oral examination by being led in fantasy to feed a dangerous animal (the professor) coming out of a wood; those fearful of their own impulses might do well to approach such animals, pat them, and make friends with them. The guide conducts the exploration, using the symbols as a protective disguise, with empathy and warmth, positive feedback, praise, and at times direct suggestion.

Clinical and Ethical Issues Guided affective imagery combines hypnotherapy with certain psychoanalytic ideas. Its major assumption is that manipulation of the symbols of conflict can resolve the conflict, a tenet that is open to question. The supportive relationship, the sense of involvement and of effectuating something through the process, and the direct suggestions must contribute considerably to whatever effectiveness the technique has.

Interest in guided-image therapy as a formal, psychoanalytically based psychotherapy has waned. Truncated and modified, however, guided imagery has gained a following in pain control, holistic medicine, and the treatment of incurable illness. In pain control it has been reported to be useful as a relaxation and distraction technique, with additional suggestions of finding a second and then several seconds of decreased pain and so extending the period of pain relief. The appeal in holistic medicine is to the limitless powers of the mind, a hopeful approach that has found favor in the nursing of patients with cancer and other terminal illnesses.

FEMINIST PSYCHOTHERAPY

History Feminist psychotherapy is a product of the women's movement. It is an eclectic mix of therapies rather than a particular form of treatment. Its uniting aims, shared with the feminist movement, are to empower women and to raise their self-esteem. The influence of militant feminism in its development and its goal of correcting what are seen as injustices to oppressed women lend a stridency of tone to writings on feminist psychotherapy that may turn some readers away from its important elements.

Theoretical Issues The overarching principles guiding feminist psychotherapy are that the personal is political and that the millennia of sexist attitudes in the socialization of women have harmed them. The aims of treatment are to recognize the harmful effects of the sexist society, to explore inherent contradictions in the roles prescribed for women, to support women in the exploration of their inner resources and their capacities for being nurturing, and to demystify and rectify power relationships.

Its subsidiary ideas are that oppression leads to feelings of impotence and to true impotence, and to low self-esteem and conflicts. Traditional therapy is seen as being a mechanism of social control in the service of the status quo and as being based on an imbalance, even in the therapeutic relationship. Feminist psychotherapy rejects such a model and rejects the idea of conflict developing and residing within the person without regard to the socioeconomic system. It tries therefore to equalize power by modeling, self-disclosure, and disclaiming expertise. It focuses on how the stresses of a patriarchal society cause symptoms—for example, on how depression, a lack of assertiveness, and job difficulties may grow from assigned sex roles and sexual harassment, with inner conflict being only secondary to exterior conditions; on how a lesbian life-style may be a choice to love and commit to a woman and have nothing to do with an unresolved dislike of men; and on how, if sexual intercourse is male aggression, a woman's best defense may be in symptoms such as dyspareunia and vaginismus.

Feminist psychotherapy believes that women of necessity teach their daughters to forgo their own needs and to nurture and please others, as mothers do themselves in childrearing. Conflicts between autonomy and dependence result and are not resolved by therapies that help women endure their suffering, mask or suppress their anger, or rely on antidepressants and sedatives.

Techniques Techniques vary with the type of therapy being adapted for feminist use. Psychodynamic therapy and expressive and supportive therapies are used, and guided imagery has been invoked. Most of the literature, however, places a heavy emphasis on the cognitive approach. Steps include redefining power and reducing guilt; defining one's own feelings and respecting them and so defining one's own personal reality; emphasizing responsibility for one's choices and actions; working through; and terminating therapy when the patient accepts her own needs as legitimate, understands the power differentials that hinder her, can assert herself appropriately, and needs the therapist less than in the past.

Cognitive beliefs common to women (which are also common to men) include the idea that a woman must be loved by everyone, that others' needs count more than her own, that she needs the support of someone strong, and that she has no control over her emotions. Recognizing these beliefs, disputing them, and practicing behavior based on alternative views are part of the treatment; assertiveness training is also commonly recommended.

Feminist psychotherapy believes that women are better therapists for women than are men. A female therapist's empathy and experience are most suited to help a woman become the best expert for herself, and male therapists are considered less likely to treat female patients as equals.

Research and Evaluation Because feminist psychotherapy is more a part of a social movement than a particular therapy, little research has been done on its effectiveness. Many of the ideas it has spawned are provocative and merit consideration. Feminists call attention to the facts that women have suffered from unequal power relationships; that male dominance in a family is taken for granted, but a special note in the case history is likely if the wife has higher status than the husband; that the description “absent father” is a less extreme judgment of the person than is the description “maternal deprivation”; and that the term “dominant mother” carries a similar pejorative quality. Other ideas, although more extreme, are piquant enough to stimulate a close look—for example, that the family is a system that perpetuates male dominance and that at the junior high school level boys do not so much catch up in school performance as that girls fall behind because their type of understanding—feelingful and intuitive—is less valued than male understanding in a structure that is focused on adapting to male-dominated ideas. The rhetoric that societal oppression is the cause of all the ills women suffer, however, ignores the possibility that women may have personal, internal conflicts. By encouraging self-justification and rationalization, such a position may serve the health of women poorly.

PSYCHOTHERAPY FOR THE DEAF

History Psychotherapy for the deaf is not a particular type of psychotherapy but a group of therapies that are adapted to the needs of a special population—people who develop a profound hearing impairment before speech is established. The impairment is defined operationally as one that renders audition useless as a means of intercourse with the hearing world, and it generally involves a hearing loss of 80 decibels or more across the speech frequencies, even with the aid of amplification. Its most obvious consequence is to interfere with the ability to learn language by simple auditory imitation and at the normal time and pace in development.

Psychiatric interest in the deaf began with the work of Franz Kallmann, John Rainer, and Kenneth Altshuler in the mid-1950s. Then the country's most prominent geneticist in psychiatry, Kallmann was approached by a branch of what is now the Department of Health and Human Services for assistance in obtaining case closure among psychiatrically ill deaf clients. Kallman recruited Rainer and Altshuler and began a series of normative studies and studies of deaf persons with mental illness. The first effort established an outpatient psychiatric clinic, and subsequent projects developed an inpatient unit for statewide services, a vocational rehabilitation liason and halfway house program, and consultation programs at a school for the deaf. Centers focused on psychiatry and the deaf were subsequently established in Chicago, San Francisco, Washington, and several other cities and countries around the world. At present, a small caucus of psychiatrists interested in working with the profoundly deaf meet regularly at annual meetings of the American Psychiatric Association.

Theoretical Issues To adapt a given psychotherapy to the needs of persons with profound early deafness demands that the therapist understand what the handicap means to one's life experience and to take into account the limitations this experience places on the therapeutic exchange.

A first guiding principle is that the simple absence of audition has no relevance to innate intelligence potentials; intelligence quotients (I.Q.s) among the deaf follow the same bell-shaped curve as in the hearing. Among the deaf, performance scores are generally higher than verbal scores because of the lag in language development. Deaf children of deaf parents develop vocabulary at the same rate as their hearing peers, albeit in sign language, because their parents are able to communicate with them freely. Occasionally, an enlightened hearing parent learns sign language to provide the only free, two-way accessibility that the handicap allows.

Too often, however, parents are caught up in an educational controversy that has gone on since Alexander Graham Bell and the 1880s about whether signing discourages the learning of speech. Evidence suggests that an educational approach that embraces all avenues of communication—combining oralism, speech and lipreading instruction, amplification, and sign language—gives the best results. Moreover, the combination supports the exercise of age-appropriate interests and language skills in accord with their natural developmental timetable. In the absence of a widespread combined approach, studies in the 1970s showed that the average deaf adolescent left high school with about fourth- and fifth-grade English and mathematical skills.

As a result of these findings and the urging of mental health professionals, since the 1970s there has been a major shift in educational practices from a near-exclusive emphasis on oralism toward some variety of the combined mode of instruction. Pockets of resistance exist, and the recent availability of cochlear implants at a relatively early age may recast expectations and heat up the issue again.

A factor contributing to the endurance of the controversy is that parents are understandably hurt and saddened when the handicap is recognized and they wish that it would go away. Motivated partly by denial and partly by the commendable desire that their child's life be like any other child's life, parents resist sign language as the visible symbol of the handicap and the harbinger of a separate and sequestered existence. What is lost in the face of these pressures is the recognition that language, generally mediated through audition, brings a tremendous amount of information and experience. Without hearing or the effective alternative of sign language, uncountable hours of speech and lipreading instruction can only provide language late and often incompletely.

Sound also brings nuance and music, and it is the sole distance receptor that scans 360 degrees of the environment at all times, perhaps even in sleep. What may be associated with missing those elements of experience is uncertain.

A final concomitant of deafness, at least in the 90 percent of those born to hearing parents, is that the parents of deaf children feel confused, uncertain, and often guilty. Their own ambivalence, the conflicting advice they may receive, and the stranger to communication in their midst often makes them overprotective, inconsistent in discipline, and erratic in their hopes and approach.

As a result of all these factors but probably influenced primarily by the language lag and the lack of general experience, deaf persons have been described as more naive, impulsive, concrete, and immature than their hearing counterparts. Such descriptions apply only as a composite, and the deaf should not be stereotyped. In a large enough number, more deaf persons may show more of those traits than their hearing peers, but the presence and the extent of the traits in a particular person are not predictable.

Techniques Communication is the sine qua non of psychotherapy. The first requirement with the deaf is to understand what life experiences the handicap entails; the second requirement is to interact freely with patients so as to apprehend their personal and particular experiences and to exchange understanding about the details. By adulthood, virtually every person with early profound deafness is comfortable and fluent in sign language (barring an accompanying organic problem that interferes with language acquisition, regardless of mode). Having the therapist equally versed in manual language would be ideal, but that is rarely possible, despite the fact that a growing number of psychiatrists and others have learned to sign. The problem is lessened to the extent that the patient's language, speech, and lipreading skills are developed. Often these skills are insufficient to allow the conduct of meaningful psychotherapy, even with exchanges in writing. In such instances an interpreter is necessary. Deaf persons often rely on interpreters, and the therapist rather than the patient may be the one who is uncomfortable with the third party's presence. One must be alert, however, to the interpreter's tendency to interpret when the therapist wants an exact translation; for example, when the patient's thoughts are to be evaluated, the interpreter's efforts to make sense of them may be counterproductive. Supportive psychotherapy can be conducted with the aid of an interpreter, but substantial insightful work probably demands a subtlety of understanding only available with manual skill on the part of the therapist or adept speech and lipreading skills on the part of the patient.

Clinical Issues Less than profound deafness and deafness after speech is well established are problems of a different nature and require different adaptations. To the extent that language has been developed before the loss of hearing and to the extent that the loss is remediable by amplification, the patient's life experiences are less affected, and therapy requires less in the way of modification. However, the loss itself, its cause, and the patient's changed life circumstances because of it are factors that affect the person's problems and the therapy.

A couple of additional points must be kept in mind in counseling the hearing parents of deaf children. Eager for their child to have a normal life, the parents may be impatient with modest results in attempts to remediate the handicap and its effects. Complaints of bad treatment at the hands of many institutions or agencies must be evaluated with that possibility in mind. Also, denial on the part of a family may be brought to an abrupt end with the child's impending adolescence. When parallel play and participation in simple games give way and the horizons of social interaction loom large, the effects of the handicap become unavoidable, and parents may become depressed.

Research The educational, developmental, and psychiatric literature on early profound deafness is considerable, but no controlled studies of psychotherapy have been reported. The psychiatric literature, mostly from the 1970s and before, suggests that major mental illness is no more prevalent among the deaf than in the hearing, that impulsive or aggressive behavior may be more common in the presentation of illness among the deaf, and that guilt and psychomotor retardation may be less frequent in cases of depressive disorders in the deaf. Anecdotal reports also indicate that various forms of psychotherapy are as useful in the deaf as in the hearing when modifications in view of the handicap are made.

COMPUTERS AND PSYCHOTHERAPY

History and Techniques Psychotherapy by means of a computer, psychotherapy by nonprofessionals, and brief psychotherapy under managed care are not particular schools of treatment. What they share are the aims of cutting costs, thereby making therapy more widely available. They lower costs by abbreviating treatments or by substituting less expensive providers for more expensive ones.

Computer programs have been written in the last few years to provide educational materials to patients or to interact with them in a more truly therapeutic way, for example, aiming at enhanced self-awareness or self-control. Psychotherapy by nonprofessionals utilizes common sense and supportive approaches that derive from general experience. Brief therapy under managed care rests on the thesis that dynamic understanding can be utilized episodically, and that widely spaced sessions providing insight and support can help most patients to overcome their acute problems in living.

Theoretical Issues Each approach raises challenging issues of theory. Is the comfort and the flexibility of a real person requisite for effective psychotherapy, or can a computer be individually responsive enough, and can patients develop transferences and a sense of safety relating to it? Is professional training necessary to obtain satisfactory results, or can well-adjusted and mature adults do just as well? Are regular meetings, weekly or more often, cogent therapeutic agents or can monthly meetings be equally efficacious?

Clinical and Ethical Issues As with all therapies, these novel approaches have been reported to be successful and have gained a following. They pose considerable challenge to traditional therapies, calling into question many of the basic and revered assumptions on which the longer-established methods rest. Since the treatments are new and research on any of them is in its infancy, it is likely that early claims will moderate over time as research establishes their limits. Meanwhile, the fact that they are experimental and unproven should be kept in mind and clearly communicated to patients. There is little danger in the computer-driven and the nonprofessional efforts because their innovative nature makes informed consent and scrutiny by institutional review boards mandatory before treatment under such conditions is initiated. The current emphasis on cost containment, however, does not afford the same protection in the case of the minimalist approaches being instituted by enthusiastic managers of care. In such cases, patients may need better information than is now offered if they are to make an informed decision.

TRANSPERSONAL PSYCHOTHERAPY

History Transpersonal psychology grew out of the humanistic movement of the 1960s. Defining itself as “the personal, plus,” it means to include all facets of personal

psychology and psychiatry *plus* deeper or higher transcendent experiences. It thus embraces a range of religious and spiritual experiences and parapsychological phenomena such as conversion; crises of faith; ecstasy, peak and near-death experiences; spiritual mystical experiences; and past life experiences. While the term *transpersonal* was first used by William James and later expanded on by Jung, it was such writers as Abraham Maslow, Robert Assagioli, Ken Wilber, and Stanislav Grof who generated its theoretical underpinnings. Each of these authors developed theories of needs and motivations or of stages of development that encompassed and were roughly modeled on traditional developmental theory, but added the extra dimensions required by the transpersonal emphasis. The *Journal of Transpersonal Psychology* started publication in 1969 and continues to exist. The Menninger Clinic sponsored the first Council Grove Conference at that time, focused on such topics as meditation, biofeedback, yoga, and psychedelic agents. Since then, several transpersonally oriented institutions were founded, mostly in California, and for the past several years about fifteen dissertations dealing with transpersonal experiences are written yearly. The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) includes religious and spiritual problems under other conditions that may be a focus of clinical attention.

Theoretical Issues In the free-for-all of theory building, several authors have contributed to transpersonal psychology and psychiatry but no single contribution dominates. Thus, the theory is an overlapping pastiche rather than a coherent whole: Abraham Maslow studied a series of self-actualized persons and found them similar to traditional descriptions of enlightened persons. He concluded that human beings have a biologically based instinctive nature that is fulfilled in spiritual self-actualization, and he and Stanislov Grof coined the term and founded the field of *transpersonal psychology*. Roberto Assagioli suggested that each person has many subpersonalities, and that a spiritual psychosynthesis is needed to unleash the transforming and creative energies of a *super conscious*, which also exists. Ken Wilber proposes prepersonal, personal, and transpersonal developmental stages; disorders of the prepersonal developmental level result in infantile psychoses or narcissistic or borderline personality disorders; disturbances at the personal level give rise to neuroses; and spiritual emergencies, Kundalani crises, and dark nights of the soul rest on disturbances at the transpersonal level. Stanislov Grof, during 17 years as scholar in residence at the Esalen Institute in California, experimented widely with psychedelics in psychotherapy and proposed that in psychedelic and other altered states of consciousness, patients reexperience the trauma of their birth. He suggested the existence of four basic perinatal matrices (BPMs) representing experiences from the entry into the intrauterine state (BPM I), through entry to the birth experience (BPM II), passage toward a light with intense anxiety and near-death experiences (BPM III), and culminating in total surrender, a sense of overwhelming and unending love, light, expansion, and forgiveness (BPM IV). After experiencing or reexperiencing BPM IV, in adulthood further transpersonal expansions may occur in two domains: expansion of ego boundaries in ordinary real terms and extensions beyond the usual framework. The first includes a sense of identification with the earth and all of life in the universe and the second includes spiritual communication; out-of-body experiences; and telepathic, precognitive, and other paranormal experiences. These experiences were often seen as psychotic by traditional psychologists, and therefore constitute spiritual emergencies that require special help. Grof urged mental health professionals to learn to distinguish these nonordinary, transpersonal states from mental illness.

Techniques Technique in transpersonal psychotherapy is an amalgam of the generally accepted and the esoteric, depending on the world view of the practitioner and the issues being addressed. The range is from the psychodynamic and behavioral through meditative approaches or the recommendation of spiritual texts, to rapid-breathing techniques, guided imagery, and the use of psychedelic drugs to promote altered states of consciousness. The teachings are variously applied to a similarly wide range of issues.

Defensive spirituality, in which religious or spiritual beliefs are used to deny feelings or conflicts, or *offensive spirituality*, in which there is an obnoxious, self-reassuring but intrusive stance of “having the one true path” may be amenable to dynamic techniques. Similarly, loss of faith or a conversion experience may be dealt with by a sensitive therapist to determine what factors are at work in the patient's life and whether the conversion, for example, is a legitimate search for truth and the comfort of faith or a magical denial doomed to fail. Expressive explorations of hallucinations or delusions or of a psychotic religious experience after the psychosis is controlled are recommended by some as a means of finding personal insights.

Transpersonal psychotherapists also try to distinguish genuine religious experiences from psychoses, the latter being often more terrifying, accompanied by deterioration in other areas of life, and containing delusions of being addressed by specific religious figures. The boundaries, however, are hard to define in *spiritual emergencies*, when the individual feels dazzled by truths too powerful to grasp, or in *Kundalani awakenings*, states in which energies expand upward from the base of the spine and explosively alter consciousness. Supportive therapy is recommended in these cases, along with education about the experience. Meditation and the use of such mantras as “May I be happy” “May I be peaceful” are also reported useful if the patient is having anxiety over a crisis of faith. Near-death experiences may also lead to a transformed view of the world, and support is recommended along with help in “those parts of the ego that may have died.” The traditional psychotherapist and psychiatrist may have difficulty in areas of transpersonal psychiatry that aim to help individuals recognize and realize a presumed “ultimate state that transcends our usual state of functioning, a state of mystical illumination or cosmic unity.” Some of these include experiences such as channeling, encounters with unidentified flying objects (UFOs), possession states, and past-life experiences. In these areas the transpersonal literature is ambiguous, on the one hand cautiously attesting that such experiences are meaningful to the person and embody content relevant to the individual's personality, and on the other accepting them as normative spiritual experiences, an ultimate state of mystic illumination or cosmic unity reflective of a reality beyond the norm.

Research and Evaluation Research on the paranormal while always of interest because of its supernatural allure, has failed to confirm the legitimacy of past-life experiences, precognition, psychokinesis, and similar phenomena. Also, because transpersonal psychotherapy is not a single discipline there have been no systematic studies of its efficacy. The field emphasizes the personally meaningful and possibly transformative effects of such things as conversions or near-death experiences; the importance of religion and mysticism in the lives of many; the difficulty of teasing apart the boundaries between psychiatric illness, personal mystique, and cultural differences in expected experience; and the need for sensitivity in working with patients whose life and experiences are different from one's own.

SUGGESTED CROSS-REFERENCES

Psychoanalysis is discussed in Section 6.1 and Section 30.1, behavior therapy in Section 30.2, hypnosis in Section 30.3, group therapy in Section 30.4, cognitive therapy in Section 30.6, couples therapy in Section 30.5, and brief psychotherapy in Section 30.8. Learning theory is discussed in Section 3.3.

30.11 EVALUATION OF PSYCHOTHERAPY

KENNETH I. HOWARD, PH.D., RONALD F. KRASNER, M.D. AND STEPHEN M. SAUNDERS, PH.D.

Psychotherapy is the most prevalent outpatient treatment for psychiatric disorders. Unlike other medical interventions, however, psychotherapy entails a particular kind of conversation between the therapist and the patient, and is not generally dependent on tangible technical interventions such as setting a bone or suturing a wound. Given the intangible nature of psychotherapy, it has been difficult to establish its scientific validity. To further complicate matters, since the introduction of psychotherapy a plethora of competing schools have emerged. Unlike many other areas of medicine, however, new psychotherapeutic techniques and ideologies were adopted before research evidence had been produced to support their superiority over current practices. Thus, the acceptance of a particular psychotherapeutic approach was dependent on the influence and charisma of the inventor of that approach.

Given this ambiguity and the need for scientific evidence, the new field of psychotherapy research emerged.

HISTORY

Psychotherapy research is focused on the empirical investigation of the processes and outcomes of psychotherapy. It aims to increase our knowledge regarding the nature of therapeutic interventions, the patients who will most benefit from those interventions, and the outcomes expected from those interventions. It is now well established that psychotherapy achieves significant positive effects over and above control conditions. However, in order to determine how such effects are achieved, how to investigate specific therapies for specific disorders, and the variables that account for positive outcome, new research paradigms and enhanced collaboration between clinicians and researchers are necessary. The overarching goals of psychotherapy research are to improve the practice of psychotherapy, inform public policies regarding psychotherapy, and streamline the provision of mental health care.

The history of psychotherapy research can be understood by considering a sequence of developmental phases, each with its own central issues and achievements. The earliest scientific investigations of psychotherapy began in the 1920s as the first clinical researchers began to document their treatment results. Studies of nonpsychoanalytic treatments appeared in the 1930s, but there was little effort through the 1940s to study either psychoanalytic or nonpsychoanalytic treatments. However, competitors to the psychoanalytic paradigm made their appearance, and researchers such as Carl Rogers brought psychotherapy from private offices to be scientifically studied.

When Hans Eysenck's landmark 1952 review resulted in the claim that 67 percent of outpatients “spontaneously” improved in 2 years without treatment, psychotherapy researchers became even more motivated to search for scientific evidence regarding the efficacy of psychotherapy. Objective methods for measuring recorded events during therapy and controlled comparative outcome studies were developed utilizing Fisherian statistical methodology (random assignment to treatment conditions, null hypothesis testing with *t*-tests, analysis of variance, and correlations). The 1960s to the early 1980s saw the significant expansion and organization of psychotherapy research efforts. New methods were employed, most significantly the results of meta-analysis (an assessment of treatment effectiveness through averaging and combining results across studies). The first of these meta-analyses, presented by Mary L. Smith, Gene Glass, and Thomas Miller in 1980, showed a mean effect size for psychotherapy of 0.85, indicating that psychotherapy was very effective indeed. Finally, from 1984 to the present there has been a consolidation and reformulation of psychotherapy research that has begun to accept eclecticism and the relevance of models, stages, and averaged growth curves that in turn yield assessments of patients' progress leading to beneficial outcome.

Psychotherapy research remains bedeviled by the diversity of the variables investigated, the varying methods of appraisal, the heterogeneity of the patients studied, the differences in therapist training and skill, and the variations in clinical settings. However, there is now a substantial body of evidence that shows that: (1) there are effective psychological treatments for a large number of psychiatric disorders; (2) psychotherapeutic approaches either alone or in combination with psychotropic medications are more effective than placebo; and (3) psychotherapeutic treatments may be at least as effective as medications and may enhance the effects of medication.

The question of whether psychotherapy works has become as useless as the question of whether surgery or antibiotics work. The main goal is to match the appropriate intervention applied by the appropriately trained practitioner to the appropriate pathological condition. Psychotherapy research can provide some guidance in this regard and can forge a link with providers of psychotherapy by furnishing information relevant to the current case in treatment.

CONSUMERS OF PSYCHOTHERAPY

A substantial proportion of the population (about 25 percent) meet the criteria for a psychiatric disorder in any given year, but the vast majority of those who do so (over 80 percent) do not get help from a mental health specialist. When evaluating the effectiveness of psychotherapy, an important issue is who receives such help, why they seek it, and how they get it.

Utilization of Psychotherapy Examining the characteristics of psychotherapy users through the use of a single national survey is difficult since only 3 to 5 percent of the general population will visit a mental health practitioner in a given year. However, based on the combined information from several large-scale, national surveys conducted in the 1980s, it has been shown that two thirds of those who make at least one mental health visit are female, and that 90 percent are white. The most educated are more likely to make a visit; about 50 percent of psychotherapy patients have had at least some college education. Age is also related to the probability of making a mental health visit: the youngest and oldest are the least likely to make an initial visit and over 50 percent of patients are between 21 to 40 years of age. Surveys indicate that income is not related to the likelihood of seeking mental health care. Having a diagnosable mental illness significantly increases the likelihood that a person will seek mental health care, and having multiple diagnoses increases the likelihood further. Patients with diagnoses such as schizophrenia, somatization, panic disorder, and major depressive disorder are more likely to seek professional help than are those with diagnoses such as obsessive-compulsive disorder, substance use disorders, dysthymic disorder and phobias. However, almost half of those seeking such care do not meet the criteria for a psychiatric diagnosis, and research indicates that the best predictor of seeking mental health care is level of distress, whether from a psychiatric illness, an interpersonal problem, or inadequate coping in a particular situation. A study in the 1990s of 500 persons seeking psychological treatment found that the most common patient complaints were interpersonal problems, depression, uncontrolled behavior, and anxiety.

Help-Seeking Behavior Given the frequent finding that most persons who need psychiatric help do not get it, it is important to establish how persons go about seeking psychotherapy. Models of help-seeking behavior focus on the series of decisions that must be made, such as recognizing that a problem exists, deciding that seeking psychotherapy is appropriate, and contacting a professional helper. Research indicates that problem recognition is the most difficult and time-consuming step to achieve, and that some individuals have a significantly easier time accepting the need for psychotherapy than do others. However, the help-seeking process is complicated. For example, it has been found that adolescents experiencing suicidal ideation realized that they needed help, but were less likely than nonideating peers to obtain it. Most persons who seek professional care will first seek help from their family, friends, acquaintances, and others outside the mental health profession (such as primary care physicians and clergy). Others will look to nonprofessional sources, such as self-help groups (e.g., Alcoholics Anonymous). This help may reduce distress to the extent that professional care becomes unnecessary. The social network might either promote or discourage the individual from seeking professional mental health care; friends and family may be able to identify psychiatric problems and provide information about and encourage the use of such care, but they may also transmit attitudes that make formal help-seeking less likely.

Utilization Because research has established that the median effective dose of therapy is between 6 and 8 sessions, an important issue is whether a person who seeks therapy actually engages in treatment (defined here as at least 8 visits). This is related to the issue of equity and cost, as it has been shown that 44 percent of

patients make less than 4 visits and account for 6.7 percent of outpatient psychotherapy expenditures, whereas 16.2 percent of patients make more than 24 visits and account for 57.4 percent of expenditures. Many possible factors have been investigated, including patient income, level of education, age, sex, race, and socioeconomic variables. Controlling for their increased likelihood of making an initial visit, females are not more likely than males to continue in therapy once they have made that initial visit. The most educated are more likely to make an initial visit as well as to enter therapy given such a visit; nonwhites are significantly less likely either to make an initial visit or to continue treatment after the initial visit. The youngest are the most likely to enter therapy given a visit, whereas those 61 and older are the least likely to enter therapy after the first visit. Income is not related to the likelihood of making at least one visit for mental health care but is positively related to the likelihood of engaging in therapy. Thus, research has shown that there is a frequent but not invariable relation between specific patient variables and length of treatment. In contrast, preparing patients for psychotherapy (e.g., via role induction interview) has not made a discernible difference in treatment engagement. Similarly, attempts to predict continuation in psychotherapy using psychological tests, measures of patient expectations, presenting problems, and social support have not been successful.

PATIENT, THERAPIST, AND TREATMENT VARIABLES RELATED TO OUTCOME

Conceptions of Outcome Reviews of studies of psychotherapy have identified at least 800 different outcome measures, the most frequent of which, the Beck Depression Inventory, has been used in only 8 percent of these studies. Obviously, many outcome measures have only been used in a single study. The plethora of outcome measures illustrates three outcome issues: (1) selection of outcome measures varies according to the beholder; (2) outcome measures are of mixed psychometric quality; and (3) outcomes measures can be grouped into categories by their similarities. Each of these points will be considered in turn.

Stakeholders The enterprise of psychotherapy involves a variety of interested parties or stakeholders. The patient is most concerned about relief from personal distress. The therapist attends most closely to symptom amelioration and to correction or removal of the pathogen or causal condition thought to underlie the patient's symptomatic condition. The client—who often is the patient, but could also be a spouse, employer, or parent—usually is most concerned with better functioning. The purchaser attends most closely to the cost efficiency of methods and outcomes. Outcome has different meanings for each of these parties.

Psychometric Properties Psychometric investigations of outcome measures indicate that many measures tap a common domain of emotion and behavior. For example, studies of self-reported depression and anxiety inventories indicate that most measure a common domain of negative affect. Nevertheless, outcomes researchers continue to use inventories and measures as if they measure the variables indicated by their label; reliability and validity studies are clearly needed in this area.

Outcome Measures Most of the outcome assessments used in controlled studies of psychotherapy have used one or more symptom measures. This focus on symptoms as the category of choice in outcomes represents the focus of the clinician and contributes to the efforts of psychotherapy advocates to achieve parity with clinical trials of medications for similar disorders. The second most frequently studied domain of outcomes, although it can be found only in a minority of published studies, is functioning. Social functioning can include leisure, intimacy, and work functioning; each of these subdomains has been studied separately. The domain of well-being (or freedom from subjective distress) has received the least attention, although it is clearly of paramount importance to the patient.

Patient Variables A number of patient variables, such as education level and race, are related to the probability both of seeking and obtaining psychotherapy. Of even more interest to clinicians and researchers is predicting who will benefit from treatment. The relationship between the ultimate effectiveness of therapy and pretherapy patient characteristics, such as age, sex, social class, intelligence, personality, and diagnosis, has been extensively researched but few consistent relationships have been uncovered. This is partly because of the complexity and related difficulty of construct measurement. For example, patient expectations about treatment have been measured in naturalistic settings and experimentally manipulated in the laboratory, and some studies suggested that patients who expect so will ultimately do better. Other research has not found this to be the case, however, and the validity of the measures and the manipulation of expectancy have been questioned. At first glance, it would seem that patient variables would be relatively easy to assess, but in fact most research in this area has had similar problems (e.g., only recently has the diagnosis of personality disorder achieved even marginally acceptable reliability).

Patient Characteristics Despite numerous studies, research has not shown a consistent relationship between treatment outcome and patient age, gender, or sociodemographic variables. A meta-analysis of over 500 studies found no correlation between age and psychotherapy outcome, and patient gender has also been shown to be unrelated to treatment effectiveness. As noted, other sociodemographic variables, such as education and race, are related to the probability both of seeking and obtaining psychotherapy, but there is no clear relationship between socioeconomic status and treatment outcome.

Research over the past 10 years has shown that there is a frequent but weak relationship between social class and length of treatment. However, the variables of sex, age, and diagnosis do not show this relationship. Although more black than white patients tend to terminate treatment early, there is no consistent pattern. Research aimed at investigating the preparation of patients for psychotherapy has not been successful in showing that patients so prepared (e.g., by a role induction interview) remain in treatment longer. Similarly, psychological tests and the study of patient expectations to predict continuation in psychotherapy have not been successful. However, the study of the interactional variables between the patient and therapist have revealed that those who dropped out liked the clinician less, felt less respected, experienced a weaker therapeutic alliance, viewed the psychotherapist as more passive, and viewed psychotherapy as being less potent that other helping interventions.

The relationship of patient characteristics to the outcome of psychotherapy has become one of the most critical areas in psychotherapy research. The patient as a factor in this interaction is complicated enough, and there are additional problems resulting from the wide variation in conceptions and assessments of outcome. Besides these, researchers have also been faced with the complications introduced by variations in the type of therapy offered, in the training and skill of the therapists studied, and in the kinds of patients treated. Based on these considerations the most recent research has shown no relations between outcome and the social class, age, and sex of the patient.

The degree of patient disturbance has been widely studied and has revealed a relation between more serious disturbances and poorer outcomes. Many other patient variables in relation to outcome have also been studied including ego strength; the personality attributes of affiliation, motivation, and intelligence; patient expectations; patient attractiveness; and patient-therapist similarity. However, none appear to be as important as in-therapy process variables such as patient openness during therapy, which has been significantly associated with better outcomes. The continuation or outcome of psychotherapy clearly cannot be predicted based on patient variables alone.

Numerous patient variables have been proposed to be prerequisites for productively engaging in the work of psychotherapy, including ego strength, motivation, and intelligence. For example, it has long been presumed that psychoanalytic psychotherapy required intelligent, verbally facile, insightful patients. In like manner, most therapists would agree that motivation for treatment is essential. There is limited empirical evidence regarding the relationship between these variables and outcome, however, because they have been relatively infrequently studied and because, with the exception of intelligence, these variables tend to change as treatment progresses (i.e., they may be the focus of treatment). The available evidence suggests that the association between ego strength and outcome is positive but unimpressive and that the association between intelligence and therapeutic outcome appears to be positive but fairly small. Finally, there is not even a clear relation between treatment effectiveness and patient motivation.

Investigations of the relation between patient disturbance and outcome has yielded the most consistent findings and a relatively consistent relation between severity of disturbance and poorer outcome has been reported. Studies converge to suggest that “the rich get richer,” that is, patients with less disturbance at the beginning of treatment continue to be relatively healthier at the end of treatment than their more distressed peers. Regarding particular mental illnesses, the efficacy of specific psychotherapies for specific conditions has been established. For example, psychosocial family education has been shown to reduce familial distress and risk for relapse in schizophrenic patients receiving medication. There is evidence supporting the effectiveness of psychosocial interventions in the treatment of depressive and anxiety disorders as, for example, exposure-based procedures have been shown to be consistently effective in the treatment of panic disorder. An exciting area of research concerns psychotherapy with individuals with personality disorders. Although individuals with comorbid personality disorders and Axis I disorders tend to have poorer outcomes in general, relatively effective treatments are being developed.

Some of the best research regarding patient variables concerns the interaction of patient and therapist and therapy variables. The idea of matching patient and therapist on either demographic or personality characteristics has begun to be examined, but theoretical reasoning is still more plentiful than are empirical findings. The research into matching patients and therapists has been too recent and inconsistent to draw firm conclusions or, more importantly, to make recommendations, but some important findings are emerging. A 1995 study in Los Angeles County examined the effect of matching patient and therapist ethnicity in the treatment of over 13,000 Asian-Americans, Mexican-Americans, African-Americans, and whites. In all ethnic groups, matched patients stayed longer in therapy, but matching was

positively related to outcome only for the Mexican-American group.

Other studies have attempted to match patient characteristics and therapy intervention. By definition, such research requires standardized therapies so research is this area is still fairly new and conclusive statements cannot be made. One study examined patient variables of coping style (i.e., externalization and defensiveness) as patients interacted with different types of therapy for major depression. Results suggested that externalizing patients and patients low in defensiveness did better in cognitive therapy, whereas internalizing patients and patients high in defensiveness did better in supportive or self-directed therapy.

Methodological problems associated with research into patient variables are complex, but the field is improving because of the introduction of standardized treatments and the development of more reliable and valid measures. Particularly interesting and exciting are efforts to match patient variables with treatment processes to optimize outcome.

Diagnosis Psychotherapy for individual conditions continues to be studied and includes a variety of psychotherapeutic modalities for a variety of psychopathological conditions. Research emphasis has focused on “empirically validated” psychotherapies, which include cognitive and behavioral psychotherapy, interpersonal psychotherapy, and short-term dynamically oriented psychotherapy.

SCHIZOPHRENIA Psychosocial family education has been shown to reduce the risk for relapse in schizophrenic patients receiving medication. Familial distress can also be reduced by this intervention.

MOOD DISORDERS The empirical evidence supporting the role of psychotherapy and psychosocial interventions in the treatment of patients with depression has become increasingly established. Based partially on improved research design and data analysis, this body of research has established the efficacy of psychosocial treatments of depression in its acute phase. The role of cognitive therapy in the treatment of depression also has become firmly established by meta-analyses of the results of psychotherapy research and in a review of the American Psychiatric Association's *Practice Guidelines on Manic Depressive Disorder and Bipolar Disorder*. According to other researchers this form of psychotherapeutic intervention has even been shown to be superior to pharmacotherapy in many cases. This treatment has also been studied and judged to be effective in its application to some specific populations, for example, to treat depressed patients infected with human immunodeficiency virus (HIV). It has been suggested that alone or in combination with medication, psychotherapy is probably the most effective treatment for many individuals suffering from depression because of its lack of side effects, because of its acceptance by certain patients, and because it deals with some of the social issues that may prolong depression or lead to relapse.

ANXIETY DISORDERS There is now evidence that psychosocial treatments are effective in the treatment of every anxiety disorder when compared to no treatment. However, many of these psychosocial interventions, which can be characterized as cognitive-behavioral with contributions from interpersonal and dynamic approaches, have limited clinical applicability and further research is needed. In panic disorder exposure-based procedures have been shown to be consistently effective. Meta-analyses of treatment outcome of panic disorder have also supported these findings. In addition, empirical studies of defense mechanisms in panic disorders have also been undertaken and have proven useful in the psychotherapy of this condition. Further research has been undertaken recently on the psychotherapeutic treatment of social phobia, generalized anxiety disorder, obsessive-compulsive disorder, specific phobia, and posttraumatic stress disorder. Combinations of exposure and cognitive therapies have shown some initial promise, and comparisons to pharmacotherapy have continued to show that psychotherapeutic treatments (most often cognitive-behavior therapy) demonstrate superior results.

P>**SUBSTANCE ABUSE AND DEPENDENCE** There are only a few well-controlled studies on the psychosocial treatment for substance abuse, but the existing data suggest that treatment for substance abuse should involve multiple modalities targeted to various specific problems in this population, including comorbid psychiatric disorders. Studies have shown that psychosocial treatments for substance abuse seem to be beneficial. In recent research supportive-expressive psychotherapy for patients with opioid dependence during methadone (Dolophine) maintenance treatment in community programs resulted in longer-lasting gains than did drug counseling. Specific recommendations based on empirical research indicate the usefulness of community reinforcement approaches with a subset of patients with cocaine dependence, family therapy for adolescents with substance abuse problems, and equivocal results with relapse prevention therapy, which perhaps is more effective for cocaine-dependent than for marijuana-dependent individuals.

PERSONALITY DISORDERS The psychotherapeutic treatment of individuals with personality disorders remains challenging and complex because of the heterogeneity and the variable severity of these disorders, and the observation that personality traits and their corresponding disorders are resistant to change and very difficult to modify. Individuals with a personality disorder in addition to an existing Axis I disorder have been shown to have poorer outcomes in general. In one study patients with major depression with a comorbid personality disorder were found to have more severe psychiatric disturbance at intake and they did not improve as much as those without a personality disorder. Although research findings support a poorer response to treatment for those with a personality disorder, the limited data that are available suggest that the presence of depression may be a positive prognostic indicator for patients with antisocial personality disorder. Here too the efficacy of short-term psychotherapy is an area of increasing interest. In a 1994 study two forms of short-term psychotherapy were employed to treat patients with personality disorders and patients in both therapies improved significantly as compared to patients who were not treated in this way.

Therapist Variables Therapist variables—the qualities or characteristics of psychotherapists that contribute to the process and outcome of psychotherapy—have been frequently studied and most empirical studies have failed to demonstrate a significant correlation between therapist demographic variables and outcome. There is a modest relation between age similarity of therapist and patient and outcome. Most reviews of research on the topic of therapist gender have failed to support the concern that male therapists may inhibit the progress of female patients. There is some evidence that patients of female therapists may have greater symptomatic improvement, but most studies do not indicate an effect on treatment outcome based on the sex of the therapist or on a match between the sex of the therapist and the patient. The opinion that ethnic similarity and ethnic sensitivity of the therapist result in enhanced outcomes has only received limited support from the empirical literature.

Therapist characteristics such as personality and coping patterns, emotional well-being, values and beliefs, and cultural attitudes are difficult to study experimentally because they are not amenable to experimental control. Recent research has focused on therapist traits such as dominance, locus of perceived control, and therapist conceptual level. Some findings suggest that similarity of cognitive style and level may facilitate patients remaining in therapy and experiencing speedier improvement. The emotional well-being of the therapist has been studied in terms of degree of perceived therapist distress on disturbance and whether the therapist has undergone personal therapy. Positive therapist mental health can enhance treatment effectiveness, especially in high-functioning patients, and a therapist's emotional problems can impact negatively on therapeutic progress. However, because the reasons why patients go into psychotherapy are so varied, the role of personal therapy on effectiveness is also quite varied. The therapist's values, attitudes, and beliefs have come under scrutiny because of the concern that these traits may exert an unwanted influence on the practice of psychotherapy. Religious beliefs and other general attitudes and values have been studied. Many studies have found that psychotherapy improvement may be augmented by a complex pattern of similarity and dissimilarity. No reliable conclusions have been drawn to date regarding attributes such as gender, lifestyle, and socioeconomic background.

The theoretical orientation of psychotherapists has been shown to have differing effect sizes in a number of meta-analytic studies. However, since the effects of specific interventions have been difficult to separate from therapist orientation, conclusions about any particular therapeutic orientation are as yet premature. Three interrelated variables have been studied in relation to the therapist's professional background and the effectiveness of therapy: level of professional training, amount of experience, and professional discipline. Research in these areas has yielded equivocal and contradictory results. Recently, however, a meta-analysis of graduate training in psychotherapy has found that treatment outcomes and treatment duration are associated with more training. Therapeutic styles are inexorably intertwined with therapeutic interventions. Interpersonal styles, verbal styles, nonverbal styles, and combined verbal and nonverbal patterns have all been studied, but no stable conclusions have emerged. Therapist interventions or technical procedures designed to bring about psychotherapeutic results relate to both therapist qualities and therapy processes. One such device for attaining therapeutic efficacy is the therapy or treatment manual. Because therapies that use therapy manuals can be empirically distinguished, they are often used in psychotherapy research. Results from studies employing therapy manuals show that a significant positive relation exists between compliance with a treatment manual and outcome of treatment. Additional research also shows that therapists' relationship skills and supportiveness may be diminished because of the therapists' focus on compliance with a manual so the use of these treatments may only be effective on certain types of patients. Specific therapist interventions have also been studied and include therapist directiveness; therapist self-disclosure; and therapist interpretations on transference, motives, and resistance, but no clear trends have emerged from these studies.

Treatment Process Variables: The Therapeutic Alliance Studying the effectiveness of psychotherapy entails identifying its curative elements, that is, determining what process variables are related to patient improvement. One aspect that has been repeatedly and consistently identified is the *therapeutic alliance*, sometimes called *therapeutic relationship, working alliance*, or *therapeutic bond*. For example, studies have shown that patients who dropped out of therapy prematurely liked the clinician less, felt less respected, viewed the psychotherapist as more passive, and generally experienced a weaker therapeutic alliance. Research reviews also have consistently concluded that a positive therapeutic relationship, whether measured from the perspective of nonparticipant observers or from the perspective of the

patient or the therapist, is related to therapeutic effectiveness across a wide variety of therapeutic modalities and patient problems. A meta-analysis of 24 studies of the relation between working alliance and treatment outcome concluded that there is a consistent relation between the quality of the alliance and positive outcome. The quality of the alliance appears to be influenced by a variety of interpersonal and intrapersonal patient characteristics. Patients who have a better history of and capacity for social relationships tend to develop a better alliance than defensive and negativistic patients. Interestingly, problem severity does not appear to affect the quality of the alliance. An exciting area of research concerns tracking the alliance across therapy, including monitoring therapist interventions when there are problems in the alliance. There is convergent evidence that measures of the alliance early in treatment are more strongly related to eventual outcome than later measures. This appears to reflect the fluctuating nature of the quality of the relationship across therapy and the frequent finding that during longer-term treatments the alliance is often disrupted and must be attended to in the course of successful treatment.

Current research is investigating whether the alliance mediates or moderates change. Carl Rogers proposed that the alliance was curative in and of itself, theorizing that the patient's experience of a nonjudgmental, warm, genuinely caring attitude on the part of the therapist mediated positive personality change. In contrast, Freud postulated that the relationship was a necessary precondition to or moderator of the work of psychoanalysis, which was responsible for positive change. Whether the relationship between the patient and the therapist is real or distorted has to do with the analytic concept of *transference*, which holds that the feelings that patients have toward therapists are always a mixture of attributes displaced onto the therapist from figures in the patient's past and the real characteristics of the therapist. Further research into the causes, uses, and effects of the alliance is clearly needed.

Patient Treatment Matching The aptitude-by-treatment-interaction approach to psychotherapy research attempts to identify the treatment strategies and procedures that produce optimal outcomes for individual patients. The aptitude-by-treatment interaction approach describes patients and therapists dimensionally with quantitative differences (e.g., resistive, impulsive, extroverted, directive, supportive). The questions addressed in aptitude-by-treatment interaction research include: (1) What procedures are important to effective treatment in different contexts? (2) Which patients are likely to respond therapeutically to therapist/therapy characteristics? and (3) How can patients be effectively assigned to therapies and their response monitored within those therapies?

The aptitude-by-treatment interaction model has been used to show that highly anxious, repressed patients are more responsive to emotion clarification on supportive approaches whereas externally cued patients respond better to more directive therapies such as cognitive behavioral psychotherapy. Also, supportive therapy has been shown to be more effective with patients having higher levels of distress; cognitive therapy has been shown to be more effective with patients presenting with lower levels of subjective distress. Research has provided evidence that depressed caregivers of older adults are differentially responsive to psychodynamic and cognitive behavior psychotherapy depending on the length of time in the caregiving role. Although largely unreplicated and few in number, these aptitude-by-treatment interaction studies support the principle of differential treatment selection.

Psychotherapy Combined With Pharmacotherapy A large proportion of patients who obtain treatment for mental disorders receive a combination of psychotherapy and medication. This blending of treatments is used widely for the treatment of depression, anxiety disorders, substance use disorders, schizophrenia, and some personality disorders. The American Psychiatric Associations Practice Guidelines on the treatment of depression and substance use disorders have embodied this combination of therapeutic approaches. Since the 1990s research on the relative efficacy of pharmacotherapy and psychotherapy, both in comparison and in combination with one another, has greatly expanded. Double-blind, controlled clinical trials have been the standard research design employed to study medications alone. However, newer strategies, such as the four-group factorial design in which both treatments are evaluated individually against one another, against a control group, and against their combination and the six-group design in which the placebo effect is evaluated, have been developed. The addition of a supplemental treatment to a proven standard treatment is another research design useful in assessing the value of combined treatments.

There are three possible outcomes of comparative and combined psychotherapy-drug treatments: (1) no therapeutic effect (i.e., combined treatment provides the same effect as individual treatment; (2) positive effects (i.e., combined treatment is better than individual treatment either by an additive and synergistic effect)—greater than the sum of the two treatments—or by a facilitative interaction—the treatment is only effective when combined; and (3) negative effects, (i.e., combined treatment shows less improvement than individual treatments). The hypothesized clinical mechanisms of positive action of medications on combined treatments are that medications facilitate psychotherapeutic accessibility, medications influence ego functions for participation in psychotherapy, medications promote psychotherapeutic abreaction, and medications have a positive effect on attitude and expectations. The hypothesized clinical mechanisms of positive action of psychotherapy on pharmacotherapy are that psychotherapy facilitates compliance with medications, that psychotherapy itself is rehabilitative, and that psychotherapy teaches skills that can be used to prevent relapse. However, it has also been hypothesized that combined psychotherapy and pharmacotherapy may have some general negative effects, but little empirical research has been done in this area. In relation to psychotherapy, medications may produce a placebo effect that promotes authoritarianism, reduces symptoms such that psychotherapy is prematurely terminated, and may undermine useful defenses. On the other hand, in relation to pharmacotherapy, psychotherapy may undercut compliance.

A number of different strategies have been identified for combining treatment modalities. The combination of either individual, group, or family psychotherapy with psychopharmacotherapy has been studied. In addition, psychoeducational approaches, self-help groups, and medication groups have proved useful in some instances. These strategies have been shown to improve psychotherapy process and outcome as well as to enhance medication compliance, treatment adherence, the prevention of relapse, and the recurrence of illness.

EFFICACY, EFFECTIVENESS, AND EFFICIENCY

Psychotherapy has been evaluated from three research perspectives: efficacy, effectiveness, and efficiency. Each of these perspectives has a distinct purpose, methodology, and interpretative context.

Efficacy Efficacy studies typically address the sufficiency of a particular highly controlled treatment in a specific setting with a carefully selected set of patients having a specific disorder. Efficacy studies are designed to control extraneous mediating factors such as therapist training (e.g., degree of treatment structure, protocol compliance), other treatments (single, combined, or multiple), the roles of the therapist (e.g., assessment and selection, monitoring of patient progress), participant selection (homogeneous or comorbid presentations), and treatment parameters (duration, dose, modality). The *sine qua non* of efficacy research is random assignment to treatment and control conditions. What constitutes an appropriate control condition has received considerable attention. Among the control group alternatives are (1) the no-treatment control, (2) the waiting-list control, (3) the placebo-attention control, and (4) the “usual care,” “best alternative treatment” control, also labeled the “minimal-treatment” control). Confidence in treatment efficacy increases as study comparisons reveal that a particular psychotherapy is better than no therapy, better than a nonspecific therapy, and better than an alternative therapy.

Over the past 15 years controlled clinical trials of psychotherapy have attempted to standardize therapy structure through the use of treatment manuals that provide a treatment rationale, goals, specification of treatment processes, and a sequence of action for conducting the psychotherapy. These manuals are efforts to standardize and operationalize treatments with greater specificity.

Prominent book-length examples of the treatment manual include David Barlow's *Anxiety and Its Disorders;* Aaron Beck, John Rush, Brian Shaw, and Chad Emery's *Cognitive Therapy of Depression;* Gerald Klerman, Myrna Weissman, Bruce Rounsaville, and Eve Chevron's *Interpersonal Psychotherapy of Depression;* Marsha Linehan's *Cognitive Behavioral Treatment of Borderline Personality Disorder;* Lester Luborsky's *Principles of Psychoanalytic Psychotherapy: A Manual for Supportive-Expressive Treatment;* and Hans Strupp and Jeffrey Binder's *Psychotherapy in a New Key: A Guide to Time-Limited Dynamic Psychotherapy*. Many more textbook and manual approaches take the form of methodological manuscripts in scientific journals. In 1995 the Task Force on Promotion and Dissemination of Psychological Procedures of the American Psychological Association drafted and published the empirical evidence to support these therapies; this list is periodically updated as new studies are published.

Psychotherapy manuals promote the use of a single conceptual framework for a therapy, and a set of prescribed techniques within that framework. Psychotherapy manuals are not so specific as to dictate the therapist's actions at each moment during the therapeutic interaction. Rather, they supply guidelines for the application of specific interventions and goals for sessions. Reactions to treatment-manual therapies include claims of excessive rigidity, of overlooking patient and therapist variability, and of irrelevance to the clinical practice of psychotherapy. Defenders of treatment-manual therapies have cited the importance of codifying effective behaviors for treating specific problems, the manuals' value in training new therapists, and the development of even more improved psychotherapies. There is some evidence that studies using treatment manuals had larger effect sizes than studies that did not use them.

The specification of therapies in manuals led to an interest in the evaluation of adherence to those prescriptions. Efficacy studies typically have included a compliance review through video tapes or audiotapes of therapy sessions. This review often uses a scale developed to assess that particular textbook psychotherapy. Scales are

available for cognitive therapy, interpersonal psychotherapy, time-limited dynamic psychotherapy, and supportive-expressive psychotherapy, among others.

Meta-analyses of psychotherapies collectively and of types of psychotherapy individually yield effect sizes of 0.75 to 0.85. Regardless of the outcome measure used, the means of the treated groups are at about three fourths of a standard deviation better than the means of the untreated groups. Meta-analyses of types of psychotherapy generally have not established the advantages of one type of therapy over another when considered across contexts, patients, and presenting problems.

Effectiveness Effectiveness studies are concerned with the delivery of psychotherapy in applied clinical settings. Psychotherapy may be only one component of an integrated intervention effort involving other health and social services. The experimental controls used in efficacy studies are usually absent in effectiveness studies. Patients may satisfy diagnostic criteria for multiple disorders. Moreover, the length of treatment may be determined more by patient motivation or resources or by the limitations of health care financing than by treatment prescription. Paradoxically, it seems that time-limited, planned short-term treatments are actually of longer median duration than naturally occurring traditional psychotherapies. Also, in effectiveness research, mental health professionals are likely to come from several disciplines and to vary in levels of training and experience. The goal of effectiveness research is to describe the response to the typical delivery of psychotherapy for patients who seek it, and to identify the treatment parameters that best predict patient response.

Some effectiveness studies begin with a program audit of a treatment package. These studies may include an assessment of the characteristics of settings and providers, the representativeness of the treatment samples, the treatment actually delivered, the barriers to treatment, and the costs of treatment. Examples include clinic studies of psychotherapy with children and adolescents, and a combination of medication, social skills training, and family education for patients with severe mental illness. Effectiveness studies often employ quasi-experimental designs and involve nonequivalent comparison groups in an attempt to make findings most relevant for actual practice.

Another approach to effectiveness studies is to describe the patterns of mental health service delivery assuming that efficacy studies have established the causal relation linking psychotherapy and outcome. This approach makes use of repeated measurements (multiwave data) in the course of psychotherapy, and uses the tenets of measurement reliability such as the “reliable change index” and “clinically significant change” to show how patients change over time. This has produced several models of patients' change in the course of psychotherapy, including the explication of a dose-response relation between the logarithm of the number of sessions and the normalized probability of improvement. A dose response of 50 percent (of patients improving) has been observed with approximately 8 sessions of psychotherapy; a dose reponse of 75 percent occurred with approximately 26 sessions; and improvement reached asymptope at approximately 85 percent after a little over a year of psychotherapy. The phase model has identified categories of change—subjective well-being, symptoms, and life functioning—that improve at different rates and in a probabilistically necessary causal sequence. Patients must first be remoralized (improvement in subjective well-being) before symptoms can improve, and symptoms must improve before life functioning can improve. Clinical trials of the treatment of depression with psychotherapy have shown that work functioning does not improve until the symptoms of depression have ameliorated. Other research using this approach to effectiveness research has shown that symptoms can be categorized as *acute, moderate*, and *chronic*, each with a different dose-response pattern.

The results of effectiveness studies are more generalizable to actual clinical practice than are the results of efficacy studies. However, because of the use of random assignment the results of efficacy studies may be less confounded by other influences than are the results of effectiveness studies. In defense of the onsumer Reports study, Martin Seligman has persuasively argued the relative merits of these approaches. That study showed that in actual practice psychotherapy was a very effective intervention for a wide variety of psychiatric conditions.

Efficiency The identification of patterns of change for aggregated cases of individual psychotherapy patients has provided a context for the study of individual patients and an assessment of the efficiency of treatment for each individual. Hierarchical linear modeling techniques have been used to show that a set of variables collected at intake could be used to predict the pattern of response of an individual psychotherapy patient. For some patients, the expected pattern of response is rapid and likely to require relatively few sessions of psychotherapy; for other patients the expected pattern of improvement is gradual and likely to require many sessions of psychotherapy to reach clinically significant change. Identification of these predictive patterns takes into account the variables—severity, previous experience with psychotherapy, difficulty of attending sessions—that mediate and moderate patient change. A particular treatment can be judged against its expected pattern of change, and a therapist's performance with severe or less severe cases can be more fairly judged against expected patterns of change. The monitoring of progress in psychotherapy and the allocation of therapeutic resources (e.g., sessions) also are made more rational; patients are judged against an expected pattern of change instead of against a prototype or ideal pattern.

The field of psychotherapy research is represented by the international interdisciplinary Society for Psychotherapy Research, which has over 1300 members from about 40 countries. The Society holds an annual meeting, and individual chapters (e.g., North America, Europe, United Kingdom, South America) also hold regular meetings. These meetings provide a forum for the exchange of ideas and findings. Research methods and findings are published in the Society's journal, *Psychotherapy Research* and in the several editions of the *Handbook of Psychotherapy and Behavior Change*, which is edited by Alan Bergin and Sol Garfield.

On the basis of over 1000 controlled studies, it can be stated unequivocally that psychotherapy is efficacious for a broad range of psychiatric disorders. However, efficacy and effectiveness studies have not yet clearly shown one kind of psychotherapy to be consistently superior to another; the average outcomes of treatments (across therapists, patients, and settings) are fairly equivalent. Comparable average effects over a range of patients would also be true of antibiotics and antidepressants. The task remains to show differential outcomes for different treatments for different patients. Until specific treatments that are consistently superior for homogeneous groups of patients can be found, the focus must remain on concurrent assessments to provide feedback regarding a patient's response to current treatment. As in the rest of medicine, the idea here is to conduct research that will yield information that can be used as systematic feedback to shape treatment in a way that indicates the need for a different intervention when the patient is not benefiting and indicates the continuation of a beneficial course.

30.12 COMBINED PSYCHOTHERAPY AND PHARMACOTHERAPY

GLEN O. GABBARD, M.D.

Psychiatry is the medical specialty that integrates the biological and the psychosocial perspectives in both diagnosis and treatment. The provision of optimal clinical care requires avoiding biological or psychological reductionism. Often the best psychiatric treatment plan for a given patient involves a combination of medication and psychotherapy. Of all medical specialists and mental health professionals, the psychiatrist is uniquely positioned to administer both treatments.

The challenge of integrating a psychosocial and biological understanding of the patient is a formidable one. The breadth of psychiatry as a specialty requires psychiatrists to be knowledgeable about neurotransmitters, the latest psychopharmacological agents, and the interface between genetics and environment. At the same time, they must be familiar with intrapsychic conflicts, patterns of relationships, and psychological meanings of symptoms. This interface between “mind” and “brain” makes psychiatry one of the most intellectually stimulating of all pursuits. Moreover, if the specialty were reduced to the prescription of medication, other medical specialists could easily replace psychiatrists. Similarly, if psychiatry were confined to psychotherapeutic interventions, other mental health professionals could perform similar functions and make psychiatrists unnecessary. Combined psychotherapy and pharmacotherapy is the daily bread and butter of the psychiatric clinician.

MIND-BRAIN INTERFACE

The notion that mind and brain are separate entities, often referred to as *Cartesian dualism*, has long since given way to the recognition that mind and brain are inextricably linked. Nevertheless, the task of integrating what is psychological and what is biological can be extraordinarily complex. Much of this difficulty arises from the irreducible subjectivity of consciousness that makes the reduction of the psychological to the biological highly problematic. William James suggested that consciousness should be regarded as a process rather than a substance. Subsequent philosophers of the mind-body problem have stressed that even though all mental states are embodied and therefore coexist with physical states, neuroscientific explanations of psychological states fail to capture the indispensable nature of first-person subjectivity.

One investigation used positron emission tomography (PET) to measure cerebral blood flow in seven healthy subjects while at rest. The patterns of the blood flow were then compared to measures of the same subjects when they imagined or recalled a sad event. When the subjects were sad, the researchers identified significant differences in the regional cerebral blood flow in the inferior and orbitofrontal cortices. This investigation illustrates that the psychological and biological, while interconnected, are different domains with different languages. The subjective state of sadness has physiological correlates in the brain that are measurable. However, the memories and personal meanings associated with the state of sadness cannot simply be reduced to changes in cerebral blood flow in specific areas of the cortex.

There was a time in psychiatry when medication would be prescribed for disorders regarded as having a biological etiology, and psychotherapy would be employed for psychological disturbances, but recent research has rendered this dichotomy highly questionable. Studies using PET have demonstrated that behavior therapy and cognitive therapy have effects similar to those of fluoxetine (Prozac) on the cerebral metabolic rates in the head of the right caudate nucleus in patients with obsessive-compulsive disorder. The most biological disorder in psychiatry, schizophrenia, is the one with perhaps the most persuasive evidence that psychotherapy can prevent relapse; indeed, some studies suggest that family therapy reduces relapse of schizophrenia to the same extent as antipsychotic medication does.

Recent investigation with cancer patients provides further evidence of the impact of psychotherapy on patient physiology. Metastatic breast cancer patients experiencing group psychotherapy lived an average of 18 months longer than did a randomly assigned control group who did not receive such therapy. Similarly, patients with malignant melanoma who attended a support group had more lengthy remissions and more favorable mortality rates than a control group who was not given the support group protocol.

The evidence accumulating from these studies suggests that psychotherapy must work by changing the brain. If psychotherapy is a form of learning, then studies on animals who are lower on the phylogenetic ladder may be specially relevant. Scientific studies on rats and marine snails have demonstrated that the number of synapses per neuron actually increases in response to learning based on environmental experiences and social contacts with others of the same species; in other words, neuroanatomical changes accompany learning and group interaction.

Also, the impact of neurotransmitters may change according to psychosocial influences. A neuron in the crayfish has a dramatically different response to serotonin depending on the animal's social status. In dominant animals, serotonin makes the neuron fire; in subordinate creatures, serotonin suppresses firing. This neuron that controls the tail-flip reflex (involved in the fight-or-flight-response) can change from firing to suppressing within the same animal. When two previously subordinate crayfish are put together, one becomes dominant and the neuron starts firing in response to serotonin as a result.

Although the leap from lower animals to human beings is substantial, the data are highly suggestive of a complex interaction between environmental and innate biological factors. Similarly, it is now known that environment has a substantial effect on gene expression. Less than 2 percent of all diseases in medicine follow familiar Mendelian patterns of inheritance; most involve some degree of genetic diathesis triggered by environmental stressors. Studies of depression, for example, have shown that genetic factors appear to influence the vulnerability of the individual to react to psychosocial stressors with a major depressive episode.

The interface of mind and brain was further complicated by research demonstrating that there are robust genetic and biological influences on what have often been considered to be personality traits. Shyness, reward-dependence, novelty-seeking, introversion-extroversion, persistence, and other features of personality appear to be influenced by genetic factors. In a similar vein, recent psychopharmacologic studies demonstrate that psychotropic medications may alter traits that have long been considered characterological.

This abbreviated overview of some of the recent research on the mind-brain interface and the interaction of genes and environment underscores the complexity of the conceptual underpinnings of combining medication and psychotherapy. Clearly, there is no simple one-to-one correlation between psychotherapeutic interventions and the so-called psychological aspects of illness. Neither can it be assumed that psychotropic agents affect only “hardwired” dimensions of the illness. What is fairly certain is that psychotherapy and medication often work synergistically to provide the best possible treatment for the patient.

PSYCHOTHERAPEUTIC MANAGEMENT

In conceptualizing how psychotherapeutic interventions and medication work together, two general strategies can be delineated. One is the psychotherapeutic management inherent in skilled pharmacotherapy practice; the other is the combination of formal psychotherapy and the prescription of medication.

In considering the former, a good starting point is the American Psychiatric Association “Practice Guidelines for Treatment of Major Depressive Disorder in Adults,” which stress that psychotherapeutic management is an essential component of every medication-based treatment plan. One way of understanding the recurrent finding that a placebo condition in a controlled trial is often an effective treatment for a significant number of patients is that good clinical management has psychotherapeutic effects. Simply by asking about symptoms and taking a history, the clinician often helps patients to become aware of connections between external events, the meaning of those events, and symptoms that lead them to insight about their illness. The fact that a caring physician is listening and providing help may be a powerful corrective emotional experience for some patients. Another mechanism of action may involve the so-called transference cure, in which the patient gets

better to please the physician.

Many psychodynamic principles derived from psychotherapy apply equally to pharmacotherapy practice. A pharmacotherapeutic alliance is essential to ensure that the patient understands the reasons for the medication and complies with the treatment plan, just as a psychotherapeutic alliance is essential to enlist the patient as a collaborator in psychotherapy.

This principle was persuasively demonstrated in an analysis of the role of the therapeutic alliance in the outcome of 225 depressed outpatients enrolled in the Treatment of Depression Collaborative Study sponsored by the National Institute of Mental Health. The patients were given one of four treatments: (1) 16 weeks of cognitive-behavior therapy, (2) 16 weeks of interpersonal therapy, (3) imipramine (Tofranil) plus clinical management, or (4) placebo plus clinical management.

Using videotapes and an instrument designed to measure patient and therapist behaviors, trained raters scored the therapeutic alliance for all patients in the project. Outcome was also assessed using standard depression-rating measures. The investigators found that the therapeutic alliance was just as important for drug therapy as for psychotherapy. Also, the alliance continued to be important whether it was measured in early sessions or later ones. The nature of the therapeutic alliance accounted for more of the variance in treatment outcome (21 percent) than the treatment method itself (1 percent). The patient's contribution to the alliance, rather than the therapist's, seemed to be the significant factor related to outcome. The investigators speculated that the importance of a good therapeutic alliance in the outcome of pharmacotherapy may partially explain why depressed patients often do worse in primary-care settings. Physicians average only about 8 minutes per patient in primary-care practice, and this constraint may interfere with the time and the psychotherapeutic management necessary to establish a good alliance.

Other dynamic principles, such as transference, resistance, and countertransference, also are an integral part of pharmacotherapy practice. Many problems with noncompliance can be traced to these principles. The application of psychodynamic constructs to compliance problems in pharmacotherapy is often referred to as *dynamic pharmacotherapy*.

Transference is not a phenomenon limited to psychotherapy. The attribution of qualities to the prescribing physician that stem from figures in the patient's past occurs routinely in clinical practice. A patient may perceive the psychiatrist as authoritarian and refuse to cooperate with the prescribed treatment plan because it reminds him of how his father used to bark orders at him and try to control him. If the psychiatrist then feels irritated at the patient for not cooperating and becomes more insistent, the problem may worsen because the clinician is behaving in the authoritarian manner that the patient fears. In this case, the psychiatrist's countertransference has entered into the equation and affected the patient's capacity to collaborate with a good alliance.

Resistance to taking medication may relate to issues of transference and countertransference in many cases. In others, the resistance stems from a fundamental ambivalence about getting better. In cases of depression, in particular, some patients may feel that they have committed such sinful and evil acts that they deserve to be punished for them by remaining depressed. An antidepressant medication may have a specific meaning for such patients,—the potential to relieve their suffering—so they may not fill their prescription or take the tablets as prescribed.

Medication may be imbued with a myriad of other meanings. Many patients view medication as a crutch. They may make no distinction between being addicted to a narcotic and taking maintenance dosages of antidepressant medication. Some patients may interpret needing medication as a sign of weakness, so they will often discontinue it on their own as soon as their symptoms start to abate. In still other cases, the medication has a meaning connected with a family member.

A woman who was not responding optimally to desipramine (Norpramin, Pertofrane) was prescribed lithium (Eskalith) in addition to the desipramine as an augmentation strategy. She took the prescription from her psychiatrist, but when she returned the following week, she acknowledged when asked that she had not filled the prescription. She promised that she would. At her appointment the following week, her psychiatrist asked her if she would come in to have her blood drawn for a lithium level. She sheepishly acknowledged that she had not been taking her lithium. When the psychiatrist inquired why she had chosen not to, she responded with intense emotion in her voice: “I will not be genetically tied to my mother.” Although the statement was absurd at one level, the psychiatrist understood what she meant. Her mother had been diagnosed as having bipolar disorder, had been prescribed lithium, and had ultimately committed suicide. To this particular patient, taking lithium meant that she would end up exactly like her mother.

Optimal psychotherapeutic management of a pharmacotherapy patient involves attention to these psychological dimensions of the relationship and to the medication itself. In addition, the clinician must empathize with the patient's perception of medication and try to appreciate the meaning it has for that patient. Good listening skills, attention to rapport, and a systematic effort to establish a good alliance based on careful explanations are all integral parts of this approach to pharmacotherapy.

MEDICATION IN COMBINATION WITH FORMAL PSYCHOTHERAPY

History In the 1940s and 1950s when psychoanalysis dominated the landscape of psychiatric practice, there was a reluctance to combine medication with psychotherapy. One of the general concerns about combined treatment was the fear that psychotropic agents might alleviate the anxiety or depression that motivated the patient to tolerate the frustrations and deprivations of psychotherapeutic exploration. Another concern was that the prescription of medication by the analyst or therapist would interfere with the development of the transference to the clinician and the subsequent understanding of that transference.

This belief regarding the inherent incompatibility of psychotherapy and medication persisted into the 1960s and 1970s, despite a number of studies showing no sign of the kinds of problems that clinicians had feared; in fact, research showed just the opposite. In many cases medication and psychotherapy working in concert produced superior results to either modality alone. In a 1993 review of 13 studies comparing dynamic psychotherapy versus other forms of psychotherapy, the investigators found the main trend of all the comparative studies to be nonsignificant differences in outcome. However, their conclusion of the nonsignificant-difference effect did not hold when applied to combined treatments versus single treatments. The advantage for combined treatments was striking. Psychotherapy plus pharmacotherapy was clearly superior to psychotherapy or pharmacotherapy alone.

In clinical practice today there is a widespread acceptance of the combined use of medication and psychotherapy. Even among psychoanalysts, who were once the most vocal critics of combined treatment, prescribing is commonplace. In a survey of members of the American Academy of Psychoanalysts, 90 percent of respondents said they were prescribing medications. In a study of psychoanalytic candidates' training cases at the Columbia University Center for Psychoanalytic Training and Research, medication was combined with psychoanalysis in 29 percent of the cases, reflecting the fact that medication is no longer seen as interfering with certification or graduation.

Many analysts and other therapists have noted that medication and psychotherapy work synergistically to improve outcomes in a wide variety of illnesses. Investigations of outcome geared to specific disorders consistently demonstrate advantages to combined approaches.

Specific Diagnostic Categories

Schizophrenia An extensive series of studies have examined the rate of relapse when a specific form of psychoeducational family therapy is combined with antipsychotic medication. This intervention is based on the observation that high levels of expressed emotion in the families of patients with schizophrenia predicted relapse following hospital discharge. High-expressed-emotion families have been characterized as excessively intrusive, critical, and overinvolved with the patient who suffers from schizophrenia. Psychoeducational family therapy is aimed at helping the family reduce the factors that constitute expressed emotion and at educating the family about schizophrenia and the need to continue antipsychotic medication indefinitely.

In a 1991 study by a team of investigators led by Gerard Hogarty, the addition of psychoeducational family therapy to antipsychotic medication reduced the relapse rate of patients with schizophrenia by half. The relapse rate was even further reduced at 1-year follow-up when social skills training was added to family therapy and medication. A similar study in 1994 found that there was a 77 percent hospital readmission rate in an 18-month period when patients with schizophrenia were given no medication and no family intervention. Either medication alone or family intervention alone reduced the rate of schizophrenia by approximately 50 percent. However, when the family intervention and medication were combined, only 10 percent of patients required readmission during the 18-month period.

An innovative form of individual therapy, termed personal therapy, has also shown promise in combination with antipsychotic medication. A 3-year controlled trial using random assignment, reported in 1997 that combining personal therapy and medication (most commonly fluphenazine or haloperidol [Haldol] administered intramuscularly) was more effective than family and supportive therapies in preventing psychotic and affective relapse as well as noncompliance. This effect, however,

was demonstrated only for those patients with schizophrenia who were living with their families. The personal therapy focused on the patient's characteristic response to stress and avoided symbolic interpretation or exploration of unconscious issues. The approach encouraged the patient to identify the cognitive, physiological, and affective experience of stress. Techniques drawn from social skills training encouraging the resumption of expected roles, and the provision of social and avoidance techniques were also part of the therapy.

Psychoeducational measures about the prodromes of psychosis, adaptive strategies, and successful rehabilitation were included. In all cases, selected principles of personal therapy were carefully tailored to the patient's individual needs and the stage of the patient's illness.

Personal therapy appeared to have other positive effects on the patients beyond the prevention of relapse. There were pervasive improvements in the area of social adjustment. While supportive therapy had some impact on adjustment, the improvement peaked at 12 months and leveled off thereafter. By contrast, patients receiving personal therapy continued to improve in social adjustment in the second and third years after discharge.

Major Depressive Disorder The differential effects of medication versus psychotherapy have been studied more extensively for depression than for other disorders. Whereas antidepressant medication seems to have its greatest effects on anhedonia, psychomotor retardation, sleep disturbances, appetite disturbances, delusions, and hallucinations, psychotherapy seems to act preferentially on interest, mood, social relationships, and vocational issues. Yet the landmark National Institute of Mental Health (NIMH)-Treatment of Depression Collaborative Research Project did not include a combined-treatment cell in its investigation of treatments for depression. The study clearly demonstrated that cognitive and interpersonal therapy are effective treatments for depression, but whether combined treatments had an advantage was not possible to discern from the study design. Fortunately, other studies have investigated the impact of combining psychotherapy and medication.

A study of interpersonal therapy (IPT) plus medication included comparison groups of medication alone and IPT alone. After 16 weeks, there was a clear advantage for combined treatments over either single modality. As predicted, the two approaches appeared to target different symptoms preferentially; medication seemed most useful for vegetative symptoms, and psychotherapy had a greater impact on interest and mood. Also, medication acted more rapidly than psychotherapy.

Studies of cognitive therapy have also shown some modest evidence of advantages for the combined therapy. Adding cognitive therapy to antidepressants appears to be more effective in preventing relapse than medication alone. Studies combining behavior therapy with antidepressants have methodological problems, but the combined treatment does appear to work more rapidly than behavior therapy alone. Combinations of psychodynamic therapy and antidepressants have not been tested in randomized, controlled trials.

Investigations of the combination of couples and family therapy with medication suggest that combined treatment produces greater improvements in the overall quality of the marital and family relationships while medication produces more rapid symptom change. Hence the combination enhances the breadth of the response, because both sets of target symptoms are improved when the combined modalities are part of the treatment plan.

Studies of the combination of medication and psychotherapy in the maintenance phase of major depressive disorder also show superiority of combined treatment. In a randomized controlled trial involving 107 elderly patients who had fully recovered from a major depressive episode, patients were assigned to one of four maintenance therapy conditions: (1) medication clinic with nortriptyline (Pamelor), (2) medication clinic with placebo, (3) monthly maintenance interpersonal therapy and nortriptyline, or (4) monthly maintenance interpersonal therapy with placebo. The recurrence rates over the 3-year period of the study were only 20 percent when nortriptyline and interpersonal therapy were combined, compared with 43 percent in the group who received nortriptyline and medication clinic visits and 64 percent in the group that received interpersonal therapy and placebo. In this elderly population there was a clinically significant advantage of combining medication and psychotherapy compared to either treatment alone, and the investigators concluded that combined treatment was the optimal clinical strategy in preventing relapse.

In elderly depressed patients, there is some research that allows the clinician to determine whether maintenance psychotherapy or antidepressant medication is indicated. Recovery of good subjective sleep quality during early continuation treatment is associated with the maintenance of a good remission with only monthly maintenance interpersonal psychotherapy. Patients who do not have such rapid recovery of good subjective sleep quality may be vulnerable to recurrence of major depressive episodes if the antidepressant medication is withdrawn.

In summary, psychotherapy and medication work on different target symptoms in patients with recurring major depressive disorder and therefore combine to enhance the overall breadth of response. Medication works more rapidly than psychotherapy and may provide more reliable relief from acute distress, but psychotherapeutic modalities enhance social functioning and appear to extend the relapse-free period. A 1997 “mega-analysis” comparing nonbipolar depressed patients treated with psychotherapy alone to those receiving combined treatment found that the advantage of the combination is particularly striking in more severe depressions that are recurrent.

Bipolar I Disorder Much less controlled research has been conducted on combined treatments of bipolar disorders, although there is a growing consensus that psychosocial interventions are essential in the treatment of the majority of patients. A German study looked at relapse rates in 20 cases of bipolar I disorder and 10 cases of schizoaffective disorder before and after treatment with systemic family therapy in conjunction with medication. The average duration of the treatment was 14.7 months with a range of 0 to 35 months, and the average number of sessions was 6.60 with a range of 1 to 19. The relapse rate was measured by the number of hospitalizations during the period of observation. Following family therapy, there was a 77.6 percent reduction of relapse in the total sample (67.8 percent for the patients with bipolar I disorder and 89.8 percent for patients with schizoaffective disorder).

This statistically significant reduction in relapse rate was accompanied by far lower rates of hospitalization. Before family therapy, only 1 of 30 cases required no hospitalization whatsoever; after family therapy, 14 of the 30 cases required no hospitalization. Only an average of 6.6 sessions of family therapy was required, so this intervention was also highly cost effective because of the reduction in hospital costs.

Several characteristics were noted in the families with improved relapse rates. Most significantly, the patients were no longer viewed by themselves or by their family members as victims of an illness beyond their control; family embers and patients felt empowered and gained a sense of active mastery over the illness.

Although this study did not utilize random assignment or control groups, the results nevertheless suggest that some family interventions that have proven so effective in prevention of relapse in schizophrenia may also be useful in the treatment of bipolar disorder. An American study at Cornell University Medical Center, utilizing both random assignment and a control group, has lent further support to the value of combining family therapy and medication. In this study 60 patients with a major mood disorder were randomly assigned to an inpatient family intervention plus medication in the context of standard hospital treatment, or to medication and standard hospital treatment without family intervention. Twelve patients who received the family therapy and 9 in the control group were diagnosed as having bipolar I disorder. At 18-month follow-up, significantly fewer patients from the family intervention group had been rehospitalized as compared with the group who did not receive the family treatment. Similarly, on measures of global outcome and work or primary role functioning, the patients who received the family intervention were doing significantly better than those who did not.

With the increasing awareness that lithium alone does not constitute effective prophylaxis for many patients with bipolar I disorder, individual psychotherapy has been added to increase occupational and social functioning, encourage compliance with lithium or other mood stabilizers, and cut through the denial so common in these patients. Many patients deny that their manic or hypomanic episodes are part of their illness, insisting that it is simply part of who they are; others will manifest a form of psychic discontinuity in which the manic “self” is split off from the euthymic “self,” as though the two are in no way connected. Some clinicians will use videotapes or audiotapes of the patient during a manic episode to help them integrate that aspect of themselves into the illness and overcome their denial. Patients with bipolar I disorder may also need assistance in mourning losses they have incurred through their erratic behavior during manic phases. Finally, individual psychotherapy may assist these patients in identifying the stressors that are instrumental in producing relapses. Research on patients with bipolar I disorder who are followed longitudinally and are systematically interviewed regarding life events reveals that those with the most frequent relapses are also subject to higher rates of major stressors.

At least one controlled study has demonstrated that the addition of individual cognitive therapy to lithium treatment improves compliance with the treatment and prevents relapse. Many patients have acknowledged that psychotherapy has been an important adjunct in their overall treatment.

Panic Disorder and Phobias Meta-analyses of the existing studies on the combination of behavior therapy and imipramine have consistently shown that greater improvement occurs when the treatments are combined than when either is used alone. Combined treatment shows superior efficacy for reducing specific phobia, social phobia, and functional impairment; it is roughly equivalent to medication in terms of reducing the frequency of panic attacks.

The advantage of combined treatments does not appear to hold when a combination of benzodiazepines and behavior therapy is compared to either modality alone. Some research suggests that high doses of benzodiazepines may undermine positive posttreatment outcomes with cognitive-behavior therapy, especially when the medication has been discontinued after the completion of the therapy. There may be some exceptions, however, when the combination may be useful. The addition of situational exposure therapy for patients with clinically significant agoraphobia being treated with benzodiazepines may be one such example; multimodal cognitive-behavior therapy may be useful when benzodiazepines are being withdrawn over time.

A Scandinavian study compared clomipramine (Anafranil) alone for patients with panic disorder with clomipramine plus 15 weekly sessions of dynamic psychotherapy. All patients in both treatment groups were panic-free within 26 weeks. On termination of clomipramine after 9 months, the relapse rate was significantly lower in the clomipramine-plus-psychotherapy group. The investigators concluded that dynamic therapy reduces psychosocial vulnerability associated with panic disorder.

In selected cases, couples or family therapy may be necessary in combination with medication or behavior therapy.

> A middle-aged housewife was virtually housebound because of her anxiety about having a panic attack in the shopping mall. Her husband had adapted to her disorder to a large extent, and he frequently performed routine tasks like grocery shopping for her. When she was successfully treated with exposure plus imipramine, she described deterioration in her marital relationship. The treating psychiatrist asked her to bring her husband into the sessions with her. It soon became apparent that her husband was highly ambivalent about her improvement because he was convinced that she would be attracted to another man when she went out shopping and have an extramarital affair. His jealous rage had led him to become extremely controlling of his wife at home, and she was wondering whether it would be better if she just returned to being housebound again.

This case vignette reflects how the marital couple may reach a stable equilibrium around an illness. Without attention to the marital issues that support and maintain the disorder, there is little likelihood that improvement will be lasting. One 3-year study of the marital interaction between 36 married agoraphobic women and their husbands found that 7 of the husbands reacted with abnormal jealousy when their wives responded to treatment. In each case the husband's reaction adversely influenced the treatment outcome. Even when the husband does not react with a jealous rage, there may be strong clinical reasons to involve the spouse in the behavioral treatment of a phobia. In one study of 66 agoraphobic patients, those in a home-based program that used the husband as a cotherapist fared better than patients whose husbands were not involved in the treatment. Including the husband encourages the couple to collaborate in strategies that improve the agoraphobic patient's ability to leave the home.

Obsessive-Compulsive Disorder Treatment of obsessive-compulsive disorder usually takes one of two directions. Treatment with selective serotonin reuptake inhibitors (SSRIs) often results in patients with obsessive-compulsive disorder making significant symptomatic improvement. While clomipramine is also useful, its adverse effects make SSRIs the preferred agents. In addition, about three quarters of patients with obsessive-compulsive disorder who comply with behavior therapy and who consciously apply the techniques show sustained improvement in symptoms.

Because the improvements effected by SSRIs are limited in terms of overall symptom reduction in patients who relapse rapidly when the agents are discontinued, there is a strong case to be made for combining behavior therapy and SSRIs. Some studies suggest both short-term and long-term improvements as well as more rapid response when both treatments are used. Behavior therapy also holds out the possibility that the medication can be discontinued without risking patient relapse.

Despite some suggestive data, however, the reports published so far on the advantages of combined medication and behavior therapy are not entirely convincing. Overall, combining treatments appears to improve the outcome as compared to medication alone, but this is not necessarily true for behavior therapy alone. Nevertheless, for behavior therapy to maintain robust results, the patient needs to invest time, energy, and money. Usually, daily therapy sessions are conducted for several weeks, after which these patients are expected to devote a good deal of time to exposure work. Hence it may not always be practical to provide behavior therapy at that intensity, and many patients may benefit with a less intense exposure accompanied by the use of SSRIs.

Some patients with obsessive-compulsive disorder become highly invested in their symptoms. Although psychodynamic therapy has not been shown to be effective in directly reducing the obsessions and rituals of obsessive-compulsive disorder, it may be useful in helping these patients to understand their resistance to receiving effective treatments like behavior therapy and SSRIs. Often the patient has involved the whole family system in a variety of cleaning rituals, and family therapy may be helpful as well in assisting family members to reduce their overinvolvement with the patient. When family members hear that they would be more helpful by refusing to collude with the patient's rituals and demands and by encouraging exposure (e.g., allowing the patient to touch doorknobs), they often feel a great sense of relief. Many feel obligated to collude with the patient, and only family intervention can give them permission to try other approaches.

Substance Dependence Both psychotherapy and methadone (Dolophine) have shown encouraging success with patients with opioid dependence. Data are also accumulating that the combination of the two approaches may achieve even better outcomes. In a randomized, controlled trial comparing treatments, opioid-dependent patients were assigned to one of three groups. One group had only methadone and virtually no psychotherapy. The second group had methadone plus meetings with a counselor that were oriented towards behavioral interventions. The third group had enhanced services involving the same dose of methadone and the same form of counseling, but also received additional resources, including a half-time employment counselor, a full-time psychiatrist, and a half-time family therapist.

Analysis of the results of this trial showed that the groups receiving psychotherapy had greater earning power, less welfare income, and strikingly lower rates of hospitalization as compared to the group that did not receive psychotherapy. In addition, a beneficial impact on costs could be inferred because of the reduced rate of hospitalization when psychotherapy was added. The investigators also noted that the stepwise, incremental value of the enhanced services over simple counseling in the second group indicated that family therapy, the presence of a psychiatrist, and employment counseling were highly useful interventions.

Personality Disorders In all of psychiatry, psychology and biology may come together most clearly in the realm of personality disorders. Personality appears to be composed of two broad components: *temperament*, which is constitutional and based on heritable traits, and *character*, which is primarily influenced by experiences in the environment. The seven-factor psychobiological model of personality developed by C. Robert Cloninger and his colleagues lends itself to treatment strategies that incorporate both medication and psychotherapy (Fig. 30.12-1).

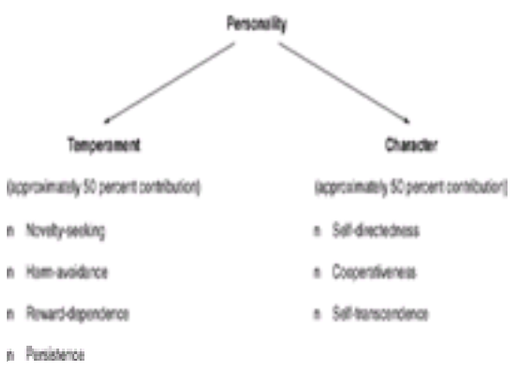

FIGURE 30.12-1 A psychobiological model of personality.

Temperament is composed of four heritable traits that are genetically homogeneous and inherited independently from one another. These include harm-avoidance, novelty-seeking, reward-dependence, and persistence. These traits are observable early in childhood and are relatively stable throughout the life cycle. These temperament traits account for approximately 50 percent of personality. The other half of personality is accounted for by character, within which three major character traits can be distinguished: self-directedness, cooperativeness, and self-transcendence. Character is heavily influenced by environmental experiences and matures in a stepwise manner throughout development. The DSM-IV personality disorders are all characterized by low ratings on self-directedness and cooperativeness. Self-transcendence does not appear to discriminate personality disorders from normal personality.

One clinical implication of the growing understanding of the relative contributions of biology and psychology to personality disorder is that psychopharmacological intervention may target temperament traits while psychotherapeutic approaches address character difficulties. It is an oversimplification to think of medication as the exclusive treatment for Axis I disorders and psychotherapy as the exclusive treatment for Axis II disorders. Even in normal personality functioning, serotonergic function appears to modulate aspects of affective experience and social behavior. In a placebo-controlled study of normal volunteers, paroxetine (Paxil) was administered for 4 weeks, and changes in personality variables were studied. Compared to placebo, paroxetine decreased negative affect and increased social affiliation.

Although no systematic studies have been reported on the combination of psychotherapy and medication compared to either treatment alone in patients with personality disorders, recent investigations of the role of psychopharmacological intervention on personality disorder patients suggest that the effect of such agents on temperament may facilitate psychotherapeutic work with character. Double-blind controlled studies have demonstrated that monoamine oxidase inhibitors (MAOIs) may improve atypical depression in patients with borderline personality disorder, particularly if symptoms such as hyperphagia and hypersomnia are present. Carbamazepine (Tegretol) has also been shown to decrease behavioral dyscontrol in patients with borderline personality disorder. Brief psychotic episodes in this patient group have been effectively treated by low-dose antipsychotic medication. However, much recent attention has been directed to the role of SSRIs. One study using fluoxetine (Prozac) showed that patients with borderline personality disorder showed improvement in depression, anxiety, paranoia, interpersonal sensitivity, obsessionality, hostility, and global functioning compared to a control group who received placebo. However, higher daily dosages of fluoxetine, averaging 80 mg, were necessary to produce these changes.

A second controlled study using fluoxetine found that intense anger of patients with borderline personality disorder can be significantly reduced through the use of this medication. The reduction of hostility and anger does not appear to be confined only to patients with borderline personality disorder. In a third study, patients with a variety of personality disorders were treated with an average daily dosage of 20 mg to 40 mg of fluoxetine. Compared to the control group on placebo, these patients showed statistically significant reductions in impulsive aggressive behavior. The medication seemed to be particularly useful for verbal aggression and aggression against objects rather than on assaultive behavior.

Hence the rationale for combining medication and psychotherapy is in part the fact that negative affects can be reduced by the administration of agents such as SSRIs. When rage and aggression are lowered, the patient may be more accessible to psychotherapeutic interventions. The decreased intensity of affect may allow the patient to reflect on and contemplate internal states and problems that occur in relationships.

Aggression is not the only focus of pharmacotherapy. Indeed, there are four general symptom domains that may benefit from targeted psychopharmacological intervention in personality disorders: (1) aggression and behavioral dyscontrol, (2) affective instability and mood symptoms, (3) anxiety, and (4) psychotic symptoms and other cognitive perceptual distortions. The empirical research suggesting that several different agents are of benefit with patients who suffer from borderline personality disorder reflects the fact that these different domains can be targeted by different agents.

Several types of psychotherapy have been effective in treating the various personality disorders. A randomized controlled trial of dialectical behavior therapy with borderline personality disorder found that substantial improvements in suicidal and parasuicidal behavior as well as reductions in the need for hospitalization are possible with 1 year of that modality. Similarly, longitudinal studies of dynamic psychotherapy suggest that improvements in personality disorders can be expected with long-term dynamic psychotherapy. While clinical trials involving combined therapies are not yet available to provide definitive evidence, a strong argument can be made for the combination in clinical practice based on the independent findings of psychopharmacological and psychotherapeutic studies.

Eating Disorders For many years the typical treatment for bulimia nervosa has been a combination of psychotherapy and an antidepressant. A 1997 study using a randomized, controlled design has demonstrated that combined treatment is better than either modality alone. A total of 120 women with bulimia nervosa were assigned to one of five conditions: (1) cognitive-behavior therapy plus placebo, (2) cognitive-behavior therapy plus an antidepressant, (3) dynamically oriented supportive therapy plus placebo, (4) dynamically oriented supportive therapy plus an antidepressant, and (5) an antidepressant alone. There was a two-stage medication intervention in which a second antidepressant, fluoxetine, was employed if the first antidepressant, desipramine, was either ineffective or poorly tolerated.

This study yielded a number of significant results. First, cognitive-behavior therapy was found to be superior to supportive therapy in reducing the behavioral symptoms of bulimia nervosa such as vomiting and bingeing. Patients who received medication in combination with psychotherapy experienced greater improvement in binge eating and depression than did patients receiving placebo and psychological treatment. Cognitive-behavior therapy plus an antidepressant was also superior to medication alone, but supportive therapy plus the antidepressant was not. The investigators concluded that cognitive-behavior therapy was the treatment of choice for patients with bulimia nervosa but that the two-stage antidepressant intervention added modestly to the benefit of the psychotherapy.

CLINICAL CONSIDERATIONS

In considering various combinations of pharmacotherapy and psychotherapy, there are two models commonly used in clinical practice today. The one-person model involves a psychiatrist conducting the psychotherapy and prescribing medication for the same patient at the same time. The two-person model divides the functions so that the clinician conducting the psychotherapy and the physician prescribing the medication are two separate individuals. Practical considerations determine which model is used. If a psychotherapist does not feel competent in prescribing certain medications, a psychopharmacology consultant must be involved. Conversely, if a psychopharmacologist does not feel sufficiently skilled to provide the psychotherapy, the patient must be referred to a separate psychotherapist. For financial reasons, a managed-care company may stipulate that a psychiatrist can only see the patient for 15 minutes to prescribe medications and may assign the psychotherapy to a less expensive nonmedical therapist. Another common situation occurs when psychotherapy begins with a nonmedical therapist and the patient becomes depressed; a consultation with a psychopharmacologist is then requested. If a psychiatrist is the primary treater and is competent at both treatment modalities, there are several factors that must be taken into account in deciding which approach to recommend.

One-Person Model Psychiatrists who decide to employ the one-person model must accustom themselves to thinking about both mind and brain in their regular sessions with the patient. Just like the physicist who simultaneously thinks in terms of particles and waves, the psychiatrist must think about a dysfunctional brain and a distressed mind as part of a unified whole. In practice this may require a flexible shifting back and forth between an empathic, introspective subjective approach versus a more objective descriptive approach. While psychotherapy often encourages verbalization as opposed to action, prescribing medication requires clear action on the part of the clinician (and the patient). Moreover, the clinician must ask direct questions designed to elicit information about symptoms and adverse effects rather than the more open-ended approach of allowing the patient to set the agenda in a dynamic therapy process.

Also, whereas a dynamic therapist may not assume an authoritarian posture toward the patient, this position may shift when the clinician discusses medication and cites the literature on such things as maintenance dosages and prevention of relapse. Both patient and clinician alike may need to shift mental sets in the course of a session.

One strategy for managing these difficulties is to set aside a few minutes at the beginning or the end of each session to review how the medication is affecting the patient's symptoms and to write a prescription, if necessary. During the remainder of the session, the medication may be discussed more from the standpoint of its meaning to the patient. Indeed, one of the advantages of this arrangement is that the prescribing and the psychotherapy do not get split off from one another in a way that fragments the treatment. All transferences and resistances are dealt with by one clinician. Compliance problems may be readily linked to specific transference paradigms because of the clinician's intimate knowledge of the patient's internal object relations.

Two-Person Model Surveys have shown that approximately 65 percent of psychiatrists have prescribed medication to patients who are in psychotherapy with other clinicians. In some cases two clinicians have to be involved because one is a nonmedical therapist. In other cases, however, psychiatrists who are conducting psychotherapy do not feel comfortable with the kind of bimodal thinking necessary to prescribe the medication as well and they may prefer to keep the transference uncontaminated by feelings about the medication; they may also not feel qualified to prescribe because they have not kept up with psychopharmacology data.

Although the two-person model may be effective for some patients, it also runs the risk of serving as a nidus for splitting, particularly but not exclusively with patients with borderline personality disorder.

A 27-year-old woman with a diagnosis of borderline personality disorder had been seeing a psychotherapist once a week for 1 year. She and her therapist had felt that they were at an impasse, and the therapist suggested that she consult a local psychopharmacologist. She saw the psychopharmacologist for 30 minutes, and he diagnosed her as having a major depression. He explained all about the illness to her, and he prescribed fluoxetine.

The patient felt an almost immediate positive response to the medication, and at her next psychotherapy appointment, she blasted her psychotherapist with a long tirade about her inadequacies: “You sit there for 1 year, just listening and trying to understand me. All this time I had a depression that needed drug treatment. Dr. A (her psychopharmacologist) was so helpful. He took my complaints seriously, and for God's sake, he took some action! All you do is talk, talk, talk. Why didn't it occur to you sooner that something needed to be done?”

In this brief vignette the psychopharmacologist becomes the idealized object who was responsive to the patient's needs, in contrast to the psychotherapist, who is seen as the bad object, almost sadistic in her perceived refusal to “do something.” The individual prescribing the medication may contribute to the split by implying either directly or indirectly that the psychotherapist has been derelict in her duty by not sending the patient for medication sooner.

The cleavage may occur along opposite lines as well. Some patients with borderline personality disorder feel that the prescribing psychiatrist is eager to get rid of them because the appointment is scheduled for only 15 minutes. They may object to being “thrown out” of the doctor's office without the opportunity to talk more about what they are experiencing. In this case, the prescriber becomes the bad object, while the therapist is idealized for taking the time to listen and express concern about the patient's internal experience.

Splitting of this nature cannot be entirely prevented, but there are steps that can be taken to minimize the potential destructiveness of this form of behavior. From the outset the patient should understand that the psychotherapist and the prescribing psychiatrist must be given permission to communicate about diagnosis and treatment. They should consider themselves as part of a treatment team rather than isolated individuals. Discussing the patient's perceptions about the other clinician openly and honestly reduces a great deal of the tension created by such splits. In addition, the two clinicians should agree on which one of them is responsible for making decisions about hospitalization, vacation coverage, changes in medication, and the investigation of any potential medical problems.

Although communication between the two is an ideal arrangement with which few would disagree, studies suggest that frequently such communication is rather minimal. In some two-person treatments, the contacts between the two clinicians may be limited to an as-needed basis, which in practice means that almost no communication occurs unless there is a major crisis. In other situations prescribing psychiatrists also supervise the psychotherapy of patients for whom they prescribe medication. Physicians who prescribe for patients whose therapy they are supervising should recognize that they are potentially liable for the acts of those hierarchically below them, a situation referred to as *vicarious liability*. They can also be directly liable for failure to adequately supervise the psychotherapist.

Although it is rarely done in practice, some forensic experts have suggested that a written three-way agreement among psychotherapist, pharmacotherapist, and patient should be drawn up and signed at the beginning of such an arrangement. The details of the agreement would include the purpose of each treatment, the relative roles of each of the clinicians, policies for communication between the clinicians, any supervisory responsibilities entailed in the arrangement, and who should be called in an emergency.

The frequency and duration of the communication between clinicians cannot be arbitrarily established, but it certainly must take place often enough so that each clinician has a clear understanding of the treatment approach of the other. Often a critical factor in the evolution of splitting is that the patient distorts to one clinician what the other is saying or doing. If the clinician hearing this report simply takes it at face value without calling and checking out the veracity of the account with the other clinician, the situation may rapidly deteriorate. The clinician hearing the report may subsequently collude with the patient's feeling of being victimized by the other clinician. When communication finally occurs, the colluding clinician may accuse the colleague, which results in greater defensiveness. A tactful inquiry about whether the patient's account is accurate is generally much more productive.

Other Clinical Issues When pharmacotherapy is added to dynamic psychotherapy or psychoanalysis, several responses are possible. Patients often respond by assuming that the analyst or therapist believes all change should come about through psychological interventions, so that a particular patient may view the addition of medication as something of a failure. In one report, a patient was convinced that his analyst regarded the positive effects of taking medication as primarily psychological. This patient, on the other hand, thought 90 percent of the effect was pharmacological. Turning treatment over to medication in the context of a well-established psychotherapeutic process will mean different things to individual patients, and the clinician conducting the analysis or therapy should be alert to these interpretations.

Patients who are in both treatments are often in a quandary about the relative roles of medication and psychotherapy. Are their problems caused by an alteration in brain chemistry for which they have no responsibility? Or are their feelings of incapacitation and disability secondary to psychological issues that they should be able to master? These questions may blend into concerns about identity and self. Patients may wonder who they actually are after their chronic depression improves substantially with medication. They may need psychotherapy to adjust to a new identity based on being euthymic.

COST EFFECTIVENESS

Many managed-care companies insist that psychiatrists do not need to conduct psychotherapy because nonmedical therapists can do just as well at a cheaper price. Hence they allow the psychiatrist to see the patient for a 15-minute medication check while referring the psychotherapy to someone whose time is much less expensive, often a counselor with a Bachelor's degree who is really not well trained in psychotherapy. While this may appear on the surface to be more cost effective, the treatment may become fragmented to the point where the patient's condition deteriorates and hospitalization is necessary. In that event, the hospital costs far outweigh the added expense of one clinician serving both functions. Moreover, the division of labor between two clinicians requires extremely close collaboration. The time the two clinicians spend communicating with each other is often a hidden cost, one not generally reimbursed, that must ultimately be factored into a comprehensive consideration of cost effectiveness. Meanwhile, data need to be collected on the two alternative arrangements to systematically study whether one is ultimately more cost effective than the other.

In the absence of definitive data, clinical experience suggests that in a number of situations, there are clear advantages to a psychiatrist performing both roles. A few examples include the following: (1) for patients with schizophrenia and other psychotic disorders who are not compliant with prescribed medication; (2) patients with bipolar I disorder who deny illness and do not cooperate with the treatment plan; (3) patients with serious or unstable medical conditions, where the psychiatrist's medical knowledge is important in the overall management; (4) patients with severe personality disorders, such as borderline personality disorder, where the treatment can be potential for being disrupted by splitting maneuvers; (5) impulsive and severely suicidal patients who are likely to require hospitalization in the course of outpatient treatment; (6) patients with eating disorders who present complicated management problems; and (7) patients who present a clinical picture in which the need for medication is unclear, and an ongoing assessment of that need is an integral part of the treatment (Table 30.12-1). The psychiatrist is in a position to evaluate the need for medication by following the patient over time. Just as a surgeon is trained to know when to operate and when to refrain from surgery, the psychiatrist is trained to assess when it is best not to prescribe medication. In all these clinical situations one central clinician who works with the patient and possibly the family on both medication and psychological issues may ensure an overall integration of the treatment plan that may lead to better compliance.

- Patients with schizophrenia and other psychotic disorders who are not compliant with prescribed medication.
- Patients with bipolar I disorder who deny illness and do not cooperate with the treatment plan.
- Patients with serious or unstable medical conditions.
- Patients with severe personality disorders.
- Impulsive and severely suicidal patients who are likely to require hospitalization.
- Patients with eating disorders who present complicated management problems.
- Patients who present a clinical picture in which the need for medication is unclear, thus requiring ongoing assessment.

Table 30.12-1 Clinical Situations Where It Is Especially Advantageous for One Psychiatrist to Provide Both Medication and Psychotherapy.

In many discussions of the value of combined psychotherapy and pharmacotherapy, dissenters argue that the combination of the two treatments may be unduly expensive and without benefits commensurate with the additional cost. This perspective has led some to suggest innovative means of gaining benefit from both modalities. For example, for agoraphobic patients, some have suggested that the prescription of imipramine plus the provision of instructions for systematic self-directed exposure may be a cost-efficient way to derive benefits from both treatments. Similar efforts have been made to assist obsessive-compulsive disorder patients with self-administered exposure in vivo practice.

Generalizations about the expense of combined treatments must be made with caution, however. In a well-designed study of the delivery of treatment for depression in primary-care settings, the Rand Corporation found that in the general practitioner's office, where the average appointment lasted 8 minutes, the diagnosis of depression was frequently missed. Also, when medication was prescribed, either benzodiazepines or suboptimal dosage of antidepressants were frequently prescribed. When mental health professionals became involved with the patients, they frequently delivered a combination of psychotherapy and appropriate dosages of antidepressant medication. The specialist treatment was somewhat more expensive to deliver, but the small increase in money quadrupled the effectiveness of the overall treatment in terms of vastly improved functional outcomes for the depressed patients. The investigators pointed out that too often the emphasis is placed only on cost rather than being placed equally on effectiveness. The concept of cost effectiveness should not be synonymous with cheap rather, it should be viewed as high value.

The combination of antipsychotic medication and family therapy in the treatment of schizophrenia prevents relapse and avoids the need for further inpatient care to the extent that the additional cost of the combined treatments is more than offset by the savings in fewer inpatient days. Similarly, in patients with bipolar and schizoaffective disorder, an average of six family therapy sessions significantly reduced the need for hospitalization and thus more than paid for itself. When cost effectiveness is considered from the standpoint of all costs, including the direct costs of treatment and the indirect costs of work disability and absenteeism, the combined use of pharmacotherapy and psychotherapy is often the most cost-efficient intervention available.

SUGGESTED CROSS-REFERENCES

Schizophrenia is covered in Chapter 12, mood disorders in Chapter 14, and anxiety disorders in Chapter 15. The other sections of Chapter 30 cover various schools and approaches of psychotherapy. Chapter 31 extensively covers psychopharmacology.

CHAPTER 31. BIOLOGICAL THERAPIES

31.1 GENERAL PRINCIPLES OF PSYCHOPHARMACOLOGY

JACK A. GREBB, M.D.

The use of drugs to treat psychiatric disorders is often the foundation for a successful treatment approach that can also include other types of interventions such as psychotherapy or behavioral therapies. As knowledge about the biology of normal and abnormal brain function continues to grow, the practice of clinical psychopharmacology continues to evolve in scope and effectiveness. Those involved in the prescribing and clinical follow-up of psychiatric drug treatments must remain current with the research literature, including the emergence of new agents, the demonstration of new indications for existing agents, and the identification and treatment of drug-related adverse effects. The emergence of new drugs and new indications is one of the most exciting areas of psychiatry.

The practice of pharmacotherapy in psychiatry should not be oversimplified—for example, it should not be reduced to a one-diagnosis-one-drug approach. Many variables affect the practice of psychopharmacology, including drug selection and administration; the psychodynamic meaning to the patient; and family and environmental influences. Some patients may view drug treatment as a panacea and others may view it as an assault. The patient, the patient's relatives, and the nursing staff must be instructed on the reasons for the drug treatment as well as the expected benefits and potential risks. In addition, the clinician may also find it useful to explain the theoretical basis for pharmacotherapy to the patient and other involved parties.

Drugs must be used in effective dosages for sufficient periods, as determined by previous clinical investigations and clinical experience. Subtherapeutic doses and incomplete therapeutic trials should not be given to a patient simply because the psychiatrist is excessively concerned that the patient will develop adverse effects. The use of dosages that are too low or durations that are too short merely exposes the patient to some risk, without providing the patient the maximum chance of therapeutic benefit. Treatment response and the emergence of adverse effects must be monitored closely; drug dosage should be adjusted accordingly, and appropriate treatments for emergent adverse effects must be instituted as quickly as possible.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics is the study of how the body handles a drug; *pharmacodynamics* is the study of the effects of the drug on the body. Pharmacokinetic drug interactions are the effects of drugs on the plasma concentrations of each other, and pharmacodynamic drug interactions are the effects of drugs on the biological activities of each other.

Pharmacodynamics The major pharmacodynamic considerations include receptor mechanisms; the dose-response curve; the therapeutic index; and the development of tolerance, dependence, and withdrawal phenomena. The receptor for a drug can be defined generally as the cellular component to which the drug binds and through which the drug initiates its pharmacodynamic effects on the body. A drug can be an agonist for a receptor, thus stimulating the specific biological activity of the receptor; or an antagonist, thus inhibiting the biological activity. Some drugs are classified as partial agonists because they are not capable of fully activating a specific receptor. The receptor site for a psychopharmacological drug is often the receptor for an endogenous neurotransmitter. For example, most antipsychotic medications are receptor antagonists at the dopamine type 2 (D_2) receptor. However, this may not be true for other psychotherapeutic drugs (e.g., lithium [Eskalith], which may act by inhibiting the enzyme inositol-1-phosphatase).

The dose-response curve plots the drug concentration against the effects of the drug (Fig. 31.1-1). The potency of a drug refers to the relative dose required to achieve certain effects. Haloperidol (Haldol), for example, is more potent than chlorpromazine (Thorazine) because approximately 5 mg of haloperidol is required to achieve the same therapeutic effect as 100 mg of chlorpromazine. However, both these drugs are equal in their clinical efficacy—that is, the maximum clinical response achievable by administration of a drug.

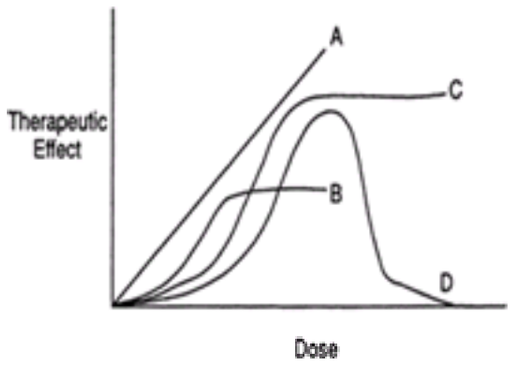

FIGURE 31.1-1 Dose-response curves plotting the therapeutic effect as a function of increasing the dose, often calculated as the log of the dose. Drug A has a linear dose response, drugs B and C have sigmoidal curves, and drug D has a curvilinear dose-response curve. Although doses of drug B are more potent than are equal doses of drug C, drug C has a higher maximum efficacy than does drug B. Drug D has a therapeutic window, such that both low and high doses are less effective than are midrange doses.

The adverse effects of most drugs are often a direct result of their primary pharmacodynamic effects. *Therapeutic index* is a relative measure of the toxicity or safety of a drug and is defined as the ratio of the median toxic dose to the median effective dose. The *median toxic dose* is the dose at which 50 percent of patients experience a specific toxic effect, and the *median effective dose* is the dose at which 50 percent of patients have a specified therapeutic effect. The therapeutic index for haloperidol and cardiovascular effects is quite high, as evidenced by the wide range of dosages in which haloperidol is prescribed. Conversely, the therapeutic index for lithium is quite low, thus requiring careful monitoring of serum lithium levels in patients for whom the drug is prescribed. Both interindividual and intraindividual variations can affect the response to a specific drug. An individual patient may be hyporeactive, normally reactive, or hyperreactive to a drug. For example, some patients require 150 mg a day of imipramine (Tofranil) whereas others may require 300 mg a day. Idiosyncratic drug responses occur when a patient experiences a particularly unusual or rare effect from a drug. For example, some patients become quite agitated when given a benzodiazepine, such as diazepam (Valium).

A person may become less responsive to a particular drug as it is administered over time, a process that is referred to as the development of tolerance. The development of tolerance may sometimes be associated with the appearance of physical dependence on the drug, which can be seen with drugs such as opioids or benzodiazepines. A patient who has developed physical dependence to a drug will experience withdrawal symptoms if the drug is discontinued. Withdrawal symptoms can be mentally and physically quite uncomfortable, and in some cases, even fatal.

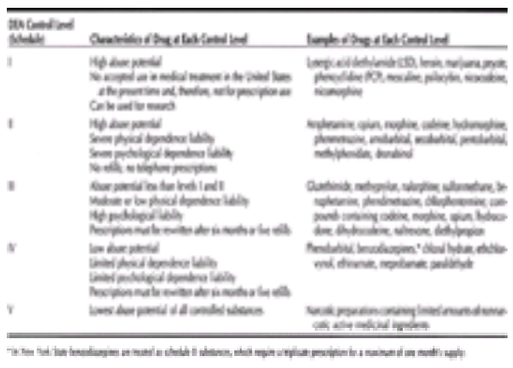
CLINICAL GUIDELINES

The practice of clinical psychopharmacology requires skill as both a diagnostician and as a psychotherapist, knowledge of the available drugs, and the ability to plan a pharmacotherapeutic regimen. The selection of a drug and the initiation of treatment should be based on the patient's history, the patient's current clinical state, and the treatment plan. The treating clinician should know the purpose or the goal of a drug trial, the length of time that the drug needs to be administered to assess its efficacy, the approach to be taken to reduce any adverse effects that may occur, alternative drug strategies to be used should the current one fail, and whether long-term maintenance of the patient on the drug is indicated. In almost all cases the treating clinician should explain the treatment plan to the patient and often to the family and other caretakers. The patient's reaction to and ideas about a proposed drug trial should be considered; however, if the clinician believes that accommodating the patient's wishes would hinder treatment, this should also be clearly explained to the patient.

Choice of Drug The first two steps in selecting a specific drug for the treatment of a patient are diagnosis and the identification of target symptoms. Although this process is often best accomplished when the patient is not receiving any drug treatments, it is often not possible to evaluate patients in a drug-free state because of severity of symptoms or insurance coverage that strictly limits the amount of time a patient can be hospitalized. If a patient presents to the clinician and is receiving a suboptimal dosage of an otherwise appropriate drug, the clinician may decide to continue the current drug at a more appropriate dosage. In many cases, however, deciding how effective the drugs that the patient is currently taking are is a very difficult clinical decision. In such cases it is often advisable to taper off and stop the current drugs and then initiate new therapy that can be evaluated more accurately and completely.

From among the drugs appropriate to a particular diagnosis, the specific drug should be selected according to the patient's history of drug response (compliance, therapeutic response, adverse effects), the patient's family history of drug response, the profile of adverse effects for that drug with regard to the particular patient, and the prescribing clinician's usual practice. If a drug has previously been effective in treating a patient or a family member, the same drug should be used again unless there is some specific reason not to do so. A history of severe adverse effects from a specific drug is a strong indicator that the patient would not be compliant with that particular drug. It is unfortunate that patients and their families are often quite ignorant about which drugs have been used before, in what dosages, and for how long. This ignorance may reflect the tendency of clinicians not to explain drug trials to their patients, and the low frequency of the practice of giving patients and their caregivers a written record of drug treatments for their personal medical records. One caveat to obtaining a past history of drug response is that because of their mental disorders patients may report the effects of a previous drug trial inaccurately. If possible, patients' medical records should be obtained to confirm their reports. Most psychotherapeutic drugs of a single class have been demonstrated to be equally efficacious; however, the drugs do differ in their adverse effects on individual patients. A drug should be selected that minimally exacerbates any pre-existing medical problems that a particular patient may have.

Nonapproved Dosages and Uses Under the federal Food, Drug, and Cosmetic (FDC) Act, the Food and Drug Administration (FDA) has the authority to control the initial availability of a drug by approving only those drugs that demonstrate both safety and effectiveness, and then to ensure that the drug's proposed labeling is truthful and contains all information pertinent to the safe and effective use of that drug. An additional level of government regulation is directed by the Drug Enforcement Agency (DEA), which has classified drugs according to their abuse potential (Table 31.1-1), and clinicians are advised to exercise increased caution when prescribing controlled substances (control level II-IV).



DEA Control Level (Schedule)	Characteristics of Drug at Each Control Level	Examples of Drugs at Each Control Level
I	High abuse potential No accepted use in medical treatment in the United States at the present time and, therefore, not for prescription use Can be used for research	Lysergic acid diethylamide (LSD), heroin, marijuana, peyote, phencyclidine (PCP), mescaline, psilocybin, nicocodeine, nicomorphine
II	High abuse potential Severe physical dependence liability Severe psychological dependence liability No refills, no telephone prescriptions	Amphetamine, opium, morphine, codeine, hydromorphine, phenmetrazine, amobarbital, secobarbital, pentobarbital, methylphenidate, dronabinol
III	Abuse potential less than levels I and II Moderate or low physical dependence liability High psychological liability Prescriptions must be rewritten after six months or five refills	Glutethimide, methyprylon, nalorphine, sulfomethane, benzphetamine, phendimetrazine, chlorphentermine, compounds containing codeine, morphine, opium, hydrocodone, dihydrocodeine, naltrexone, diethylpropion
IV	Low abuse potential Limited physical dependence liability Limited psychological dependence liability Prescriptions must be rewritten after six months or five refills	Phenobarbital, benzodiazepines,* chloral hydrate, ethchlorvynol, ethinamate, meprobamate, paraldehyde
V	Lowest abuse potential of all controlled substances	Narcotic preparations containing limited amounts of noncontrolled active medicinal ingredients

*In New York State benzodiazepines are treated as schedule II substances, which require a triplicate prescription for a maximum of one month's supply.

Table 31.1-1 Characteristics of Drugs at Each DEA Level

Once a drug is approved for commercial use, the physician may, as part of the practice of medicine, lawfully prescribe a different dosage for a patient or otherwise vary the conditions of use from what is approved in the package labeling without notifying the FDA or obtaining its approval. Specifically, the FDC Act does not limit the manner in which a physician may use an approved drug. Although physicians may treat patients with an approved drug for unapproved purposes—that is, for indications not included on the drug's official labeling—without violating the FDC Act, the patient retains the right to redress for possible medical malpractice. This is a significant concern because the failure to follow the FDA-approved label may create an inference that the physician was varying from the prevailing standard of care. Although the failure to follow the information on the drug label does not impose liability per se and should not preclude a physician from using good clinical judgment in the interest of the patient, the physician should be aware that the label presents important guidelines regarding the safe and effective use of the drug.

Clinicians may prescribe medication for any reason that they believe to be medically indicated for the welfare of the patient. However, when using a drug for an unapproved indication or in a dose outside the usual range, it is good clinical practice to document the reasons for such treatment decisions in the patient's chart, as well as the explanation to the patient regarding this treatment recommendation. If clinicians are in doubt about a treatment plan, they should consult a colleague or suggest that the patient obtain a second opinion.

Therapeutic Trials The therapeutic trial of a particular drug should last for a previously determined length of time, unless abbreviated because of the appearance of adverse effects. Because the symptoms of psychiatric disorders are more difficult to assess than other physiological symptoms, such as hypertension, it is important for specific target symptoms to be identified at the initiation of a drug trial. The clinicians and the patient can then assess the target symptom over the course of the trial to help determine whether the drug has been effective; the use of patient or clinician rating scales might be useful for this purpose. If a drug has not been effective in reducing target symptoms in the specified length of time, and if other reasons for the lack of response can be eliminated, the drug should be tapered and stopped.

The brain is not a group of on-off neurochemical switches; rather, it is an interactive network of neurons in a complex homeostasis. Thus, the abrupt discontinuation of virtually any psychiatric drug is likely to disrupt the functioning of the brain further. Another common clinical mistake is the routine addition of medications without the discontinuation of a prior drug. Although this practice is indicated in specific circumstances, such as lithium augmentation of an unsuccessful trial of antidepressant agents, it often results in increased noncompliance and adverse effects and in the clinician's not being able to determine whether it was the second drug alone or the combination of drugs that resulted in a therapeutic success or a particular adverse effect.

Therapeutic Failures The failure of a specific drug trial should prompt the clinician to ask a number of questions regarding the patient, the illness, and the treatment. First, was the original diagnosis correct? In answering this question, the clinician should include the possibility of a mental disorder due to an undiagnosed medical condition, and also the possibility of illicit drug abuse. Second, are the observed symptoms related to the original disorder or are they actually adverse effects of the drug treatment? Some antipsychotic drugs, for example, can produce akinesia, which resembles psychotic withdrawal, or akathisia and neuroleptic malignant syndrome, which resemble increased psychotic agitation. Third, was the drug administered at an appropriate dosage for a sufficient length of time? Because patients can vary greatly in their absorption and metabolism of drugs, the clinician may need to measure plasma levels of a drug to ensure a sufficient dose of the drug. Fourth, did a pharmacokinetic or pharmacodynamic interaction with another drug the patient was taking reduce the efficacy of the newly prescribed drug? Fifth, did the patient take the drug as directed? Drug noncompliance is a common clinical problem that arises as a result of complicated drug regimens (more than one drug in more than one daily dosage), adverse effects (especially if unnoticed by the clinician), and poor patient education about the drug treatment plan (Table 31.1-2).

Excessively complex regimen (multiple agents, multiple small doses)
Early onset and persistence of side effects
Slow onset of beneficial effects
Low apparent relapse risk experienced if treatment is interrupted
Psychosis, confusion, dementia, pseudodementia, low intelligence, impaired hearing or vision, illiteracy
Simple lack of information, need for patient education
Financial hardship, conflicting obligations of time or money
Resentment, lack of confidence or trust
Specific psychopathology: paranoid delusions, hopelessness, masochism, anxiety and fear, ambivalence, control, splitting, passive aggression, passive dependence, denial, sociopathy, substance abuse
Involvement of multiple clinicians
Poor clinician-patient relationship
Inevitable human error

Adapted from Baldessarini RJ, Cole JO: Chemotherapy. In *The New Harvard Guide to Psychiatry*, AM Nichols, editor. Belknap Press, Cambridge, MA, 1988.

Table 31.1-2 Conditions That May Reduce Adherence to Recommended Treatment

COMBINED PSYCHOTHERAPY AND PHARMACOTHERAPY

Using drugs that affect the brain in combination with psychotherapy is standard therapy in contemporary psychiatry. When pharmacotherapy and psychotherapy are used together, the approach should be coordinated, integrated, and synergistic (Table 31.1-3). In many cases it has been demonstrated that the results of combined therapy are superior to those of either type of therapy alone. The term *pharmacotherapy-oriented psychotherapy* is used by some practitioners for this combined approach. When the psychotherapy and the pharmacotherapy are directed by two separate clinicians, the clinicians must communicate clearly with each other.

Stage	Engagement	Pattern Search	Change	Termination
Goals	Trust Credibility Self-observer alliance	To define problem patterns that, if changed, would lead to a desirable outcome	1. Relinquish old pattern(s) 2. Initiate new pattern(s) 3. Practice new pattern(s)	To separate efficiently
Techniques	Convey empathic understanding Effective suggestions Effective medications	Questions/queries Homework—idiosyncratic meanings ascribed to medication	Interpretation Reframing Behavioral suggestion Medication-induced change	Mutually agreed Patient initiates Therapist initiates Medication influenced
Content	Medication responsive Diagnosis	Does response to medication reflect a problem pattern?	Medication effects or insight around medication use accelerates change	Medications may prolong termination
Resistance	Are excessive side effects resistant to treatment?	Does pattern of nonadherence to medication regimen reflect a problem pattern?	Do new side effects suggest resistance to change?	Symptom recurrence not necessarily indication for medication change
Transference	Physician seen as malevolent or all-powerful	A key interpersonal pattern reflected in meaning of medication?	Unresolved distortions may be signaled by a new medication issue inhibiting change	Desire for new or more medication reflects desire to hold therapist
Countertransference	Physician failure to prescribe appropriately	Medication prescription reflects disbelief response to patient	Sudden change in regimen reflects an attempt to undermine change	New medication reflects desire to keep contact

Table 31.1-3 Stages of Individual Psychotherapy: A Medication Emphasis

Countertransference As in all types of psychotherapy, clinicians must be aware of their conscious and unconscious feelings toward their patients as well as of their own psychological attitudes towards psychotherapeutic drugs. Medications cannot replace a strong therapeutic alliance between a clinician and a patient. Therapists who are pessimistic about the value of psychotherapy or who misjudge the patient's motivation may prescribe medications out of their own nihilistic beliefs; others may withhold medication if they overvalue psychotherapy or undervalue pharmacological treatments. Each patient must be evaluated individually without clinician bias, and each treatment should be evaluated on the basis of a risk-benefit ratio.

Combined Therapy in Specific Disorders

Depressive Disorders Some patients and clinicians fear that medication will mask the depression and that psychotherapy will thus be impeded. However, that medication can be viewed as a facilitator in overcoming the anergia that may inhibit communication between the clinician and patient. The clinician can point out to the patient that the medication may have helpful effects on some of the associated symptoms of depression such as poor sleep and appetite, and even on such symptoms as irritability or social withdrawal.

Suicidal Behavior The possibility of suicide must be considered in treating patients with schizophrenia, bipolar I disorder, depressive disorders, severe personality disorders, and anxiety disorders (especially those who have panic attacks). If the clinician decides that the patient is at imminent risk for suicidal behavior, hospitalization is always indicated. If the patient can be managed outside a hospital, the patient's medication supply should be given to a responsible family member who can monitor the dosage and frequency of the prescribed medication. As a further precaution, the clinician may prescribe the patient a drug that is known to have little or no lethal potential when taken in overdose; however, even these drugs can become lethal when a patient takes multiple different medications in an overdose.

Bipolar I Disorder Most psychotherapists insist that patients with bipolar I disorder be medicated before they start any insight-oriented therapy. Without such medication, most patients with bipolar I disorder are unable to establish the necessary therapeutic alliance with their therapists. When such patients are depressed their abulia seriously disrupts their flow of thoughts, and the sessions are generally nonproductive. When they are manic, their flow of associations can be so rapid and their speech so pressured that the therapist may be flooded with material and unable to make appropriate interpretations or to assimilate the material into the patient's disrupted cognitive framework.

Anxiety Disorders Many drugs are effective in managing the signs and symptoms associated with the wide range of anxiety disorders. As symptoms are controlled by medication, patients are reassured and develop confidence that they will not be incapacitated by the disorder. This effect is particularly relevant to panic disorder, which is often associated with significant anticipatory anxiety about the attack. Depression may also complicate the symptom picture in patients with anxiety disorders and has to be addressed both pharmacologically and psychotherapeutically.

Schizophrenia and Other Psychotic Disorders Drug therapy is almost always used in the treatment of these disorders. In attempting individual psychotherapy with these patients, the therapist must work especially hard to establish an effective treatment relationship and therapeutic alliance with the patient. The schizophrenia patient generally defends against closeness and trust, and often becomes suspicious, anxious, hostile, or regressed in therapy.

Substance Abuse Patients who abuse alcohol or other substances present special challenges to therapists who wish to combine psychotherapy with pharmacotherapy. Some clinicians rarely use medications in this patient group, although treatment of underlying anxiety or depression might help with the abuse in particular patients. The clinician conducting psychotherapy with a patient who abuses substances should have no reservations about requesting random urine toxicological tests; as in all forms of insight-oriented psychotherapy, the psychological significance of such tests should be examined.

SPECIAL TREATMENT CONSIDERATIONS

Children Special care must be taken when administering psychotherapeutic drugs to children. Although the small volume of distribution suggests the use of lower doses than in adults, a child's higher rate of metabolism suggests that a higher ratio of mg of drug to kg of body weight should be used. In practice it is best to begin with a small dose and to increase it until clinical effects are observed. However, the clinician should not hesitate to use adult dosages in children if these dosages are effective and the adverse effects are acceptable.

Geriatric Patients The two major concerns when treating geriatric patients with psychotherapeutic drugs are that elderly persons may be more susceptible to adverse effects (particularly cardiac effects) and may metabolize and excrete drugs more slowly (Table 31.1-4), thus requiring lower dosages of medication. Another concern is that because geriatric patients often take more than one medication the clinician needs to consider the possible drug interactions. In practice clinicians should begin treating geriatric patients with a small dose, usually about one-half of the usual starting dose. The dosage should be raised in small increments more slowly than for middle-aged adults until either a clinical benefit is achieved or unacceptable adverse effects appear. Although many geriatric patients require a small dosage of

medication, many others require the usual adult dosage.

Phase	Change	Effect
Absorption	Gastric pH increases Decreased surface villi Decreased gastric motility and delayed gastric emptying Intestinal perfusion decreases	Little overall change Absorption is slower but just as complete
Distribution	Total body water and lean body mass decrease Increased total body fat, more marked in women Albumin decreases, gamma globulin increases, alpha$_1$ glycoprotein unchanged	Volume of distribution (Vd) increases for lipid-soluble drugs, decreases for water-soluble drugs The free or unbound percentage of albumin-bound drugs increases
Metabolism	Renal: renal blood flow and glomerular filtration rates decrease Hepatic: decreased enzyme activity and perfusion	Decreased metabolism leads to prolonged half-lives, if Vd remains the same
Total body weight	Decreases	Think on a mg-per-kg basis
Receptor sensitivity	May increase	Greater effect

Table 31.1-4 Pharmacokinetics and Aging

Pregnant and Nursing Women The basic rule is to avoid administering any drug to a woman who is pregnant (particularly during the first trimester) or who is breastfeeding a child. This rule, however, occasionally needs to be broken when the mother's psychiatric disorder is severe. If psychotherapeutic medications need to be administered during pregnancy, the possibility of therapeutic abortion should be discussed. The two most teratogenic drugs in the psychopharmacopeia are lithium and the standard anticonvulsant agents. Lithium administration during pregnancy is associated with a high incidence of birth abnormalities, including Ebstein's malformation, a serious abnormality in cardiac development. Other psychoactive drugs (antidepressants, antipsychotics, and anxiolytics) are less clearly associated with birth defects but should also be avoided during pregnancy if at all possible. The most common clinical situation occurs when a pregnant woman becomes psychotic. If a decision is made not to terminate the pregnancy, treatment with antipsychotic drugs or electroconvulsive therapy (ECT) is preferable to lithium.

The administration of psychotherapeutic drugs at or near delivery may cause the baby to be overly sedated at delivery, thus requiring a respirator, or to be physically dependent on the drug, requiring detoxification and the treatment of a withdrawal syndrome. Virtually all psychiatric drugs are secreted in the milk of a nursing mother; therefore, mothers on those agents should be advised not to breastfeed their infants.

Medically Ill Patients Considerations when administering psychiatric drugs to medically ill patients include a potentially increased sensitivity to adverse effects, either increased or decreased metabolism and excretion of the drug, and interactions with other medications. As with children and geriatric patients, the most reasonable clinical practice is to begin with a small dosage, increase it slowly, and watch for both clinical benefit and adverse effects. Determining the plasma drug concentrations may be helpful for such patients.

COMMON ADVERSE EFFECTS

Patients generally have less trouble with adverse effects if they have been told to expect them. It is reasonable to explain the appearance of adverse effects as evidence that the drug is working, especially if the receptor mechanism for the adverse effects is the same as for the therapeutic effect. However, clinicians should distinguish between probable or expected adverse effects and those that are rare or unexpected.

Most psychotherapeutic drugs neither affect a single neurotransmitter system nor are their effects localized to the brain. The effects of psychotherapeutic drugs on neurotransmitter systems result in a wide range of adverse effects associated with their use. For example, some of the most common adverse effects of psychotherapeutic drugs are caused by the blockade of muscarinic acetylcholine receptors (Table 31.1-5). Many psychotherapeutic drugs antagonize dopaminergic, histaminergic, or adrenergic receptors, resulting in the adverse effects listed in Table 31.1-6.

Blurred vision
Constipation
Decreased salivation
Decreased sweating
Delayed or retrograde ejaculation
Delirium
Exacerbation of asthma (through decreased bronchial secretions)
Hyperthermia (through decreased sweating)
Memory problems
Narrow-angle glaucoma
Photophobia
Sinus tachycardia
Urinary retention

Table 31.1-5 Potential Adverse Effects Caused by Blockade of Muscarinic Acetylcholine Receptors

Antidopaminergic
Endocrine dysfunction
Hyperprolactinemia
Menstrual dysfunction
Sexual dysfunction
Movement disorders
Akathisia
Dystonia
Parkinsonism
Tardive dyskinesia
Antiadrenergic (primarily α_1)
Dizziness
Postural hypotension
Reflex tachycardia
Antihistaminergic
Hypotension
Sedation
Weight gain
Multiple neurotransmitter systems
Agranulocytosis (and other blood dyscrasias)
Allergic reactions
Anorexia
Cardiac conduction abnormalities
Nausea and vomiting
Seizures

Table 31.1-6 Potential Adverse Effects of Psychotherapeutic Drugs and Associated Neurotransmitter Systems

Treatment of Common Adverse Effects Many adverse effects are seen in patients who take psychotherapeutic drugs. The management of the adverse effects is similar regardless of which psychotherapeutic drug the patient is taking.

Dry Mouth Dry mouth is caused by the blockade of muscarinic acetylcholine receptors. When patients attempt to relieve the dry mouth by sucking on sugar-containing hard candies, they increase their risk of dental caries. They can avoid the problem by chewing sugarless gum or sucking on sugarless hard candies. Some clinicians recommend the use of a 1-percent solution of pilocarpine (Salagen), a cholinergic agonist, as a mouthwash three times daily. Other clinicians suggest 10 to 30 mg of bethanechol (Urecholine, Myotonachol) tablets, another cholinergic agonist, once or twice daily. It is best to start with 10 mg once a day and to increase the dosage slowly. Adverse effects of cholinomimetic drugs, such as bethanechol, include tremor, diarrhea, abdominal cramps, and excessive eye watering.

Blurred Vision The blockade of muscarinic acetylcholine receptors causes mydriasis (pupillary dilation) and cycloplegia (ciliary muscle paresis), resulting in presbyopia (blurred near vision). The symptom can be relieved by cholinomimetic eye drops. A 1-percent solution of pilocarpine can be prescribed as one drop in

each eye four times daily; bethanechol can be used for dry mouth as an alternative.

Urinary Retention The anticholinergic activity of many psychiatric drugs can lead to urinary hesitation, dribbling, and retention, as well as an increased rate of urinary tract infections. Elderly male patients with enlarged prostate glands are at increased risk for such adverse effects; 10 to 30 mg of bethanechol three to four times daily is usually effective in the treatment of the adverse effects on urination.

Constipation The anticholinergic activity of psychotropic drugs can result in the adverse effect of constipation. The first line of treatment involves the prescribing of bulk-forming laxatives, such as psyllium (Metamucil, Fiberall). If that treatment fails, cathartic laxatives, such as milk of magnesia, can be tried. Prolonged use of cathartic laxatives can result in a loss of their effectiveness. Bethanechol, 10 to 30 mg three to four times daily, can also be used.

Orthostatic Hypotension Orthostatic hypotension is caused by the blockade of a_1-adrenergic receptors. It is necessary to warn patients of this possible adverse effect, particularly if patients are elderly. The risk of hip fracture from falls is significantly elevated in patients who are taking psychotropic drugs. With patients at high risk of experiencing orthostatic hypotension, the clinician should choose a drug with low a_1-adrenergic activity. The patient can be instructed to get up slowly and to sit down immediately if dizziness is experienced. The patient can also try support hose to help reduce venous pooling of blood.

Sexual Dysfunction The use of psychiatric drugs can be associated with sexual dysfunction—decreased libido, impaired ejaculation and erection, and inhibition of female orgasm. Although warning patients about these adverse effects may increase their concern, they are not likely to report sexual dysfunction spontaneously to the physician. Also, some sexual dysfunctions may be related to the primary psychiatric disorder. Nevertheless, if sexual dysfunction emerges after pharmacotherapy has begun, it may be worthwhile to attempt to treat the symptoms. Neostigmine (Prostigmin), 7.5 to 15 mg orally 30 minutes before sexual intercourse, may help alleviate impaired ejaculation. Impaired erectile function may be helped with bethanechol given regularly, or possibly yohimbine (Yocon). Cyproheptadine (Periactin), 4 mg every morning, can be used to treat inhibited female orgasm, or 4 to 8 mg orally 1 to 2 hours before anticipated sexual activity for the treatment of inhibited male orgasm secondary to serotonergic drugs. Sildenfinil (Viagra) may also help in both men and women. The clinician and patient should consider switching treatment to another drug less or not at all associated with sexual dysfunction if this adverse effect is not acceptable to the patient.

Weight Gain Weight gain accompanies the use of many psychotropic drugs as a result of retained fluid, increased caloric intake, decreased exercise, or altered metabolism. Weight gain is a very common reason for noncompliance with the drug treatment regimen. Edema can be treated by elevating the affected body parts or by administrating a thiazide diuretic. If the patient is taking lithium or cardiac medications, the clinician must monitor blood concentrations, blood chemistries, and vital signs carefully. The patient should also be instructed to minimize the intake of fats and carbohydrates and to exercise regularly. If patients have not been exercising, the clinician should recommend that they start an exercise program at a modest level of exertion.

OVERDOSES

Clinicians must always be aware of the risk that a psychiatric patient will use the prescribed psychotherapeutic medication in an overdose in an attempt to commit suicide. It is good clinical practice to write nonrefillable prescriptions for small quantities of drugs when suicide is a consideration. In extreme cases an attempt should be made to verify that patients are taking the medication and not hoarding it for a later overdose attempt. Patients may attempt suicide just as they are beginning to get better. Clinicians therefore should continue to be careful about prescribing large quantities of medication until recovery is almost complete. Another consideration for clinicians is the possibility of accidental overdose, particularly by children in the household. Patients should be advised to keep psychotherapeutic medications in a safe place. A guide to the symptoms and treatment of overdoses from psychotherapeutic drugs is given in Table 31.1-7.

Table 31.1-7 Intoxication and Overdose With Selected Psychotherapeutic Drugs

PSYCHOTHERAPEUTIC DRUGS

The numerous pharmacological agents used to treat psychiatric disorders are referred to by three general terms that are used interchangeably: *psychotropic drugs, psychoactive drugs*, and *psychotherapeutic drugs*. Traditionally, these agents were divided into four categories: (1) antipsychotic or neuroleptic drugs used to treat psychosis; (2) antidepressant drugs used to treat depression; (3) antimanic drugs or mood stabilizers used to treat bipolar I disorder; and (4) antianxiety or anxiolytic drugs used to treat anxious states, although those same drugs were also effective as hypnotic agents in higher doses. The division, however, is less valid now than it was in the past for the following reasons: (1) Many drugs of one class are used to treat disorders previously assigned to another class. For example, many so-called antidepressant drugs are used to treat anxiety disorders, and some so-called antianxiety drugs are used to treat psychosis, depression, or bipolar I disorder. (2) Drugs from all four categories are used to treat disorders not previously treated with drugs (e.g., eating disorders, panic disorders, and impulse-control disorders). (3) Such drugs as clonidine (Catapres), propranolol (Inderal), and verapamil (Isoptin) can effectively treat a variety of psychiatric disorders and do not fit easily into the aforementioned classification of drugs.

Guide to Use An alphabetical list of generic drug names is presented in Table 31.1-8, with cross-references to the sections in which they or their class are discussed. A list of therapeutic indications and the drugs commonly used for those indications is presented in Table 31.1-9, also with cross-references to the sections in which they are discussed.

Table 31.1-8 Cross-References by Generic Name of Drug

Generic Name	Brand Name	Section Title	Section Number
Acebutolol	Sectral	b-Adrenergic Receptor Antagonists	31.5
Acetophenazine	Tindal	Dopamine Receptor Antagonists	31.17
Alprazolam	Xanax	Benzodiazepine Agonists and Antagonists	31.10
Amantadine	Symmetrel	Anticholinergics and Amantadine	31.6
Amobarbital	Amytal	Barbiturates and Similarly Acting Substances	31.9
Amoxapine	Asendin	Tricyclic and Tetracyclic Drugs	31.30
Aprobarbital	Alurate	Barbiturates and Similarly Acting Substances	31.9
Atenolol	Tenormin	b-adrenergic Receptor Antagonists	31.5
Benztropine	Cogentin	Anticholinergics and Amantadine	31.6
Biperden	Akineton	Anticholinergics and Amantadine	31.6

Brofaromine	Consonar	Monoamine Oxidase Inhibitors	31.20
Bromocriptine	Parlodel	Other Pharmacological and Biological Therapies	31.33
Buprenorphine	Buprenex	Opioid Agonists	31.23
Bupropion	Wellbutrin	Bupropion	31.11
Buspirone	BuSpar	Buspirone	31.12
Butabarbital	Butisol	Barbiturates and Similarly Acting Substances	31.9
Butaperazine	Repoise	Dopamine Receptor Antagonists	31.17
Carbamazepine	Tegretol	Anticonvulsants	31.7
Carisprodol	Soma	Barbiturates and Similarly Acting Substances	31.9
Carphenazine	Proketazine	Dopamine Receptor Antagonists	31.17
Chloral hydrate	Noctec	Chloral Hydrate	31.14
Chlorpromazine	Thorazine	Dopamine Receptor Antagonists	31.17
Chlorprothixene	Taractan	Dopamine Receptor Antagonists	31.17
Citalopram	Celexa	Selective Serotonin Reuptake Inhibitors	31.25
Clomipramine	Anafranil	Tricyclics and Tetracyclics	31.30
Clonazepam	Kionopin	Benzodiazepine Receptor Agonists and Antagonists	31.10
Clonidine	Catapres	Clonidine	31.16
Clorgyline	—	Monoamine Oxidase Inhibitors	31.20
Clozapine	Clozaril	Serotonin-Dopamine Antagonists	31.26
Cycrimine	Pagitane	Anticholinergics and Amantadine	31.6
Cyproheptadine	Periactin	Antihistamines	31.8
Dantrolene	Dantrium	Other Pharmacological and Biological Therapies	31.33
Desipramine	Norpramin, Pertofane	Tricyclics and Tetracyclics	31.30
Dexfenfluramine	—	Other Pharmacological and Biological Therapies	31.33
Dextroamphetamine	Dexedrine	Sympathomimetics	31.27
Diazepam	Valium	Benzodiazepine Receptor Agonists and Antagonists	31.10
Diltiazem	Cardizem	Calcium Channel Inhibitors	31.13
Disulfiram	Antabuse	Other Pharmacological and Biological Therapies	31.33
Diphenhydramine	Benadryl	Antihistamines	31.8
Divalproex	Depakote	Anticonvulsants	31.7
Donepezil	Aricept	Cholinesterase Inhibitors	31.15
Doxepin	Adapin, Sinequan	Tricyclics and Tetracyclics	31.30
Droperidol	Inapsine	Dopamine Receptor Antagonists	31.17
Estazolam	ProSom	Benzodiazepine Receptor Agonists and Antagonists	31.10
Ethinamate	Valmid	Barbiturates and Similarly Acting Substances	31.9
Ethopropazine	Parsidol	Anticholinergics and Amantadine	31.6
Ethchlorvynol	Placidyl	Barbiturates and Similarly Acting Substances	31.9
Fenfluramine	Pondimin	Other Pharmacological and Biological Therapies	31.33
Flumazenil	Mazicon	Benzodiazepine Receptor Agonists and Antagonists	31.9
Fluoxetine	Prozac	Selective Serotonin Reuptake Inhibitors	31.25
Fluphenazine	Prolixin, Permitil	Dopamine Receptor Antagonists	31.17
Flurazepam	Dalmane	Benzodiazepine Receptor Agonists and Antagonists	31.10
Fluvoxamine	Luvox	Selective Serotonin Reuptake Inhibitors	31.25
Gabapentin	Neurontin	Anticonvulsants	31.7
Glutethimide	Doriden	Barbiturates and Similarly Acting Substance	31.9
Halazepam	Paxipam	Benzodiazepine Receptor Agonists and Antagonists	31.10
Haloperidol	Haldol	Dopamine Receptor Antagonists	31.17
Hydroxyzine	Atarax, Vistaril	Antihistamines	31.8
Imipramine	Tofranil	Tricyclic and Tetracyclic Drugs	31.30
Isocarboxazid	Marplan	Monoamine Oxidase Inhibitors	31.20
Labetalol	Normodyne, Trandate	b-adrenergic Receptor Antagonists	31.5
Lamotrigine	Lamictal	Anticonvulsants	31.7
Levodopa	Larodopa	Levodopa	31.33
Levomethadyl acetate	ORLAAM	Opioid Antagonists	31.23
Levothyroxine	Levoxine, Levothroid, Synthroid	Thyroid Hormones	31.28
Liothyronine	Cytomel	Thyroid Hormones	31.28
Lithium	Eskalith, Lithobid	Lithium	31.18
Lorazepam	Ativan	Benzodiazepine Receptor Agonists and Antagonists	31.10
Loxapine	Loxitane	Dopamine Receptor Antagonists	31.17
Mephobarbital	Mebaral	Barbiturates and Similarly Acting Substances	31.9
Meprobamate	Miltown	Barbiturates and Similarly Acting Substances	31.9
Mesoridazine	Serentil	Dopamine Receptor Antagonists	31.17
Methadone	Dolophine, Methadose	Opioid Agonists	31.23
Metharbital	Gemonil	Barbiturates and Similarly Acting Substances	31.9
Methohexital	Brevital	Barbiturates and Similarly Acting Substances	31.9

Methylphenidate	Ritalin	Sympathomimetics	31.27
Methypryton	Noludar	Barbiturates and Similarly Acting Substances	31.9
Metoprolol	Lopressor, Toprol	b-Adrenergic Receptor Antagonists	31.5
Midazolam	Versed	Benzodiazepine Receptor Agonists and Antagonists	31.10
Mirtazapine	Remeron	Mirtazapine	31.19
Moclobemide	Aurorix	Monoamine Oxidase Inhibitors	31.20
Molindone	Moban	Dopamine Receptor Antagonists	31.17
Nadolol	Corgard	b-Adrenergic Receptor Antagonists	31.5
Nefazodone	Serzone	Nefazodone	31.22
Nifedipine	Adalat, Procardia	Calcium Channel Inhibitors	31.13
Nimodipine	Nimotop	Calcium Channel Inhibitors	31.13
Nortriptyline	Pamelor, Aventyl	Tricyclics and Tetracyclics	31.30
Olanzapine	Zyprexa	Serotonin Dopamine Antagonists	31.26
Orphenadine	Norflex, Dispal	Anticholinergics and Amantadine	31.6
Oxazepam	Serax	Benzodiazepine Receptor Agonists and Antagonists	31.10
Paraldehyde	Generics	Barbiturates and Similarly Acting Substances	31.9
Paroxetine	Paxil	Selective Serotonin Reuptake Inhibitors	31.25
Pemoline	Cylert	Selective Sympathomimetics	31.27
Phenelzine	Nardil	Monoamine Oxidase Inhibitors	31.20
Phenobarbital	Solfoton	Barbiturates and Similarly Acting Substances	31.9
Pentobarbital	Nembutal	Barbiturates and Similarly Acting Substances	31.9
Perphenazine	Trilafon	Dopamine Receptor Antagonists	31.17
Pimozide	Orap	Dopamine Receptor Antagonists	31.17
Pindolol	Visken	b-Adrenergic Receptor Antagonists	31.5
Piperacetazine	Quide	Dopamine Receptor Antagonists	31.17
Prazepam	Centrax	Benzodiazepine Receptor Agonists and Antagonists	31.10
Prochlorperazine	Compazine	Dopamine Receptor Antagonists	31.17
Procyclidine	Kemadrin	Anticholinergics and Amantadine	31.6
Promazine	Sparine	Dopamine Receptor Antagonists	31.17
Promethazine	Phenergan	Antihistamines	31.8
Propranolol	Inderal	b-Adrenergic Receptor Antagonists	31.5
Protriptyline	Vivactil	Benzodiazepine Receptor Agonists and Antagonists	31.10
Quazepam	Doral	Benzodiazepine Receptor Agonists and Antagonists	31.10
Quetiapine	Seroquel	Serotonin-Dopamine Antagonists	31.26
Reboxetine	Edronax, Norebox	Other Pharmacological and Biological Therapies	31.33
Reserpine	Diupres	Dopamine Receptor Antagonists	31.17
Risperidone	Risperdal	Serotonin-Dopamine Antagonists	31.26
Secobarbital	Seconal	Barbiturates and Similarly Acting Substances	31.9
Selegiline	Eldepryl	Monoamine Oxidase Inhibitors	31.20
Sertindole	Serlect, Serdolect	Serotonin-Dopamine Antagonists	31.26
Sertraline	Zoloft	Selective Serotonin Reuptake Inhibitors	31.25
Sulpiride	Dogmatil, Sesif	Dopamine Receptor Antagonists	31.17
Tacrine	Cognex	Cholinesterase Inhibitors	31.15
Temazepam	Restoril	Benzodiazepine Receptor Agonists and Antagonists	31.10
Thiopental	Pentothal	Barbiturates and Similarly Acting Substances	31.9
Thioridazine	Mellaril	Dopamine Receptor Antagonists	31.17
Thiothixene	Navane	Dopamine Receptor Antagonists	31.17
Topiramate	Topamax	Anticonvulsants	31.7
Tiagabine	—	Anticonvulsants	31.7
Tranylcypromine	Parnate	Monoamine Oxidase Inhibitors	31.20
Trazodone	Desyrel	Trazodone	31.29
Triazolam	Halcion	Benzodiazepine Receptor Agonists and Antagonists	31.10
Trihexyphenidyl	Artane	Anticholinergics and Amantadine	31.6
Trifluoperazine	Stelazine	Dopamine Receptor Antagonists	31.17
Triflupromazine	Vesprin	Dopamine Receptor Antagonists	31.17
Trimipramine	Surmontil	Tricyclics and Tetracyclics	31.30
L-Tryptophan	—	Other Pharmacological and Biological therapies	31.33
Valproate	Depakene	Anticonvulsants	31.7
Valproic Acid	Depakene	Anticonvulsants	31.7
Venlafaxine	Effexor	Selective Serotonin-Noradrenaline Reuptake Inhibitors	31.24
Verapamil	Calan, Isoptin	Calcium Channel Inhibitors	31.13
Vigabatrin	Sabril	Anticonvulsants	31.7
Yohimbine	Yocon	Other Pharmacological and Biological Therapies	31.33
Ziprasidone	Zeldox	Serotonin-Dopamine Antagonists	31.26
Zolpidem	Ambien	Benzodiazepine Receptor Agonists and Antagonists	31.10

Table 31.1-9 Major Mental Disorders and the Most Common Drugs and Classes of Drugs Used in Their Treatment

Disorder	Section Number
Aggression and agitation (see Intermittent explosive disorder)	
Akathisia (see Medication-induced movement disorders)	
Alcohol use disorders	
b-adrenergic receptor antagonists	31.5
Benzodiazepines	31.10
Carbamazepine	31.7a
Disulfiram	31.33
Lithium	31.18
Naltrexone	31.21
Anorexia nervosa (see Eating disorders)	
Anxiety (see also specific anxiety disorders)	
Antihistamines	31.8
Benzodiazepines	31.10
Buspirone	31.12
Bipolar I disorder	
Anticonvulsants	31.7
Benzodiazepines (especially clonazepam)	31.10
Calcium Channel inhibitors	31.13
Dopamine receptor antagonists	31.17
Lithium	31.18
Serotonin-dopamine antagonists	31.26
L-tryptophan	31.33
Bulimia nervosa (see Eating disorders)	
Cyclothymic disorder (see Bipolar I disorder)	
Delusional disorder (see Schizophrenia)	
Dementia of the Alzheimer's type (cognitive symptoms)	
Cholinesterase inhibitors	31.15
Depressive disorders	
Anticonvulsants	31.7
Benzodiazepines (especially alprazolam)	31.10
Bromocriptine	31.33
Bupropion	31.11
Calcium channel inhibitors	31.13
Lithium	31.18
Mirtazapine	31.19
Monoamine oxidase inhibitors	31.20
Nefazodone	31.22
Reboxetine	31.33
Serotonin-noradrenaline reuptake inhibitors	31.24
Selective serotonin reuptake inhibitors	31.25
Sympathomimetics	31.27
Thyroid hormones	31.28
Trazodone	31.29
Tricyclic and tetracyclic drugs	31.30
L-Tryptophan (withdrawn from U.S. market)	31.33
Dysthymic disorder (see depressive disorders)	
Dystonia (see Medication-induced movement disorders)	
Eating disorders	
Lithium	31.18
Monoamine oxidase inhibitors	31.20
Selective serotonin reuptake inhibitors	31.25
Trazodone	31.29
Tricyclics and tetracyclics	31.30
Generalized anxiety disorder	
b-adrenergic receptor antagonists	31.5
Barbiturates and similarly acting drugs	31.9
Benzodiazepines	31.10
Buspirone	31.12
Selective serotonin-noradrenaline reuptake inhibitors	31.24
Selective serotonin reuptake inhibitors	31.25
Trazodone	31.29
Tricyclics and tetracyclics	31.30
Intermittent explosive disorder	

COMBINATION DRUGS

In addition to drugs that contain a single active ingredient, a small number of combination drugs are available in the United States (Table 31.1-10). It is possible that the use of such drugs may increase the patients' compliance by simplifying the drug regimen. A problem with combination drugs, however, is that the clinician has less flexibility in adjusting the dosage of one of the components; that is, the use of combination drugs may cause two drugs to be administered when only one drug continues to be necessary for therapeutic efficacy.

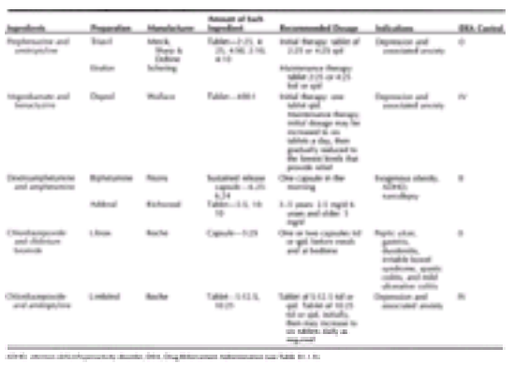

Table 31.1-10 Combination Drugs Used in Psychiatry

SUGGESTED CROSS-REFERENCES

The process by which new drugs are approved in the United States is explained in Section 31.3; pharmacokinetics and drug interactions are described in Section 31.2; and combined psychotherapy and pharmacotherapy is explained in Section 30.12. Medication-induced movement disorders are discussed in Section 31.4.

31.2 PHARMACOKINETICS AND DRUG INTERACTIONS

PHILIP G. JANICAK, M.D., AND JOHN M. DAVIS, M.D.

Pharmacokinetics describes the various phases that a drug undergoes when it enters the body, including absorption, distribution, metabolism, and elimination. Pharmacokinetics influences the process by which critical drug concentrations reach the sites of action (typically a neuron or group of neurons). Important related pharmacokinetic factors are described in Table 31.2-1. *Pharmacodynamics* describes what a drug does in the body, which depends on an agent reaching its site or sites of action (e.g., neurotransmitters, receptors, second messengers) in the appropriate concentration. Interaction with the targeted site then produces a series of changes in subcellular neuronal activity that culminates in clinically relevant behavioral effects.

Absorption	Process by which a drug proceeds from the site of administration to the site of measurement (generally plasma or whole blood)
First-pass effect	Hepatic extraction of orally administered drugs prior to reaching the systemic circulation
Volume of distribution (V_d)	How much drug is distributed throughout the body
Steady-state concentration (C_{ss})	Drug concentration achieved when the amount administered per unit time equals the amount eliminated per unit time
Biological half-life ($t_{1/2}$)	Time required for the drug concentration in plasma (or blood) to fall by one-half
Elimination rate constant (K_e)	Percentage of drug in the body eliminated per unit time
Clearance (Cl)	A measure of a drug's elimination from the body (i.e., the amount of drug in the body times the elimination rate constant)
First-order kinetics	Amount of drug eliminated per unit time is directly proportional to its plasma concentration
Zero-order kinetics	A fixed amount of drug is eliminated per unit time regardless of plasma concentration

Table 31.2-1 Pharmacokinetic Factors

Drug interactions change the clinical effect of one or more concurrently administered agents by altering their respective pharmacokinetics or pharmacodynamics. Recently discontinued agents with long elimination half-lives (e.g., fluoxetine [Prozac] and its metabolite norfluoxetine) can also be involved in drug interactions.

PRIMARY PHARMACOKINETIC PHASES

Absorption Most agents are administered orally and absorbed through the small bowel. They then enter the portal circulation and pass through the liver, where they may undergo significant presystemic metabolism (i.e., first-pass effect) before reaching the systemic circulation. Since most psychotropic agents are highly lipophilic, they quickly cross the blood-brain barrier and are then delivered to the site of action via the cerebral circulation. Because of their lipophilicity, these agents are usually rapidly and completely absorbed, have a high first-pass effect, have a large volume of distribution, and are readily available to the central nervous system (CNS).

Bioavailability is the portion of a drug that is absorbed from the site of administration. Intravenous administration presumably produces 100 percent absorption. Various factors that attenuate a drug's bioavailability when given orally or intramuscularly include its physicochemical properties, specific formulation, precipitation at the site of injection, and disease states that alter gastrointestinal function or first-pass effect. A shorter time to peak concentration (T_{max}) translates to a more rapid onset of a drug's clinical effect (Fig. 31.2-1). While this is often desirable (e.g., for a sedative-hypnotic), at times too-rapid absorption may result in a toxic peak concentration (C_{max}). A drug's lipophilicity and polarity are also pertinent. For example, more-polar compounds penetrate the gastrointestinal tract and blood-brain-barrier slowly. Thus, oxazepam (Serax), the most polar benzodiazepine, is a poor sedative because of its delayed absorption into the systemic and cerebral circulations.

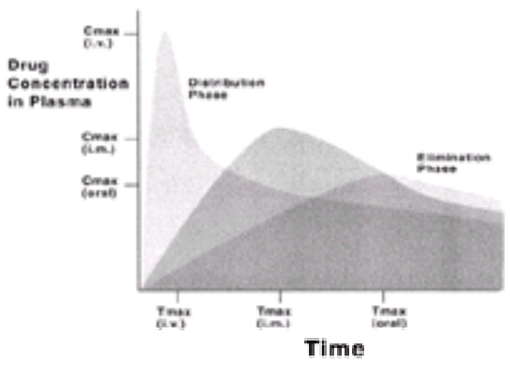

FIGURE 31.2-1 Single-dose plasma drug concentration versus time curves for same drug given intravenously, intramuscularly, or orally.

Different formulations (e.g., two different generic antipsychotic agents) can have substantially different bioavailabilities. While the Food and Drug Administration (FDA) requires that a generic formulation differs from a brand name product by no more or no less than 30 percent in bioavailability, two different generic formulations can differ by up to 60 percent. Thus switches from one generic product to another can involve a substantial difference in efficacy or toxicity. Route of administration can affect absorption as well as the ratio of parent compound to its various metabolites. While the intramuscular route usually results in more-rapid absorption, this is not always true. For example, certain benzodiazopines (e.g., diazepam [Valium]) tend to crystallize after injection and are actually less available than their oral counterpart because of the slower, more erratic, and less complete release from muscle tissue sites.

The first-pass effect can be altered by various diseases (e.g., cirrhosis, congestive heart failure) and by a number of substances ingested concurrently (e.g., alcohol, selective serotonin reuptake inhibitors [SSRIs]). In turn, this influences the C_{max} and ratio of parent compound to metabolites. Avoiding hepatic metabolism may enhance drug potency. For example, parenteral administration avoids the first-pass effect, so many agents have greater potency when given intramuscularly than when given orally. Diseases such as cirrhosis can lead to portacaval shunting; thus drugs can bypass the hepatic metabolism and directly enter the systemic circulation. Finally, acute alcohol intoxication can, in the absence of liver dysfunction, increase absorption and decrease first-pass metabolism of agents such as tricyclic drugs, contributing to the greater toxicity seen when they are combined (e.g., in an overdose).

Distribution Distribution depends on an agent's lipophilicity as well as an organ's fat and protein content. The vascularity of an organ determines the rate of accumulation. After a single oral dose, drug concentration reaches C_{max} and then undergoes an initial, relatively rapid decline as it is distributed into other body compartments (e.g., adipose tissue, aqueous, bone) rather than elimination (Fig. 31.2-1). In addition, most psychoactive drugs are highly protein bound, and only a small amount of an unbound drug (i.e., free fraction) is available at the site of action. Even a small shift in the bound-unbound ratio can substantially increase the free-drug fraction, at times increasing toxicity. Malnutrition, aging, and other drugs (e.g., divalproex [Depakote], fluoxetine) that compete for protein binding sites will

affect this ratio. Alterations in the relative fat, protein, and total body water content in elderly patients partially explain why this age group often has a longer drug effect than younger adults.

Metabolism Most psychotropic drugs are hepatically transformed to more-polar metabolites that are then excreted. Biotransformation may involve hydroxylation, demethylation, oxidation, and sulfoxide formation. While most agents undergo these phases, some (e.g., lorazepam [Ativan]) only undergo simple conjugation with glucuronic acids or are excreted without being transformed (e.g., lithium [Eskalith]). Since conjugation can occur in organs other than the liver, hepatic compromise usually does not substantially affect the rate of clearance of agents metabolized in this manner. Various metabolites are formed in biotransformation, which may significantly determine the ultimate behavioral effects (intended or adverse) of a drug. For example, fluoxetine's primary metabolite, norfluoxetine, has actions similar to those of the parent compound but is cleared more slowly. Over time this metabolite accumulates and becomes the primary acting agent (rather than fluoxetine). Alternatively, certain metabolites are less effective and more toxic than the parent compound (e.g., 2-hydroxyimipramine versus imipramine [Tofranil]). Thus, a shift in the ratio of parent compound to metabolite may decrease the antidepressant effect and increase toxicity.

Enzyme Induction and Inhibition An important related issue is the alteration of activity in the cytochrome P450 enzyme system. These isoenzymes are primarily located in the endoplasmic reticulum of hepatocytes and the gut wall. They make up a family of more than 30 known and related enzymes responsible for the oxidative metabolism of many drugs, including most psychotropic agents. Certain substances may induce this system and thus accelerate the clearance of agents that are substrates of these enzymes; examples include alcohol, smoking (polyaromatic hydrocarbons), barbiturates, and anticonvulsants. Indeed, some are such potent inducers that they can increase their own metabolism to a clinically significant degree (e.g., carbamazepine [Tegretol]).

Other substances may inhibit this system and diminish the metabolism of coadministered substrates, leading to potential problems with toxicity. Examples include SSRIs; quinidine (Quinidex), a potent inhibitor used as a reference standard for inhibition studies of the cytochrome P450 (CYP) 2D6 (CYP 2D6) isoenzyme; certain antipsychotic drugs; and grapefruit juice (flavonoids, furanocoumarins). One of the best-known examples of this phenomenon is the decrease in terfenadine (Seldane) metabolism by agents that inhibit the CYP 450 3A3/4 isoenzyme (e.g., ketoconazole [Nizoral], erythromycin [E-Mycin]). As a result, there may be an increase in the concentration of the prodrug parent compound, which lacks the antihistaminic properties of its major metabolite. More importantly, increased prodrug concentrations are potentially cardiotoxic (e.g., torsades des pointes).

Various diseases that directly (e.g., cirrhosis, viral infections) or indirectly (e.g., cardiac failure) compromise hepatic function can also alter the rate of drug metabolism. This may result in toxicity because of increased concentration of a drug (e.g., cardiac arrhythmias due to elevated concentrations of a tricyclic drug).

Elimination Most psychoactive agents are eliminated by biotransformation to one or more metabolites with greater polarity. The increased water solubility and decreased lipid solubility of these polar metabolites then causes a distribution shift from various organs to plasma and increases renal clearance. This is represented on the single-dose, concentration-time curve as the terminal elimination phase (Fig. 31.2-1). Typically, there is a gradual but steady decline in plasma concentration over time. Renal insufficiency, dehydration, changes in plasma pH, and certain drugs may affect the kidney's ability to excrete a given agent. For example, certain diuretics and nonsteroidal anti-inflammatory drugs (NSAIDs) can interfere with renal excretion of lithium.

For many of the factors discussed, therapeutic drug monitoring has become the standard of care for a variety of psychotropics under certain clinical circumstances (e.g., tricyclic drugs; lithium, divalproex and carbamazepine; some antipsychotic agents).

DRUG INTERACTIONS

Drug combinations are being used increasingly to enhance efficacy (e.g., lithium plus an antidepressant) or to counteract adverse effects of a drug (e.g., antiparkinsonian agents plus neuroleptic drugs). Fortunately, most interactions between concurrent drug therapies are not clinically relevant, but some may interfere with drug efficacy or cause serious morbidity or mortality. Elderly persons are usually at greatest risk for adverse drug interactions since they often receive multiple drugs, often self-prescribed, and use more over-the-counter (OTC) agents; tend to see several physicians for a variety of complaints; and are especially vulnerable to CNS sedation because of increased sensitivity and alterations in pharmacokinetics. Drug interactions may be secondary to pharmacokinetic factors, pharmacodynamic factors, or both. Problems can arise in any or all pharmacokinetic phases (Table 31.2-2).

Phase	Interaction
Absorption	Antacids or anticholinergic agents may impede absorption of other agents
Distribution	Agents with higher protein-binding affinity may displace other drugs, thus increasing their free fraction (e.g., divalproex plus carbamazepine)
Metabolism	Drugs that induce or inhibit CYP 450 isoenzymes can increase or decrease metabolism of coadministered agent
Elimination	Sodium bicarbonate or ascorbic acid can increase excretion of various agents; angiotensin-converting enzyme (ACE) inhibitors may increase lithium concentrations

Table 31.2-2 Drug Interactions at Various Pharmacokinetic Phases

Pharmacokinetic Interactions CYP 2D6 isoenzyme inhibition or induction can alter drug metabolism. This has taken on increased importance with the advent of potent inhibitors (e.g., fluoxetine and paroxetine [Paxil]) and potent inducers (e.g., carbamazepine), many of which are commonly used for various psychiatric disorders. In addition, 5 to 10 percent of white persons possess an autosomal recessive genetic defect in the expression of the isoform CYP 2D6, making them poor metabolizers. Individuals can be genotyped for CYP 2D6 activity by use of polymerase chain reaction (PCR) techniques. Thus, drug inhibition or genetic polymorphism may cause toxic increases of drug in the concentration such as certain tricyclic agents. Fluvoxamine (Luvox) inhibits CYP 1A2 and has resulted in a twofold increase in concentrations of substrates such as theophylline (Theo-Dur) when coadministered. CYP 2C19 also exhibits genetic polymorphism in Japanese (20 percent), African-Americans (2 to 20 percent), Africans (4 to 8 percent), and whites (3 to 5 percent), who have been reported to be poor metabolizers. Important potential interactions may occur when inhibitors (e.g., fluvoxamine, fluoxetine, and sertraline [Zoloft]) and substrates of this isoenzyme (e.g., diazepam, clomipramine [Anafranil]) are administered. CYP 3A4 is possibly the most important isoenzyme, accounting for up to 60 percent of the total CYP 450 content. Potent inhibitors of CYP 3A4 (e.g., nefazodone [Serzone], fluvoxamine, norfluoxetine-fluoxetine, paroxetine, and sertraline) raise concern about the potential for cardiotoxic effects when they are combined with the nonsedating antihistamines terfenadine or astemizole (Hismanal). This does not appear to be an issue, however, when they are used in combination with the nonsedating antihistamines loradatine (Claritin) or citrizine (Zyrtec). Further, this may only have clinical relevance when more than one CYP 3A4 inhibitors are combined or when a single agent is taken in large amounts, such as in an overdose.

Extrapolation from in vitro studies of the CYP 450 enzyme system to the clinical setting is presently littered with possible confounds. Further, other factors are almost certainly involved, since most patients receiving such drug combinations do not exhibit cardiotoxicity. In part, this is due to wide interindividual variability in drug metabolism resulting from genetic polymorphism in the functional expression of various CYP 450 isoenzymes. Thus, while in vitro evidence allows a ranking of various agents in terms of their inhibition potency for various isoenzymes, the relative lack of direct comparison between in vitro data and clinically significant drug interactions does not permit ranking most agents in this latter respect.

Given our present state of knowledge about the CYP 450 enzyme system, the following recommendations seem appropriate.

CYP 2D6 isoenzyme: Antidepressants and antipsychotic drugs should be used cautiously with fluoxetine and paroxetine. Type 1C antiarrhythmic agents should not be used in combination with certain SSRIs.

CYP 3A4 isoenzyme: Fluvoxamine, nefazodone, and fluoxetine should be used with caution when combined with terfenadine, astemizole, certain benzodiazepines (e.g., triazolam [Halcion]), and carbamazepine.

CY 1A2 isoenzyme: Fluvoxamine should be avoided with patients on theophylline or clozapine (Clozaril).

CYP 2C9/10 and CYP 2C19 isoenzymes: Combined fluoxetine plus phenytoin (Dilantin), sertraline plus tolbutamide (Orinase), and fluvoxamine plus warfarin (Coumadin) should be used cautiously.

CYP 2B6 isoenzyme: While its clinical relevance is unclear, it is known that bupropion (Wellbutrin) is converted to its major metabolite by this isoenzyme.

Finally, even after discontinuing fluoxetine administration, given the prolonged elimination half-life of norfluoxetine, administration of substrates with the potential for adverse interactions should be carefully monitored for several weeks.

Flavin-containing Monooxygenases (FMO) The FMO system is also responsible for drug metabolism. While it is probably not an inducible system like the cytochrome P450, its metabolic capacity may be inhibited. Presently, there are only five known FMO families (FMO 1–5), which may work in conjunction with the cytochrome P450 system. For example, olanzapine (Zyprexa) is metabolized by CYP 1A2, CYP 2D6, and FMO 3. Thus, alterations in the metabolism of either system may alter the metabolism of the other, with the subsequent potential for clinically relevant drug interactions.

Pharmacodynamic Interactions Pharmacodynamic interactions may cause changes in efficacy or toxicity in the absence of changes in pharmacokinetics. These may occur because of CNS changes that affect the sites of action. These types of interactions have not been studied as extensively as pharmacokinetic interactions and thus are not as well understood. One example is the antagonism that may occur when parkinsonian patients on levodopa (Levodopa) or carbidopa (Lodosyn) are given an antipsychotic drug to control associated psychotic symptoms, often leading to a recurrence of parkinsonian symptoms (e.g., akinesia, increased rigidity).

Another is the potential for developing the serotonin syndrome when SSRIs are combined with monoamine oxidase inhibitors (MAOIs). This syndrome carries the potential for significant morbidity and mortality; it is characterized by symptoms such as confusion, myoclonus, hyperreflexia, diaphoresis, and possibly cardiovascular compromise.

Clinicians should always anticipate the potential for adverse interactions, which are best managed preventively. In this context, the following steps are appropriate:

Obtain a detailed medication history, including the use of other prescribed drugs, OTC drugs, illicit drugs, and alcohol

Identify high-risk groups such as elderly and very young patients and those with certain medical disorders such as renal or hepatic disease

Educate patients, including written instructions when appropriate (e.g., MAOI diet)

Avoid polypharmacy when possible

Keep detailed, updated references on important potential drug interactions

Table 31.2-3, Table 31.2-4, Table 31.2-5, Table 31.2-6, Table 31.2-7, Table 31.2-8, Table 31.2-9, Table 31.2-10, Table 31.2-11 and Table 31.2-12 summarize some of the more common clinically relevant potential drug interactions, the type of data that supports these interactions, and their suggested clinical management.

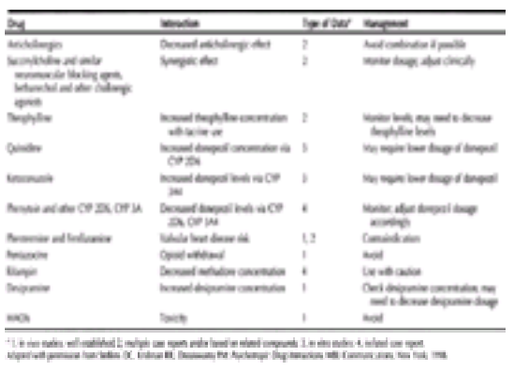
Table 31.2-11 Selected Antipsychotic Drug Interactions



Drug	Interaction	Type of Data*	Management
Anticholinergics	Decreased anticholinergic effect	2	Avoid combination if possible
Succinylcholine and similar neuromuscular blocking agents, bethanechol and other cholinergic agonists	Synergistic effect	2	Monitor dosage; adjust clinically
Theophylline	Increased theophylline concentration with fluoxetine use	2	Monitor levels; may need to decrease theophylline levels
Quinidine	Increased donepezil concentration via CYP 2D6	3	May require lower dosage of donepezil
Ketoconazole	Increased donepezil levels via CYP 3A4	3	May require lower dosage of donepezil
Phenytoin and other CYP 2D6, CYP 3A	Decreased donepezil levels via CYP 2D6, CYP 3A4	4	Monitor; adjust donepezil dosage accordingly
Pimozide and fluvoxamine	Valvular heart disease risk	1, 2	Contraindication
Pentazocine	Opioid withdrawal	1	Avoid
Rifampin	Decreased methadone concentration	4	Use with caution
Desipramine	Increased desipramine concentration	1	Check desipramine concentration; may need to decrease desipramine dosage
MAOIs	Toxicity	1	Avoid

31.3 DRUG DEVELOPMENT AND APPROVAL PROCESS IN THE UNITED STATES

PAUL LEBER, M.D.

Before a new drug may be legally marketed in the United States, it must, under the requirements of the Federal Food, Drug and Cosmetic (FDC) Act, a national drug-regulatory law, be evaluated in applicable preclinical and clinical tests and be found by the Food and Drug Administration (FDA), based upon a review of the results of those tests, to be both “safe for use” and “effective in use” under the conditions of use that are recommended in its proposed or approved labeling. This chapter reviews selected aspects of the history, requirements, and enforcement of the Act.

FEDERAL GOVERNMENT INVOLVEMENT IN THE REGULATION OF DRUGS INTENDED FOR HUMAN USE

Government regulation of drug development and marketing is vital to the safety and effectiveness of the armamentarium. However, this was not always the case. Well into the twentieth century the pharmaceutical industry and its political allies were able to defeat or delay the passage of measures granting the federal government the authority to regulate the marketing of new drugs. A historical account of the development of the government's regulatory powers not only serves to explicate the aims of drug regulation, but testifies compellingly to the necessity for a federal drug regulatory system.

Although a federal law banning the importation of adulterated drugs was enacted in 1848, historians generally view the federal government's regulation of the drug industry to have begun with the passage of the Pure Food and Drugs Act of 1906. Enacted in an era of public concern that followed a series of sensationalistic revelations in the press about unscrupulous practices and deplorable conditions extant in the food and drug industries, the Pure Food and Drugs Act gave the federal government the authority to take legal action against the marketers of adulterated or misbranded drug products.

Enforcement of the 1906 Act proved difficult, however, because it required the government to assume the burden of proving that a product was adulterated or that its labeling was “false or misleading in some particular.” The latter proved exceedingly difficult to do in any case that turned on the opinions of experts rather than on findings of fact.

One factor undermining the utility of the 1906 Act as a tool to control false and misleading health claims was the conservative manner in which the judiciary of the time interpreted its provisions. In a celebrated Supreme Court case involving a product advanced as a cure for cancer, Chief Justice Oliver Wendell Holmes, Jr., offered the view that Congress could not have intended the Act's ban against the marketing of products bearing labeling that was “false or misleading in any particular” to apply to more than the accuracy of statements concerning the identity, purity, and strength of the product's chemical components. Holmes justified his interpretation on the grounds that an application of the Act's provisions to matters involving the accuracy of a claimed therapeutic use would require that the staff of the FDA be competent to assess medical claims, and this, Holmes opined, was so far beyond their talents and competency that Congress, in its wisdom, could not possibly have intended it.

Although Congress subsequently attempted to overcome this limitation by explicitly amending (Sherley Amendment of 1911) the 1906 Act to include fraudulent therapeutic claims among those that would cause a product to be misbranded, the action had little practical effect. Under the amended 1906 Act, the government was obliged to establish the existence of fraudulent intent on the part of a sponsor advancing a false and misleading therapeutic claim and this proved to be even more difficult than documenting that a claim was false. Thus, the 1906 Act, a relatively weak measure to begin with, turned out to be a far less effective antiquackery tool than those who had fought for its passage intended.

However, subsequent efforts of FDA officials and their allies to obtain the passage of more potent drug legislation met with repeated failures, in no small measure because of the political power of the regulated industry. Indeed, it is widely believed that despite the sweeping social and political changes wrought by Roosevelt's New Deal, the original version of the current drug regulatory law, the FDC Act, would have been unlikely to have been enacted into law had it not been for the disastrous consequences of an error made in 1937 by a chemist working for a respected, long-established, pharmaceutical house.

In an attempt to satisfy an unmet market demand for a liquid preparation of a sulfanilamide antibiotic, the firm's chief chemist prepared a formulation that employed diethylene glycol as the means to solubilize the antibiotic. Unknown to the chemist, diethylene glycol was a renal toxin, a fact that might have been discovered had the sponsor bothered to carry out even rudimentary premarket safety tests. Ironically, the product had undergone premarket testing, but only for fragrance, appearance, and palatability. Thus, when the elixir was put into commercial distribution, the consequences were calamitous.

In retrospect, it was estimated that upwards of 107 individuals died needlessly and painfully as a direct consequence of the firm's negligence. The toll in lives might have been far greater had not the FDA been able to use the limited powers it had under the 1906 law to recover all but 0.8 percent of the 240 gallons of the elixir that had been distributed throughout the country. Although the FDA's success in limiting the extent of the injury done by the firm's recklessness was widely acclaimed, so too was the irony that the FDA's authority to intervene had been based on a technicality. Under the 1906 act, the FDA had no authority to prevent the interstate distribution of a manifestly dangerous drug. Accordingly, it had only been able to intervene because the so-called elixir was misbranded. Elixirs are solutions in which alcohol serves as the solvent; accordingly, the product being distributed by Massengill which employed diethylene glycol as the solvent was misbranded under the provisions of the 1906 Act.

The story of the elixir of sulfanilamide tragedy illustrates how an unexpected event that heightens public anxiety, even if only transiently, can have far-reaching and long-lasting consequences for federal law and government policy. In 1938 public outrage about the elixir disaster, coupled with knowledge that the entire episode could have been prevented and fear that it might be repeated virtually compelled Congress to replace the 1906 act with one that had been pending before it and bottled up in committee, for more than 5 years.

Law-making is not an entirely coherent nor logical process, turning as much if not more on the political exigencies of the moment as on philosophical convictions, scientific principles, or sound analyses. As a wag once advised, “those who have a liking for either sausage or law should avoid observing either being made.”

It follows that authority gained as a consequence of public anxiety can just as readily be lost because of it, a point that has not been missed by those who are opposed to federal controls over drug development and marketing. Much of current antiregulatory rhetoric strives, for example, to heighten public anxieties by linking the current lack of effective treatments for a wide variety of life-threatening and devastating conditions (e.g., acquired immune deficiency syndrome [AIDS], cancer, dementia, schizophrenia) to the adverse effects of government regulation on incentives for new drug development.

In any event, the net value of drug regulation notwithstanding, the FDC Act of 1938 was seminal, creating a system for the premarket testing and clearance of new drugs that endures, albeit in slightly modified form, to the present time.

In passing the act, Congress relied upon the federal government's authority to control interstate commerce. The 1938 act obliged those planning to market new drugs to submit their products for pre-market clearance by making it a violation under the act to introduce into interstate commerce a new drug that was not the subject of an effective New Drug Application (NDA). To obtain an effective NDA, a sponsor of a new drug was to submit an application containing reports of all tests reasonably applicable to show that the drug product met the requirements established by the act for a marketed drug. Among other requirements, the act specified that the reports would have to show that the drug was not only what its labeling claimed it to be in regard to its strength, identity, and purity, but that it would be “safe for use”

under the conditions of use recommended in its proposed or approved product labeling.

On its part, the FDA was obliged by the act to accept a sponsor's application and to allow it to become effective, unless upon review, the agency determined that reports it contained failed to show that the drug met the act's requirements.

The 1938 act provided an exemption, now known as an Investigational New Drug (IND) application, to allow experts “qualified by training and experience to assess the safety of drugs” to obtain supplies of unapproved new drugs to conduct clinical experiments. An exemption from the act's provisions was required if there was to be research with unapproved new drugs because the Act banned the introduction into interstate commerce of any drug for which an NDA was not in effect. This investigational exemption was essentially available for the asking and drug distribution under the exemption was not closely monitored by the FDA, a fact that was to have important political consequences 25 years later.

Although the 1938 act was a major advance, it was not without limitations. One glaring weakness was its failure to require that marketed drugs be shown to be effective in use. In fairness, in 1938 a regulatory demand that a product be shown effective prior to marketing would have been exceedingly difficult to implement. Although individual academics of the time were mindful that uncontrolled clinical observations were an unreliable basis upon which to assess the efficacy of drug products, especially those that lacked an immediate and dramatic effect (e.g., treatments for tuberculosis or cancer), the medical community at large would have been unlikely to have shared that view. Moreover, from a practical perspective there was no clear consensus extant in 1938 as to the methods that might be employed to assess drug efficacy. It was not until the mid-1950s that prominent authorities in pharmacology and medical therapeutics began more or less uniformly to assert that reliable evidence of drug efficacy could only be gained in valid controlled clinical trials.

The shift in views among medical authorities about the nature of the evidence required to document the effectiveness of drugs did not, however, lead to an immediate change in the 1938 act's requirements. Advocates seeking to strengthen the provisions of the 1938 act did not meet with success until the political equilibrium was again perturbed by public alarm arising in the wake of yet another drug-caused calamity.

In 1961 thalidomide, a drug that had been widely and successfully marketed as a hypnotic in Europe since 1957, was determined to be the cause of limb reduction defects in children born to mothers who had used it during their pregnancies. The news about thalidomide's teratogenic potential broke during the time a series of Congressional hearings were being held on the drug industry and its alleged price-fixing practices. Although thalidomide had not been marketed in the United States, it had been distributed relatively widely to physicians under the Act's investigational exemption provisions. The distribution was more promotional than investigatory, intended largely to draw attention to thalidomide's pending marketing. The marketing of thalidomide had been delayed for several months, however, because Frances Kelsey, the FDA medical officer assigned to the NDA, had unresolved concerns about the drug's potential to cause peripheral neuritis.

Publicity about thalidomide's capacity to cause limb reduction defects and the agency's refusal to allow the product to be marketed because of concerns about its toxicity clearly affected Congressional attitudes about the need for reform and revision of the provisions of the 1938 act. Although only a handful of American children actually suffered injury as a direct result of the domestic distribution of thalidomide, the narrowness of the nation's escape from yet another drug-linked disaster is widely credited with securing the passage of the 1962 Kefauver-Harris amendments.

The 1962 amendments revised the 1938 act in several important ways, two of which are of major interest. First, under the revised act, marketed drugs were required not only to be safe for use, but to be effective in use. Specifically, the amended act instructed the FDA to disapprove an NDA if, upon review, the agency determined that there was a lack of “substantial evidence” of the drug's effectiveness in use.

Second, the 1962 amendments gave the agency explicit authority to control and monitor the investigational use of unapproved new drugs. Under the FDC Act's revised IND provisions, the Secretary was allowed to link the granting of investigational exemptions to (1) the adequacy of preclinical tests justifying the use of the investigational drug in humans, (2) the adequacy of procedures that would be employed to control the distribution and disposition of supplies of the investigational drug, (3) the promise of IND holders to maintain records of the results of their clinical investigations and the making of reports of these results to the agency, and (4) the promise of investigators to obtain informed consent from research subjects, except in those circumstances in which “. . . [the sponsor or his representative]. . . deem it not feasible or, in their professional judgment, contrary to the best interests of such human beings.

Although the FDC Act has subsequently been amended on a variety of occasions and in a number of important ways (e.g., the Patent Term Restoration and Generic Drug Act, the Prescription Drug User Fee Act, the FDA Modernization Act of 1997) the 1962 amendments remain the most important set of amendments to the 1938 act. Indeed, with minor exceptions, the structure, function, and operation of the current drug regulatory system is based upon those amendments.

IMPLEMENTATION AND ENFORCEMENT OF THE ACT

The text of federal laws typically provide little more than an outline of Congressional aims and intent. Accordingly, the agency that has responsibility for the enforcement of a federal law must develop and promulgate regulations, that is, detailed rules and procedures, for its actual enforcement.

ENFORCEMENT OF THE ACT'S INVESTIGATIONAL NEW DRUG REGULATIONS

The conditions under which INDs may be granted, and the requirements that must be met by sponsors and sponsor-investigators to conduct clinical trials under their provisions are detailed in the agency's IND regulations, which appear in Title 21 in the Code of Federal Regulations (21 CFR 312).

An IND is required of any person or persons intending to conduct clinical research with an unapproved new drug within the United States. An IND is ordinarily not required for clinical investigations of marketed drug products, however, unless the sponsor of the study intends to rely upon its results for some regulatory purpose (e.g., to seek a new claimed use for the product.).

Agency regulations on INDs are written as if all who conduct clinical research with unapproved new drugs do so with the intent to develop the information and evidence necessary to gain approval of an NDA for the product. Accordingly, the regulations describe the requirements for clinical testing in reference to three more or less sequentially ordered, phases of premarket testing. Phase 1 is intended to study a drug's clinical pharmacology and to identify its common toxicities. In phase 2 it is contemplated that the sponsor will conduct carefully controlled clinical studies to document the product's effectiveness. In phase 3 clinical testing is to be conducted under conditions that more closely mimic those likely to obtain when the drug is marketed. Throughout each phase of a drug's development, the requirements that must be met to support clinical testing are intentionally limited to those deemed essential to protect human subjects from unreasonable, unnecessary, and potentially avoidable risks.

The preclinical tests required to support initial, short-term studies of a drug in humans are limited to those necessary to establish that the drug, administered at the levels and for the duration proposed, will be unlikely to cause death, catastrophic events, or serious and lasting damage to organ structure or function. Although a more comprehensive set of preclinical toxicity tests must ordinarily be completed prior to the conduct of large-scale phase 2 and 3 trials, their purpose is not to guarantee the safety of human subjects participating in these trials, but to identify and develop the means to monitor the function and integrity of organ systems that may be uniquely susceptible to injury by the drug.

Positive findings of in vitro and in vivo animal teratogenicity and carcinogenicity studies are an exception. Because clinical experience is almost never a reliable means to assess a drug's oncogenic and teratogenic risk, the positive results of such studies are ordinarily considered definitive. However, evidence that a drug is teratogenic or tumorigenic in animals only rarely leads to a decision to preclude further development. Typically, such findings affect how and in whom the drug is tested and, if and when the drug is marketed, are invariably described in its product labeling. Preclinical safety tests serve primarily to guide clinical drug development; regulatory conclusions about the safety or lack of safety of an investigational drug are based almost entirely on clinical experience.

However, serious toxicity findings in animal tests are not ignored, and typically lead to the (1) conduct of additional preclinical studies (i.e., to determine the mechanism by which the drug causes injury—it may not be operative in humans), and (2) intensified monitoring of human subjects during and immediately following their exposure to the investigational drug.

Although the sponsor and the agency often agree about the nature of the remedial steps that should be taken when a potential drug-related risk is identified in either preclinical or clinical tests, disagreements can arise. If a disagreement cannot be resolved through negotiations with a sponsor, agency officials are authorized to

place a clinical “hold” on the sponsor's ongoing studies with the drug. However, such holds may only be imposed under certain specified conditions. Specifically, before imposing a clinical hold an agency official must conclude that the circumstances extant meet one or more of the conditions described at 21 CFR 312.42 (b) of the IND regulations. Of note, all but one of the five enumerated conclusions are linked to concerns about the safety of human subjects. The sole exception applies when a clinical trial intended to gain evidence of a drug's effectiveness in use is determined to be “. . . clearly deficient in design to meet its stated objectives.”

To ensure that agency scientific staff have sufficient time to evaluate all information relevant to the first use of a new investigational drug, sponsors who apply for an IND are obliged to agree not to initiate clinical testing under their IND until 30 days elapse after the time of its receipt by the agency. If agency officials do not impose a hold within these 30 days, the sponsor may initiate clinical testing. Even if it does not impose a hold, the agency may offer suggestions and comments about the conduct of clinical testing; typically, these are communicated to the sponsor in writing.

IND regulations also impose ongoing monitoring and reporting requirements and obligations in regard to clinical research conducted under active INDs. Not only must sponsors of IND make periodic reports to the agency about the status of their work with the investigational drug, but they must report, in a timely manner as prescribed by regulation, new information bearing on adverse preclinical and clinical experiences that have occurred in association with the investigational agent's use. Sponsors are also obliged to submit, in advance of the initiation of any new clinical investigation, a protocol describing how that trial will be carried out. It is through the operation of these and other requirements that the agency monitors, and, as required, can act to modify the course of a new investigational drug's testing and development.

ENFORCEMENT OF THE ACT'S NDA REGULATIONS

In passing the FDC Act Congress sought to ensure that every drug lawfully marketed within the United States would, prior to marketing, have been shown to be both safe for use and effective in use under the conditions of use described in its product labeling. To secure this result, Congress instituted the system of premarket clearance administered by the FDA. The act, however, describes in only very broad brush strokes, how that system is to operate.

Although the act enumerates four findings of an agency review of an NDA that justify a conclusion that a drug has not been shown to be “safe for use,” (i.e., the extent of testing for safety is inadequate, the findings of tests performed show the drug to be unsafe, the findings of tests performed fail to show that the drug is safe, there is insufficient information in general to reach a conclusion about the drug's safety), the act provides no guidance at all concerning the identity of the specific tests that sponsors should employ to assess the safety of a drug.

While this might seem at first sight to be a shortcoming, it is not. To the contrary, Congress would have been ill-advised to offer instruction about a technical subject lying outside its expertise. Accordingly, in its wisdom, Congress delegates to the FDA the task of identifying the tests most appropriate for securing its intent. This strategy not only ensures that the choice of methods is guided by appropriately informed experts, but that the methods used are those consistent with the best, most up-to-date scientific practice. Had Congress specified precise methods for the assessment of drug safety set by statute, the requirements of the act would have rapidly become outdated.

There are instances, however, where Congress is specific about its intent. The definition of substantial evidence provided in the FDC Act is a case in point:

> . . . evidence consisting of adequate and well-controlled investigations, including clinical investigations, by experts qualified by scientific training and experience to evaluate the effectiveness of the drug involved, on the basis of which it could fairly and responsibly be concluded by such experts that the drug will have the effect it purports or is represented to have under the conditions of use prescribed, recommended, or suggested in the labeling or the proposed labeling thereof.

The definition makes clear that regulatory determinations concerning the effectiveness of a drug must derive from evidence adduced in valid experiments, in particular, clinical experiments. Admittedly, the definition allows a role for medical experts, but only to the extent that their expertise in the management of patients with a disease speaks to their capacity to offer not only a fair and responsible but also an informed opinion about the meaning of the evidence adduced. The definition of substantial evidence gives no weight to the views of experts in regard to their beliefs or their impressions gained in the course of clinical practice.

Although the definition of substantial evidence provided in the Act espouses the highest principles of epistemology and the scientific method, the definition is not without limitations from a regulatory enforcement perspective. What, precisely, is intended by the phrase “adequate and well-controlled clinical investigations?” What did Congress intend, if anything, by its use of the plural of the word “investigations?” The agency has long interpreted it to reflect Congressional intent to require independent replications and corroborations of experimental results bearing on drug efficacy. Although this interpretation is entirely consistent with the use of the word, it is hardly as explicit a defense of the principle as those who champion the scientific method would prefer. In 1997 Congress clarified its intent, amending the FDC Act (FDA Modernization Act of 1997) to allow the agency in selected circumstances to conclude that substantial evidence exists when results from but one adequate and well-controlled clinical investigation are provided. The agency has yet to revise its regulations to conform to this change, but a document promulgated in March of 1997 (Evidence document), indicates that reliance on the results of a single adequate and well-controlled clinical investigation will continue to be the exception rather than the rule. In large part, an agency's regulations are intended to clarify potential ambiguities of the sort just described. Unfortunately, it is not always evident to those drafting regulations, especially when drafting those written in the immediate aftermath of an act's passage, just what in the words of a statute will or will not prove ambiguous.

To illustrate, it soon became apparent following the passage of the 1962 amendments that the agency would have to enumerate explicitly what attributes a clinical trial must possess to be considered adequate and well controlled. The result of that effort now appears at 21 CFR 314.126.

There are still other cases, however, where the need for clarifying regulations would clearly be helpful but are not provided. One reason is that it is often impossible to draft meaningful regulations. The set of adverse effects reported in association with the use of a new drug during its premarketing development that would regularly lead to a regulatory determination that the drug is “unsafe for use” is a case in point. The findings that lead to a regulatory determination that a drug is safe or unsafe for use derive much less from objective evidence-based judgments than from opinions, albeit those of medical professionals reasonably experienced and competent in the management of the condition that the investigational drug is intended to treat. In contrast to a regulatory effectiveness determination that turns on the finding of a statistically significant difference favoring a new drug over a control in more than one valid experiment, a conclusion that a drug is safe for use derives from a complex and inchoate process that requires experts to weigh several factors simultaneously, including not only the severity and incidence of the harms and injuries associated with the use of a drug, but the magnitude of the drug's therapeutic effects (which are, at best, only imprecisely and imperfectly estimated), the severity and the natural history of the condition under treatment and the availability, if any of alternative treatments.

It is also important to be mindful that agency regulations are written at a level that applies to all therapeutic drug classes. To be clear, agency policy and guidance on specific psychotherapeutic indications are available, but they do not have the force of regulations; however, this does not present a practical problem. At least in regard to issues of clinical trial design, conduct, and analysis, all product classes can be considered identical. Similarly, the methods and strategies used to assess the safety of a drug in use are indistinguishable in form, whatever the therapeutic class involved. Admittedly, the methods and techniques used to assess, collect, and classify mental phenomena are discipline specific, but the strategies for their analysis are not.

To the extent that discipline-specific enforcement of the FDC Act is necessary, it is available because the authority to make decisions regarding the development of psychotherapeutic drug products is delegated to clinicians and scientists trained and experienced in the neurosciences, psychiatry, and psychology as well as to those with expertise in matters pharmacological. Thus, the assessment of INDs and NDAs for products with psychotherapeutic indications are carried out by reviewers and supervisors with expertise and skills relevant to the task.

COMMERCIAL DEVELOPMENT OF PSYCHOTHERAPEUTIC DRUG PRODUCTS UNDER AN IND

A sponsor seeking to develop a commercial drug product for a psychotherapeutic indication submits an IND to the Division of Neuropharmacological Drug Products. The information provided in the initial IND is assessed by a division team comprised of chemists, pharmacologists, and clinicians and their supervisors. Assisted as required by biopharmacokineticists and statisticians, the team seeks not only to determine whether the information submitted in the IND is sufficient to support the initiation of the clinical study proposed, but provides feedback to the sponsor about relevant issues and findings potentially affecting the product's further development. A decision is required within 30 days; accordingly, division scientists reviewing the IND have less than 20 working days to complete their initial assessment.

Throughout the subsequent course of a drug product's development under an IND, the Division staff and consultants seek to ensure that the extent and scope of clinical testing is appropriately supported by the extent and adequacy of preclinical test and their results. This effort is facilitated by agency regulations that require the sponsor to make periodic reports concerning the progress of the development effort. In particular, sponsors are obliged to report, within a time frame dictated by their severity, information concerning drug-associated adverse events. Although there is no formal requirement that a sponsor make reports to the IND of analyses of efficacy data obtained from clinical trials, protocols for all clinical trials are submitted to the agency prior to their initiation. Because the ultimate goal of a commercial sponsor is to collect evidence that can be used to gain approval of an NDA, sponsors typically not only keep the Division apprised of the results of clinical studies completed under their IND, but seek the Division's advice in regard to the design, conduct, and plans for analyses of all major clinical trials that might serve as a source of support for approval of an NDA. The extent of agency-sponsor cooperation in the 1990s is quite extensive, extending to almost every aspect of a drug's preclinical and clinical evaluation including, in particular, the characterization of its pharmacokinetic and pharmacodynamic attributes.

It is noteworthy that, despite the joint efforts of agency and sponsor, only a small proportion of drug products for which INDs are submitted eventually become the subject of an NDA submission. This is not surprising because any number of events may occur that cause a sponsor to abandon a drug development effort. A drug being developed may prove to be too toxic or too difficult to use. Still, in other instances a drug may be found, the positive findings of preclinical models and earlier clinical reports notwithstanding, to be ineffective or effective, but only at doses that prove intolerable or unsafe. Not uncommonly, a drug development program is abandoned for reasons that have nothing whatsoever to do with the drug's performance or its pharmacological properties. A commercial sponsor may determine that a changing market has removed virtually all likelihood of the drug product being marketed profitably or a firm may simply lack the funds to pursue development.

As drug development proceeds, the Division of Neuropharmacological Drug Product and firm continue in their efforts to ensure that by the completion of the testing program, all information necessary to support an approvable NDA will be available. The division's staff and the sponsor's representatives typically work out the substantive details of the format and organization of an NDA well before its time of submission.

REVIEW AND EVALUATION OF A COMMERCIAL SPONSOR'S NDA

Once an NDA for a psychotherapeutic drug product has been submitted to the FDA, the Division has 60 days to determine whether or not it is sufficiently complete from a technical perspective to warrant review. This preliminary inspection period is intended to ensure that the FDA's limited resources are not wastefully expended in efforts to review an application that will have to be rejected. Why the review of an application that is disorganized or lacking an accurate index would pose a problem becomes obvious once its physical size is appreciated.

The typical NDA is comprised of hundreds of 3– to 4–inch-thick volumes of standard-sized pages containing a diversity of test results, reports, tables, and analyses. The information contained within these volumes deals with everything from the source of the raw materials used to manufacture the drug substance, to the specifications of the limits on impurities allowed in the drug product, to statistical analyses of clinical data, to descriptions of individual patients and the adverse events that befell them in the course of their exposure to the drug or the agent used as a comparative control.

The formal goal of an FDA review is to determine whether or not the reports submitted show that the drug, on whose behalf the NDA was submitted, meets the standards set by the FDC Act for a marketed drug product. Much of the review, accordingly, actually involves the concurrently conducted systematic review of each report contained in the application by a scientist or clinician who is qualified to evaluate them.

A substantive proportion of the Division's review effort, for example, is carried out by industrial chemists on reports about drug chemistry, manufacturing, and controls. Likewise, reports of preclinical pharmacology and toxicity tests are examined by staff pharmacologists and toxicologists. A team of clinicians and statisticians jointly reviews the reports of all controlled clinical trials capable by design of assessing the efficacy of the drug for the claim or claims advanced by the sponsor. The review of each such study entails a systematic assessment of issues ranging from the means used to evaluate and diagnose subjects, the fidelity to which the study protocol was followed in regard to subject selection and exclusion criteria, randomization, blinding, use of proscribed concomitant medications, and methods of outcome assessment. Subjects prematurely discontinued from clinical trials are closely examined because such “censoring” may, depending upon its kind and causes, so bias estimates of treatment effect adduced in a trial as to render them worthless or uninterpretable. Clinicians, including psychiatrists and internists, also scrutinize reports of abnormal laboratory tests and adverse clinical events in an effort to determine whether these findings are likely to be caused by the new drug, and if so to what extent. The clinical team also seeks to determine the conditions and regimen under which the drug can be used with minimum risk and maximum benefit.

Once these discipline-specific reviews are completed, all the diverse findings of the review team's effort must be assessed to determine whether the benefits likely to be gained from the use of the drug are sufficient to outweigh the risks likely to be associated with its use. This assessment entails a number of subjective judgments and hence any close call on an application is invariably arguable.

In general, current agency policy favors the approval of NDAs for products of documented effectiveness, even in the face of serious risks, provided product labeling can describe those risks fully and accurately. Thus, a major part of a division's review team's effort is devoted to the development of labeling under which it can be concluded, as required by law, that the drug will be both safe for use and effective in use. In this regard it is worth noting that at the time of a product's initial approval, its full panoply of risks, in particular those that occur at relatively low incidence, are often unrecognized.

This limitation in the knowledge of a drug's risks of use is not attributable to the shortcomings of the efforts of either the FDA or the sponsor, but to the relatively small number of patients exposed to a drug during the course of a typical commercial development program. Experience gained with even a few thousand patients is inadequate to ensure that a single example of an event caused by the drug infrequently will be observed. For example, there is a 5 percent chance that an event that affects 1 in every 1000 patients will not be observed even once in a clinical development program involving 3000 patients. While a risk of 0.1 percent may seem small enough from the perspective of the individual patient, it is quite large from a public health perspective. For example, a drug that causes hemolytic anemia at that rate would, if administered to 100,000 patients, be expected to cause 100 cases. In theory, depending on the nature of the illness being treated, this incidence might be deemed acceptable from a regulatory perspective so long as the product labeling gives adequate warning of the risk. Regulatory acceptance of such a product is not enough, however; a sponsor might, the medical value of the drug notwithstanding, be obliged to withdraw such a product from marketing because of the tort liability considerations.

DRUG REGULATION AFTER THE APPROVAL OF AN NDA

Those who drafted the Act were obviously mindful of the fact that the risks of a drug might not be discovered until after it has been marketed. Accordingly, the sponsor of a marketed drug continues to have an obligation to report all new information bearing on the safety of the product to the NDA file. This requirement of the Act is the basis for the FDA's authority to require sponsors to collect, classify, and summarize reports made to them of adverse events associated with the use of their drugs to the FDA. Physician and other health care practitioners may report adverse clinical experiences directly to the FDA as well.

The role a drug product actually plays in the genesis of an untoward clinical or laboratory event reported in association with its use is exceedingly difficult to ascertain with any degree of certainty, a fact often overlooked by the lay media and even by medical professionals. Nevertheless, although it is far from a perfect science, the analysis of spontaneous reports made by practitioners is an FDA responsibility, one in which the division staff participates in association with colleagues from the agency's Office of Epidemiology and Biostatistics. The FDA is responsible for ensuring that marketed drug products are, as required by the FDC Act, safe for use and effective in use under the conditions of use recommended in their approved labeling and the federal government bears the responsibility for ensuring the quality and reliability of drugs, and how that responsibility is met through the operation of the Act.

31.4 MEDICATION-INDUCED MOVEMENT DISORDERS

EDMOND HSIN-TUNG PI, M.D., AND GEORGE M. SIMPSON, M.D.

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) included a new diagnostic category, medication-induced movement disorders, and listed research criteria for further study in an appendix. This recommendation should promote early detection and help to develop well-defined and effective clinical psychopharmacological approaches for these disorders.

Since the first neuroleptic, chlorpromazine (Thorazine), was introduced in 1952, a variety of neuroleptic drugs have been discovered. While their relative potency to block the dopamine type 2 (D_2) receptors differed, they nonetheless all possess an antipsychotic property and affect the D_2 receptors in the central nervous system, particularly the basal ganglia. Thus they are associated with extrapyramidal adverse effects as well as tardive dyskinesia. These adverse effects may be confounded with negative symptoms of psychosis (e.g., blunted affect, avolition, alogia, and asociality), which can further impair patients' psychosocial function and can also interfere with medication compliance and other aspects of treatment. Medication noncompliance secondary to extrapyramidal averse effects is a major cause of relapse of psychoses and adversely affects the prognosis. Thus, these adverse effects represent a significant clinical issue that limits the effectiveness of antipsychotic drugs in the treatment of psychiatric patients, more so the seriously and persistently ill.

The term *neuroleptic* (“to take the neuron”) has been used broadly to refer to medications including both the “typical” and “atypical” neuroleptic agents. Typical conventional neuroleptics (dopamine receptor antagonists) refers to those medications (e.g., chlorpromazine, fluphenazine [Prolixin], haloperidol [Haldol]) that diminish or abolish positive psychotic symptoms more than negative symptoms and also produce extrapyramidal effects. Atypical neuroleptics (predominantly serotonin-dopamine antagonists) refers to those medications (e.g., clozapine [Cloxaril]) that diminish or abolish psychotic symptoms but do not produce or produce fewer extrapyramidal effects and do not fit classic behavioral or biochemical models for neuroleptic drugs such as catalepsy and stereotypic behavior in animals. The absence of or presence of few extrapyramidal adverse effects is perhaps related to improvement in both negative and positive symptoms of psychosis. Serotonin (5-hydroxytryptomine [5-HT]) type 2 [5-HT_2] receptor antagonistic effects are thought to play a major role in mitigating extrapyramidal adverse effects with atypical neuroleptic drugs including clozapine, olanzapine (Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), and sertindole (Serlect). Risperidone has dose-related extrapyramidal adverse effects above the dosage range of 2 to 6 mg a day. Other medications that also have dopamine-blocking properties and can cause extrapyramidal adverse effects are dopamine receptor antagonists drugs used in the treatment of nausea, such as prochlorperazine (Compazine) or metoclopramide (Reglan). Amoxapine (Asendin), which is marketed as an antidepressant, is chemically related to loxapine (Loxitane) and has D_2 receptor blocking properties. Amoxapine can produce akathisia, cogwheel rigidity, and tardive dyskinesia.

The most common neuroleptic-induced movement disorders are parkinsonism, acute dystonia, and akathisia. In terms of reversibility, the extrapyramidal adverse effects are, in large part, diminished or abolished by administering antiparkinsonian agents and discontinuing or lowering the dose of the neuroleptic. Tardive dyskinesia is a late-onset movement disorder associated with neuroleptic treatment and can be irreversible.

NEUROLEPTIC-INDUCED PARKINSONISM

DSM-IV describes the disorder as:

> [p]arkinsonian tremor, muscular rigidity or akinesia developing within a few weeks of starting or raising the dose of a neuroleptic medication (or after reducing a medication used to treat extrapyramidal symptoms).

The essential feature of neuroleptic-induced parkinsonism is the presence of muscular rigidity, akinesia, and tremor. Muscular rigidity and akinesia occur more frequently than tremor. Associated symptoms and signs may include worsening of negative symptoms of schizophrenia, depressive-like manner, dysphoria, slow speech, bradyphrenia (slow thinking), excessive salivation, drooling, difficulty in swallowing or drinking, shuffling gait, micrographia, seborrhea, and positive glabellar tap. The clinical picture is indistinguishable from that of idiopathic parkinsonism. Differential diagnosis includes idiopathic or other neurological condition–induced parkinsonism and other psychiatric conditions with bradykinetic features.

Muscular rigidity may affect any skeletal muscle, for example, the extremities, neck, shoulders. There are two types of muscular rigidity: continuous (“lead-pipe”) and cogwheel (rhythmic, ratchet-like resistance). Akinesia is a lack of spontaneous motor activity, difficulty in initiating movements, a stooped and shuffling gait, and slow monotonous speech. Depressive-like manner with dysphoria described as akinetic depression should be differentiated from primary depression, demoralization, and residual schizophrenic defect. Tremor is a steady, rhythmic oscillation, 3 to 6 cycles per second, more prominent in the resting position. Tremor may affect extremities (unilateral or bilateral), head, jaw, mouth, tongue, or lips (“rabbit syndrome”). Objectively defined rating scales (e.g., Simpson's Neurological Rating Scale) have helped clinicians to assess extrapyramidal effects. At least 50 percent of outpatients receiving long-term neuroleptic therapy develop parkinsonian symptoms or signs at some point in the treatment course. These symptoms usually develop within a few days to a few weeks of starting or increasing the dosage of a neuroleptic medication. Symptoms may also develop insidiously or exacerbate after the reduction or withdrawal of an antiparkinsonian medication (e.g., benztropine [Cogentin], diphenhydramine [Benadryl], trihexyphenidyl [Artane], amantadine [Symmetrel]). Severity of the symptoms tends to remain stable or gradually decrease when maintained on the same dosage of neuroleptic and symptoms are reversible after discontinuation of the neuroleptic. Elderly patients are at the highest risk for neuroleptic-induced parkinsonism. Other risk factors are a coexisting neurological condition and past history of neuroleptic-induced parkinsonism.

The neuropathophysiology of the condition is related to the postsynaptic blockade of D_2 receptors in the basal ganglia, which causes an imbalance of dopamine and acetylcholine. The occurrence of extrapyramidal adverse effects with neuroleptic drugs is related to dosage and relative occupancy of D_2 and muscarinic receptors. It has been reported that extrapyramidal adverse effects are associated with 80 percent or greater blockade of D_2 receptors. On the other hand, only 50 to 75 percent occupancy of D_2 receptors is necessary to attain antipsychotic efficacy.

The prophylactic administration of antiparkinsonian agents remains controversial. For patients with known risks of developing parkinsonism, an antiparkinsonian agent may be prescribed concomitantly with the neuroleptic drug. For others, when signs of parkinsonism appear, first consider reducing the neuroleptic dosage, or start concurrent administration of a low dosage of an antiparkinsonian agent. Assess patients periodically and attempt to taper then discontinue the antiparkinsonian agent. In most cases, antiparkinsonian agents can be withdrawn without recurrence of symptoms. Abrupt withdrawal of antiparkinsonian agents may lead to the recurrence of extrapyramidal adverse effects; it is therefore always recommended that antiparkinsonian agents be decreased gradually. If parkinsonism symptoms do not respond totally, then switch to a neuroleptic that produces less (e.g., thioridazine [Mellaril]) or no (e.g., clozapine) parkinsonism symptoms. Also, serotonin-dopamine antagonists, such as olanzapine, quetiapine, risperidone, and sertindole, which possess a reduced risk for extrapyramidal adverse effects, may be prescribed. A clear relation between high risperidone dosage and the occurrence of extrapyramidal adverse effects has been reported. The DSM-IV criteria for neuroleptic-induced parkinsonism are listed in Table 31.4-1.

A. One or more of the following signs or symptoms has developed in association with the use of neuroleptic medication:
   (1) parkinsonian tremor (i.e., a coarse, rhythmic, resting tremor with a frequency between 3 and 6 cycles per second, affecting the limbs, head, mouth, or tongue)
   (2) parkinsonian muscular rigidity (i.e., cogwheel rigidity or continuous "lead-pipe" rigidity)
   (3) akinesia (i.e., a decrease in spontaneous facial expression, gestures, speech, or body movements)
B. The symptoms in criterion A developed within a few weeks of starting or raising the dose of a neuroleptic medication, or of reducing medication used to treat or prevent acute extrapyramidal symptoms (e.g., anticholinergic agents).
C. The symptoms in criterion A are not better accounted for by a mental disorder (e.g., catatonic or negative symptoms in schizophrenia, psychomotor retardation in a major depressive episode). Evidence that the symptoms are better accounted for by a mental disorder might include the following: the symptoms precede the exposure to neuroleptic medication or are not compatible with the pattern of pharmacologic intervention (e.g., no improvement after lowering the neuroleptic dose or administering anticholinergic medication).
D. The symptoms in criterion A are not due to a nonneuroleptic substance or to a neurological or other general medical condition (e.g., Parkinson's disease, Wilson's disease). Evidence that the symptoms are due to a general medical condition might include the following: the symptoms precede exposure to neuroleptic medication, unexplained focal neurological signs are present, or the symptoms progress despite a stable medication regimen.

Table 31.4-1 DSM-IV Diagnostic and Research Criteria for Neuroleptic-Induced Parkinsonism

NEUROLEPTIC MALIGNANT SYNDROME

DSM-IV defines this disorder as:

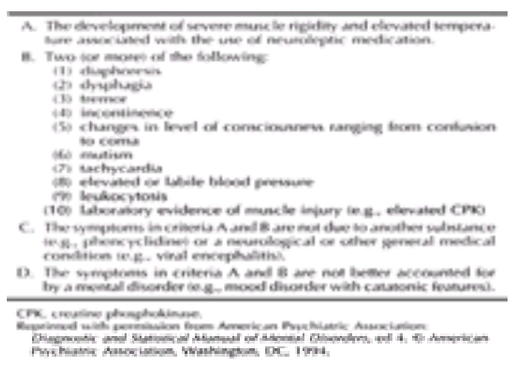
> [s]evere muscle rigidity, elevated temperature, and other related findings (e.g., diaphoresis, dysphagia, incontinence, changes in level of consciousness ranging from confusion to coma, mutism, elevated or labile blood pressure, elevated creatine phosphokinase [CPK]) developing in association with the use of neuroleptic medication.

Neuroleptic malignant syndrome has been reported since 1960, but it is still poorly defined. The syndrome may represent a heterogeneous group of neuroleptic-induced extrapyramidal adverse effects with concurrent fever. One should not automatically diagnose extrapyramidal adverse effects and fever as neuroleptic malignant syndrome. Estimates of the 1-year prevalence of this syndrome in individuals exposed to neuroleptic medications range from 0.02 to 2.4 percent. It is a rare but potentially fatal disorder; mortality rates reported are in the 10 to 20 percent range. No clear evidence implicates any particular typical neuroleptic agent as more or less likely to cause neuroleptic malignant syndrome; atypical neuroleptics (e.g., clozapine and risperidone) have also been reported to be associated with neuroleptic malignant syndrome, but with clozapine it is thought to be rare.

The syndrome tends to develop when neuroleptic treatment is initiated or the dosage is increased, particularly when the dose is high or parenteral. Patients have been reported more likely to be agitated or dehydrated and often to need restraint or seclusion before development of neuroleptic malignant syndrome. The syndrome most often affects young males. Characteristic symptoms include muscular rigidity with elevated body temperature and serum CPK and, in severe cases, myoglobinuria and acute renal failure. The syndrome usually lasts 5 to 10 days after discontinuation of neuroleptic treatment. Differential diagnoses include catatonia, medical condition–induced movement disorders, malignant hyperthermia, and heat stroke.

Prevention is an essential part of managing this heterogeneous condition. The lowest dosage of neuroleptic is recommended, with monitoring of the onset of extrapyramidal adverse effects. Early detection and prompt intervention to eliminate extrapyramidal adverse effects, particularly severe muscular rigidity, may prevent its progress and development of neuroleptic malignant syndrome and its serious complications. Once the syndrome is confirmed, initiate supportive measurements to stabilize autonomic dysfunction, discontinue neuroleptic treatment, continue administering an anticholinergic agent to alleviate muscle rigidity if cardiac status is stable, and institute necessary measurements to lower fever. b-Adrenergic receptor antagonists (beta-blockers) or benzodiazepines may be indicated for akathisia or agitation if there is no clinical contraindication. Amantadine, bromocriptine [Parlodel], and dantrolene [Dantrium] have also been used in some cases. Dopamine agonists are important in patients with a fever over 103°F when a reduction or withdrawal of the anticholinergic agent may be advisable.

Two weeks after the resolution of neuroleptic malignant syndrome, rechallenge with a neuroleptic may be considered. If a neuroleptic drug is clinically indicated, prescribe the lowest dosage with gradual incremental increases plus anticholinergic therapy or prescribe a neuroleptic drug with more anticholinergic property (e.g., thioridazine or an atypical neuroleptic agent). Adequate hydration and well-controlled ambient temperature are effective prophylactic measurements to lower the risks of recurrent neuroleptic malignant syndrome. The DSM-IV criteria for neuroleptic malignant syndrome are presented in Table 31.4-2.



A. The development of severe muscle rigidity and elevated temperature associated with the use of neuroleptic medication.
B. Two (or more) of the following:
   (1) diaphoresis
   (2) dysphagia
   (3) tremor
   (4) incontinence
   (5) changes in level of consciousness ranging from confusion to coma
   (6) mutism
   (7) tachycardia
   (8) elevated or labile blood pressure
   (9) leukocytosis
   (10) laboratory evidence of muscle injury (e.g., elevated CPK)
C. The symptoms in criteria A and B are not due to another substance (e.g., phencyclidine) or a neurological or other general medical condition (e.g., viral encephalitis).
D. The symptoms in criteria A and B are not better accounted for by a mental disorder (e.g., mood disorder with catatonic features).

CPK, creatine phosphokinase.

Table 31.4-2 DSM-IV Research Criteria for Neuroleptic Malignant Syndrome

NEUROLEPTIC-INDUCED ACUTE DYSTONIA

DSM-IV defines this condition as an:

> [a]bnormal positioning or spasm of the muscles of the head, neck, limbs, or trunk developing within a few days of starting or raising the dosage of a neuroleptic medication (or after reducing a medication used to treat extrapyramidal symptoms).

These are acute, dramatic, bizarre muscular spasms (tonic reaction) mainly affecting the head, neck (torticollis), facial muscles (grimacing), eye muscles (oculogyric crises), jaw (trismus), and upper extremities. In rare instances the muscles of the back are affected (opisthotonos). Onset usually occurs within the first 24 to 48 hours after initiating neuroleptic therapy or after increases of the neuroleptic dosage. Risk for this disorder factors include being young, male, taking a high-potency antipsychotic, taking large dosages of an antipsychotic, or receiving parenteral administration of an antipsychotic. These spasms are usually dramatically relieved by parenteral administration of antiparkinsonian agents, followed by oral antiparkinsonian treatment, which should be assessed periodically.

Acute dystonia involving the laryngeal and pharyngeal musculature has been associated with neuroleptic medication. Characteristic symptoms of acute laryngeal dystonia include dyspnea and gestures indicating subjective respiratory distress, such as pointing to or clutching the throat. Immediate intravenous administration of antiparkinsonian agents (e.g., benztropine or diphenhydramine HCl) provides rapid relief of laryngeal dystonia and may be life saving for this potentially lethal condition. The DSM-IV criteria for neuroleptic-induced acute dystonia are listed in Table 31.4-3.

A. One (or more) of the following signs or symptoms has developed in association with the use of neuroleptic medication:
   (1) abnormal positioning of the head and neck in relation to the body (e.g., retrocollis, torticollis)
   (2) spasms of the jaw muscles (trismus, gaping, grimacing)
   (3) impaired swallowing (dysphagia), speaking, or breathing (laryngeal pharyngeal spasm, dysphonia)
   (4) thickened or slurred speech due to hypertonic or enlarged tongue (dysarthria, macroglossia)
   (5) tongue protrusion or tongue dyskinesias
   (6) eyes deviated up, down, or sideward (oculogyric crisis)
   (7) abnormal positioning of the distal limbs or trunk
B. The signs or symptoms in criterion A developed within seven days of starting or rapidly raising the dose of neuroleptic medication, or of reducing a medication used to treat (or prevent) acute extrapyramidal symptoms (e.g., anticholinergic agents).
C. The symptoms in criterion A are not better accounted for by a mental disorder (e.g., catatonic symptoms in schizophrenia). Evidence that the symptoms are better accounted for by a mental disorder might include the following: the symptoms precede the exposure to neuroleptic medication or are not congruous with the pattern of pharmacological intervention (e.g., no improvement after neuroleptic lowering or anticholinergic administration).
D. The symptoms in criterion A are not due to a nonneuroleptic substance or to a neurological or other general medical condition. Evidence that the symptoms are due to a general medical condition might include the following: the symptoms precede the exposure to the neuroleptic medication, unexplained focal neurological signs are present, or the symptoms progress in the absence of change in medication.

Table 31.4-3 DSM-IV Research Criteria for Neuroleptic-Induced Acute Dystonia

NEUROLEPTIC-INDUCED ACUTE AKATHISIA

According to DSM-IV this condition is associated with:

> [s]ubjective complaints of restlessness accompanied by observed movements (e.g., fidgety movements of the legs, rocking from foot to foot, pacing, or inability to sit or stand still) developing within a few weeks of starting or raising the dose of a neuroleptic medication (or after reducing a medication used to treat extrapyramidal symptoms).

The reported prevalence of akathisia has varied between 20 and 75 percent. Its onset is within a few days of initiation of medication, but it can also occur later in neuroleptic treatment.

Akathisia is more likely to occur in recent-onset psychosis, associated with subjective feelings of dysphoria, anxiety, or restlessness; inability to relax, stand still, or stay still; and pacing and shifting of the legs in the sitting position. Many individuals, particularly patients with a chronic psychotic disorder, do not report any subjective complaints, and in the authors' opinion, the objective component is the more important one in all but those with new-onset of acute psychotic disorder. Patients with severe cases may present with agitated, importunate, demanding, or almost histrionic behavior. The condition may be misdiagnosed as an exacerbation of the psychotic condition, resulting in increased dosage of neuroleptic drug, which further worsens akathisia. Akathisia may result in medication noncompliance because of uncomfortable adverse effects. Recently, it was reported that akathisia observed at any time (whether treated or not) was associated with a poor treatment outcome. The reported prevalence of akathisia associated with atypical neuroleptic drugs, including risperidone and olanzapine, is considerably lower than that with conventional neuroleptic drugs.

Treatment strategies for akathisia are similar to those for neuroleptic-induced parkinsonism. b-Adrenergic receptor antagonists have been found to be efficacious, and benzodiazepines may be useful. Recently, the 5-HT_2 antagonist cyproheptadine (Periacitin) was reported to reduce akathisia that did not respond to standard pharmacotherapy. The DSM-IV criteria for neuroleptic-induced acute akathisia are presented in Table 31.4-4.

A. The development of subjective complaints of restlessness after exposure to a neuroleptic medication.
B. At least one of the following is observed:
   (1) fidgety movements or swinging of the legs
   (2) rocking from foot to foot while standing
   (3) pacing to relieve restlessness
   (4) inability to sit or stand for at least several minutes
C. The onset of the symptoms in criteria A and B occur within four weeks of initiating or increasing the dose of the neuroleptic, or of reducing medication used to treat (or prevent) acute extrapyramidal symptoms (e.g., anticholinergic agents).
D. The symptoms in criterion A are not better accounted for by a mental disorder (e.g., schizophrenia, substance withdrawal, agitation from a major depressive or manic episode, hyperactivity in attention-deficit/hyperactivity disorder). Evidence that symptoms may be better accounted for by a mental disorder might include the following: the onset of symptoms preceding the exposure to the neuroleptics, the absence of increasing restlessness with increasing neuroleptic dose, and the absence of relief with pharmacologic interventions (e.g., no improvement after decreasing the neuroleptic dose or treatment with medication intended to treat the akathisia).
E. The symptoms in criterion A are not due to a nonneuroleptic substance or to a neurological or other general medical condition. Evidence that symptoms are due to a general medical condition might include the onset of the symptoms preceding the exposure to neuroleptics or the progression of symptoms in the absence of a change in medication.

Table 31.4-4 DSM-IV Research Criteria for Neuroleptic-Induced Acute Akathisia

NEUROLEPTIC-INDUCED TARDIVE DYSKINESIA

DSM-IV defines this disorder as:

> [i]nvoluntary choreiform, athetoid, or rhythmic movements (lasting at least a few weeks) of the jaw or extremities developing in association with the use of neuroleptic medication for at least a few months (may be for a shorter period of time in elderly persons).

Tardive dyskinesia is sometimes associated with rocking movements, and truncal muscles and respiratory muscles may be involved. Differential diagnoses include spontaneous dyskinesias (which were reported during the preneuroleptic era), mannerism or stereotyped motor behavior, senile dyskinesia, Huntington's disease, Tourette's disorder, Wilson's disease, Meige's syndrome, nonneuroleptic medication-induced dyskinesia (e.g., with tricyclics, antihistamines, phenytoin [Dilantin], sympathomimetics, steroids, selective serotonin reuptake inhibitors), dental problems, mouth sores, somatoform disorder, or factitious disorder.

Tardive dyskinesia is a well-recognized adverse effect associated with the long-term use of neuroleptic therapy and usually occurs insidiously, but early and more rapid onset sometimes occurs. During the past four decades, continuous efforts have been made to study the epidemiology, to identify the risk factors involved, and to develop effective treatment for tardive dyskinesia. The reported cumulative incidence is 5 percent after 1 year, 10 percent after 2 years, 15 percent after 3 years, and 19 percent after 4 years, up to about 25 percent. The overall incidence among young persons ranges from 3 to 5 percent per year. In individuals over age 45 years with a median duration of 21 days of total lifetime neuroleptic treatment, the cumulative incidence of tardive dyskinesia was 26 percent after 1 year, 52 percent after 2 years, and 60 percent after 3 years of neuroleptic treatment. The prevalence of spontaneous dyskinesia in patients with schizophrenia who have never been exposed to neuroleptic treatment is 2 to 4 percent. The reported prevalence of neuroleptic-induced tardive dyskinesia in individuals who have received long-term neuroleptic treatment (including cross-cultural studies) ranges from 0.5 to 65 percent, with an average prevalence of 20 percent. Such a wide variation in the reported prevalence is perhaps due to a lack of a precise objective definition of tardive dyskinesia, different examination techniques, variable diagnostic criteria for this movement disorder as well as training of the examiners. The increased use of standardized rating scales (e.g., Abnormal Involuntary Movement Scale [AIMS]), and more rigorous diagnostic criteria should eliminate these problems.

The disorder has expanded from the initial buccolingual-masticatory syndrome (pouting, puckering, and smacking of lips; tongue protrusion, curling worm-like movements and lateral movements of the tongue, which thrusts against the cheeks to produce the “bonbon” sign; plus chewing movement of the lower jaw) to include various additional abnormal movements and signs. These include facial grimacing; blinking of the eyes, movement of the eyelids; choreoathetoid movements of the fingers, wrists, ankles and toes; axial hyperkinesia, rocking or torsion movement of neck and trunk or both; diaphragmatic involvement resulting in grunting (glottal dyskinesia) and difficulty breathing. The abnormal tongue movements are best detected by having the patient stand with the mouth open and eyes closed; to activate the condition further or manifest it, the patient is asked to tap the thumbs against the fingers while the tongue is observed inside the mouth. As a rule, patients with tardive dyskinesia either are not aware of or do not present subjective complaints of the abnormal movement except in severe cases. Dyskinetic movements disappear during sleep.

Age (i.e., being elderly) and sex (i.e., being female) are the two most consistent risk factors identified in tardive dyskinesia, and advanced age is more likely to be

associated with persistent tardive dyskinesia. A history of extrapyramidal adverse effects, particularly with development early in the course of neuroleptic treatment or severe effects such as akathisia resistant to anticholinergic treatment, is reported to be significantly associated with tardive dyskinesia. The risk ratio for those with extrapyramidal adverse effects is 2.32 times that of those without. Antiparkinsonian agents are not thought to be a risk factor, but they can temporarily worsen tardive dyskinesia. Duration of neuroleptic treatment and intermittent or interrupted neuroleptic treatment are also reported to increase the risk of tardive dyskinesia. Other possible risk factors include individual susceptibility, ethnicity (being African-American, organicity, having negative symptoms of psychosis or deficit states, having diabetes mellitus, and history of alcohol-related or mood disorder). The total cumulative dosage of neuroleptic drugs administered may relate to increased severity of tardive dyskinesia. All dopamine receptor antagonists have been associated with tardive dyskinesia. At present, there are insufficient data to affirm that serotonin-dopamine antagonists neuroleptic drugs are not associated with tardive dyskinesia. Clozapine, an atypical neuroleptic drug, may not cause tardive dyskinesia, and at the least, the risk is likely to be lower with clozapine than with typical neuroleptic drugs. Although the early findings with other atypical neuroleptic drugs suggest that these agents also possess a low risk, this needs to be evaluated in prospective studies.

Tardive dyskinesia can be classified into persistent (irreversible) and withdrawal (reversible) types; reversibility following neuroleptic medication discontinuation has been reported to be from 0 to 90 percent. In general, when individuals with tardive dyskinesia are off neuroleptic medication, in one-third of patients dyskinetic movements become reversible within 3 months, and in more than 50 percent of patients movements remit within 12 to 18 months. Reversibility is lower in elderly than younger groups. It has been estimated that 5 to 40 percent of all tardive dyskinesia cases remit, and 50 to 90 percent of mild cases remit after discontinuation of neuroleptic medication. Although it is impossible to predict reversibility precisely, these findings suggest a better prognosis for patients treated with neuroleptic drugs at lower doses or for shorter durations, or both. Both patients removed from neuroleptic medication as well as those maintained on low-dose neuroleptic drugs appear to have continuous improvement or even resolution of tardive dyskinesia over many years. Therefore clinicians must recognize tardive dyskinesia as early as possible and assess the indications for prolonged neuroleptic treatment. In summary, a favorable long-term outcome correlates with younger age; early recognition; lower doses, shorter duration of neuroleptic treatment, or both; and increased duration of follow-up.

Although the exact neuropathophysiology of tardive dyskinesia remains to be clarified, the most accepted theory involves supersensitivity of dopamine receptors in the basal ganglia following neuroleptic treatment. Various pharmacological agents including both agonists and antagonists for different central nervous neurotransmitters (dopamine, acetylcholine, norepinephrine, serotonin, g-aminobutyric acid), as well as vitamin E have been tried, but none shows evidence of consistent efficacy. Thus, the primary focus of the clinical management of tardive dyskinesia is prevention. The most important point in prevention is prescribing neuroleptic agents only when they are clinically indicated. Neuroleptic drugs should not be prescribed for disorders that can be treated effectively with other medications or alternative treatments. For patients who need neuroleptic treatment, the benefit-to-risk consideration dictates the treatment decision. Whenever neuroleptic dosages are being titrated upward or downward, the risks of psychosis must be balanced against the risk of tardive dyskinesia for each patient. When neuroleptic treatment is indicated, prescribe the lowest possible dosage of neuroleptic and antiparkinsonian agents for the shortest possible period of time. Then assess the patient's psychiatric status and carefully evaluate the need for continual or maintenance neuroleptic treatment, and periodically (e.g., every 3 to 6 months or more frequently if necessary) assess for abnormal movements. Document the presence or absence of tardive dyskinesia. If the patient's psychiatric status is unstable, discuss with the patient, family, or both as appropriate the necessity and possible adverse effects of continual neuroleptic treatment. If clinically possible (i.e., the psychiatric condition is stable), a careful trial of discontinuation of neuroleptic medication should be made with close follow-up. Tardive dyskinesia may appear or worsen following the discontinuation or lowering of neuroleptic doses (withdrawal dyskinesia). In mild situations, withdrawal of the neuroleptic drug should be slowed and benzodiazepines may temporarily be prescribed (as muscle relaxants and to alleviate the patient's anxiety) or both. If withdrawal dyskinesia is severe enough to interfere with daily routine activities such as eating and sleeping, then pure dopamine receptor antagonists (e.g., fluphenazine, haloperidol) may be prescribed and titrated to suppress the movements. This should be followed by a gradual taper of the neuroleptic agent at a later date. If the psychotic symptoms recur or the psychosis worsens, neuroleptic treatment must be reinstituted, and the procedures described above should be followed. Atypical drugs such as clozapine are indicated for patients suffering from both tardive dyskinesia and schizophrenia, especially those with negative symptoms. Clozapine improves and may also prevent tardive dyskinesia. The DSM-IV criteria for neuroleptic-induced tardive dyskinesia are presented in Table 31.4-5.

A. Involuntary movements of the tongue, jaw, trunk, or extremities have developed in association with the use of neuroleptic medication.
B. The involuntary movements are present over a period of at least four weeks, and occur in any of the following patterns:
(1) choreiform movements (i.e., rapid, jerky, nonrepetitive)
(2) athetoid movements (i.e., slow, sinuous, continual)
(3) rhythmic movements (i.e., stereotypies)
C. The signs or symptoms in criteria A and B develop during exposure to a neuroleptic medication or within 4 weeks of withdrawal from an oral (or within 8 weeks of withdrawal from a depot) neuroleptic medication.
D. There has been exposure to neuroleptic medication for at least three months (one month if age 60 or older).
E. The symptoms are not due to a neurological or general medical condition (e.g., Huntington's disease, Sydenham's chorea, spontaneous dyskinesia, hyperthyroidism, Wilson's disease); ill-fitting dentures; or exposure to other medications that cause acute reversible dyskinesia (e.g., L-dopa, bromocriptine). Evidence that the symptoms are due to one of these etiologies might include the following: the symptoms precede the exposure to the neuroleptic medication or unexplained focal neurological signs are present.
F. The symptoms are not better accounted for by a neuroleptic-induced acute movement disorder (e.g., neuroleptic-induced acute dystonia, neuroleptic-induced acute akathisia).

Table 31.4-5 DSM-IV Research Criteria for Neuroleptic-Induced Tardive Dyskinesia

MEDICATION-INDUCED POSTURAL TREMOR

According to DSM-IV, this disorder is characterized by:

> [f]ine tremor occurring during attempts to maintain a posture that develops in association with the use of medication (e.g., lithium, antidepressants, valproate).

In addition to neuroleptics, other medications well documented to induce postural tremor include adrenocorticosteroids, alcohol, amphetamines and other sympathomimetics agents, bronchodilators, caffeine, hypoglycemic agents, levodopa (Dopar, Larodopa) lithium salts, monamine oxidase inhibitors, thyroid hormone, tricyclic drugs, and valproate (Depakene).

In general, treatment strategies include lowest possible dosage of psychotropic medication, monitoring and adjusting the dosage of other agents or decreasing the use of agents (e.g., caffeine, alcohol) that induce or worsen tremor. b-Adrenergic receptor antagonists help to reduce tremor. Lithium-induced hand tremor is a common nuisance rather than a serious adverse effect unless it is associated with lithium neurotoxicity. Tremor occurs with therapeutic lithium levels but may be related to dosage and serum lithium concentrations. Lowering the concentration of lithium in serum within the therapeutic range can decrease the tremor and b-adrenergic receptor antagonists can reverse lithium-induced postural tremor. Tremor occurs as part of sedative-hypnotic withdrawal and may signal the impending onset of more serious and severe withdrawal reaction including seizures; thus tremor needs careful evaluation and treatment. The DSM-IV criteria for medication-induced postural tremor are listed in Table 31.4-6.

A. A fine postural tremor that has developed in association with the use of a medication (e.g., lithium, antidepressants, valproic acid).
B. The tremor (i.e., a regular, rhythmic oscillation of the limbs, head, mouth, or tongue) has a frequency between 8 and 12 cycles per second.
C. The symptoms are not due to a preexisting nonpharmacologically induced tremor. Evidence that the symptoms are due to a preexisting tremor might include the following: the tremor was present before the introduction of the medication, the tremor does not correlate with serum levels of the medication, and the tremor persists after discontinuation of the medication.
D. The symptoms are not better accounted for by neuroleptic-induced parkinsonism.

Table 31.4-6 DSM-IV Research Criteria for Medication-Induced Postural Tremor

MEDICATION-INDUCED MOVEMENT DISORDER NOT OTHERWISE SPECIFIED

A variety of medications other than neuroleptic agents have been associated with movement disorders that do not meet the criteria for any of the specific disorders listed in DSM-IV (Table 31.4-7). These medications include anticholinergic drugs; antihistaminic drugs; lithium; monamine oxidase inhibitors; oral contraceptives; phenytoin and other anticonvulsants (when toxicity presents); reserpine (Diupres, Serpasil); tetrabenazine; tricyclic drugs; and dopamine agonists such as apomorphine, bromocriptine, or levodopa.

This category is for medication-induced movement disorders not classified by any of the specific disorders listed above. Examples include: (1) parkinsonism, acute akathisia, acute dystonia, or dyskinetic movement that is associated with a medication other than a neuroleptic; (2) a presentation that resembles neuroleptic malignant syndrome that is associated with a medication other than a neuroleptic; or (3) tardive dystonia.

Table 31.4-7 DSM-IV Diagnostic Criteria for Medication-Induced Movement Disorder Not Otherwise Specified

An akathisia-like syndrome associated with abrupt withdrawal of imipramine (Tofranil) has been reported. Dyskinetic movements were attributed to the anticholinergic action from long-term treatment with tricyclic drugs in a few cases. Although no definite association between selective serotonin reuptake inhibitors (SSRIs) and extrapyramidal adverse effects has been established, reports have described their association. The most common adverse effect is akathisia, followed by dystonia, parkinsonism, and tardive dyskinesia–like states.

DSM-IV lists tardive dyskinesia as a distinct diagnostic entity but only mentions one other tardive condition (tardive dystonia) under medication–induced movement disorder not otherwise specified. Other tardive conditions, so-called tardive syndrome, have been proposed and include many subtypes: tardive dystonia, tardive akathisia, tardive Tourette's syndrome, tardive myoclonus, tardive parkinsonism. Also, there are four proposed subtypes of severe tardive dyskinesia: tardive dystonia, blepharospasm, choreoathetosis, and tardive akathisia.

Tardive dystonia is a late-onset (frequently of earlier onset than other tardive conditions), persistent dystonia associated with neuroleptic treatment, which usually affects younger male patients. It commonly involves the muscles of the neck, shoulders, and trunk, causing opisthotonos. It is characterized by sustained abnormal posture with torticollis (abnormal position of the head caused by spasmodic contraction of neck muscles), hemiballismus (jerking and twitching movements of one side of the body), truncal torsion (twisting of the trunk of the body (e.g., Pisa syndrome caused by flexion of the trunk to one side accompanied by slight backward rotation), blepharospasm (twitching or spasmodic contraction of muscles of the eyelids), and grimacing (distortion of the face). The prevalence is given as 1 to 2 percent. As with tardive dyskinesia, there is no effective treatment for this sometimes incapacitating condition. In contrast to tardive dyskinesia, increasing the dosage of neuroleptic drugs may not suppress the dystonic movements; anticholinergic agents in high dosages and tetrabenazine may be helpful. Only few of the reported patients in the literature achieved full recovery. Injection of botulinum toxoid every few months is frequently helpful for severe eye blinking and even when larger muscles are affected.

Tardive Tourette's syndrome appears either during neuroleptic treatment or following discontinuation of treatment. It can usually be suppressed by increasing neuroleptic doses and is worsened by neuroleptic withdrawal. There is clear need for further study to gain more understanding about these tardive conditions.

ADVERSE EFFECTS OF MEDICATION NOT OTHERWISE SPECIFIED

This category allows clinicians to record the adverse effects of medications, other than movement symptoms, that become a focus of treatment (Table 31.4-8). Examples of such adverse effects include priapism, severe hypotension, and cardiac abnormalities.

This category is available for optional use by clinicians to code side effects of medication (other than movement symptoms) when these adverse effects become a main focus of clinical attention. Examples include severe hypotension, cardiac arrhythmias, and priapism.

Table 31.4-8 DSM-IV Diagnostic Criteria for Adverse Effects of Medication Not Otherwise Specified

FUTURE DIRECTIONS

Because no adverse effect–free psychotropic medication is available, clinicians must follow the basic principles of rational psychopharmacotherapy (viz., to maximize the therapeutic effects and minimize the adverse effects). Higher dosages lead to more adverse effects but do not necessarily lead to more therapeutic effects. Therefore, the general recommendation is to use the lowest possible amount of neuroleptic drug necessary to produce clinically desirable benefits and at the same time lower the risk of extrapyramidal adverse effects and tardive dyskinesia. However, there is still a need to define how low a dosage should be to effectively treat active psychopathology and to minimize the risks of relapse in maintenance treatment. Meantime, the effort to develop new neuroleptic drugs that are therapeutically equal but carry low or no risk of causing these adverse effects is encouraging and exciting. These so-called atypical agents will inevitably replace typical neuroleptic drugs for the treatment of psychotic state.

SUGGESTED CROSS-REFERENCES

Neuroleptics are discussed in Chapter 31, dopamine antagonists other than neuroleptics are discussed in Section 31.17, lithium is discussed in Section 31.18, b-adrenergic receptor antagonists are discussed in Section 31.5, and cholinesterase inhibitors are discussed in Section 31.15.

31.5 b-ADRENERGIC RECEPTOR ANTAGONISTS

GEORGE M. SIMPSON, M.D., AND CALVIN J. FLOWERS, M.D.

HISTORY

Most organs in the body are controlled to some extent by the two types of adrenergic receptors (a and b). The b-adrenergic receptors are further subdivided into b1 and b2, based on target tissue effects. Both selective and nonselective antagonists of b-receptors have been developed and are used to control hypertension, cardiac arrhythmias, hyperthyroidism, glaucoma, and tremor; for migraine prophylaxis; and for various neuropsychiatric purposes. The first b-adrenergic receptor antagonist (beta-blocker) was dichlorisoproterenol, which was abandoned because of partial agonist properties, which at the time were thought to be clinically unacceptable. This was followed by pronethalol, which produced thymic tumors and was discarded but prompted the discovery of propranolol (Inderal) the prototype b-adrenergic receptor antagonist. The most common b-adrenergic receptor antagonists used in psychiatry are propranolol, nadolol (Corgard), pindolol (Visken), labetalol (Normodyne, Trandate), metoprolol (Lopressor, Toprol), atenolol (Tenormin), and acebutolol (Sectral), though a multitude of others exist and theoretically could be used.

CHEMISTRY

Non-Subtype-Selective b-Adrenergic Antagonists Propranolol is chemically described as 1-(isopropylamino)-3-(1-naphthyloxy)-2-propanol hydrochloride; its molecular structure is shown in Figure 31.5-1. Propranolol hydrochloride is a stable, white, crystalline solid that is readily soluble in water and ethanol. Its molecular weight is 295.81.

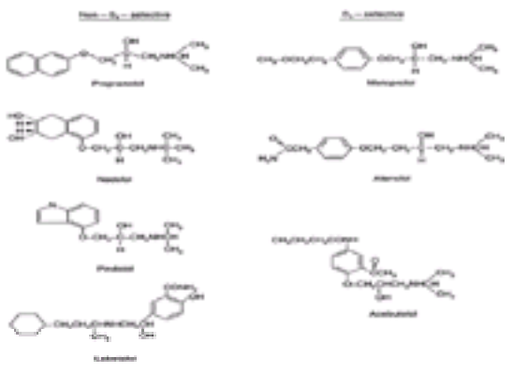

FIGURE 31.5-1 Molecular structures of b-adrenergic receptor antagonist.

Nadolol is chemically designated 1-(*tert*-butylamino)-3-[(5,6,7,8-tetrahydro-*cis*-6,7-dihydroxy-1-naphthyl)oxy]-2-propanol. Its molecular structure is shown in Figure 31.5-1. The molecular weight is 309.40. Nadolol is a white crystalline powder. It is freely soluble in ethanol, soluble in hydrochloric acid, slightly soluble in water and in chloroform, and very slightly soluble in sodium hydroxide.

Pindolol is chemically described as 1-(indol-4-yloxy)-3-(isopropylamino)-2-propanol. Pindolol is a white to off-white odorless powder soluble in organic solvents and aqueous acids. Its structural formula is shown in Figure 31.5-1. Its molecular weight is 248.33.

Labetalol is chemically designated 5-[1-hydroxy-2-[(1-methyl-3-phenylpropyl)amino]ethyl]salicylamide monohydrochloride. Labetalol HCl has the empirical formula $C_{19}H_{24}N_2O_3$.HCl and a molecular weight of 364.9. It has two asymmetrical centers and therefore exists as a molecular complex of two diasteroeisomeric pairs. Dilevalol, the *R,R*' stereoisomer, makes up 25 percent of racemic labetalol. Labetalol is a white or off-white crystalline powder, soluble in water. The molecular structure is shown in Figure 31.5-1.

Subtype-Selective b-Adrenergic Antagonists Metoprolol is chemically described as 1-(isopropylamino)-3-[*p*-(2-methoxyethyl)phenoxy]-2-propanol (2:1) *dextro*-tartrate salt. Metoprolol is a white, practically odorless, crystalline powder with a molecular weight of 684.82. It is very soluble in water; freely soluble in methylene chloride, in chloroform, and in alcohol; slightly soluble in acetone; and insoluble in ether. The molecular structure is shown in Figure 31.5-1.

Atenolol is chemically described as benzeneacetamide, 4-[2'-hydroxy-3'-[(1-methylethyl)amino]propoxy]. The molecular formula is $C_{14}H_{22}N_2O_3$, and the structural formula is shown in Figure 31.5-1. Atenolol (free base) has a molecular weight of 266. It is a relatively polar hydrophilic compound with a water solubility of 26.5 mg/mL at 37°C and a log partition coefficient (octanol/water) of 0.23. It is freely soluble in 1N HCl (300 mg/mL at 25°C).

Acebutolol has the molecular formula $C_{18}H_{28}N_2O_4$·HCl. Its molecular weight is 372.9. Acebutolol HCl is a white or slightly off-white powder freely soluble in water and less soluble in alcohol. Chemically it is defined as the hydrochloride salt of butanamide, *N*-[3-acetyl-4-[2-hydroxy-3-[(1-methylethyl)amino]propoxy]phenyl], (+/–)- or (+/–)-3'acetyl-4'-[2-hydroxy-3-(isopropylamino)propoxy]butyranilide.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption After oral administration, propranolol, pindolol, labetalol, acebutolol, and metoprolol are almost completely absorbed from the gastrointestinal tract. Nadolol and atenolol are incompletely absorbed. The general pharmacological properties of commonly used b-adrenergic receptor antagonists are given in Table 31.5-1.

	Selectivity	Lipid Solubility	Half-Life (hr)	Bioavailability (%)
Propranolol	No	High	3–6	30
Nadolol	No	Low	14–24	35
Pindolol	No	Moderate	3–4	80
Labetalol	No	Moderate	4–6	30
Metoprolol	Yes	High	3–4	50
Atenolol	Yes	Low	5–8	40
Acebutolol	Yes	Low	3–4	50

Table 31.5-1 Pharmacological Characteristics of b-Adrenergic Receptor Antagonists

Distribution The b-adrenergic receptor antagonists have markedly different lipophilic properties. The least lipophilic of them, nadolol and atenolol, cross the blood-brain barrier poorly and thus have a higher ratio of peripheral to central effects. The highly lipophilic b-adrenergic receptor antagonists, propranolol and metoprolol, have potent central and peripheral effects. The others have intermediate lipophilic properties and a more balanced central and peripheral effect. Certain b-adrenergic receptor antagonists (e.g., pindolol), have intrinsic sympathomimetic effects as a result of their partial agonist properties. Most b-adrenergic receptor antagonists with the exception of nadolol and atenolol, are extensively metabolized in the liver, with only 25 to 45 percent reaching the systemic circulation. Nadolol and atenolol are not extensively metabolized and are excreted largely unchanged in the urine. All currently available b-adrenergic receptor antagonists are excreted in breast milk and should be administered with caution to nursing women.

Metabolism The elimination of b-adrenergic receptor antagonists from the body is quite variable. Nadolol and atenolol have relatively long half-lives, which allows once-a-day dosing. The other b-adrenergic receptor antagonists have shorter half-lives and require multiple daily dosing, with the exception of propranolol and metoprolol, which are available in long-acting forms. Table 31.5-2 presents the half-lives of commonly used b-blockers.

Definitely effective
Performance anxiety
Lithium-induced tremor
Neuroleptic-induced akathisia
Probably effective
Adjunctive therapy for alcohol withdrawal and other substance-related disorders
Adjunctive therapy for aggressive or violent behavior
Possibly effective
Antipsychotic augmentation
Antidepressant augmentation

Table 31.5-2 Psychiatric Uses for b-Adrenergic Receptor Antagonists

Pharmacodynamics

Mechanism of Action The neurotransmitters norepinephrine and epinephrine share two different types of adrenergic receptors called a and b. a-Receptors are divided into type 1 and type 2. Type 1 a (a_1)-receptors are located postsynaptically and produce vasoconstriction, whereas a_2-receptors are generally presynaptic inhibitory autoreceptors. There are three types of postsynaptic b receptors. b_1-activation produces increased heart rate, force of contraction and conduction; b_2-receptors cause bronchodilation. The exact function of b_3-receptors is unclear.

In the central nervous system, the major noradrenergic nucleus is in the locus ceruleus, located in the dorsal pons. The noradrenergic neurons in the brain are responsible for central regulation of the sympathetic nervous system, modulation of pain, and hormone release. b-adrenergic receptor antagonists produce their effects by competitive inhibition of the b-receptors, thus they interfere with, or block, the effect of natural agonists.

Blood Concentrations and Relation to Action The high individual variation in b-adrenergic receptor antagonists concentration is a function of many factors including extent of hepatic metabolism, coadministered medications, food ingestion, and length of therapy. The lower lipophilic nature of nadolol and atenolol, with their lower hepatic clearance results in reduced interindividual variation. There currently is no application in psychiatry for the use of plasma concentrations of b-adrenergic receptor antagonists.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

b-Adrenergic receptor antagonists have been used to treat a variety of psychiatric conditions (Table 31.5-2). There have been reported studies of their effective use in anxiety disorder, panic attacks, alcohol withdrawal, aggression, and neuroleptic-induced akathisia.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

b-Adrenergic receptor antagonists generally have minimal effects on healthy individuals when taken at doses commonly used in psychiatry. They do have a marked blood pressure–lowering effect in patients with hypertension. Likewise, patients with airway disease may experience severe bronchoconstriction. b-adrenergic receptor antagonists also affect carbohydrate metabolism.

THERAPEUTIC INDICATIONS

Neuroleptic-Induced Akathisia Akathisia produced by neuroleptic agents is a common, distressing adverse effect that has significant implications for treatment. It is most commonly described as an objective and subjective restlessness that occurs to some degree in a large proportion of patients treated with neuroleptics. It is often underdiagnosed and not treated or misdiagnosed and inappropriately treated as increased psychosis. Of the various agents used to treat this condition, the b-adrenergic blocking drugs are the best studied and generally accepted. Propranolol is the prototype agent and was first used for this purpose in the early 1980s. In case studies and both open-label and controlled trials, propranolol has produced fairly rapid, well-tolerated relief from akathisia induced by neuroleptics. In several randomized, double-blind studies propranolol yielded significant decreases in subjective and objective akathisia compared with placebo, anticholinergics, and benzodiazepines. Generally low doses of propranolol are effective, usually less than 100 mg per day, in divided doses. The effectiveness of propranolol in treating neuroleptic-induced akathisia, prompted considerable interest in other b-adrenergic receptor antagonists as antiakathisia agents to determine whether the lipophilic properties and subtype-selective properties produced any differential efficacy. The question has not been clearly answered, but results thus far indicate a trend toward greater efficacy with lipophilic agents, probably indicating a central cause for neuroleptic-induced akathisia. The results of nonselective versus selective b-adrenergic receptor antagonists in treating neuroleptic-induced akathisia are mixed, with studies reporting effectiveness with members of each group.

Lithium-Induced Tremor Lithium-induced tremor occurs in most patients taking lithium (Eskalith). It is more common in men than women and occurs early in lithium therapy and in patients taking multiple other psychotropic medications. It presents as a fine, 5 to 12 cycles-a-second action tremor, but may occur at rest. b-adrenergic receptor antagonists are effective in controlling lithium-induced tremor; however, other pharmacological strategies must always be attempted first, including using the lowest therapeutically effective dose, reducing consumption of agents such as caffeine that worsen tremor, and trials of bedtime-dosing strategies. Once these

attempts have failed, administering b-adrenergic receptor antagonists is usually effective both subjectively and objectively. No well-controlled, head-to-head trials exist regarding differential effectiveness of b-adrenergic receptor antagonists. However, low-dose propranolol is well established, and several case series describe adequate control of lithium-induced tremor with atenolol and metoprolol in patients with asthma.

Anxiety Disorders (Performance Anxiety, Panic Disorder, Social Phobia, Posttraumatic Stress Disorder, Generalized Anxiety Disorder Not long after their development, b-adrenergic receptor antagonists were shown to possess anxiolytic properties in patients treated for cardiac dysfunction. This led to multiple comparisons with other anxiolytics including benzodiazepines for the treatment of different anxiety syndromes. Early studies focused on acute stress reactions such as performance anxiety, with claims for their effectiveness in nervous musicians and in subjects with excess anxiety before public speaking. Studies show improved performance on test scores of students taking 40 mg of propranolol prior to the examination. The logical extension of this research was the use of b-adrenergic receptor antagonists in patients with panic disorder. Unfortunately results have been inconsistent, and comparisons with benzodiazepines reveal the latter to be generally more effective. A limited number of studies indicate that atenolol and propranolol decrease some of the somatic symptoms of social phobia and generalized anxiety disorder. Two uncontrolled studies exist of b-adrenergic receptor antagonists in patients with posttraumatic stress disorder, one in war veterans and one in childhood sexual abuse victims; both showed propranolol effective in reducing symptoms, but more studies are needed.

Substance-Related Disorders Because b-receptor antagonism tends to reduce some of the withdrawal symptoms of alcohol and benzodiazepines such as tachycardia, hypertension, and tremor, their use in these syndromes continues to be investigated. b-Adrenergic receptor antagonists will not prevent or treat all alcohol withdrawal symptoms, especially delirium. Their main function is as an adjunct to benzodiazepines, to relieve the somatic sympathetic symptoms of sedative-hypnotic withdrawal. Several small, open-label studies found propranolol helpful in opioid and nicotine withdrawal. Some evidence indicates that b-adrenergic receptor antagonists may help reduce opioid craving in heroin users.

Aggressive or Violent Behavior b-Adrenergic receptor antagonists have gained considerable acceptance as adjunctive pharmacotherapy for patients with behavioral syndromes, including aggression, agitation, and violent outbursts. Most studies have included patients with a number of associated neuropsychiatric conditions (e.g., dementia, traumatic brain injuries, severe developmental disorders, and other brain syndromes). Generally, propranolol has been effective in case series and in open trials; large double-blind controlled studies are rare. Furthermore, in several studies patients received multiple other psychotropic medications in addition to b-adrenergic receptor antagonists, which makes it difficult to draw conclusions. b-Adrenergic receptor antagonists do possess serotonergic properties, and decreased central serotonin concentrations have been associated with increased aggressive and impulsive behavior; this may explain their effectiveness. Most studies indicate that high dosages of propranolol (up to 500 mg per day or more) decrease the frequency and intensity of violent behavior syndromes.

Communication Disorders (Stuttering) Stuttering is a speech disorder that has been attributed to many different causes, including incomplete language lateralization and conflicting cerebral dominance. It is also an uncommon adverse effect of antidepressant and antipsychotic medication. Whatever the cause, it clearly worsens during periods of anxiety. Several recent case reports describe improvement in stuttering with b-adrenergic receptor antagonists and while controlled trials are needed, low-dose propranolol may be a useful adjunct to speech therapy.

Antidepressant Augmentation Recently interest has developed in the use of b-adrenergic receptor antagonists in antidepressant augmentation or adjunctive therapy strategies. The rationale for this involves the ability of many b-adrenergic receptor antagonists to inhibit the serotonin (5-hydroxytryptamine [5-HT]) subtype 1A (5-HT_{1A}) presynaptic receptors. Several case reports and open-label trials have shown pindolol to be safe and effective in combination with selective serotonin reuptake inhibitors (SSRIs) and moclobemide (Aurorix) in untreated depressed patients and treatment-resistant patients. A recent double-blind, controlled trial of fluoxetine (Prozac) plus pindolol or placebo failed to detect any differential efficacy.

Antipsychotic Augmentation Beta-adrenergic receptor antagonists may produce some improvement in patients with agitated psychosis, but it is doubtful that this is an antipsychotic effect. Possibly concomitant use of b-adrenergic receptor antagonists and antipsychotics raises the antipsychotic concentration, which may explain the improvement in some studies of patients with schizophrenia. Studies comparing propranolol with chlorpromazine (Thorazine) in the treatment of schizophrenia have generally used subtherapeutic doses of neuroleptic.

PRECAUTIONS AND ADVERSE REACTIONS

The b-adrenergic receptor antagonists have a number of important adverse effects on different organ systems including cardiovascular (e.g., hypotension, bradycardia), respiratory (e.g., exacerbation of asthma), metabolic (e.g., exacerbation of diabetes), sexual dysfunction, neuropsychiatric (e.g., fatigue and irritability), and gastrointestinal (nausea and diarrhea). The adverse effects and toxicity of these drugs are summarized in Table 31.5-3.

Cardiovascular
Hypotension
Bradycardia
Dizziness
Congestive failure (in patients with compromised myocardial function)
Respiratory
Asthma (less risk with β_1-selective drugs)
Metabolic
Worsened hypoglycemia in diabetic patients on insulin or oral agents
Gastrointestinal
Nausea
Diarrhea
Abdominal pain
Sexual Function
Impotence
Neuropsychiatric
Lassitude
Fatigue
Dysphoria
Insomnia
Vivid nightmares
Depression (!)
Psychosis (rare)
Other (rare)
Raynaud's phenomenon
Peyronie's disease
Withdrawal syndrome
Rebound worsening of preexisting angina pectoris when β-adrenergic receptor antagonists are discontinued

Table 31.5-3 Adverse Effects and Toxicity of b-Adrenergic Receptor Antagonists

Historically the possible link between the use of b-adrenergic receptor antagonists and the development of depression has been quite controversial. While it is difficult to completely rule out, a recent large retrospective study provided little evidence to support a causal association between administration of b-adrenergic receptor antagonists and the development of depressive symptoms.

Much of the caution in b-adrenergic receptor antagonist use centers around their possible exacerbation of two conditions: asthma and chronic obstructive pulmonary disease. In both cases, this is a function of b_2-adrenergic receptor antagonism causing bronchial smooth muscle contraction and increased airway resistance. In patients with no history of pulmonary disease b_2-receptor blockade has little influence on pulmonary function. The newer subtype-selective b-adrenergic receptor antagonists theoretically provide some safety margin, but at higher dosages, subtype-selective agents become increasingly nonselective. Since b-adrenergic receptor antagonists tend to interfere with the peripheral manifestations of hypoglycemia they must be used with caution in diabetic patients prone to low blood glucose concentrations. As with any medication administered to pregnant women, the potential benefits and risks to both mother and fetus need careful consideration. To date no adequate, well-controlled studies of b-adrenergic receptor antagonists in pregnant women exist. Some b-adrenergic receptor antagonists were toxic to embryos in animal studies at dosages much higher than the maximum human dosage. Most b-adrenergic receptor antagonists are excreted in human milk, and thus they should be used with caution in nursing mothers. The safety and effectiveness of these drugs in treating neuropsychiatric conditions in children and adolescents has not been established.

DRUG INTERACTIONS

Cholesterol-lowering agents such as cholestyramine (Questran) and colestipol (Colestid) decrease absorption of b-adrenergic receptor antagonists. Certain medications (e.g., phenytoin [Dilantin] and phenobarbital [Luminal]) induce the hepatic enzymes responsible for their biotransformation and lower the plasma level of b-adrenergic receptor antagonists, as does smoking. b-Adrenergic receptor antagonists reportedly increase theophylline concentration when administered concomitantly and may increase concentrations of certain antipsychotics and antidepressants. Combined use of b-adrenergic receptor antagonists and calcium channel blockers has an additive effect on cardiac conduction.

DOSAGE AND ADMINISTRATION

Propranolol is available in 10-, 20-, 40-, 60-, 80-, and 90-mg tablets and 4-, 8-, and 80-mg/mL solutions, as well as 60-, 80-, 120, and 160-mg sustained-release capsules. Nadolol is available in 20-, 40-, 80-, 120-, and 160-mg tablets. Pindolol has 5- and 10-mg tablets and labetalol comes in 100-, 200-, and 300-mg tablets. Metoprolol is available in both 50- and 100-mg tablets and 50-, 100-, and 200-mg sustained-release tablets. Atenolol is available in 25-, 50-, and 100-mg tablets, and acebutolol in 200- and 400-mg capsules. Atenolol, labetalol, metoprolol, and propranolol are also available in parenteral forms.

For the treatment of chronic disorders, propranolol treatment is usually initiated at 10 mg given orally three times a day or 20 mg given orally twice a day. The dosage can be raised by 20 to 30 mg a day until a therapeutic effect begins to emerge. The dosage should be leveled off at the appropriate range for the disorder under treatment. The treatment of aggressive behavior sometimes requires dosages up to 800 mg a day, and therapeutic effects may not be seen until the patient has been receiving the maximal dosage for 4 to 8 weeks. The patient's pulse and blood pressure should be taken regularly, and the drug should be withheld if the pulse is below 50 or the systolic blood pressure is below 90. The drug should also be temporarily withheld if the patient has severe dizziness, ataxia, or wheezing. Treatment with b-adrenergic antagonists should never be discontinued abruptly. Propranolol should be tapered at 60 mg a day until a dosage of 60 mg a day is reached, after which the drug should be tapered by 20 mg a day every 3 or 4 days.

Lithium can be associated with a tremor even when lithium concentrations are within normal therapeutic ranges. Propranolol (20 to 160 mg a day, two or three times a day) is effective treatment for lithium-induced tremor. Whether nonlipophilic, peripherally acting b-adrenergic antagonists are as effective as propranolol is controversial.

Some studies indicate that b-adrenergic antagonists are effective in treating the aggressiveness and violent behavior that can be associated with schizophrenia and organic mental diseases such as trauma, tumor, anoxic injury, encephalitis, alcoholism, and Huntington's disease. Most of the patients studied in the reports have not been responsive to antipsychotics, lithium, anticonvulsants, and benzodiazepines. Approximately 50 percent of the patients in the studies improved with b-adrenergic antagonist treatment. The range of propranolol dosages for aggression and violent behavior is from 50 to 960 mg a day. Two lipophilic, centrally acting drugs, pindolol and metoprolol, have also been used successfully for this indication in case reports and open trials.

Propranolol has been reported useful in reducing the peripheral manifestations of anxiety (e.g., tremor, tachycardia) associated with social phobia and the anxiety associated with performance, such as examinations and musical recitals. Propranolol (10 to 40 mg) taken 20 to 30 minutes before the performance is the usual dose.

Propranolol has been reported useful as an adjuvant to benzodiazepines but not as a sole agent in the treatment of alcohol withdrawal. One study used the following dose schedule: no propranolol for a pulse less than 50; 50 mg propranolol for a pulse between 50 and 79; 100 mg propranolol for a pulse of 80 or more. The patients who also received propanolol had less severe withdrawal symptoms, more stable vital signs, and a shorter hospital stay than patients who received only benzodiazepines.

SUGGESTED CROSS-REFERENCES

Dopamine antagonist treatment and complications are discussed in Section 32.15, treatment of lithium-induced adverse-effects are discussed in Section 32.16, and anticholinergics are discussed in Section 31.6.

31.6 ANTICHOLINERGICS AND AMANTADINE

JONATHAN M. MEYER, M.D., AND GEORGE M. SIMPSON, M.D.

HISTORY

Although the sedating effects of plants in the *Solanaceae* family were known for centuries, it was the vagolytic properties that prompted Jean-Martin Charcot to use these compounds therapeutically in Parkinson's disease, a disorder then ascribed to parasympathetic overactivity. Under his aegis, a treatise was published in 1867 documenting the effectiveness of belladonna alkaloids in Parkinson's disease, and these compounds continued as a mainstay of Parkinson's disease treatment until the development of levodopa (Larodopa) a century later. At present, anticholinergic medications are primarily used for the prophylaxis and treatment of extrapyramidal adverse effects induced by postsynaptic dopaminergic blockade from antipsychotic medications; however, the increasing use of serotonin-dopamine antagonists (atypical antipsychotics) and an appreciation of therapeutic efficacy with lower doses of dopamine receptor antagonists (typical antipsychotics) will undoubtedly contribute to a decline in their routine use for extrapyramidal adverse effect prophylaxis. Important issues in the prophylactic use of anticholinergics include low rates of acute dystonia in most patients, the negative impact on cognition and memory produced by anticholinergics, the relative risk of exacerbating and possibly producing tardive dyskinesia when anticholinergic use is associated with long-term neuroleptic treatment, and short-term risks of increased extrapyramidal adverse effects produced by abrupt withdrawal of anticholinergics during neuroleptic treatment. The available anticholinergic agents appear equally effective for the treatment of medication-induced dystonia, rabbit syndrome, and parkinsonism but less so for akathisia.

Amantadine (Symmetrel), initially marketed as an antiviral agent for the prophylaxis and treatment of influenza A, was fortuitously noted in 1969 to improve the symptoms of Parkinson's disease. While the mechanism of action is unclear, amantadine appears to act presynaptically, where it blocks reuptake and facilitates release of stored dopamine from terminals, and postsynaptically by direct agonism and receptor modulation. There is also pharmacologic evidence for noncompetitive antagonism of *N*-methyl-d-aspartate (NMDA) glutamate receptors. Amantadine largely lacks the cognitive impairment associated with anticholinergic administration and treats extrapyramidal effects effectively but has enjoyed only modest use in the United States.

CHEMISTRY

Selected anticholinergics are shown in Figure 31.6-1. The molecular structure of amantadine is shown in Figure 31.6-2. Benztropine (Cogentin), and trihexyphenidyl (Artane) are tertiary amines with significant muscarinic cholinergic blockade, but benztropine also possesses antihistaminic activity.

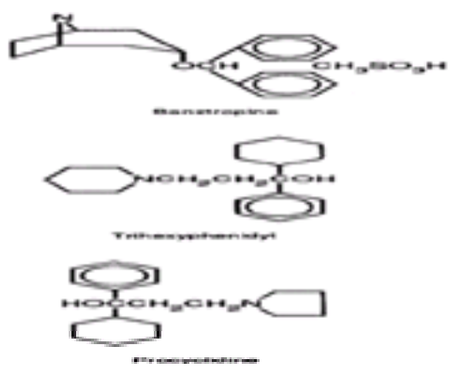

FIGURE 31.6-1 Molecular structures of selected anticholinergic drugs.

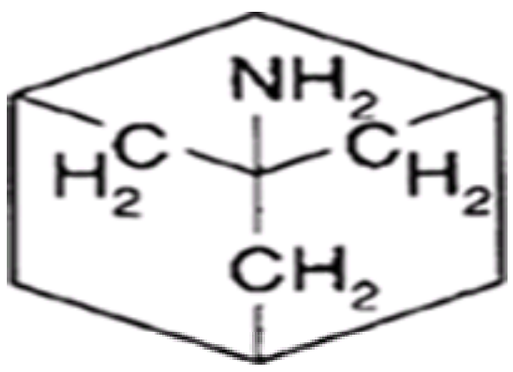

FIGURE 31.6-2 Molecular structure of amantadine.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Amantadine Amantadine is well absorbed after oral administration, with peak levels achieved 1 to 4 hours after ingestion. More than 90 percent of a single dose can be recovered unmetabolized in the urine. The plasma half-life is 12 to 18 hours in healthy young adults but sufficiently longer in those with renal impairment and elderly persons that a dose reduction of 50 percent in elderly adults will achieve adequate concentrations in serum. A dose of 100 mg twice a day yields peak concentrations in plasma of 0.5 to 0.8 μg/mL, and plasma trough levels of 0.3 μg/mL. Toxicity is seen at serum levels of 1.0 to 5.0 μ/mL and may be associated with delirium, hallucinations, seizures, or arrhythmias. The neurological symptoms of overdose have been reported to be reversible by physostigmine (Antilirium, Eserine). At low dosages, the side-effect profile is comparable to that of placebo, but continued usage has been occasionally associated with reversible effects on the cardiovascular system including livedo reticularis, peripheral edema, and orthostatic hypotension. Atropine-like adverse effects such as dry mouth, blurred vision, and palpitations have also been reported, usually at higher dosages.

Animal studies demonstrate evidence of teratogenicity but typically at doses many times the human dose, on a milligram per kilogram basis. There are a limited number of cases in the literature of in utero amantadine exposure during the first trimester. One woman used amantadine to prevent relapse of multiple sclerosis

throughout two of her pregnancies and delivered two normal infants, yet there is a report of a woman treated with amantadine in the first trimester who gave birth to an infant at 29 weeks gestation with tetralogy of Fallot and tibial hemimelia. Given the lack of extensive experience in pregnant women, this drug should be avoided in the first trimester unless the physician feels that the benefits to the mother outweigh the risks to both mother and fetus. Amantadine has a large volume of distribution and is found in breast milk and in nearly serum concentrations in saliva.

Anticholinergics The piperidine compound trihexyphenidyl, one of the first synthetic anticholinergic agents available, replaced the belladonna alkaloids for treatment of Parkinson's disease in the 1940s because of its more favorable adverse-effect profile. Biperiden (Akineton) is also in this class, along with procyclidine (Kemadrin) and cycrimine (Pagitane). The anticholinergic potency of trihexyphenidyl exceeds that of the antihistamines but is less than that of benztropine. It is considered the most stimulating anticholinergic agent and therefore has a concomitant higher risk of abuse than the antihistamines or benztropine. Trihexyphenidyl has good gastrointestinal absorption, achieving peak plasma concentration in 1 to 2 hours, with a serum half-life of approximately 10 to 12 hours, generally necessitating thrice-daily dosing to achieve satisfactory clinical results. The dosage range is 2 to 5 mg thrice daily.

For parenteral administration, diphenhydramine (Benadryl) and benztropine are most commonly used. Diphenhydramine is an antihistamine with sufficient anticholinergic properties to be useful for extrapyramidal adverse effect treatment. For intramuscular administration in patients with acute dystonia dosages of 25 to 50 mg are typically used. Benztropine was synthesized in the 1950s in an attempt to use the effective moieties of the belladonna alkaloids and the antihistamines. It thus combines a benzhydryl group with a tropine group to create a compound that is more anticholinergic than trihexyphenidyl but less antihistaminic than diphenhydramine. The clinical effect of a single dose appears to last 5 hours, thereby necessitating two or three daily doses. Dosing usually starts at 0.5 to 1 mg twice a day, with a daily maximum of 6 mg, although slightly higher dosages are used in rare circumstances. For treatment of acute dystonia intramuscular doses are 1 to 2 mg.

While no significant pharmacokinetic interactions exist between anticholinergics and other drugs, the studied effect on levodopa kinetics reveals some findings worth examining. In one group of six Parkinson's disease patients receiving levodopa with and without anticholinergic therapy, plasma levodopa kinetics were unchanged, but delayed absorption occurred in one patient, and reduced peak plasma concentrations in two. Impaired absorption of chlorpromazine (Thorazine) was reported in rats administered trihexyphenidyl. Presumably, reduced gastrointestinal motility caused these findings.

Pharmacodynamics Cholinergic receptors are divided into two broad classes: nicotinic and muscarinic, with the former located in striated muscle and autonomic ganglia. Muscarinic receptors are the primary type within the central nervous system (CNS) and are also present on smooth muscle, cardiac muscle, and other tissue with parasympathetic innervation. Five subtypes of muscarinic cholinergic receptors have been cloned (numbered M_1 through M_5), but only 4 distinct pharmacological types can be distinguished M_1, M_2, M_3 and M_4. All anticholinergic drugs used for treatment of extrapyramidal adverse effects are competitive muscarinic antagonists with good CNS penetration. Affinity studies using cloned human muscarinic receptors show little selectivity among the receptor subtypes for the commonly used anticholinergic agents (Table 31.6-1). The parasympatholytic activity of these drugs produces the systemic adverse effects such as dry mouth, cycloplegia, tachycardia, delayed gastrointestinal transit, and urinary hesitancy. Recent data demonstrate that benztropine may also produce its therapeutic effect by the inhibition of dopamine reuptake.

	M_1	M_2	M_3	M_4

Table 31.6-1 Relative Antagonism of Human Muscarinic Receptor Subtypes

The importance of central cholinergic activity in parkinsonism was clarified in 1967 by an investigator who demonstrated that peripherally acting agents (agonists and antagonists) had no effect on existing parkinsonism, while physostigmine-induced exacerbation of symptoms was reversible by centrally acting anticholinergics. A concept of cholinergic-dopaminergic balance within the basal ganglia has evolved in which a hypodopaminergic state from Parkinson's disease or neuroleptic use increases relative cholinergic activity. Cholinergic agonism alone does not suffice to produce extrapyramidal adverse effects; however, in the context of ongoing dopaminergic blockade, cholinergic rebound may result in extrapyramidal effects where none had previously existed. (Withdrawal phenomena are discussed below in the section on parkinsonism and long-term usage.)

The propensity of the various antipsychotics to cause extrapyramidal effects is due in part to differences in antagonism of type 2 dopamine (D_2) receptors and inherent anticholinergic activity. High-potency drugs such as haloperidol (Haldol) lack significant muscarinic antagonism and have increased liability to extrapyramidal effects, while thioridazine (Mellaril) and other low-potency antipsychotics are strongly anticholinergic with proportionally fewer extrapyramidal effects. Clozapine (Clozaril) and olanzapine (Zyprexa) are among the most anticholinergic antipsychotics, although their unique properties are felt in part to derive from low affinity for dopamine type 2 (D_2) receptors and significant serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT_2) antagonism. While published binding affinities indicate relative in vitro muscarinic activity, clinical pharmacological equivalence data yield different relative activities, which should be kept in mind when switching between various drugs (Table 31.6-2).

Drug	Pharmacological Equivalent

Table 31.6-2 Clinical Benztropine Equivalents (mG)

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Both anticholinergics and amantadine are effective for the prophylaxis and treatment of extrapyramidal adverse effects with the exception of tardive phenomena and akathisia. Akathisia does not respond robustly to these drugs, and other treatment strategies are required including the use of benzodiazepines or b-adrenergic receptor antagonists, dose reduction, or switching to a less potent or atypical antipsychotic. While they possess similar effectiveness, the difference in adverse effect profiles between anticholinergics and amantadine has been demonstrated in several studies. One of the few double-blind, controlled studies noted comparable efficacy between amantadine and benztropine in a group of 44 schizophrenic patients, regardless of extrapyramidal effect severity. While amantadine produced fewer adverse effects, benztropine produced a statistically significant improvement in rigidity. When amantadine or biperiden were blindly substituted for trihexyphenidyl in

one group of 26 chronic schizophrenics no differential effects were seen on parkinsonism or existing tardive dyskinesia severity. Studies in the Parkinson's disease population have also demonstrated comparable efficacy of amantadine and anticholinergic therapy in decreasing symptoms such as tremor, but a controlled 2-week trial comparing trihexyphenidyl and amantadine in Parkinson's disease patients with unilateral tremor revealed greater reduction in tremor amplitude with trihexyphenidyl.

Amantadine's general lack of significant anticholinergic adverse effects in therapeutic doses, especially on memory, constitutes its major advantage over anticholinergic agents for the treatment or prophylaxis of extrapyramidal effects. In one group of 26 schizophrenic patients, significantly worse visual recall was noted in those given biperiden, with poorer performance on all recall tests, but no memory effects were found among those on amantadine. This potential benefit is somewhat mitigated by clinical concerns that the dopaminomimetic properties may exacerbate underlying psychosis in some individuals. Although the aforementioned study revealed no exacerbation of positive symptoms among the amantadine patients, an open study of 30 patients with chronic schizophrenia described worsening of positive symptoms among the more severely ill patients after amantadine was substituted for benztropine.

Prophylaxis Studies The overuse of prophylactic anticholinergic medications has been the subject of numerous studies, prospective and retrospective. Recent prospective studies using lower doses of antipsychotics demonstrate a 20.9 to 33 percent incidence of acute dystonic reactions in patients receiving no prophylaxis (Table 31.6-3). With increased dosages of higher-potency antipsychotics, the incidence of dystonia rose to 47 percent. Regardless of antipsychotic dosage, over 90 percent of all dystonic reactions reported in various studies occur within the first 3 days of treatment. The trends toward higher incidence among younger patients and those of male sex was observed in most studies. In particular, one retrospective study revealed a markedly higher incidence of acute dystonia in the 10- to 19-year-old group (65 percent) than in 20- to 29-year-olds (46 percent) and 30- to 39-year-olds (32 percent). These combined data suggest that only when sufficient dosages (>12 mg a day of haloperidol or its equivalent) of high-potency antipsychotics are required in a group at high risk by age and sex should anticholinergic prophylaxis be entertained on a routine basis. The anticholinergic dosage should be tapered during the second week of treatment unless the emergence of further extrapyramidal effects warrants continuation.

Study	Treatment Group	N	Daily Dosage: Chlorpromazine Equivalent	Dystonia (%)

Table 31.6-3 Anticholinergic Prophylaxis Studies

A consensus statement of the World Health Organization (WHO) published in 1990 summarizes this position:

> On the basis of these considerations, the prophylactic use of anticholinergics in patients on neuroleptic treatment is not recommended, and may be justified only early in treatment (after which it should be discontinued and its need should be reevaluated). As a rule, these compounds should be used only when Parkinsonism has actually developed, and when other measures, such as the reduction on neuroleptic dosage or the substitution of the administered drug by another less prone to induce Parkinsonism, have proven ineffective.

Among the concerns addressed in the WHO consensus statement are the deleterious effects of anticholinergics on both cognition and the development of tardive dyskinesia. Several studies convincingly demonstrate the negative effects of various anticholinergic agents on the cognition of normal volunteers and individuals with schizophrenia. Among patients with schizophrenia, these deficits appear to be independent of neuroleptic dose, intelligence, or clinical status, and reliable improvement in memory occurs upon anticholinergic discontinuation. Whether anticholinergics play a causal role in the development of tardive dyskinesia is unclear, but their long-term use has been associated with an increased risk of tardive dyskinesia. One 7-year prospective trial of 50 patients maintained solely on depot neuroleptics noted a significant ($P < .01$) positive association between anticholinergic use and change in tardive dyskinesia rating.

THERAPEUTIC INDICATIONS

Dystonia While rarely a life-threatening event, development of an acute dystonic reaction can be a frightening, painful experience for the patient that potentially undermines future compliance. Dystonia can be caused by any agent with sufficient dopamine blockade, including low-potency drugs such as prochlorperazine (Compazine). Acute dystonia occurs in the early hours and days of treatment, more often with the administration of high-potency neuroleptics, in younger males, and especially during initial treatment in neuroleptic-naive subjects or after significant dosage increases. Dystonic symptoms may appear in a stuttering or discontinuous fashion, so a patient may complain of tongue thickness or deviation for a minute that resolves, only to later return. This picture often confuses clinicians and staff and may lead to an erroneous conclusion that the patient is malingering or fabricating symptoms. Similarly, anxiety can exacerbate movement disorders arising from the basal ganglia, so that reassurance or the administration of a benzodiazepine may significantly relieve milder dystonias, at times leading clinical staff to attribute the symptoms to other causes.

Depending on severity, benztropine (1 to 2 mg intramuscularly) or diphenhydramine (25 to 50 mg intramuscularly) are most commonly used. Clinical onset is relatively rapid, with full effect seen in 10 to 15 minutes. If symptoms persist, another dose may be administered at that time or sooner with severe reactions or rare instances of airway compromise. Some advocate the addition of small amounts of lorazepam (Ativan) (1 to 2 mg) for those requiring an additional parenteral dose; however, one must monitor the combined sedative effects of multiple drugs on respiration. When the dose of an antipsychotic is subsequently discontinued, significantly reduced, or switched to a low-potency or atypical neuroleptic, there may be no need to continue anticholinergic therapy. If the patient continues to receive the current dosage of neuroleptics, short-term prophylaxis against future episodes should be instituted with benztropine (1 to 2 mg orally twice a day), trihexyphenidyl (2 mg orally three times a day), or amantadine (100 mg orally twice a day).

Parkinsonism and Issues Regarding Long-Term Use The clinical syndrome of neuroleptic-induced parkinsonism is virtually identical to idiopathic Parkinson's disease. In its milder forms, however, it may be difficult to istinguish iatrogenic parkinsonism from the negative symptoms of schizophrenia. The clinician should routinely assess patients taking neuroleptics with a standardized rating scale sensitive to parkinsonism (e.g., the Simpson-Angus Neurological Rating Scale) and maintain a low threshold for treatment. Parkinsonism typically develops after 1 to 3 weeks of treatment and involves the classic symptoms of rigidity, tremor, and bradykinesia. Elderly adults are particularly prone to the parkinsonian effects of all dopamine receptor antagonists. Female sex and use of high-potency neuroleptics are also associated with higher risk for this complication. Clozapine does not induce parkinsonism and was the first drug of choice for the treatment of levodopa-induced psychosis in Parkinson's disease prior to the release of quetiapine. Clozapine's effect in this group is seen at very low dosages, in the range of 6.25 to 25 mg a day.

Once diagnosed, dose reduction is the first option, as parkinsonism responds slowly and at times incompletely to anticholinergics and amantadine. These drugs should be considered temporizing measures only, to alleviate symptoms while modifying the antipsychotic regimen. Elderly persons are particularly sensitive to the cognitive effects of anticholinergic medications, and these drugs should be avoided in this population. Amantadine treatment can be started at 100 mg twice a day and titrated upward over a period of days to a maximum of 400 mg a day as necessary. It is also available as a 50 mg/5 mL syrup to permit lower starting dosages in elderly patients or those with renal dysfunction. Any of the common antiparkinsonian medications may also be used, starting at the equivalent of 1 mg benztropine twice daily. If antipsychotic dose reduction is not possible or effective, one can switch to any of several available atypical antipsychotics that exert significantly less dopamine D_2 blockade.

Another important issue regarding continued treatment with combined anticholinergics and antipsychotics is the induction of cholinergic sensitivity induced by chronic muscarinic blockade. Schizophrenic patients maintained on anticholinergics have rates of extrapyramidal effects as high as 68 percent when these medications are

abruptly discontinued. These high rates of extrapyramidal adverse effects can be understood as the result of disturbed cholinergic-dopaminergic balance in the basal ganglia, which drives the system toward a hypodopaminergic state because of cholinergic overactivity. Even residual serum concentrations of competitive dopamine antagonists suffice to cause extrapyramidal effects in this context. This mechanism of withdrawal extrapyramidal adverse effects is illustrated by a study of individuals with chronic schizophrenia who were titrated on trifluoperazine (Stelazine) to produce a predefined level of extrapyramidal effects. No significant symptoms occurred upon abrupt withdrawal of trifluoperazine alone; however, patients subsequently given the same trifluoperazine dose plus benztropine for 4 weeks showed a marked increase in both extrapyramidal effects and other physical symptoms of cholinergic rebound when administration of both was abruptly discontinued. The availability of serotonin-dopamine antagonists with low D_2 binding should obviate the need for long-term combined anticholinergic-antipsychotic therapy in the near future. Patients currently on such regimens should be slowly tapered off the anticholinergic medication at a rate of 0.5 mg of benztropine equivalent per week. More-precipitant withdrawal may cause extrapyramidal effects, other physical symptoms, and possible exacerbation of underlying psychosis.

Akathisia Akathisia is a neuroleptic-induced syndrome of restlessness with both mental and physical components, associated with the use of antipsychotics and other drugs including serotonin reuptake inhibitors. These patients experience an intense subjective sense of anxiety that is extremely distressing. The complications of akathisia include noncompliance, frank agitation, and (rarely) suicidal ideation or behavior in an attempt to relieve the intense dysphoria that accompanies this feeling of restlessness. Akathisia must be sought when examining patients on neuroleptics for adverse effects, as behavioral manifestations may be subtle or absent in milder forms. Reliable, standardized akathisia scales are available to document the progress of interventions. While differentiating akathisia from anxiety due to underlying psychosis can be difficult, worsening after the administration of neuroleptics, particularly high-potency agents, should raise the level of suspicion. Among the antipsychotics, dopaminergic blockade is essential for development of akathisia, with an increased incidence noted when potent antipsychotics are used and near absence with clozapine administration. Nonetheless, anticholinergics and amantadine are only modestly successful in relieving akathisia, implying central mechanisms involving other subcortical structures and possibly spinal dopamine or norepinephrine systems.

For milder symptoms in relatively stable patients, anticholinergics alone can be used and are sometimes quite effective. Benzodiazepines and the more lipophilic b-adrenergic receptor antagonists have documented efficacy and should be used for more severe symptoms. Experience with amantadine in treating akathisia is limited. Once akathisia is diagnosed, dose reduction strategies should be used if possible, as symptoms may be ongoing. The experience with clozapine also points to favorable outcomes with serotonin-dopamine antagonists.

Direct Effects on Positive and Negative Symptoms Involvement of cholinergic mechanisms in the pathophysiology of schizophrenia has gained increasing popularity in recent years, especially in regard to clozapine's postulated mechanism of action. Interpretation of data from add-on studies is problematic, given the inherent difficulty in distinguishing the improvement in negative symptoms due to the anticholinergic medication from a decrease in parkinsonism. Attempts at antipsychotic-free trials have been performed with mixed results. In one double-blind, placebo-controlled crossover study of 17 stable outpatients with schizophrenia taking no antipsychotic medication for 2 months, no significant differences were noted in levels of psychosis, depression, Brief Psychiatric Rating Scale (BPRS) score, or negative symptoms after administration of trihexyphenidyl for 4 weeks. When 40 schizophrenic inpatients, medication-free for 2 weeks, were given 4 mg twice a day of biperiden for 2 days, investigators noted both an increase in positive symptoms ($P < .001$) and a decrease in negative symptoms ($P < .01$).

PRECAUTIONS AND ADVERSE REACTIONS

Mild systemic symptoms can be seen with therapeutic dosages of any anticholinergic medication, and the additive effects of various medications may give rise to symptoms of toxicity. Elderly persons are especially prone to develop memory impairment or frank delirium when using even modest dosages of drugs with anticholinergic properties. All such agents should be eschewed as much as possible in this age group. Urinary retention is a specific concern in older males. Care should also be exercised in patients with angle-closure glaucoma, those with known cognitive impairment, and those with poorly compensated heart disease who may not tolerate tachycardia.

Toxicity from accidental or intended overdose produces symptoms including tachycardia, dry mucosa and skin, and confusion or delirium, at times with hallucinations. When severe, the patient may be comatose with autonomic instability, cardiac arrhythmias, and a flushed appearance (“red as a beet”) with elevated body temperature. The latter is more common in the very young because of impaired cholinergic-mediated sweating. Anticholinergic overdose should always be treated in an emergency room setting where proper life support measures are available. Physostigmine, an acetylcholinesterase inhibitor with good CNS penetration, should be administered intravenously in doses of 0.5 to 2.0 mg in more serious cases. This medication must be given with continuous cardiac monitoring, as it may induce unstable cardiac rhythms. Parenterally administered physostigmine is metabolized within 2 hours, so repeat doses may be necessary.

Epidemiologically based estimates of anticholinergic abuse vary widely (1 to 17 percent), but certain patterns emerge from these data. In general, these agents are used for their direct euphoriant effects or to potentiate the effects of alcohol or psychoactive drugs. The more-stimulating anticholinergic trihexyphenidyl has the highest potential for abuse and can be purchased on the street. Some schizophrenic patients may misuse their anticholinergic medications because of the subjective feeling of improvement in negative symptoms at higher doses, although no euphoria is experienced. For this reason or possibly because of previous experiences with extrapyramidal effects weaning certain patients from their anticholinergic regimen is sometimes very difficult.

LABORATORY INTERFERENCES

The anticholinergic medications and amantadine are not known to affect directly the results of urinalysis, routine serum chemistries, or blood counts.

DOSAGE AND ADMINISTRATION

Amantadine is available as 100-mg capsules, typically initiated at 100 mg twice daily and titrated over several days to a maximum of 400 mg a day as necessary. The typical dosage is 100 mg thrice daily. For elderly persons or those with renal dysfunction, it is also available as a 50-mg/5-mL syrup to permit lower starting dosages. Table 31.6-4 outlines the dosage forms and average daily oral dosage for the common anticholinergic medications available in the United States.

Generic Name	Brand Name	Preparations	Daily Oral Dosage
Benztropine	Cogentin	Tablets: 0.5, 1.0, 2.0 mg Injection: 1 mg/mL	0.5–2.0 mg BID-TID
Biperiden	Akineton	Tablets: 2 mg Injection: 5 mg/mL	2 mg BID-QID
Trihexyphenidyl	Artane	Tablets: 2, 5 mg	2–5 mg TID
Diphenhydramine	Benadryl	Capsules: 25, 50 mg Injection: 25–50 mg/mL Elixir: 12.5 mg/5 mL	25–50 mg BID, 25 mg QID

Table 31.6-4 Anticholinergic Dosages and Preparations

Acute dystonic reactions require the use of a parenteral agent, with benztropine (1 to 2 mg intramuscularly) or diphenhydramine (25 to 50 mg intramuscularly or intravenously) being the drugs most readily available. For prophylaxis of extrapyramidal effects or treatment of parkinsonism, the lower dosage range is used to initiate therapy with all agents. Subsequent dosage is titrated on the basis of the tolerance of adverse effects or the emergence of extrapyramidal effects.

SUGGESTED CROSS-REFERENCES

Detailed information on medication-induced movement disorders can be found in Section 31.4. Further characteristics of dopamine receptor antagonists are extensively covered in Section 31.17. Section 31.15 on cholinesterase inhibitors provides interesting background on cholinergic pathways within the CNS.

31.7 ANTICONVULSANTS

31.7A CARBAMAZEPINE

CARLOS A. ZARATE, JR., M.D., AND MAURICIO TOHEN, M.D., DR.P.H.

Carbamazepine (Tegretol) is an iminostilbene drug with a chemical structure similar to that of the tricyclic drug imipramine (Tofranil). Carbamazepine was developed in the late 1950s in the laboratories of J. R. Geigy in Basel, Switzerland. Its antiepileptic properties were first reported in 1963. Carbamazepine was approved for use in the United States for the treatment of trigeminal neuralgia in March 1968 and for temporal lobe epilepsy in August 1974. Carbamazepine was first synthesized as a potential antidepressant but was later found to have a beneficial effect in the treatment of a variety of medical conditions, including seizure disorders and paroxysmal pain syndromes. Carbamazepine is particularly effective in the treatment of complex partial seizures and generalized seizures thought to arise from the temporal lobe and limbic systems. Additionally, carbamazepine has been increasingly recognized as an effective alternative to lithium (Eskalith, Lithobid) and valproate (Depakene) in the treatment of bipolar disorder.

CHEMISTRY

Carbamazepine's chemical name is 5-*H*-dibenz[*b,f*]azepine-5-carboxamide. When a carbamyl (carboxamide) group is added to the 5 position of iminodibenzyl, considerable antiepileptic activity is conferred. However, a more intense antiepileptic effect occurs when the carbamyl side chain is combined with iminostilbene to make carbamazepine; the structure is similar to that of iminodibenzyl except for a double bond between the 10 and 11 positions (Fig. 31.7a-1). Carbamazepine is oxidized by cytochrome P450 oxidase to an active 10,11-epoxide metabolite that possesses both anticonvulsant and antinociceptive properties. The epoxide is further hydrolyzed to a dihydroxy compound that is inactive. A congener of carbamazepine includes a keto compound called oxcarbazepine, which also has anticonvulsant and antinociceptic properties. Carbamazepine is highly insoluble in water and is difficult to dissolve in most preparations. Because of its insolubility, no intravenous formulation is available for human use.

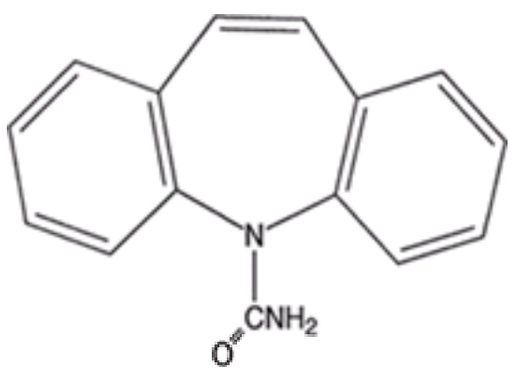

FIGURE 31.7a-1 Molecular structure of carbamazepine.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption Carbamazepine is absorbed slowly and erratically through the gastrointestinal tract. Peak plasma concentrations are generally attained 2 to 8 hours after oral ingestion. However, the suspension is absorbed somewhat faster, and the carbamazepine extended-release (Tegretol-XR) tablet slightly slower, than the conventional tablet. Following a twice-a-day dosage regimen, the suspension provides higher peak concentrations and lower trough concentrations than those obtained with conventional tablets. Carbamazepine extended-release tablets offer the advantage of providing steady-state plasma concentrations comparable to those obtained with conventional carbamazepine tablets given four times a day. Carbamazepine distributes rapidly into all tissues, with 70 to 80 percent bound to plasma proteins. Concentrations of carbamazepine in cerebrospinal fluid correspond with concentrations of free drug in plasma and range from 17 to 31 percent of those in plasma. The average half-life after a single dose is 26 hours (18 to 54 hours), but with long-term treatment, carbamazepine may induce its own metabolism (a phenomenon called autoinduction), and its half-life may be decreased to 5 to 26 hours. Carbamazepine's irregular absorption has been attributed to the anticholinergic properties of the drug modifying gastrointestinal transit time and to a very slow dissolution rate in gastrointestinal fluid.

Elimination Carbamazepine is metabolized in the liver, mainly by the microsomal cytochrome P450, and excreted by the kidneys. Only 1 percent is eliminated by biliary excretion. The predominant pathway of metabolism in humans involves conversion to the 10,11-epoxide by the cytochrome P450 (CYP) isozyme 3A4 (CYP 3A4). This metabolite is as active as carbamazepine and has neurotoxic effects. Its concentrations in plasma and brain may reach 50 percent of those of carbamazepine. The keto derivative of carbamazepine, oxcarbazepine, is metabolized only minimally by CYP 3A4, so that autoinduction and heteroinduction are less clinically problematic than with carbamazepine. The half-life of the 10,11-epoxide is much shorter than that of the parent compound (6 to 7 hours). Its metabolism results in the inactive monohydroxy derivative rather than the active metabolite of carbamazepine. After oral administration of [^{14}C]-carbamazepine, 72 percent of the administered radioactivity was found in the urine and 28 percent in the feces. The urinary radioactivity was composed largely of hydroxylated and conjugated metabolites, with only 3 percent of unchanged carbamazepine. Younger age groups (below the age of 15) metabolize carbamazepine to carbamazepine 10,11-epoxide more rapidly than adults. The effects of race and sex on the pharmacokinetics of carbamazepine have not been systematically studied.

Pharmacodynamics

Mechanism of Action Despite the widespread clinical use of carbamazepine, the molecular mechanisms underlying both its anticonvulsant and mood-stabilizing effects have not been identified. Carbamazepine's antiepileptic action is believed to occur by two basic mechanisms: (1) effects on neuronal ion channels, and (2) effects on synaptic and signal transduction pathways. The first mechanism has been attributed to either its ability to reduce high-frequency neuronal discharge by binding and inactivating voltage-sensitive sodium channels and decreasing sodium influx, or its effect on potassium channels to increase potassium conductance, or both. However, because carbamazepine's effects on sodium channels are acute, and because its antiepileptic and antinociceptic effects are more rapid in onset than its antimanic or antidepressant effects, some authors have speculated that the drug's sodium channel effects do not account for its mood-stabilizing properties.

The anticonvulsant effects of carbamazepine on amygdala-kindled seizures have been attributed to its ability to decrease release of the excitatory amino acid aspartate and its effects on a_2-adrenergic receptors. Also, it has been suggested that carbamazepine's antiepileptic actions result from its acute binding and antagonistic action at the peripheral-type benzodiazepine receptors rather than central-type benzodiazepine receptors, (which are linked to chloride channels and related to the antiepileptic effects of diazepam [Valium], clonazepam [Klenopin], and lorazepam [Ativan]. The anticonvulsant actions of carbamazepine have also been

linked to a variety of other neurotransmitter systems including complex effects on norepinephrine and decreases in g-aminobutyric acid (GABA) turnover as well as an ability to decrease calcium influx through *N*-methyl-d-aspartate (NMDA) receptors. A recent study failed to find that the inhibition of glutamate release was responsible for carbamazepine's antiepileptic action.

The antinociceptive effects of carbamazepine have been linked to its effects on the type B ($GABA_B$) receptors, as the antinociceptive effects of both carbamazepine and baclofen (Lioresal) are inhibited by $GABA_5$ antagonists.

Long-term administration of carbamazepine is associated with increases in adenosine receptors, substance P levels, and sensitivity; decreased somatostatin concentration in the cerebrospinal fluid; and greater decreases in GABA turnover. Other actions reported to occur with carbamazepine include complex effects on second messenger systems such as decreased activity of both basal cyclic adenosine monophosphate (cAMP) and forskolin-stimulated cAMP production. It appears that the action of carbamazepine on cAMP is likely mediated through an inhibitory G-independent protein mechanism. To date, the data suggest that carbamazepine inhibits cAMP production by acting directly on adenylyl cyclase, through factors that are associated with adenylyl cyclase, or both. In addition, carbamazepine decreases some aspects of phosphoinositide turnover that are not dissimilar from those of lithium carbonate. Carbamazepine has been reported to stimulate, not inhibit, inositol monophosphatase.

The antimanic effects of carbamazepine show a lag in onset. Carbamazepine has been shown to attenuate forskolin-induced c-*fos* (an immediate-early gene). c-*fos* and other immediate-early genes are known to be involved in a number of long-term neuronal responses. Thus, the inhibitory effects of carbamazepine on adenylyl cyclase can potentially bring about long-term changes in gene expression and thereby regulate cellular function. This may explain in part the lag in carbamazepine's antimanic effects. Recent studies have attributed the efficacy of mood stabilizers to a protein kinase substrate, the myristoylated alanine-rich C kinase substrate (MARCKS) protein. MARCKS binds calmodulin, which has been implicated in cellular processes associated with cytoskeletal restructuring and neuroplasticity. While lithium and valproate have been found to produce a significant time-dependent downregulation of MARCKS expression, carbamazepine has not. These data suggest that the mechanism mediating the clinical efficacy of carbamazepine in the treatment of mania may be independent of that of lithium and valproate.

None of these mechanisms have been definitely linked with the psychotropic effects of carbamazepine, and it remains unknown whether the actions underlying the drug's antiepileptic effects are also responsible for its mood-stabilizing properties.

CLINICAL DRUG STUDIES

Bipolar Disorder

Manic Episodes Over a dozen double-blind studies comparing carbamazepine with a placebo, with lithium, or with antipsychotic agents have been published. Most studies indicate positive antimanic effects for carbamazepine and find it superior to placebo and comparable to lithium and antipsychotic agents for the treatment of acute mania, with approximately two-thirds of patients showing improvement. However, only a few of these studies are unconfounded by concomitant medications. Pooled results from these latter studies reveal an overall response rate for carbamazepine in manic episodes of 50 percent, compared with 56 percent for lithium monotherapy and 61 percent for dopamine receptor antagonist monotherapy (differences not significant). Its antimanic effects may be augmented by, or synergistic with concurrent administration of other mood-stabilizing agents (i.e., lithium and valproate) and dopamine receptor antagonists.

Bipolar Depression Only three controlled studies have found carbamazepine effective for the depressive episodes in bipolar disorders, the response rate approximating 30 percent. Some studies have reported that its antidepressant effects may be augmented by concurrent administration of lithium. Factors suggesting a positive antidepressant response to carbamazepine during the depressed phase of bipolar I disorder include a greater thyroid hormone decrement thyroxine [T_4] or free T_4).

Prophylaxis Several controlled long-term prophylaxis studies suggest that carbamazepine is effective in preventing the recurrences of both manic and depressive episodes. A meta-analysis of eight randomized double-blind studies that compared carbamazepine with lithium for the maintenance treatment of bipolar I disorder found both drugs to be comparable in reducing relapses and prolonging euthymic intervals over an average of 1.7 years of treatment. Also, carbamazepine's mood-stabilizing effects are reportedly augmented by the concurrent administration of lithium, valproate, thyroid hormones, antipsychotic agents, and antidepressants. As with other mood-stabilizing drugs (i.e., lithium and valproate), carbamazepine appears better for preventing a recurrence of manic than depressive episodes. Some authors report that tachyphylaxis may occur in patients maintained on carbamazepine. This apparent loss of efficacy has been hypothesized to be due to tolerance or to progression of the illness. Although the available partially controlled, long-term, prophylactic studies have been criticized for various methodological flaws, they are highly consistent with a much larger uncontrolled case series indicating carbamazepine's efficacy and tolerability.

Predictors of Response Initial studies reported that a history of poor response to lithium, rapid cycling, severe mania, mixed or dysphoric mania, and a lower prevalence of familial bipolar disorders predicted a favorable outcome to carbamazepine therapy. More-recent studies indicate that decreasing or stable episode frequencies and decreasing mania severity correlate with favorable carbamazepine response.

Blood Concentrations and Relation to Action Therapeutic blood concentrations for carbamazepine as an anticonvulsant are between 4 and 12 µg/mL; however, the ideal range for carbamazepine as a mood stabilizer is unknown. Standard clinical practice is to achieve a range of 8 to 12 µg/mL. In general, monitoring of plasma concentrations is recommended until stability, monthly for the next 6 months, and every 6 to 12 months thereafter (Table 31.7a-1).

	Baseline	Weekly to Stability	Monthly for 6 Mo	6–12 Mo
CBC	+	+	+	+
Bilirubin	+		+	+
Alanine aminotransferase	+		+	+
Aspartate aminotransferase	+		+	+
Alkaline phosphatase	+		+	+
Carbamazepine level		+		+

CBC, complete blood count.

Table 31.7a-1 Laboratory Monitoring of Carbamazepine for Adult Psychiatric Disorders

After approximately 2 to 3 weeks of administration, carbamazepine induces hepatic enzymes that facilitate metabolism of the drug (autoinduction of metabolism.) Thus, a patient who is unable to tolerate 800 or 1000 mg a day in the first several weeks of treatment may not experience adverse effects at these or higher dosages after the third or fourth week of treatment.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

The most common adverse effects of carbamazepine administration are neuromuscular. Adverse events may be divided into those that are largely dosage dependent and those that are idiosyncratic (Table 31.7a-2). Adverse events from carbamazepine that are dosage dependent may be minimized by either dosage reduction or by more gradual titration of the dosage.

Dosage-Related Adverse Effects	Idiosyncratic Adverse Effects
Double or blurred vision	Agranulocytosis
Vertigo	Stevens-Johnson syndrome
Gastrointestinal disturbances	Aplastic anemia
Task performance impairment	Hepatic failure
Hematological effects	Rash
	Pancreatitis

Table 31.7a-2 Adverse Events Associated With Carbamazepine

Central Nervous System The most common neurological adverse effects include dizziness, sedation, ataxia, and diplopia. These effects can largely be minimized or avoided with slow, gradual titration of the dosage. Carbamazepine may also produce mild peripheral polyneuropathies and involuntary movements. Carbamazepine's effects on memory and psychomotor performance have been reported to be minimal in comparison with those of the more behaviorally toxic anticonvulsants, such as phenobarbital. Several studies suggest that carbamazepine's effect on cognition (as determined by neuropsychiatric tests) was not significantly different from that observed with lithium. Initial studies of carbamazepine in normal volunteers and in epileptic patients suggest that it has little adverse effect on cognitive processes, especially compared with the anticonvulsant phenytoin (Dilantin) and phenobarbital. A recent report suggests that the effects of carbamazepine and valproate monotherapy on cognitive functioning are similar and that both drugs produce minimal effects compared with pretreatment baseline performance.

Blood Carbamazepine appears to cause a mild leukopenia in approximately 1 to 2 percent of patients. In most patients treated, this leukopenia is mild and is usually without clinical impact as the lower white blood cell count is usually within normal range. The leukopenia primarily involves granulocytes but does not predispose patients to infection. Reports of agranulocytosis in aplastic anemia associated with carbamazepine continue to appear in the literature. The most recent estimate of incidents is eight patients per million treated, or approximately 1 in 125,000. The benign suppressive effects on granulocytes are thought to be exerted by an inhibitory action at the level of colony-stimulating factor in the bone marrow. In the event of asymptomatic leukopenia or thrombocytopenia, the carbamazepine dosage can be reduced or (in patients with severe changes) the drug discontinued. There is considerable disagreement in the neurological and hematological literature as to the recommended frequency of hematological monitoring to deal adequately with this rare but potentially fatal complication of carbamazepine therapy. The most conservative recommendations are to obtain a complete blood count (CBC) at baseline, weekly to stability and 6 to 12 months thereafter (Table 31.13-1). In addition, patients should be counseled to contact the physician immediately in the event of fever, sore throat, malaise, petechiae, or other signs of hematological dysfunction.

Hormones Many studies have reported that carbamazepine suppresses circulating concentrations of the thyroid hormone T_4, free T_4, and triiodothyronine (T_3) without significantly increasing thyroid-stimulating hormone (TSH) concentrations; however, the methods used in those studies involved dilution of serum. A recent study suggests that carbamazepine-treated patients initially exhibit a transient increase in free T_4, a transient decrease in serum TSH, decrease in total T_4, and normal free T_4 in the serum. However, in patients receiving long-term treatment with carbamazepine, the concentrations of free T_4 and free T_3 in serum are within the normal range.

Based on the drug's ability to stimulate vasopressin receptor function directly or indirectly, carbamazepine on occasion has been associated with hyponatremia and (rarely) with water intoxication. This retention of water in dilutional hyponatremia thus has an effect opposite to that of lithium, which impairs the suppressant function and is associated with nephrogenic diabetes insipidus. Carbamazepine is an alternative to lithium for patients with severe diabetes insipidus. However, carbamazepine does not reverse the effects of lithium-induced diabetes insipidus when the two drugs are used concurrently. Patients on high dosages of carbamazepine and elderly patients appear more prone to hyponatremia. Checking serum electrolytes would appear warranted, as it would when any patient develops a confusional syndrome or a sign that could be associated with hyponatremia (such as severe weakness or headache).

A recent 5-year prospective follow-up study of 36 consecutive patients with recently diagnosed idiopathic epilepsy treated with carbamazepine found changes in serum lipid levels. Serum total cholesterol and high-density lipoprotein cholesterol concentrations increased after 2 months of treatment with carbamazepine and remained high after 1 and 5 years. However, concentrations of low-density lipoprotein cholesterol and triglycerides in serum increased only initially and did not remain elevated by 1 and 5 years follow-up. The authors suggest that the change in lipid metabolism may be associated with induction of liver enzymes during carbamazepine medication. Carbamazepine increases total serum cholesterol largely by increasing the high-density lipoproteins, so that the effect is unlikely to have deleterious cardiovascular consequences. Other endocrinological changes include decreases in free androgen concentrations and increases in the excretion of urinary free cortisol.

Liver Occasional mild elevations in liver function tests are relatively frequent in many series of psychiatric and neurological patients treated with carbamazepine. They do not appear to warrant special attention or drug discontinuation. With more persistent enzyme elevation, drug discontinuation would appear indicated. Rarely, carbamazepine has been associated with severe cases of hepatitis, which on pathological examination showed either an inflammatory or a toxic-metabolic picture. Liver function should therefore be monitored at 6- to 12-month intervals.

Heart Cardiac toxic reactions related to carbamazepine occur but are infrequent. Conduction disturbances (sometimes resulting in bradycardia or Stokes-Adams syndrome) have been reported.

Skin Carbamazepine-induced rashes are common in psychiatric patients. Although most reports in the literature indicate that rashes are observed in only a small percentage of patients treated with carbamazepine, certain authors suggest that rashes occur in 12 to 16 percent of patients. The risk of having a serious adverse skin reaction appears to be 3 cases per million users per week. The rashes induced by carbamazepine appear to be pleomorphic. The most common is a macular papular rash associated with pruritus emerging usually within the first 3 weeks after initiation of drug use. In most cases rashes resulting from carbamazepine are benign and self-limiting; however, more severe cases may occur such as exfoliative dermatitis, erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis (Lyell's syndrome). Therefore, most authors recommend discontinuing carbamazepine with the onset of rash, because exfoliate reactions and Stevens-Johnson syndrome can occur but are relatively uncommon. Some patients have been reexposed to carbamazepine without the reemergence of a rash, but in most cases the rash returns, usually with a rapid onset. Until recently, valproic acid had often been viewed as safer with respect to cutaneous reactions. However, one study suggests that the crude relative risk of severe adverse cutaneous reactions including Stevens-Johnson syndrome and toxic epidermal necrolysis is similar for carbamazepine and valproic acid if the drugs are used for short periods (<2 months) but is much higher for carbamazepine when the drugs are used for longer periods.

Weight In contrast to other psychotropic agents used in the treatment of mood disorders, such as lithium and valproic acid, carbamazepine does not appear to be associated with significant weight gain.

Other Adverse Effects Rare idiosyncratic adverse effects reported include psychological disturbances (e.g., sporadic cases of mania and psychosis), pancreatitis, and renal complications (e.g., renal failure, oliguria, hematuria, and proteinuria).

THERAPEUTIC INDICATIONS

Carbamazepine is approved by the Food and Drug Administration (FDA) for use in the following seizure types: (1) partial seizures with complex symptomatology (psychomotor, temporal lobe, (2) generalized tonic-clonic seizure (grand mal), and (3) mixed seizure patterns that include the above. It is also approved for use in a variety of paroxysmal pain syndromes, including trigeminal neuralgia. However, carbamazepine is not FDA approved for the treatment of bipolar disorders. Nevertheless, carbamazepine is being widely used in both short-term and long-term treatment of mood disorders. However, because of the availability of lithium and divalproex (Depakote) and their FDA approval for bipolar I disorder, carbamazepine should be considered a second-line agent for this indication. Carbamazepine is often used as a substitute to lithium or valproate or as an adjunct to lithium for the partial responder. In patients with refractory seizure disorders and refractory mood disorders, it is occasionally used in combination with valproate. In these instances, the dosage of carbamazepine should be decreased (as valproic acid displaces carbamazepine from its protein-blind sites and also increases the concentrations of the 10,11-epoxide metabolite), and valproate dosages may need to be increased

to maintain therapeutic concentrations.

A 2- to 3-week trial of carbamazepine in the treatment of a manic episode usually suffices to ascertain whether a patient is going to respond, although longer periods may be required to assess antidepressant efficacy. Some 50 to 70 percent of patients show a reduction in manic and depressive episodes with the use of carbamazepine for prophylaxis. In general, lithium may be considered as an adjunctive treatment in patients who have achieved a partial response on carbamazepine alone. There have been occasional reports of neurotoxicity with this combination; however, the two drugs appear to be well tolerated in combination by most patients. Thus, in the management of acutely severe manic patients administration of the drugs may be started simultaneously. When used in this combination, carbamazepine, like an antipsychotic agent, may help control the extreme elements of excitation and aggression prior to the onset of the inadequate response to lithium. If control is not adequate, antipsychotics may be added to this combination. Therefore, it is quite reasonable to treat the most severely manic patient with usual therapeutic dosages of several agents together, rather than to resort to extremely high dosages of lithium or antipsychotic agents and the risk of toxicity.

Some patients show a selective response to carbamazepine but not to other anticonvulsants such as valproate or phenytoin (Dilantin). In addition, some patients appear to respond to valproate when they do not respond adequately to carbamazepine alone. Thus, valproate may be considered an alternative to carbamazepine in the management of severe manic episodes that are refractory to traditional treatment.

It was previously suggested that carbamazepine need not be tapered for discontinuation, as nonepileptic patients showed no apparent risk for seizures after withdrawal. However, a recent study suggests that 12 epilepsy patients from whom carbamazepine was withdrawn rapidly (over 4 days) experienced significantly more generalized tonic-clonic seizures than those from whom carbamazepine was withdrawn more slowly (over 10 days). Manic or psychotic symptoms may reemerge rapidly however.

Schizophrenia and Schizoaffective Disorder Several double-blind studies comparing the addition of carbamazepine or placebo with ongoing treatment with antipsychotic agents suggests that the adjunctive use of carbamazepine may be effective in some patients with schizophrenia or schizoaffective disorder, particularly those with florid positive symptoms or problems with aggressive behavior.

Impulse-Control Disorders Carbamazepine has been reported to have a role in a variety of impulse-control disorders including borderline and other personality disorders.

Other Uses Several studies suggest that carbamazepine and benzodiazepines have comparable efficacy in the management of acute alcohol withdrawal syndromes. Since carbamazepine does not have the same abuse potential as benzodiazepines, it may have a role in the long-term treatment of alcoholic patients. However, further studies are required to clarify its exact role in this population. Carbamazepine has also been reported to have a role in a variety of pain syndromes including diabetic neuropathy and migraine prophylaxis. However, high-quality studies are needed to determine the effects of carbamazepine in treating chronic pain syndromes and for comparisons of antidepressants with anticonvulsants.

Contraindications Carbamazepine should be avoided in patients with a history of bone marrow suppression, narrow-angle glaucoma, hypersensitivity to the drug, or known sensitivity to any of the tricyclic compounds, such as amitriptyline (Elavil) or imipramine. It should be avoided in patients taking a monoamine oxidase inhibitor. Before administration of carbamazepine, monoamine oxidase inhibitors should be discontinued for a minimum of 14 days, or longer if the clinical situation permits. Carbamazepine should be used with caution in patients with preexisting significant cardiovascular disease because it can slow the atrioventricular system.

Safety in Overdose In determining the overall risk-benefit ratio of a medication effectively for ill patients who are at substantial risk for suicide, the relative safety of the agent in an overdose situation is an important consideration. Although uncommon, fatal carbamazepine toxicity does occur. Carbamazepine overdose is characterized by neurological symptoms such as diplopia, dysarthria, ataxia, vertigo, nystagmus, hypoflexia or hyperflexia, and coma. In addition, seizures, respiratory depression, hypothermia, oral dyskinesias, and cardiac conduction defects may occur. Plasma concentrations of carbamazepine are only moderately correlated with severity, 10,11-epoxide serum concentrations have been reported to correlate better with carbamazepine intoxication. Supportive techniques including gastric lavage (which should be undertaken up to 12 hours after ingestion) with activated charcoal (50–100 grams, then 12.5 grams an hour until the patient is symptom free) have been attempted in such cases. Early charcoal hemoperfusion before the patient becomes hypotensive and administration of flumazenil (Ranazicon) to block central-type benzodiazepine receptor effects for coma, have also been tried. The benefit from plasmapheresis remains unclear. Forced diuresis, peritoneal dialysis, and hemodialysis, however, are not recommended. Previous reports indicated that many patients have survived large overdoses. Few fatalities have occurred, and people have been reported to survive ingested doses of carbamazepine as high as 20 grams (i.e., 100 capsules).

Use During Pregnancy Carbamazepine has been reported to have teratogenic effects. First-trimester exposure may be associated with an increased risk of neural tube defects, craniofacial defects, fingernail hypoplasia, and developmental delay. Exposure to antiepileptic drugs during pregnancy is associated with increased risk of congenital anomalies in offspring. The incidence of malformations in infants of mothers with epilepsy who are treated with antiepileptic drugs is two or three times that of infants of mothers without epilepsy. The incidence of malformations associated with carbamazepine has been estimated to be approximately 7.3 percent. A recent prospective case-control study examining the risk of fetal death and anomalies from antiepileptic drugs compared the outcomes of pregnant women with epilepsy treated with antiepileptic drugs (N = 174) and their offspring with a control group of 355 healthy women and their offspring. They found that the offspring of women with epilepsy who were exposed to antiepileptic drugs had statistically significant higher rates of fetal death and anomalies than the control group. This risk of an abnormal outcome (death and anomalies) was highest with phenobarbital, followed by phenytoin and carbamazepine. The risk of neural tube defects associated with in utero antiepileptic agent exposure may be reduced by prophylactic treatment with high doses of folate—ideally before conception.

Thus, while the conservative approach to medication should be taken during pregnancy (i.e., no medications unless they are absolutely required), the initial data from the epilepsy literature speaks to the relative safety of carbamazepine, particularly in relation to lithium. Both carbamazepine and its epoxide metabolite have been reported to transfer to breast milk.

LABORATORY INTERFERENCES

Carbamazepine may interfere with the dexamethasone-suppression test and with some pregnancy tests. Carbamazepine increases the metabolism of sex hormones used in birth control preparations, so higher-dose formulations of those preparations may be required for the oral contraceptives to maintain their efficacy.

As listed in Table 31.7a-3, clinically meaningful drug interactions have occurred with concomitant medications. Most drug interactions result from carbamazepine's induction of hepatic microsomal CYP 2D6, 1A2, 3A4, and 2C9/10, which leads to an accelerated elimination of drugs normally metabolized by this system, including the barbiturates and oral contraceptives. Thus, carbamazepine may decrease the blood levels and efficacy of a variety of drugs. Most notably, carbamazepine may interact with commonly prescribed agents, such as antidepressants, antipsychotic drugs, oral contraceptives, and anticoagulants. Plasma concentrations of these coprescribed agents may decrease to a clinically significant degree, requiring dosage adjustments to compensate for the lowered plasma concentrations. Carbamazepine has been reported to decrease levels of haloperidol by 40 to 60 percent. While administering carbamazepine to refractory excited psychotic patients taking neuroleptic drugs, such as haloperidol is generally effective, occasional exacerbations may be associated with reduction of serum neuroleptic levels to the undetectable range.

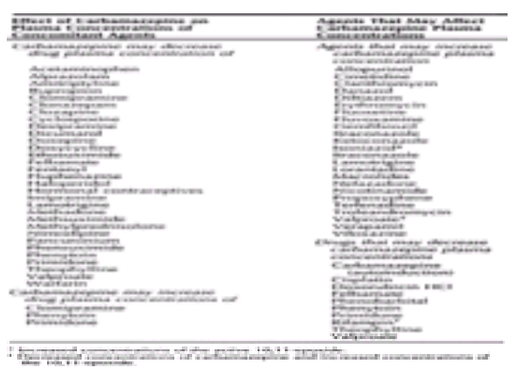

Table 31.7a-3 Carbamazepine-Drug Interactions

Several drugs have been reported to markedly increase concentrations of carbamazepine, sometimes leading to toxic symptoms in patients otherwise well maintained. CYP 3A4 inhibitors that inhibit carbamazepine metabolism can increase plasma carbamazepine concentrations. These drugs include the commonly used antibiotic erythromycin and its congeners. Epoxide produces the same effect, although this has not been reported with other monamine oxidase inhibitors. Calcium channel inhibitors can increase carbamazepine concentrations, with verapamil (Cardizem) having a greater effect than nifedipine (Procardia). The concentration of carbamazepine in blood can also be significantly (up to 40 percent) and rapidly increased with erythromycin. Symptoms of carbamazepine toxicity (confusion, sedation, and ataxia) may develop. Reduction of the carbamazepine dosage is required when administration of erythromycin is started. Other types of antibiotics are preferred, if possible. Verapamil and diltiazem in particular can significantly increase carbamazepine concentrations in blood. Similarly, concentrations of carbamazepine are increased by divalproex, selective serotonin reuptake inhibitors (especially fluoxetine [Prozac] and fluvoxamine [Luvox]), erythromycin, propoxyphene (Darvon), cimetidine (Tagamet), and isoniazid (Cortinazin). Valproate produces slight increases in the concentrations of the 10, 11-epoxide metabolite but no substantial toxicity is associated with this combination.

CYP 3A4 inducers can increase the rate of carbamazepine metabolism. Drugs that have been shown, or that would be expected, to decrease the concentration of carbamazepine in plasma include barbiturates, phenytoin, and primidone (Mysoline).

Both carbamazepine and clozapine (Clozaril) can suppress bone marrow leukocytogenesis. Therefore their combination should be avoided. In one study, neutropenia (<1500 neutrophils per µL) was more common in 14 patients given both agents than in 133 patients not given the anticonvulsant.

DOSAGE AND ADMINISTRATION

Carbamazepine is available for oral administration as chewable tablets of 100 mg, tablets of 200 mg, sustained-release tablets of 100, 200, and 400 mg, and a suspension of 100 mg per 5 mL. When prescribing carbamazepine in the treatment of manic episodes, initial dosages may be 400 to 600 mg a day in divided doses (three or four times a day), with daily increments of 200 mg a day every few days until subjective adverse effects or clinical response is reached. Until tolerance to adverse effects develops, titration many need to be slowed or even reversed. Lower initial dosages should be used in the euthymic or depressed patient. Response is often observed in a dosage range of 1000 to 1200 mg a day, although increases to 1600 mg a day may be indicated in some patients in the absence of adverse effects. Because of carbamazepine's short half-life, the drug may need to be given in divided doses three or four times a day, with the bulk of the dose administered at bedtime to take advantage of its sedating effects. Recently, an extended-release carbamazepine tablet was developed, permitting patients to take carbamazepine only twice daily. The long-acting carbamazepine would help improve compliance by avoiding the inconvenience of multiple-daily dose therapy. Patients may be switched on a mg-per-mg basis from multiple-daily-dose-form of carbamazepine to the extended-release form twice daily from one day to the next without retitrating the daily dosage. Carbamazepine should be stored in a cool dry place, not in humid places such as the bathroom, because tablets may absorb considerable moisture and lose up to one-third of their activity. The recommended laboratory monitoring of carbamazepine for adult psychiatric disorders is described in Table 31.7a-1.

31.7 ANTICONVULSANTS

31.7B VALPROATE

SUSAN L. MCELROY, M.D., HARRISON G. POPE, ,R., M.D., AND PAUL E. KECK, ,R., M.D.

The indications for valproate (Depakene) currently recognized by the U.S. Food and Drug Administration (FDA) are (1) the treatment of the manic episodes associated with bipolar disorder; (2) sole and adjunctive therapy for complex partial seizures that occur either in isolation or in association with other types of seizures, sole and adjunctive therapy for simple and complex absence seizures, and adjunctive therapy for multiple seizure that includes absence seizures; and (3) the prophylaxis of migraine headaches. Controlled studies have shown valproate to be effective in other primary generalized seizures occurring in idiopathic epilepsies, including generalized tonic-clonic and myoclonic types, and in infantile spasms and photosensitive epilepsy. In addition, growing reports suggest that valproate may be helpful in other neurological and psychiatric conditions, including some chronic pain and movement disorders as well as depressive, schizoaffective, anxiety, eating, alcohol use, substance use, impulse control, personality, and cognitive disorders. Reports concerning the efficacy of valproate in schizophrenia, however, have not been encouraging.

HISTORY

Valproic acid, also known as valproate, (Depakene), and divalproex (Depakote), was originally developed in Europe after its antiepileptic properties were serendipitiously discovered in 1963 while it was being used as a vehicle for other drugs that were being screened for antiepileptic activity. It was first used clinically in France in 1964 and was first approved for use in the United States as an antiepileptic drug for absence seizures in 1978.

As early as 1966 in France researchers reported that valpromide (the amide prodrug of valproate) might be effective in the treatment of bipolar disorders. After that report, numerous open and controlled studies found that valproate had short-term and long-term mood-stabilizing effects in some patients with bipolar and schizoaffective disorders, with particularly robust efficacy in the manic phase of bipolar I disorder. In 1996, valproate received approval in the United States for use in acute mania. Later that same year, the drug received approval for use in complex partial seizures and migraine headache prophylaxis.

CHEMISTRY

Valproate, also known as *n*-dipropylacetic acid or 2-propylpentanoic acid (Fig. 31.7b-1), is a simple branched-chain carboxylic acid and thus is chemically different from other available antiepileptic drugs. Four oral preparations of valproate are currently marketed in the United States: valproic acid; sodium syrup; divalproex, an enteric-coated stable coordination compound composed of sodium valproate and valproic acid in a 1 to 1 molar relationship; and divalproex sprinkle capsules, which may be opened and sprinkled on food. Of note, divalproex tablets may be administered rectally. An intravenous form (Depacon) is also available for use in the United States. Valpromide, the amide precursor of valproate, is marketed in Europe.

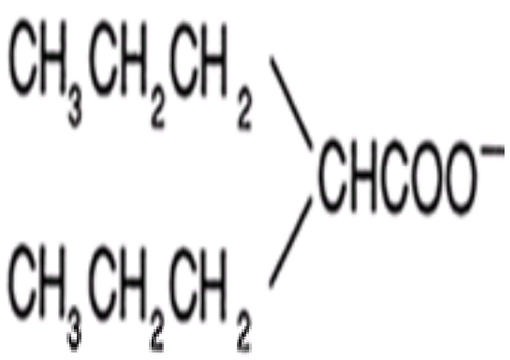

FIGURE 31.7b-1 Molecular structure of valproate.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics All valproate preparations are rapidly and completely absorbed after oral administration. Approximately 90 percent of the drug is bound to plasma proteins. However, the unbound portion of valproate increases as serum concentrations increase, apparently because the binding sites on plasma proteins become saturated as the serum concentration of the drug approaches the therapeutic range, which is generally believed to be between 50 and 125 or 150 µg/mL in both neurological and psychiatric applications. Free valproate in the blood crosses readily into the cerebrospinal fluid by passive diffusion and possibly by carrier-mediated transport.

Valproate is metabolized almost entirely by the liver, primarily by conversion to a glucuronide conjugate and by mitochondrial b-oxidation. Several of valproate's metabolites, such as 2-propyl-2-pentenoic acid, have potent anticonvulsant effects. Valproate has a half-life of 8 to 17 hours, with a shorter half-life in patients taking drugs that accelerate hepatic metabolism, including other antiepileptic drugs.

Pharmacodynamics Valproate has been hypothesized to mediate both its antiepileptic effects and its psychiatric effects in part through potentiation of central nervous system (CNS) g-aminobutyric acid (GABA) function. GABA is the major inhibitory neurotransmitter in the mammalian CNS. Valproate inhibits the catabolism of GABA, increases its release, decreases GABA turnover, increases GABA type B ($GABA_B$) receptor density, and may also enhance neuronal responsiveness to GABA. Studies have suggested that valproate-induced increased concentrations of GABA in brain and improved neuronal responsiveness to GABA are associated with seizure control. Other research, however, suggests that valproate exerts its antiepileptic effects by direct neuronal effects (i.e., reducing sodium influx and increasing potassium efflux) or by interactions with gamma hydroxybutyrate (GHB), a product of GABA metabolism that may have epileptogenic properties.

Although the role of GABA in mood disorders is not well understood, several lines of evidence have implicated GABA in mood disorders. Many drugs known to be effective in the treatment of manic episodes—including lithium (Eskalith), antipsychotics, and carbamazepine (Tegretol)—influence GABA transmission. Also, GABA transmission may modulate circadian rhythms in the suprachiasmatic nucleus of the hypothalamus, and some have suggested that valproate exerts its antimanic effects by normalizing an abnormally long endogenous circadian period. Moreover, GABA concentrations in the CNS are low in some animal models of aggression. Irritability and aggression are common manic symptoms. Also, the administration of GABA antagonists induces killing behavior in rats, whereas the administration of

various GABAergic compounds (including valproate) inhibits aggressive behavior in rats and mice.

Other effects of valproate that might contribute to its mood-stabilizing properties include decreased dopamine turnover, altered serotonin function, decreased *N*-methyl-d-aspartate (NMDA)-mediated currents, decreased aspartate release, and decreased cerebrospinal fluid (CSF) somatostatin concentrations.

Growing evidence indicates that the serum concentrations of valproate required to treat manic episodes exceed 50 µg/mL, the same concentrations believed effective for epilepsy. This concentration may represent the point at which protein-binding sites are saturated and substantial free drug becomes available.

Few studies in either neurological or psychiatric patients have routinely used valproate serum concentrations above 100 µg/mL, although a few patients respond to concentrations of 100 to 200 µg/mL after failing to respond to lower concentrations. However, adverse effects are more common with valproate concentrations above 100 µg/mL.

CLINICAL DRUG STUDIES

Acute Mania In psychiatry, valproate has been studied most extensively in the manic phase of bipolar I disorder and in schizoaffective disorder, bipolar type. To date, more than 16 uncontrolled studies and 7 controlled studies have assessed the efficacy of valproate (or valpromide) in manic patients. The first 16 uncontrolled studies reported on 663 manic patients, of whom approximately 419 (63 percent) showed a moderate-or-marked response to valproate.

Three early controlled studies (in 1985 or before) compared valproate with a placebo in a total of 14 patients; of those, 10 (71 percent) were described as markedly better after taking valproate than after a placebo. Since 1991, four larger controlled studies of valproate monotherapy have appeared. In the first study, 36 inpatients meeting the criteria for bipolar disorder, manic phase, in the revised third edition of Diagnostic and Statistical Manual of Mental Disorders (DSM-III-R), were randomized to valproate (*N* = 17) or placebo (N = 19) for 7 to 21 days. Valproate serum concentrations were maintained at 50 to 100 µg/mL by an unblinded investigator. Valproate proved significantly superior to placebo at endpoint on measures of manic symptoms, overall psychiatric symptoms, global assessment of functioning, and the need for supplemental dosages of lorazepam (Ativan). Nine (53 percent) of the 17 valproate-treated patients had more than 50 percent improvement in ratings of mania, compared with 2 (11 percent) of the 19 placebo-treated patients (Fig. 31.7b-2). Patients responding to valproate displayed a prompt response, with a sharp reduction in manic symptoms occurring 1 to 4 days after achieving valproate serum concentrations of at least 50 µg/mL (Fig. 31.7b-3).

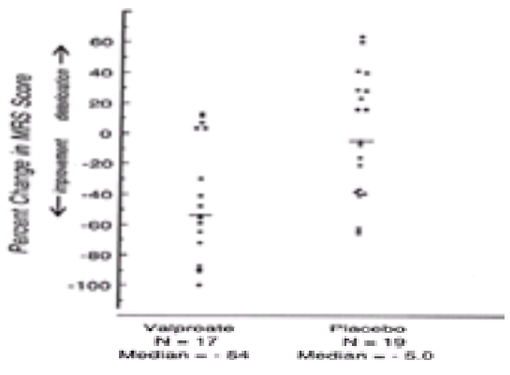

FIGURE 31.7b-2 Percentage change in Manic Rating Scale scores in 17 patients receiving valproate versus 19 patients receiving placebo. (Reprinted with permission from Pope HG Jr, McElroy SL, Keck PE Jr, Hudson JI: Valproate in the treatment of acute mania: A placebo-controlled study. Arch Gen Psychiatry *48:* 62, 1991.)

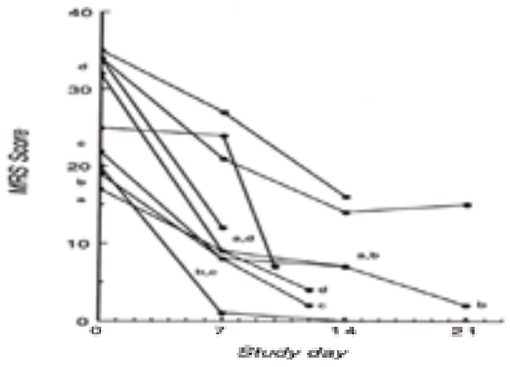

FIGURE 31.7b-3 Change in Manic Rating Scale scores by study day in nine bipolar patients who responded to valproate. (Reprinted with permission from Pope HG Jr, McElroy SL, Keck PE Jr, Hudson JI: Valproate in the treatment of acute mania: A placebo-controlled study. Arch Gen Psychiatry *48:* 62, 1991.)

In the second study, 27 acutely manic patients were randomly assigned to valproate or lithium. No group received a placebo. Twelve (92 percent) of 13 patients assigned to the lithium group were rated responders, compared with 9 (64 percent) of the 14 patients assigned to the valproate group. Although the response rate to lithium exceeded that to valproate in the study, the difference was not statistically significant (*P* = .20 by Fisher's exact test, two-tailed). Also, the response rate to lithium was unusually high in the study.

In the third study, 68 acutely manic patients meeting Research Diagnostic Criteria for manic disorder were randomized to valproate, 35 to lithium, and 73 to placebo. Premature termination due to lack of efficacy occurred in 30 percent of the patients assigned to valproate, 33 percent of patients assigned to lithium, and 51 percent of patients assigned to placebo. The difference between valproate and placebo on this index was significant (*P* = .017). The proportion of patients exhibiting at least 50 percent improvement was higher for both valproate and lithium than for placebo: 48 percent of the patients assigned to valproate, 49 percent with lithium, and 25 percent with placebo. The difference between valproate and placebo was highly significant (*P* = .004). No significant difference was observed between valproate and lithium in this study.

In the fourth study, 36 inpatients with bipolar I disorder, manic or mixed phase with psychotic features by DSM-III-R criteria were randomized to receive either valproate (20 mg/kg a day) or haloperidol (Haldol) (0.2 mg/kg a day) in single-blind fashion for 6 days. There was no placebo group. Valproate and haloperidol were equally effective in acutely reducing manic and psychotic symptoms. Ten (48 percent) of 21 patients receiving valproate and 5 (33 percent) of 15 patients receiving haloperidol were classified responders. The greatest rate of improvement for both drug regimens occurred over the first 3 days of treatment. Adverse effects were infrequent and minor for both drugs, except for extrapyramidal side effects, which were significantly more common with haloperidol.

In total, of 134 manic patients receiving valproate under blind conditions in seven studies, approximately 52 percent were rated responders. Moreover, in a recently completed multicenter, parallel group, double-blind, 3-week study from Europe, 136 patients with acute mania receiving open-label antipsychotics were randomized to treatment with valproate or placebo. Compared with placebo-treated patients, valproate-treated patients displayed a significantly greater decline in concomitant antipsychotic treatment at the end of the study.

Several preliminary findings emerge from the studies of valproate in acute mania. First, the time course of response is relatively rapid, with the onset of benefit usually evident in 1 to 2 weeks and often in several days after achieving therapeutic serum concentrations. Indeed, four recent reports have shown that valproate may be rapidly effective in acute mania when given via the oral loading strategies of 20 to 30 mg/kg a day, which produce serum concentrations of approximately 80 µg/mL and 100 to 120 µg/mL, respectively, after 1 day of treatment. In two of these studies, 50 percent of 40 acutely manic patients responded to valproate monotherapy within 5 days. Second, anecdotal reports suggest that valproate's short-term antimanic effects may be augmented by lithium, carbamazepine, typical antipsychotics, clozapine (Clozaril), and gabapentin (Neurontin). Third, several factors may be associated with a more favorable antimanic response to valproate than to lithium,

including rapid cycling (the occurrence of four or more mood episodes in 1 year) and possibly ultrarapid cycling; mania accompanied by mild, moderate, or severe depressive symptoms, including mixed or dysphoric mania; and organic or complicated mania (mania caused by, or associated with, medical or neurological illness or drugs). Recent controlled data suggest that acutely manic patients with mixed features or rapid cycling are just as likely to display an antimanic response to valproate as patients with pure mania or slow cycling. Other possible predictors of a better response to valproate than to lithium include comorbid substance abuse or panic attacks. Prior response to lithium or other antiepileptic drugs is not associated with valproate response.

More studies comparing valproate with reference agents such as lithium and carbamazepine are needed. Also needed are studies in which valproate or placebo are added to an existing medication regimen (e.g., lithium) in patients with persistent manic symptoms, and studies in prepubertal, adolescent, and elderly patients with mania. Nonetheless, valproate is now considered by many authorities to be a first-line mood stabilizer in patients of all ages with bipolar disorders (with the exception of children under 3 years of age because of hepatotoxicity).

Acute Bipolar Depression No controlled studies have assessed the efficacy of valproate in the depressed phase of bipolar I or II disorders, but uncontrolled data suggest that valproate is less effective in the short-term treatment of bipolar depression than in the short-term treatment of acute mania. In an open-label trial of valproate in 101 patients with rapid-cycling bipolar I or bipolar II disorder (43 of whom received valproate monotherapy and 58 of whom received valproate in combination with lithium, carbamazepine, antipsychotics, antidepressants, or a combination), 21 percent of patients who were depressed at the time valproate treatment was initiated displayed a short-term response to the drug, compared with 64 percent and 87 percent of the patients who were acutely manic or mixed, respectively. However, in a recent report of open-label valproate monotherapy in 6 patients with bipolar I depression, 4 were considered treatment responsive after approximately 4 weeks. At present, controlled studies comparing valproate with placebo, mood stabilizers, and standard antidepressants in acute bipolar depression are needed.

Acute Major Depressive Disorder Although no controlled studies have assessed the efficacy of valproate in acute major depressive disorder, five uncontrolled studies have provided data on the treatment of unipolar depression with valproate. In those studies, only about 58 (30 percent) of 195 patients with acute major depressive disorder receiving valproate showed a moderate-to-marked antidepressant response—a rate far below the rate of at least 60 percent in patients with acute mania. More recently, two patients with agitated major depression were described whose agitation responded when valproate was added to their antidepressant regimens.

Prophylactic Treatment More than 10 open studies and four comparison trials (two of which have not yet been published in total) have assessed valproate in the prophylactic treatment of bipolar or major depressive disorders. The open-label studies, which extended for up to 10 years, and three of the four comparison trials, which extended for 1 to 2 years, have reported significant reductions in the number, the duration, and the severity of recurrent manic and depressive episodes with prophylactic valproate treatment.

One open-label study compared 32 patients (17 with bipolar disorder, 10 with depressive disorders, 4 with schizoaffective disorder, and 1 with mixed bipolar disorder) treated for 1 year without valproate followed by 1 year with valproate. The average number of hospitalizations in that cohort decreased from 0.76 a year without valproate to 0.18 a year with valproate, and the mean duration of hospitalization decreased from 35 days to 7 days. Open-label findings on a cohort of 101 rapid-cycling bipolar patients at another center continue to suggest that valproate has marked prophylactic antimanic properties but poor-to-moderate prophylactic antidepressant properties.

In the first comparison trial, 150 patients with various bipolar (*N* = 121) or unipolar (*N* = 29) disorders were randomly assigned to open-label maintenance treatment with valpromide (*N* = 78, 1200 mg a day) or lithium (*N* = 72) for an average of 18 months. Valpromide and lithium were equally effective in reducing the frequency of recurrent manic and depressive episodes. Specifically, the number of episodes per patient per month during the 2 years preceding admission to the study was decreased by 84 percent (from 0.172 to 0.028) with valpromide treatment, and by 79 percent (from 0.163 to 0.034) with lithium treatment. Both drugs were slightly better in preventing manic episodes than depressive episodes. Valpromide was slightly better tolerated than lithium: none of the valpromide-treated patients discontinued valpromide due to intolerance, whereas six (8 percent) of the lithium-treated patients did so.

In the second comparison trial, a double-blind, placebo-controlled, study of 12 bipolar I disorder patients treated for 14 weeks to 1 year, patients receiving the combination of lithium and valproate were significantly less likely to suffer a relapse compared with those receiving lithium and placebo.

In the third comparison trial, a 2-year study of valproate versus lithium in 26 children, adolescents, and young adults (ages 11 to 21 years) with bipolar I disorder, valproate was associated with greater compliance, fewer treatment-emergent adverse effects, and a lower rate of relapse than lithium. The difference in relapse rates was attributed to better compliance with valproate.

The fourth comparison trial was a randomized, double-blind, parallel-group, multicenter study comparing the efficacy of valproate, lithium, and placebo as prophylactic therapy during a 52-week maintenance period. Patients with bipolar I disorder who met recovery criteria within 3 months of the onset of a manic episode were randomized to maintenance treatment with valproate, lithium, or placebo in a 2 to 1 to 1 ratio. Psychotropic medications were discontinued before randomization, except for open-label valproate or lithium, which were gradually tapered over the first two weeks of maintenance treatment. The main outcome measure was time to a manic episode; secondary measures were time to a depressive episode, time to either a manic or a depressive episode, and average change from baseline in scores for depression, mania, and global assessment of function. Neither the valproate- nor the lithium-treated group differed significantly from the placebo-treated group in time to a manic episode. However, valproate was superior to placebo in terms of lower rates of discontinuation for a recurrent mood episode. Also, valproate was superior to lithium regarding longer duration in the study, and less deterioration in depression and global assessment of function scores.

Several preliminary impressions emerge from these studies. First, valproate has generally appeared more effective for the prophylaxis of manic episodes than for depressive episodes (except in the fourth comparison trial in which neither valproate nor lithium separated from placebo and valproate was more effective for depressive symptoms). Second, valproate appears to be as effective as lithium in reducing recurrent affective episodes and is possibly associated with fewer adverse effects and better compliance. Third, valproate may be particularly useful in the long-term treatment of bipolar I and II disorders associated with mixed episodes, rapid cycling, or both—conditions that respond poorly to lithium prophylaxis. Fourth, valproate may be of value when used in conjunction with other agents for prophylactic treatment, such as lithium, carbamazepine, antipsychotics (including clozapine), antidepressants, gabapentin, topiramate (Topamax), and lamotrigine (Lamictal). Fifth, although there are no controlled studies of valproate in children, adolescents, or elders with bipolar disorder, valproate may be particularly indicated for young and elderly patients with acute mania (including those with mixed features, rapid cycling, cognitive or neurological abnormalities, and lithium resistance or intolerance) because of the drug's broad spectrum of efficacy in mania; its relatively benign cognitive, dermatological, thyroid, and renal adverse effect profiles; and the extensive clinical experience accumulated from its use in young and elderly patients with epilepsy.

Schizoaffective Disorder No controlled studies of valproate in schizoaffective disorder are available. Open studies suggest that in general, valproate is less effective in schizoaffective disorder than in bipolar disorders. In an open, retrospective study of 56 valproate-treated patients who all had manic symptoms, 24 (67 percent) of 36 patients with bipolar disorders responded favorably, compared with 9 (45 percent) of 20 patients with schizoaffective disorder, bipolar type. Thus, although perhaps not as effective, valproate may be a useful agent in some schizoaffective patients, particularly in those with the bipolar type of the disorder and when used adjunctively with lithium, carbamazepine, or an antipsychotic, including clozapine, risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), and sertindole (Serlect).

Schizophrenia Valproate appears to be of little value in schizophrenia. In one analysis of 99 putative schizophrenic patients in seven studies, 27 (27 percent) reportedly showed a moderate-or-marked response. However, on closer inspection, among the patients with classic schizophrenia not accompanied by symptoms of major mood disorders or of epilepsy, the response rate to valproate was probably much lower than 27 percent. For example, two reports described 14 patients with diagnoses of schizophrenia by the Research Diagnostic Criteria (8 of them were treated on an open-label basis and 6 with a placebo control), and one report described 8 patients meeting the third edition of DSM (DSM-III) criteria for schizophrenia. Among those 22 rigorously diagnosed patients, 2 were minimally improved, 15 were unchanged, and 5 were described as showing qualitatively worsened symptoms.

Panic Disorder Three case reports, three small open-label trials, and one placebo-controlled, crossover study have all suggested that valproate may be effective in the treatment of panic disorder. However, in a double-blind, placebo-controlled, parallel-group study with 35 patients, valproate was not superior to placebo in reducing the number and duration of panic attacks (possibly because of the high rate of response to placebo).

In the controlled crossover study, valproate significantly decreased the length and the frequency of panic attacks and produced significant improvement on the

Clinical Global Impressions scale and the Hamilton Rating Scale for Anxiety in 12 patients. The effect on the actual frequency of attacks, however, was not reported.

In one open-label study, 16 patients with panic disorder were given a lactate infusion followed by a 28-day period of treatment with valproate, followed by rechallenge with lactate. Of the 14 patients completing the trial, 10 (71 percent) experienced more than 50 percent reduction in the weekly frequency of their panic attacks, and 6 (43 percent) described a complete remission. Valproate blocked reinduction of the panic attack on lactate rechallenge in 10 (83 percent) of the 12 patients who had initially displayed a panic attack with lactate infusion.

In a recent open-label study, all 12 patients with DSM-III-R panic disorder treated with valproate for 6 weeks displayed moderate-or-marked improvement. Measures of panic attacks and anxiety improved more quickly and more robustly than measures of phobic avoidance. Eleven of the 12 patients elected to remain on valproate. All 11 patients displayed sustained improvement at 6-month follow-up.

Whether the efficacy of valproate is greater in patients with panic disorder who have electroencephalogram (EEG) abnormalities than in those with normal EEGs is not known. Carbamazepine, for example, may be more effective in the former group, but not the latter. EEGs were not assessed in the open or controlled valproate studies. Further investigations of the role of EEG abnormalities and response to antiepileptic drugs are therefore needed in patients with panic disorder.

Posttraumatic Stress Disorder Two case reports of three patients and one open clinical trial with 16 patients have all reported valproate to be effective in the treatment of combat-related posttraumatic stress disorder: In two cases, valproate reduced irritability and aggression. In the third case, valproate decreased flashbacks, anxiety, and hypervigilance. In the larger series, 10 of 16 Vietnam veterans meeting DSM-III-R criteria for posttraumatic stress disorder were rated significantly improved with valproate, particularly in symptoms of insomnia and hyperarousal-hyperactivity. Avoidant-withdrawal symptoms also improved significantly in most of the patients.

Obsessive-Compulsive Disorder One case series described 8 of 10 patients with obsessive-compulsive disorder, previously intolerant to serotonin reuptake inhibitors, who were subsequently able to tolerate rechallenge with these agents after pretreatment with valproate. In that series, it was speculated that obsessive-compulsive disorder and complex partial seizures have similarities and that valproate was helpful because of its anticonvulsant effects. However, the authors have observed the same phenomenon in patients with obsessive-compulsive disorder and a comorbid bipolar disorder. In such patients, serotonin-reuptake inhibitors induce hypomanic, manic, or mixed symptoms that subsequently respond to valproate and other mood stabilizers.

Alcohol and Sedative-Hypnotic Withdrawal At least five open studies and one controlled trial suggest that valproate may exert a palliative effect in withdrawal from alcohol. The controlled study found that patients with alcohol withdrawal who received standard detoxification regimens augmented by valproate required less than the usual dosage of the standard medication and improved more rapidly than with standard agents alone. However, no formal statistical analysis of those results was presented. Another controlled study of 16 patients with alcohol withdrawal randomized to valproate versus placebo ($N = 8$) or valproate ($N = 8$), found no significant difference in outcome between the two treatments.

In one small series and two case reports, valproate was reported to ameliorate withdrawal symptoms from benzodiazepines. Two of the patients in those studies also showed improvement in concomitant symptoms of panic disorder.

Substance Abuse One case report described the successful use of valproate in the short-term treatment of cocaine dependence.

Eating Disorders One open-label study of valproate describes three women with bulimia nervosa and comorbid bipolar disorders who all were previously unresponsive or partially responsive to lithium and antipsychotics and who all had mildly abnormal EEGs with focal or generalized slowing. All three patients displayed a marked decrease in both mood and bulimic symptoms in response to valproate. One patient twice experienced a recurrence of mood and bulimic symptoms when her valproate level fell below 50 µg/mL. On both occasions, her symptoms promptly remitted again when serum valproate concentrations were raised above that threshold.

Neither case series nor controlled studies of valproate in patients with eating disorders without comorbid bipolar disorders have yet appeared.

Impulse-Control Disorders Several case reports describe the successful treatment of intermittent explosive disorder or kleptomania accompanied by bipolar disorder with valproate. Below, the authors describe a woman with severe kleptomania and mixed mania, both of which worsened with fluoxetine but responded to valproate.

> Ms. A., a 36-year-old married mother employed full time as an office manager, was hospitalized in the spring of 1995 for recurrent shoplifting and severe depression. She described a near-constant urge to steal that was impossible to resist, stealing an average of four times every day (prior to admission). She also experienced very rapid (ultradian) and severe mood and energy swings, meeting DSM-III-R criteria for kleptomania and bipolar disorder, mixed, respectively. Ms. A. described the course of both her kleptomania and mixed mania as chronic—with near-daily symptoms since the ages of 15 and 14 years, respectively.
>
> It was recommended that she begin taking valproate for treatment of her mixed mania. Upon discharge, however, she was treated intermittently with fluoxetine (Prozac). At presentation to the center in the fall of 1995, after 1 month of continuous fluoxetine treatment (20 mg a day), Ms. A. continued to meet DSM-III-R criteria for kleptomania and mixed bipolar disorder. Moreover, she reported that the frequency and severity of her stealing impulses and behavior, as well as the rapidity and severity of her mood swings, had increased since beginning fluoxetine treatment (she was stealing 7 to 8 times every day). Valproate was added to her fluoxetine regimen. Within 1 month, on valproate 1500 mg a day and fluoxetine 20 mg a day, Ms. A. reported a significant reduction in the frequency and intensity of her stealing impulses and episodes as well as improvement in her mood swings. Valproate was increased to 2000 mg a day and fluoxetine was discontinued. One month later, Ms. A. described complete resolution of stealing impulses, continued remission of stealing behavior, and a further decrease in mood swings. After 8 months of valproate treatment, Ms. A. reported continued resolution of stealing impulses, no further stealing, and mild mood swings that were manageable.

Behavioral Agitation (or Disturbance) of Dementia Two small uncontrolled studies, one retrospective chart review, and one case report have examined the efficacy of valproate for behavioral agitation in elderly patients with dementia. Of 38 demented patients in these four reports, 21 (61 percent) displayed moderate-or-marked reduction in agitation in response to valproate treatment. One study noted that physical aggression, verbal aggression, and restlessness were the types of behaviors that responded best to valproate.

Several tentative impressions emerge from these studies regarding the use of valproate in dementia-related behavioral agitation. First, valproate's antiagitation effects are often apparent within 1 to 3 weeks of treatment. Second, valproate may be effective as monotherapy and in patients whose agitation has failed to respond to (or has been worsened by) antipsychotics and benzodiazepines. Third, valproate may be effective in reducing behavioral agitation in a variety of types of dementia, including dementia of the Alzheimer's type, vascular dementia, and the combination of the two. Fourth, some patients who respond acutely continue to display reduced behavioral agitation over extended periods of time with maintenance treatment. Fifth, valproate may effectively reduce behavioral agitation in some elderly demented patients at doses and serum concentrations below those generally required for efficacy in epilepsy and mania (e.g., 125 to 750 mg a day and 15 µg to 50 µg/mL). However, some patients respond only when standard doses and serum concentrations are used. Sixth, valproate was generally well tolerated, with only 5 (13 percent) of the 38 patients reported to have adverse effects.

Borderline Personality Disorder Two open-label studies have examined valproate in borderline and other personality disorders. In the first study, 11 outpatients with borderline personality disorder according to DSM-III-R criteria and without current major depression or a history of a bipolar or a psychotic disorder were given valproate for 8 weeks after an 8-week medication-free baseline period. Of the 8 patients who completed the trial, 4 (50 percent) were considered responders and were rated as displaying “less” or “much less” overall pathology and mood symptoms. Valproate was found most helpful for irritability, anxiety, anger, rejection sensitivity, and impulsivity. To confirm these findings, the authors of this study are now conducting a double-blind, placebo-controlled, parallel-group trial of valproate in 25 patients with borderline personality disorder.

In the second trial, 10 patients meeting DSM-IV criteria for at least one personality disorder (5 with borderline type) received valproate for 8 weeks for the treatment of impulsive aggressive behavior. All patients had failed a trial of a selective serotonin reuptake inhibitor. Response to valproate was assessed with the modified Overt Aggression Scale. Six of 8 completers reported significant decreases in irritability ($P = .003$) and impulsive aggressive behavior ($P = .017$). Response to valproate was

apparent by the end of 4 weeks of treatment and continued to occur through week 8 of treatment.

Other Behavioral Dyscontrol Syndromes Isolated case reports have described the successful treatment with valproate of rage attacks associated with mania and epilepsy (*N* = 1), posttraumatic stress disorder (*N* = 2), and severe closed head injury (*N* = 1). Further research on the efficacy of valproate in behavioral dyscontrol seems warranted, since several controlled studies have found the antiepileptic drugs carbamazepine and phenytoin (Dilantin) effective in patients with those symptoms. Also, valproate was shown to suppress aggressive behavior in animals.

Affective Symptoms in Persons With Mental Retardation One study examined 209 persons with mental retardation who were referred for evaluation of behavioral symptoms. Patients were assigned to valproate if they exhibited three of the following four symptoms: irritability, sleep disturbance, aggressive or self-injurious behavior, and behavioral cycling. Of 18 patients who met enrollment criteria and were followed for 2 years on drug treatment, 14 (78 percent) were described as responding favorably to treatment. A history of epilepsy or a suspicion of seizures was strongly associated with a favorable response to valproate in this study (*P* < .005).

THERAPEUTIC INDICATIONS

Neurological Conditions Valproate is approved by the U.S. Food and Drug Administration for use in simple and complex absence seizures, in multiple seizures including absence seizures as a component, in complex partial seizures, and in the prophylactic treatment of migraine headaches. Valproate continues to be increasingly used as monotherapy for primary tonic-clonic seizures and in the treatment of myoclonic seizures. It is also used in the treatment of chronic (especially neurological) pain syndromes, where it may ameliorate the lancinating or shooting component, and in certain movement disorders, such as nonepileptic myoclonus, clozapine-induced myoclonus, hemiballismus, Sydenham's chorea, posttraumatic choreoathetosis, and dyssynergia cerebellaris myoclonica. However, valproate does not appear to be effective in tardive dyskinesia or Huntington's disease.

PSYCHIATRIC CONDITIONS

Divalproex is currently approved by the FDA for the treatment of the manic episodes associated with bipolar disorder. It is the only drug other than lithium approved for mania. In particular, valproate is widely used in the short-term treatment of the manic phase of bipolar I disorder and in the prophylactic treatment of patients with recurrent manic and depressive episodes. The drug is also useful in the short-term and prophylactic treatment of schizoaffective disorder, bipolar type, although it may not be efficacious in that disorder as frequently as it is in patients with classic bipolar disorder. Moreover, accumulating evidence suggests that valproate may be useful in many other psychiatric conditions (Table 31.7b-1).

Strong support
Short-term treatment of mania
Moderate support
Short-term treatment of the manic phase in schizoaffective disorder, bipolar type
Prophylactic treatment of bipolar disorders
Weak or preliminary support
Short-term treatment of major depressive disorder
Prophylaxis for recurrent major depressive disorder
Panic disorder
Posttraumatic stress disorder
Eating disorders, obsessive-compulsive disorder, and impulse-control disorders (when accompanied by symptoms of bipolar disorders)
Alcohol and sedative-hypnotic withdrawal
Borderline personality disorder
Behavioral agitation in dementia
Episodic behavioral dyscontrol or impulsive aggression

Table 31.7b-1 Psychiatric Indications for Valproate

Valproate may be particularly useful in patients with bipolar I or II disorder or schizoaffective disorder, bipolar type who (1) respond poorly to lithium or carbamazepine or are unable to tolerate their adverse effects; (2) have a partial response to lithium, carbamazepine, or antipsychotics and require an additional medication to achieve an adequate response; (3) have mania accompanied by mild, moderate, or severe depressive symptoms, including mixed or dysphoric mania; (4) have rapid-cycling bipolar disorder (four or more episodes of mania, hypomania, or depression in a year); (5) have neurological abnormalities or disorders (e.g., seizures, EEG abnormalities, head trauma, migraine, headaches); and (6) have comorbid substance use, anxiety, eating, impulse control, or attention-deficit/hyperactivity disorders. Valproate may also be indicated for persons who develop manic symptoms in the context of a neurological or medical disease. Because of the drug's efficacy in mixed mania, rapid cycling, and organic or complicated mania, together with the extensive experience accumulated from its use in children and elderly adults with epilepsy and its favorable side-effect profile, valproate may also have advantages over lithium in young and elderly patients with bipolar disorder.

Valproate may be of value in the short-term and prophylactic treatment of some patients with major depressive disorder, but present evidence suggests reserving it for patients who have clearly failed standard short-term and prophylactic antidepressant therapies. Valproate appears to be of little value for schizophrenia unaccompanied by a major mood syndrome.

Valproate may also be useful as monotherapy or adjunctively in patients with panic disorder; posttraumatic stress disorder; psychoactive substance use, eating, obsessive-compulsive, or impulse control disorders accompanied by symptoms of bipolar disorder; withdrawal from alcohol, sedative-hypnotic drugs, or cocaine; behavioral agitation associated with dementia; borderline personality disorder; and impulsive aggression (or behavioral discontrol) due to a variety of disorders.

PRECAUTIONS AND ADVERSE REACTIONS

The adverse effects of valproate are summarized in Table 31.7b-2.

Common
Gastrointestinal irritation
Nausea
Sedation
Tremor
Weight gain
Hair loss
Uncommon
Vomiting
Diarrhea
Ataxia
Dysarthria
Persistent elevation of hepatic transaminases
Rare
Fatal hepatotoxicity (primarily in pediatric patients)
Reversible thrombocytopenia
Platelet dysfunction
Coagulation disturbances
Edema
Hemorrhagic pancreatitis
Agranulocytosis
Encephalopathy and coma
Respiratory muscle weakness and respiratory failure

Table 31.7b-2 Adverse Effects of Valproate

Serious Adverse Reactions In very rare cases, valproate causes fatal hepatotoxicity, hemorrhagic pancreatitis, agranulocytosis, encephalopathy with coma, and skeletal muscle weakness with respiratory failure. To the authors' knowledge, no fatalities attributable to any of those disorders have been reported among more than 1000 patients described in the psychiatric literature. In the neurological literature, the great majority of valproate-associated fatalities are attributable to hepatotoxicity.

Valproate-associated fatal hepatotoxicity is idiosyncratic and not related to valproate dosage. It usually occurs within the first 3 months of valproate treatment and is

characterized by decreased alertness or lethargy, anorexia, nausea and vomiting, jaundice, hemorrhage, edema, ascites, and (in epileptic patients) increased seizures. Liver function test results, including those for hepatic transaminase levels and bilirubin levels, often but not invariably are elevated. The cause of the syndrome is unknown; however, risk factors for the syndrome have been clearly identified: young age (especially less than 2 years); the use of multiple antiepileptic drugs; and the presence of developmental delay or a metabolic disorder.

With the identification of these risk factors, the rate of fatal hepatotoxicity with valproate has decreased from 1 in 10,000 in 1978 to 1984 to 2.5 in 100,000 in 1985 to 1986 and 2.6 in 100,000 in 1987 to 1993. For patients receiving valproate as their sole antiepileptic drug during the latter period, the rate of fatal hepatotoxicity was 1.0 in 100,000. In patients over the age of 10 years receiving valproate monotherapy from 1978 to 1993, only one case of fatal hepatotoxicity was reported to Abbott Laboratories (the drug's manufacturer). In this case, however, the hepatotoxicity may have been due to other complicating factors. Thus, in psychiatric patients who are over the age of 10 years and are not receiving multiple antiepileptic drugs, the risk of fatal hepatotoxicity is extremely low.

Valproate may cause coma and death when taken in overdose, although recovery was described in a patient whose serum concentrations exceeded 2000 µg/mL. Valproate-induced coma has been reversed with naloxone (Narcan), and elevated serum valproate concentrations have been decreased by hemodialysis and hemoperfusion.

Valproate is well known to be teratogenic; when administered during the first trimester of pregnancy, it causes an increased incidence of neural tube defects such as spina bifida. One recent analysis estimated the rate to be 1 to 2 percent in women receiving valproate during pregnancy for the treatment of epilepsy. One recent study of 17 infants born to mothers receiving sodium valproate found that 9 had minor abnormalities and 5 of those had major malformations, described as the fetal valproate syndrome. The most frequent malformation in this series was congenital heart disease. Nine of the infants showed evidence of valproate withdrawal, including irritability, tone abnormalities, or seizures. The study found a tendency for the frequency of both minor and major abnormalities to be associated with the valproate dosage administered during the first trimester.

Valproate is excreted in breast milk at a level of 1 to 10 percent of serum concentrations. No data are available on the risk, if any, that it poses to nursing infants.

No evidence is available for a mutagenic effect of valproate. In long-term toxicity studies with rats, valproate produced a significant increase in the prevalence of pulmonary adenomas and fibrosarcomas. However, in extensive clinical experience with valproate, no evidence indicates a carcinogenic effect in humans.

Minor Adverse Effects The most frequent side effects reported with valproate are gastrointestinal (nausea, dyspepsia, vomiting, and diarrhea) and neurological (sedation, ataxia, dysarthria, and tremor). Gastrointestinal symptoms are most frequent at the beginning of treatment and often decrease with time. They tend to be more common with valproic acid and sodium valproate than with the enteric-coated formulation of divalproex sodium, although in a few cases the reverse is true.

In the double-blind study of valproate versus a placebo in manic patients described above, gastrointestinal discomfort or nausea was reported in 5 (25 percent) of 20 manic patients receiving valproate, with frank vomiting in one additional patient (5 percent). However, of 23 manic patients assigned to a placebo in the study, 5 (22 percent) had gastrointestinal discomfort or nausea, and 2 more (9 percent) had vomiting.

Persistent gastrointestinal adverse effects can be reduced by treatment with histamine type 2 (H_2) receptor antagonists, such as famotidine (Pepcid) and cimetidine (Tagamet), or sucralfate (Carafate), or by using divalproex sprinkle capsules in place of divalproex sodium tablets.

Neurological side effects, such as ataxia and sedation, are best controlled by dosage reduction. Tremor is an occasional problem with valproate alone and is a frequent complaint when valproate is combined with lithium or serotonin reuptake inhibitors. Tremor can often be controlled by b-adrenergic receptor antagonists, such as propranolol (Inderal), and sometimes, in the authors' experience, by gabapentin.

Other bothersome side effects of valproate are weight gain, reported in up to 44 percent of patients on long-term treatment, and hair loss, reported in 3 to 12 percent of patients. Although the hair loss is often transient, total alopecia has been reported in rare cases. Supplemental treatment with multivitamins containing zinc and selenium may minimize hair loss. The authors have had preliminary success treating valproate—induced weight gain with topiramate (a new antiepileptic associated with anorexia and weight loss). Thrombocytopenia may occur on initiation of valproate treatment but is usually transient (despite continuation of drug), always reversible upon drug discontinuation, and rarely clinically significant. Reversible platelet dysfunction, coagulopathies, and edema are uncommonly reported. Other infrequent minor adverse effects include headache, diplopia, and dizziness.

Valproate frequently produces modest elevations in hepatic transaminases. Those abnormalities have been described in 5 to 40 percent of patients, but are rarely associated with clinically significant hepatic dysfunction. The elevations usually subside promptly after discontinuation of valproate administration or dosage reduction, and often eventually subside despite the continuation of valproate treatment at the same dosage or even higher dosages.

Reports that women treated with valproate for epilepsy had higher rates of polycystic ovaries or hyperandrogenism than epileptic women not treated with valproate led to the speculation that valproate might cause polycystic ovaries. Polycystic ovaries are often part of a syndrome that includes hirsutism, menstrual disturbances, obesity, and elevated androgens. Reanalysis of these reports, however, suggest that severe obesity was responsible for the polycystic ovaries, not the valproate itself.

DRUG INTERACTIONS

The interactions of valproate with other drugs are summarized in Table 31.7b-3.

Drug	Interactions Reported With Valproate
Lithium	Increased tremor
Antipsychotics	Increased sedation; increased extrapyramidal effects; delirium and stupor (single report)
Clozapine	Increased sedation; confusional syndrome (single report)
Carbamazepine	Acute psychosis (single report); ataxia, nausea, lethargy (single report); may decrease valproate serum concentrations
Antidepressants	Amitriptyline and fluoxetine may increase valproate serum concentrations
Diazepam	Serum concentration increased by valproate
Clonazepam	Absence status (rare; reported only in patients with preexisting epilepsy)
Phenytoin	Serum concentration decreased by valproate
Phenobarbital	Serum concentration increased by valproate; increased sedation
Other CNS depressants	Increased sedation
Anticoagulants	Possible potentiation of effect

Table 31.7b-3 Interactions of Valproate With Other Drugs

Valproate and Other Psychotropic Drugs Valproate is commonly combined with other antimanic, antidepressant, antipsychotic, and antiepileptic agents in the short-term and prophylactic treatment of bipolar disorders. In general, combinations of valproate with lithium, antipsychotics, antidepressants, carbamazepine, gabapentin, lamotrigine, topiramate, and benzodiazepines are well tolerated and often appear to be more effective than valproate used alone.

The combination of valproate with lithium is especially common and rarely produces difficulty when both drugs are maintained in their respective therapeutic ranges. Since both drugs may precipitate tremor, however, their additive effect may produce an unacceptable degree of tremor, necessitating treatment with b-adrenergic receptor antagonists such as propranolol, or, in the authors' experience, gabapentin.

The combination of valproate and typical antipsychotics is also commonly used, especially in acutely manic patients. Although valproate and antipsychotics do not appear to affect the plasma concentrations of one another significantly, the combination may evoke increased sedation and has been reported to increase antipsychotic-induced extrapyramidal effects, which may be treated by antipsychotic dosage reduction or by the addition of an antiparkinsonian agent. One report

described delirium and stupor from the combination of valproate and antipsychotics, accompanied by diffuse EEG slowing down to the delta range. Thus, the mental status of patients receiving the combination should be monitored, and an EEG should be obtained if significant cognitive changes appear.

Clozapine may also be combined with valproate. In general, this combination is well tolerated, with sedation the most frequently reported adverse reaction. There is one report of the combination producing a confusional state with sedation, functional impairment, and slurred speech. In view of the increased risk of seizures with high dosages of clozapine, however, some authorities have suggested deliberately adding valproate when high dosages of clozapine are used to profit from valproate's antiepileptic properties. Increasing clinical experience suggests that valproate may also be safely combined with other atypical antipsychotics, including olanzapine, risperidone, quetiapine, and sertindole.

The combination of valproate and carbamazepine is occasionally administered to patients with bipolar disorders. Two reports described possible adverse effects from this combination. The first case involved acute psychosis in a patient with epilepsy in whom carbamazepine was added to a stable regimen of valproate. The authors speculated that the phenomenon was attributable to the fact that valproate increases serum concentrations of a metabolite of carbamazepine, carbamazepine-10,11-epoxide. Another report described ataxia, nausea, and daytime lethargy in a manic patient who received subtherapeutic dosages of valproate in conjunction with previously well tolerated levels of carbamazepine.

In a review of 26 consecutive patients with bipolar disorders treated with valproate plus carbamazepine, none of the patients had significant toxicity from the combination, and several appeared to respond better to the combination than to a single anticonvulsant. Also, open studies examining the efficacy and the tolerability of valproate plus carbamazepine in a substantial number of patients with refractory epilepsy indicate that the combination may be effective and is often well tolerated.

However, carbamazepine may decrease serum concentrations of valproate (since carbamazepine increases hepatic microsomal enzyme activity), valproate may increase the free carbamazepine fraction (by displacing carbamazepine from plasma proteins), or valproate may increase carbamazepine concentrations (by inhibiting its metabolism), depending on which interaction predominates.

In the authors' experience, the combination of valproate with the new antiepileptic drugs gabapentin, topiramate, and lamotrigine is generally well tolerated. However, because valproate potently inhibits the metabolism of lamotrigine, lower lamotrigine doses must be used when the two drugs are coadministered. Also, the risk of rash with lamotrigine is slightly increased when it is combined with valproate.

Antidepressants—including tricyclic drugs, monoamine oxidase inhibitors, selective serotonin uptake inhibitors, and other agents—are frequently combined with valproate, usually without difficulty. However, the tricyclic amitriptyline (Elavil) has been reported to increase valproate serum concentrations, possibly by increasing the binding of valproate to tissue. Conversely, valproate has been reported to increase the levels of tricyclic drugs, presumably by inhibiting their metabolism. Addition of fluoxetine to valproate has also been reported to increase serum valproate concentrations significantly.

When combined with benzodiazepines or carbamazepine, valproate may compete for protein-binding sites. Valproate has been reported to increase serum concentrations of unbound diazepam (Valium) and carbamazepine for that reason. However, lorazepam is apparently not displaced in that manner. The combination of valproate and clonazepam (Klonopin) has been reported to produce absence status. However, that effect appears to be rare and is presumably even more rare in psychiatric patients with no history of epilepsy.

Valproate With Other Drugs Unlike many other antiepileptic drugs, valproate does not potentiate hepatic metabolism and hence does not decrease plasma concentrations of other concomitant drugs. Rather, valproate tends to inhibit the clearance of other drugs metabolized in the liver. However, valproate has been reported to decrease phenytoin concentrations, leading in some cases to breakthrough seizures, possibly as a result of competition for protein-binding sites.

Conversely, valproate may increase the concentration of phenobarbital (Luminal) and probably other barbiturates by impairing nonrenal clearance. Even in the absence of concentration changes, the combination may result in increased sedation. Similarly, valproate may potentiate the effects of other CNS depressants, such as alcohol.

Because valproate is highly protein bound, serum valproate free fraction concentrations can be increased and valproate toxicity precipitated by coadministration of other highly protein-bound drugs (e.g., aspirin, carbamazepine, diazepam) that can displace valproate from its protein-binding sites. Serial monitoring of valproate concentrations, concentrations of concomitant drugs, and sometimes the free fractions of those drugs is particularly important when such combinations are used. However, since some of the interactions, especially CNS depression, have been described even with apparently normal concentrations of both valproate and other drugs, monitoring the patient's clinical status is also essential.

Since valproate inhibits the secondary phase of platelet aggregation, it should be used cautiously in combination with other drugs that affect coagulation, such as warfarin (Coumadin) and aspirin.

LABORATORY INTERFERENCES

Valproate rarely interferes with the results of laboratory tests. However, the drug has been reported to cause overestimation of serum-free fatty acids by about 40 percent. Serum triglyceride levels are not affected. Also, valproate metabolites may produce a false-positive result in a urinary test for ketones.

DOSAGE AND ADMINISTRATION

The pretreatment evaluation for valproate should include a medical evaluation (with focus on hepatic, hematological, and pancreatic function) and baseline hepatic and hematological laboratory tests. The latter should include a complete blood cell count (CBC) (with differential and platelet count) and serum concentrations of lactic dehydrogenase (LDH), serum glutamic oxaloacetic transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT), bilirubin, and alkaline phosphatase. Other baseline measures may include bleeding time, prothrombin time (PT), and partial thromboplastin time (PTT) for patients with bleeding abnormalities; g-glutamyltransferase (GGT), PT, PTT, and plasma protein level in patients with liver disease; renal and thyroid function tests in patients who may have renal or thyroid dysfunction; serum amylase in patients with pancreatic disease; and a pregnancy test in females who might be pregnant. Before valproate treatment is begun (or, in some instances, after some patient response), patients should be warned of the risk of hepatic, hematological, and pancreatic reactions; told about the signs and symptoms of these reactions; and instructed to report them should they occur. Patients should also be cautioned about valproate's adverse effects of appetite stimulation, weight gain, and hair loss and should be considered for prophylactic zinc and selenium supplementation to reduce any hair loss experienced. Postpubertal girls and women must be warned of the drug's teratogenic effects and should be considered for prophylactic folate supplementation.

In acutely manic adolescents and adults, valproate treatment may be begun via the oral-loading strategy of 20 to 30 mg/kg a day so that therapeutic concentrations can be achieved on the first day of treatment, often with rapid onset of response and minimal adverse effects. However, in patients who are euthymic, hypomanic, depressed, very young, or elderly, valproate treatment should be initiated in lower, divided doses (e.g., 250 to 750 mg a day in adolescents and adults, and 125 to 250 mg a day in children and elderly adults) to minimize gastrointestinal and neurological toxicity. Valproate loading has not been tested in children with mania (although it has been used in children with epilepsy), and it should be avoided in elderly patients because of the risk of neurotoxicity. Patients who cannot swallow pills, particularly children and elderly adults, can use divalproex sprinkle capsules, which can be pulled apart and sprinkled on food. The valproate dose is then titrated upward (e.g., by 125 to 750 mg every several days) according to response and adverse effects, generally to a serum concentration between 50 and 125 or 150 µg/mL. Occasional patients may respond best to valproate concentrations from 150 to 200 µg/mL (although adverse effects are more frequent with concentrations above 100 µg/mL). Once patients are stabilized, valproate dosage regimens can often be simplified to one daily dose, usually taken at night, to enhance convenience and compliance.

Most authorities recommend that hepatic and hematological parameters be regularly monitored in bipolar patients receiving valproate (i.e., weekly to every several months during the initiation of treatment, and, once stable, every 6 to 24 months while the patient is taking the drug). It has been suggested that liver function tests be monitored more frequently in children younger than 10 years.

Careful clinical monitoring is probably superior to routine laboratory screening in detecting valproate-induced life-threatening hepatic, hematological, or pancreatic reactions. Indeed, the physician must be aware that routine monitoring of hematology and blood chemistry levels does not necessarily predict the development of

severe hepatotoxicity, blood dyscrasias, or pancreatitis. Thus, clinicians must instruct patients to notify them if signs or symptoms of those effects are experienced.

If mild hepatic transaminase elevation is noted, valproate treatment may be continued at the same dosage or a lower dosage with periodic monitoring of liver function tests until the enzymes return to normal levels. If transaminase increases are pronounced (more than three times the upper limit of the normal range), valproate should be reduced in dosage or discontinued. If discontinued, rechallenge with valproate may be appropriate once the abnormalities have returned to normal. If abdominal pain occurs, a serum amylase level should be obtained to rule out pancreatitis. Guidelines for these laboratory tests are summarized in Table 31.7b-4.

Prior to treatment
Standard chemistry screen with special attention to liver function tests
Complete blood count, including white cell and platelet count
During treatment
Liver function tests monthly for 3 months, then every 3 to 24 months if no abnormalities are found
Complete blood work with platelet count monthly for 3 months, then every 3 to 24 months if findings are normal
If liver function test results become abnormal
Mild transaminase elevation (less than three times normal): monitoring every 1 to 2 weeks; if stable and patient is responding to valproate, results are monitored monthly
Pronounced transaminase elevation (more than three times normal): dosage reduction or discontinuation of valproate; increase dose or rechallenge if transaminases normalize and if the patient is a valproate responder

Table 31.7b-4 Recommended Laboratory Tests During Valproate Therapy

Valproate treatment is commonly initiated in patients already receiving lithium or antipsychotics. In such cases, valproate may usually be added to an existing regimen without difficulty, although the clinician should monitor the patient for drug interactions. If the patient responds well to the addition of valproate, the other medications can be systematically subtracted from the regimen with the hope that the patient can be successfully maintained on valproate alone.

Table 31.7b-5 summarizes the preparations of valproate currently marketed in the United States.

Generic Name	Trade Name, Form (doses)	Time to Peak
Valproate sodium injection	Depacon Injection (100 mg valproic acid/ml)	1 hr
Valproic acid	Depakene, capsules (250 mg)	1–2 hr
Sodium valproate	Depakene, syrup (250 mg/5 mL)	1–2 hr
Divalproex sodium	Depakote, delayed-release tablets (125, 250, 500 mg)	3–8 hr
Divalproex sodium coated particles in capsules	Depakote, sprinkle capsules (125 mg)	Compared with divalproex tablets, divalproex sprinkle has earlier onset and slower absorption, with slightly lower peak plasma concentration

31.7 ANTICONVULSANTS

31.7C OTHER ANTICONVULSANTS

NORMAN SUSSMAN, M.D.

Three of the newer antiepileptic drugs—gabapentin (Neurontin), lamotrigine (Lamictal), and topiramate (Topamax)—appear to have a therapeutic spectrum that extends to conditions seen in psychiatric practice. Like valproate (Depakene) and carbamazepine (Tegretol), they represent possible alternatives or adjuncts for the treatment of bipolar disorders, anxiety disorders, agitation, and substance abuse. Support for use of the newer antiepileptic drugs comes primarily from clinical observation, retrospective reviews, and prospective open-label trials. The quality and amount of available data are better for gabapentin and lamotrigine than topiramate, owing to their longer availability in clinical practice. There are few well-controlled studies.

The newer antiepileptic agents are structurally diverse (Fig. 31.7c-1) and have multiple central nervous system effects. They differ in metabolism, drug interactions, and adverse effects. The clinical significance of the neurochemical mechanisms associated with these drugs is not fully understood. None of the drugs has an identical combination of neurochemical actions. Each agent has one or more of the following cellular effects: (1) enhancement of inhibitory g-aminobutyric acid (GABA)-mediated processes, (2) reduction of processes mediated by excitatory amino acids such as glutamate, and (3) antagonistic effects on voltage-gated ion channels, such as calcium channels and sodium channels. In addition to these cellular effects, there may be other mechanisms, such as changes in monamines, adenosine, or *N*-methyl-D-aspartate (NMDA) responses. Table 31.7c-1 compares mechanism-related actions of these anticonvulsants.

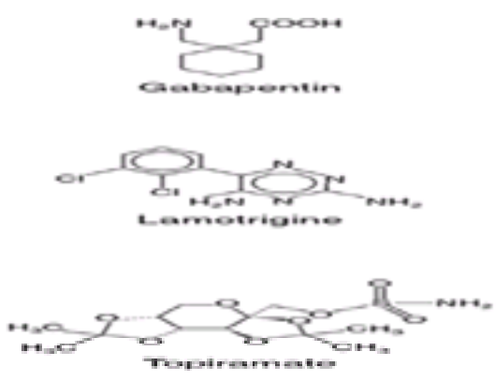

FIGURE 31.7c-1 Molecular structure of other anticonvulsants used in psychiatry.

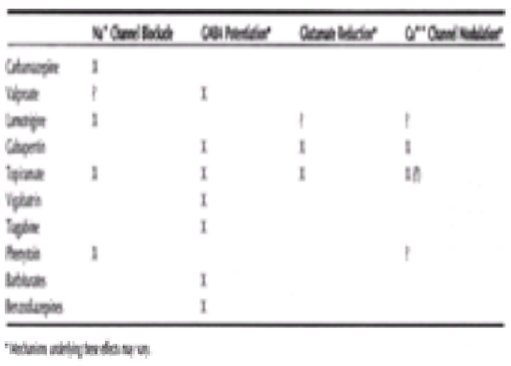

Table 31.7c-1 Comparison of Mechanism-Related Actions of Anticonvulsants

Nearly all data pertaining to the incidence of adverse events comes from experience obtained studying new anticonvulsants in combination with other antiepileptic drugs, since monotherapy is rarely attempted at the outset of epilepsy clinical trials. When used alone (and without pharmacokinetic and pharmacodynamic interactions), the type and incidence of adverse effects may vary.

GABAPENTIN

Gabapentin, approved for use by the Food and Drug Administration (FDA) in December 1993, is indicated for use as adjunctive treatment for partial seizures (both with and without secondary generalization) in patients older than 12 years of age. Gabapentin produces improvement in mood and quality of life, even when seizure control is not improved. This observed sense of well-being associated with gabapentin originally called attention to the potential value of gabapentin in the management of common psychiatric disorders.

Pharmacological Actions

Pharmacokinetics Gabapentin is poorly absorbed in the colon, with about 60 percent of a 600-mg dose being absorbed. Along with other amino acids, gabapentin is a substrate of the L-amino acid transport system found in the small intestine and on neurons and astrocytes. Thus gabapentin can easily cross cell membranes such as the blood-brain barrier and extracellular space (ECS) to glia and neuronal cytoplasm. However, this system becomes saturated at higher doses of gabapentin, which prevents a proportional increase in the amount of drug absorbed. Food does not impair the absorption of gabapentin; in fact high-protein meals significantly increase its maximal peak concentration. The time to maximum plasma concentration after ingestion is 2 to 4 hours.

Gabapentin is water soluble and can be given intravenously. It has a volume of distribution of 0.7 L/kg. Gabapentin has a half-life of 5 to 10 hours. It is not metabolized and does not have hepatically mediated drug interactions. The absorbed drug is eliminated unchanged in the urine, mainly by glomerular filtration.

Pharmacodynamics Gabapentin is an amino acid that is structurally similar to GABA. It was synthesized as a GABA analogue in the hope that it would act as a GABA receptor agonist. While gabapentin increases the synthesis and concentration of GABA, thus enhancing GABAergic activity, it does not affect GABA receptors but does cause dose-related elevations in brain GABA concentrations.

Gabapentin has been reported to alter the metabolism or concentrations of glutamate and glutamine and to bind with high affinity to a novel binding site—the

gabapentin receptor—that is associated with voltage-sensitive calcium channels. Other reported actions of gabapentin include blockade of sodium channels, interaction with an auxiliary subunit of voltage-gated Ca^{2+} channels, and increases in plasma serotonin concentrations.

The clinical effects of gabapentin are more pronounced at higher doses, but there are no established plasma concentrations that correlate with clinical response.

Therapeutic Indications

Bipolar Disorder Case reports and uncontrolled trials suggest that gabapentin facilitates stabilization of mood cycling and helps control manic episodes. In almost all reports, gabapentin is used adjunctively. These reports involve patients with different bipolar disorders (bipolar I disorder, bipolar II disorder, cyclothymic disorder, and bipolar disorder not otherwise specified) who have failed to achieve adequate control with lithium (Eskolith, Lithobid), valproate, or carbamazepine. While there are reports that gabapentin may treat the depressive phase of bipolar disorder with a lower liability for induction of mania or mood cycling than with an antidepressant, apparent mania or cycling has been reported after initiation of gabapentin treatment. Some studies suggest that gabapentin may be more useful in patients with bipolar II disorder than in those with bipolar I disorder.

In contrast to an unusually large amount of highly positive open-label data and many spontaneous case reports, no placebo-controlled trials confirm the efficacy of gabapentin for bipolar disorders as either monotherapy or adjunctive therapy. It has been suggested that the observed benefits of gabapentin therapy in bipolar patients may differ qualitatively from those associated with conventional mood-stabilizing agents, perhaps reflecting secondary anxiolytic or antiagitation properties.

Other Disorders In addition to bipolar disorders, gabapentin appears to have multiple uses in psychiatry and neurology. Patients with refractory behavioral dyscontrol have been reported to have decreases in the frequency and intensity of explosive outbursts when treated with gabapentin. Gabapentin has also been used to treat behavioral dyscontrol in children, in patients with dementia, and in patients following head injury. Animal models of anxiolytic activity strongly suggest that gabapentin has antianxiety activity. Anecdotal reports led to placebo-controlled double-blind studies that found gabapentin effective in patients with social phobia and in those with significant panic symptoms. Animal studies consistently find that gabapentin relieves induced causalgia and prevents hyperalgesia. Gabapentin has become widely used by pain specialists for the management of neuropathic pain, postherpetic neuralgia, thalamic pain, and erythromelalgia. It has been reported to relieve zoster pain, diabetic neuropathy, and intractable chronic regional pain syndrome. Gabapentin is widely used to treat reflex sympathetic dystrophy. A double-blind, randomized, placebo-controlled study that examined the effectiveness of gabapentin in the treatment of postherpetic neuralgia found that after 8 weeks in the study, the average daily pain score was significantly lower with gabapentin than with placebo. Possible effectiveness of gabapentin augmentation in obsessive-compulsive disorder patients with incomplete response to fluoxetine (Prozac), monotherapy has been reported. A mean dosage of about 2500 mg a day of gabapentin was used. Gabapentin is mildly sedating and normalizes sleep. It can be given at bedtime as an alternative to benzodiazepine agonists or other hypnotic drugs. Withdrawal symptoms and craving that accompany discontinuation of benzodiazepines, alcohol, and cocaine may be helped by gabapentin. Abrupt discontinuation of gabapentin does not cause a withdrawal syndrome.

Precautions and Adverse Reactions The most frequent side effects of gabapentin are sedation, dizziness, and ataxia, which tend to be mild and transient. Lower-extremity edema has been noted. Because gabapentin is almost exclusively eliminated through the kidneys, patients with renal impairment should be monitored closely. There is no serious toxicity with gabapentin overdose.

Drug Interactions Gabapentin does not interact with hepatic enzymes and neither inhibits nor induces them. The antacid aluminum hydroxide-magnesium hydroxide (Maalox) causes about a 25 percent reduction in absorption of gabapentin. Drugs that cause sedation may cause increased sedation when combined with gabapentin.

Laboratory Interferences Gabapentin does not interfere with any laboratory tests.

Dosage and Administration The optimal dosage of gabapentin in the management of psychiatric disorders has not been established. Both case reports and studies show extreme variability in patient response to different dosages of gabapentin. In published reports, the effective daily dosage ranges from 600 to 6000 mg. The single-dose threshold at which gabapentin may begin to interfere with its own absorption is 1200 mg; thus dosages of 3600 mg or more a day should be divided. Because this effect is not always noted and some patients derive further clinical benefit from doses as high as 6000 mg a day, when higher dosages are given, determining gabapentin concentrations can be useful.

LAMOTRIGINE

Lamotrigine, a phenyltriazine derivative, was approved in the United States in 1994. It is indicated for adjunctive treatment of partial seizures both with and without secondary generalization seizures in adults and adolescents. Both anecdotal reports and controlled trials suggest that lamotrigine may possess activity in treating both mania and depression, suggesting that it may be a truly bimodal (i.e., effective in both depression and mania) mood stabilizer.

Pharmacological Actions

Pharmacokinetics Lamotrigine is rapidly and completely absorbed. There is virtually no first-pass effect. The mean elimination half-life of lamotrigine used alone is about 30 hours, but there may be considerable individual variation—from approximately 15 to 70 hours. Maximum concentrations are achieved 2 to 4 hours after ingestion. The volume of distribution is 1.1 L/kg. It is weakly bound (55 percent) to plasma protein, and there are no clinically significant effects on hepatic drug-metabolizing enzymes. Lamotrigine is metabolized mainly by glucuronic conjugation and is eliminated almost entirely in the urine.

Pharmacodynamics Lamotrigine acts at voltage-sensitive sodium channels. Reportedly, it indirectly inhibits the presynaptic release of glutamate and aspartate and attenuates calcium entry via an effect on voltage-sensitive calcium channels. It may also alter calcium concentrations through non-voltage-dependent calcium-sensing cation channels.

Clinical Drug Studies

Bipolar Disorders Anecdotal reports, case series, prospective case studies, and controlled trials suggest utility of lamotrigine in treating bipolar disorder in treatment-refractory patients. Bipolar patients with mania, depression, mixed states, and rapid cycling have experienced significant improvement with maintenance of effect. In some cases, patients have been tapered from all other psychiatric medications.

A 7-week, multicenter, randomized, double-blind, placebo-controlled trial involving nearly 200 patients with a diagnosis of bipolar I disorder, current episode depressed, found that patients receiving lamotrigine demonstrated significant improvement in depression by week 3. The dosing schedule for lamotrigine during this trial is given in Table 31.7c-2. Significant antidepressant effects were found with lamotrigine 50 mg a day and 200 mg a day, with a greater response at the higher dose. Seven patients receiving lamotrigine (5.4 percent) and three patients receiving placebo (4.6 percent) developed manic, hypomanic, or mixed episodes.

Group	Weeks 1–2	Week 3	Week 4	Weeks 5–7
50 mg	25 mg q.d.	25 mg b.i.d.	25 mg b.i.d.	25 mg b.i.d.
200 mg	25 mg q.d.	25 mg b.i.d.	50 mg b.i.d.	100 mg b.i.d.

Table 31.7c-2 Lamotrigine: Dosing for Double-Blind Monotherapy Trial

A double-blind, placebo-controlled trial that compared gabapentin, lamotrigine, or placebo monotherapy for patients with treatment-refractory mood disorders found a statistically significant difference between lamotrigine and placebo for patients experiencing a positive response, improvement was evident by the third week of treatment for patients receiving lamotrigine and by the first week of treatment for patients receiving gabapentin. Patients responding to gabapentin experienced an apparent loss in antidepressant effect by week 5. The response rate by diagnostic subtypes (bipolar I, bipolar II, and unipolar) were, respectively, lamotrigine, 73, 47, and 29 percent; gabapentin, 42, 29, and 0 percent.

A 12-month prospective, open-label, multicenter trial evaluated the use of lamotrigine as adjunctive or monotherapy in 75 patients with bipolar disorder. All patients were either nonresponsive or intolerant to ongoing pharmacotherapy. Lamotrigine dosing was based on whether patients were receiving other drugs during the study, as summarized in Table 31.7c-3. Marked improvement was noted in 45 percent of those who entered the study in the depressed phase; 60 percent of patients who entered the study in hypomanic, manic, or mixed states, and 50 percent of patients who met criteria for rapid cycling. Three patients experienced exacerbation of mania and were hospitalized. Four patients switched from depression to mania and were hospitalized.

Treatment	Weeks 1–2	Weeks 3–4	Weeks 4–5
Lamotrigine monotherapy	25	50	100–200 (500 maximum)
Lamotrigine plus carbamazepine	50	100	200–500 (700 maximum)
Lamotrigine plus valproate	25 every other day	25	50–200 (200 maximum)

Data from 12-month prospective, open-label, multicenter trial as add-on or monotherapy in 75 patients with bipolar disorder who were either nonresponsive or intolerant of ongoing pharmacotherapy.

Table 31.7c-3 Lamotrigine Dosing (mg/day)

Other Disorders Lamotrigine can be of benefit in the treatment of psychosis arising in the course of epilepsy. This is a potentially important property since neuroleptic drugs, the usual treatment, can lower the seizure threshold. Lamotrigine possesses antinociceptive activity in animal models, although this has not been noted clinically. There have been reports of lamotrigine providing benefit to patients with restless legs syndrome.

Precautions and Adverse Reactions The most commonly observed adverse effects associated with use of lamotrigine are dizziness, ataxia, somnolence, headache, diplopia, blurred vision, nausea, vomiting, and rash. Approximately 10 percent of individuals in premarketing clinical trials discontinued treatment because of an adverse event. Lamotrigine therapy is not associated with changes in weight.

The frequency of adverse events in a placebo-controlled study of lamotrigine in bipolar disorder was similar for patients receiving lamotrigine or placebo. The only exception was headache, which occurred more frequently among patients taking lamotrigine.

The product information for lamotrigine contains a boxed warning about severe, potentially life-threatening rashes associated with use of the drug. These rashes occur in adults at an estimated rate of 1 in 1000 and include Stevens-Johnson syndrome and toxic epidermal necrolysis. Rare deaths have been reported, but their numbers are too few to permit calculation of risk. In pediatric patients, the incidence of severe rash is very much higher than that reported in adults, with reports from clinical trials suggesting an upper frequency estimate of 1 in 50 to 1 in 100 pediatric patients who may develop a potentially life-threatening rash.

Why age is a risk factor for rash is unknown. Other than age, the risk of rash may be increased by (1) combining lamotrigine with valproic acid, (2) exceeding the manufacturer's recommended starting dosage of lamotrigine, and (3) exceeding the recommended rate of dose escalation for lamotrigine. Nearly all life-threatening rashes associated with lamotrigine have occurred within 2 to 8 weeks of treatment initiation. Rash can occur after prolonged treatment (e.g., 6 months) as well. Lamotrigine should be discontinued at the first sign of rash, unless the rash is clearly not drug related. In some clinical trials the rate of rash has been significantly higher among placebo-treated patients than those being treated with lamotrigine. Routinely informing patients of the need to self-monitor for rash, while necessary, apparently leads to overrecognition in some instances.

Drug Interactions Drugs that inhibit the hepatic cytochrome P450 (CYP) system, particularly the CYP 3A4 isozyme, increase lamotrigine concentrations. Carbamazepine and other hepatic enzyme stimulators increase the metabolism of lamotrigine.

Lamotrigine does not affect the metabolism of other drugs; however, combined use of lamotrigine with other anticonvulsants can alter its pharmacokinetics. Valproate inhibits the metabolism of lamotrigine, increasing its half-life to 70 hours. Phenytoin (Dilantin), carbamazepine, phenobarbitone (Donnatal, Quadrinal), and primodone (Mysoline), hepatic enzyme–inducing agents, enhance metabolism of lamotrigine, reducing its half-life to about 13 hours.

Laboratory Interferences Lamotrigine does not interfere with common laboratory tests.

Dosage and Administration Because serious rash is an early adverse effect that is linked to plasma concentrations of lamotrigine, it is recommended that lamotrigine treatment be initiated at a dosage of 25 mg a day and increased slowly. When used as monotherapy, the suggested dosing schedule should be that indicated in Table 31.7c-3. Dosage should be adjusted for patients taking valproate or carbamazepine. The maximum daily dose varies, depending on concurrent medications. When used as monotherapy the maximum dosage is 500 mg a day in divided doses.

TOPIRAMATE

Topiramate was synthesized in an attempt to develop an analogue of fructose that could block gluconeogenesis and be used as a hypoglycemic agent. During animal testing, it failed to exhibit hypoglycemic activity but was noted to have antiseizure activity. It gained FDA approval in December 1996. It is indicated as adjunctive therapy for the treatment of adults with partial-onset seizures.

Pharmacological Actions

Pharmacokinetics Absorption of topiramate is rapid and almost complete. It has about 80 percent bioavailability and is not affected by food. Peak plasma concentrations occur about 2 hours following a 400-mg oral dose. The pharmacokinetics of topiramate are linear, with dose-proportional increases over the standard dosage range of 200 to 800 mg a day.

The mean plasma elimination half-life is 21 hours. Steady state is reached in 4 days. Topiramate is poorly bound to plasma proteins (13 to 17 percent) and thus is unlikely to displace highly protein-bound drugs.

Topiramate is not extensively metabolized, and 70 to 85 percent of an administered dose is eliminated unchanged in urine. Compared with those with normal renal function, the clearance of topiramate is reduced by about 40 percent in those with moderate renal impairment and by about 55 percent in severely renal-impaired persons. Topiramate is cleared by hemodialysis at a rate 4 to 6 times greater than that of a normal individual. The weight-adjusted clearance of topiramate is higher in children than adults. Although the mechanism is not understood, clearance of topiramate is decreased in patients with hepatic impairment.

Pharmacodynamics Three properties may contribute to the pharmacology of topiramate: sodium channel blocking, potentiation of GABA activity at the $GABA_A$ receptor, and antagonism of kainate-induced activation of the kainate–adenosine monophosphate (AMP) subtype of glutamate receptor. Topiramate also inhibits

some carbonic anhydrase isoenzymes, which may lead to formation of kidney stones but does not appear to affect topiramate's antiepileptic or mood activity.

Bipolar Disorder Open-label studies and case series reports have described the successful use of topiramate as a treatment for bipolar disorder. Populations described include both inpatients and outpatients with bipolar mood disorders who are unresponsive to conventional therapy. Too few patients have been reported to permit conclusions about the effectiveness and tolerability of topiramate as a mood stabilizer.

Precautions and Adverse Reactions The most common adverse events associated with the use of topiramate are central nervous system related. The most significant adverse effects can be classified in two broad categories: (1) psychomotor slowing, difficulty with concentration, and speech or language problems (in particular, word-finding difficulties) and (2) somnolence or fatigue. Dizziness or imbalance, confusion, memory problems, and irritability and depression are occasionally observed. The incidence of psychomotor slowing is only marginally dose related, but both language problems and difficulty with concentration or attention clearly increase in frequency with higher dosages. Detrimental effects on cognition tend to be associated with high initial dosages and rapid dosage escalation; they may develop insidiously and are often (but not always) time limited. About 1.5 percent of patients reported renal calculi during clinical trials, a tenfold increase over normal rates. There is no organ toxicity.

Unique among the anticonvulsants, topiramate use may be accompanied by significant weight loss. Of patients taking topiramate for a mean duration of 148 days, 72.3 percent lost a mean of 11 pounds. Because of this side effect, topiramate could in theory be combined with other anticonvulsants to counteract weight gain.

In reports of topiramate use to treat mood disorders, adverse effects have included anorexia and weight loss, paresthesia, agitation, confusion, hallucinations, somnolence, fatigue, and impaired concentration and memory. These effects were generally dose related. Symptoms of overdose include confusion, ataxia, hyperreflexia, and lethargy.

Drug Interactions When combined with other anticonvulsant drugs, topiramate has no effect on concentrations of carbamazepine, phenobarbital, or primodone. There is little or no increase in phenytoin concentration and a minimal decrease in valproic acid concentration. Carbamazepine and valproic acid lower concentrations of topiramate. Topiramate has no clinically relevant effect on the plasma levels of classical neuroleptic drugs, tricyclic drugs, theophylline (Theo-Dur) and coumarin. Concomitant use of topiramate with central nervous system (CNS) depressants can cause excessive sedation. Combined use with acetazolamide (Diamox) or other carbonic anhydrase inhibitors can increase the risk of renal stones. Topiramate decreases ethinyl estradiol (Brevicon, Demulen) concentrations by about one-third, possibly interfering with the effectiveness of contraceptive medication.

Laboratory Interferences Apart from laboratory values related to carbonic anhydrase inhibition, no laboratory interference has been associated with topiramate use.

Dosage and Administration Initial doses of topiramate should be as low as 25 mg a day. It can be titrated upward as tolerated to a maximum of 400 mg a day in two divided doses. In an open-label inpatient study of bipolar patients, dosages ranged from 50 to 1300 mg a day, with a mean of 614 mg a day.

TIAGABINE, VIGABATRIN, AND FELBAMATE

Three other new anticonvulsants, tiagabine (Gabatril), vigabatrin (Sabril), and felbamate (Felbatol), are available or waiting FDA approval. Unlike gabapentin, lamotrigine, and topiramate, these drugs have not been reported to have potential indications as treatments for conditions seen in psychiatric practice. Felbamate and vigabatrin are associated with serious adverse effects that have deterred casual off-label use. Because each of the newer compounds possesses mechanisms that are similar to agents shown to have behavioral and mood properties, these drugs may eventually be found to benefit patients with mental disorders.

Tiagabine Tiagabine was approved by the FDA in 1997 and is indicated as adjunctive therapy in adults and children 12 years and older in the treatment of partial seizures. It is believed to block reuptake of GABA into the presynaptic neurons, thus increasing extracellular concentrations of GABA. At concentrations 20 to 400 times those inhibiting the uptake of GABA, tiagabine binds to histamine type 1, (H_1), 5-hydroxytryptamine type 1B, ($5\text{-}HT_{1B}$), and benzodiazepine receptors and chloride channels. There have been no reports of tiagabine use in the treatment of mental disorders.

Tiagabine is rapidly and completely absorbed, with peak plasma concentrations occurring about 45 minutes after ingestion. The metabolism of tiagabine has not been fully elucidated but it is likely to involve the cytochrome P450 CYP 3A isozyme. Based on studies with anticonvulsants, tiagabine does not appear to stimulate or inhibit the metabolism of other drugs.

The most common side effects of tiagabine are CNS related: dizziness or lightheadedness, lack of energy, somnolence, nervousness, irritability, tremor, and difficulty with concentration and attention. Nausea and abdominal pain may also occur.

Vigabatrin Vigabatrin, also called g-vinyl GABA, is available in Canada and has been on the market in Europe since the late 1980s. It is awaiting approval in the United States.

Vigabatrin irreversibly inhibits GABA-transaminase, the GABA degradation enzyme, resulting in enhanced release of GABA through the GABA transporter and increased brain GABA concentrations. It has also been noted to inhibit striatal dopamine release. Vigabatrin has little protein binding, has a long half-life, and is mainly excreted unchanged by the kidneys.

Preliminary studies have shown vigabatrin to be as effective as benzodiazepines in facilitating alcohol and cocaine withdrawal. Doses used for alcohol withdrawal were 2000 mg a day. Vigabatrin attenuates cocaine-induced increases in extracellular dopamine in the striatum and nucleus accumbens of animals. Vigabatrin inhibition of GABA-transaminase may account for these effects, since that enzyme regulates dopamine concentration. In animal studies, vigabatrin blocked cocaine-related drug-seeking behavior. Imaging studies showed that it decreased in dopamine following administration.

In contrast to topiramate, vigabatrin does not have detrimental effects on cognitive function. In rare instances, when used by patients with seizure disorder, vigabatrin caused such adverse behavioral effects as agitation, irritability, depression, and psychosis.

Visual field constriction and blurring has been reported during vigabatrin therapy. These visual symptoms may be severe and persistent. They appear to be associated with retinal cone system dysfunction. Some patients may experience modest weight gain. Should vigabatrin be found to be useful as a treatment for substance abuse or mood or anxiety disorders, there is a possibility that the drug may be prone to cause rebound or withdrawal symptoms. Some epilepsy patients taking vigabatrin have experienced increased frequency or severity of seizures (compared with baseline) when the drug was stopped abruptly. These symptoms improved when vigabatrin treatment was restarted and gradually tapered.

Felbamate The FDA approved felbamate, a derivative of the antianxiety agent meprobamate (Equanil, Miltown), in 1993. It is indicated as both adjuvant therapy and monotherapy for adults with partial seizures with or without generalization and in children with partial and generalized seizures associated with the Lennox-Gastaut syndrome (i.e., epilepsy and mental retardation in children). Felbamate interacts as an antagonist at the strychnine-insensitive glycine recognition site of the NMDA-receptor complex. Felbamate reduces glutamate activity, potentiates GABA, and has sodium channel–blocking properties.

Felbamate is not generally used to treat psychiatric disorders for several reasons. There is no literature indicating that it offers special benefits. In fact, felbamate use has been associated with adverse behavioral effects. These adverse effects, noted when felbamate was used as monotherapy in patients with epilepsy, include induction of mania and stimulant-like effects. Possibly serious adverse effects also represent a deterrent to casual, off-label use; these rare but potentially serious adverse effects are aplastic anemia and hepatic failure. Because of these adverse effects the use of felbamate is restricted to patients with seizure disorder who have not responded to, or have not tolerated, other available treatments. The rate of aplastic anemia is estimated to be between 1 in 3000 and 5000 patients. Rates are highest among those with a past history of aplastic anemia or disorders of the immune system. Felbamate product information contains a special high caution “black box” warning about use of the drug.

Common adverse effects of felbamate are dose related and include insomnia, somnolence, headache, nausea, vomiting, anorexia, and dizziness. Felbamate use is further complicated by the potential for pharmacokinetic interactions.

FUTURE DIRECTIONS

The newer anticonvulsants show preliminary evidence of efficacy for mental disorders. The comparative efficacies of the newer drugs and standard agents, both for short-term treatments and prophylactic therapy, have not been established. Effectiveness for these drugs for monotherapy or adjunctive therapy has not been determined. Dose requirements for off-label uses and efficacy and safety in children and elderly adults need to be clarified. Any differences in the therapeutic spectrum of specific drugs are unknown. For example, do some drugs more effectively treat manic episodes than depressive episodes? Are there differences in effectiveness for mixed episodes or rapid cycling? Until more is known about the effectiveness of these drugs in their off-label uses, they should be reserved for patients who are unresponsive or intolerant of conventional agents. When using these drugs, inform the patient about their off-label use for medicolegal reasons. Discuss and document the rationale for use of these drugs, especially if approved treatments have not been tried first. Review risks that may be serious (e.g., the rash with lamotrigine and the visual disturbances with vigabatrin). Evidence supporting the effectiveness of topiramate beyond epilepsy is too preliminary to permit meaningful comparisons with lamotrigine and gabapentin.

SUGGESTED CROSS-REFERENCES

Bipolar disorders are discussed in Chapter 14 on Mood Disorders. Section 31.7a discusses carbamazepine, and Section 31.7b discusses valproate. Seizure disorders are covered in Section 2.4 on neuropsychiatric aspects of epilepsy.

31.8 ANTIHISTAMINES

LAWRENCE S. GROSS, M.D., AND GEORGE M. SIMPSON, M.D.

INTRODUCTION AND HISTORY

Histamine is a low-molecular-weight amine that interacts with specific receptors in various target tissues. In addition to its role in allergic reactions and gastric acid secretion, there is considerable evidence that histamine functions as a central nervous system (CNS) neurotransmitter. Histamine-blocking agents were first discovered in the 1930s, introduced into clinical medicine in the 1940s, and in common use by the 1950s. Historically, antihistamines have been used in psychiatry for nonspecific sedation, as hypnotics, and to treat anxiety, childhood behavior problems, and the adverse effects of antipsychotic medication. The antihistamines most commonly used in psychiatric practice block histamine at the H_1 receptor and are considered traditional (first-generation) antihistamines. They are listed in Table 31.8-1 and will be the focus of this discussion.

Generic Name	Brand Name
Diphenhydramine	Benadryl
Hydroxyzine	Atarax
Hydroxyzine	Vistaril
Promethazine	Phenergan
Cyproheptadine	Periactin

Table 31.8-1 Antihistamines Used in Psychiatry

A new class of drugs that blocked histamine-induced gastric acid secretion was discovered in the 1970s, leading to the development of the histamine type 2 (H_2) receptor antagonists. In the 1980s nonsedating (second-generation) histamine type 1 (H_1) receptor antagonists were developed to treat allergic diseases. Although not used as psychiatric treatments, selected drugs from these categories are listed in Table 31.8-2 and are included because their potential toxicity and interactions with other drugs is of importance to psychiatrists.

Class	Generic Name	Brand Name	Comments
H_2 receptor antagonists	Cimetidine	Tagamet	Widely prescribed for treatment of ulcers and gastroesophageal reflux. All have the potential for CNS toxicities, including psychosis and delirium
	Ranitidine	Zantac	
	Famotidine	Pepcid	
	Nizatidine	Axid	
Second-generation (nonsedating) H_1 receptor antagonists	Terfenadine	Seldane	May prolong QT interval and induce serious cardiac arrhythmia, particularly when co-administered with drugs inhibiting hepatic cytochrome P450 3A4. Production of terfenadine stopped February, 1998; use of astemizole not recommended with SSRIs or nefazodone.
	Astemizole	Hismanal	
	Loratadine	Claritin	No apparent cardiotoxicity, but increased levels can occur when co-administered with CYP 3A4 inhibitors.
	Cetirizine	Zyrtec	
	Fexofenadine	Allegra	

Table 31.8-2 Other Antihistamines With Relevance to Psychiatric Practice

CHEMISTRY

All available H_1 antagonists are reversible, competitive inhibitors of histamine at the H_1 receptors. Like histamine, they contain a substituted ethylene moiety, but, unlike histamine, they have other groupings that may be used to broadly classify the traditional (first-generation) antihistamines. The classes of the agents most widely used in psychiatry include the ethanolamines (diphenhydramine [Benadryl]), the piperazines (hydroxyzine [Vistaril], hydrochloride [Atarax]), and the phenothiazines (promethazine [Phenergan]). Cyproheptadine (Periactin) contains a tricyclic nucleus with a piperadine side ring. The chemical structures of these compounds are shown in Figure 31.8-1.

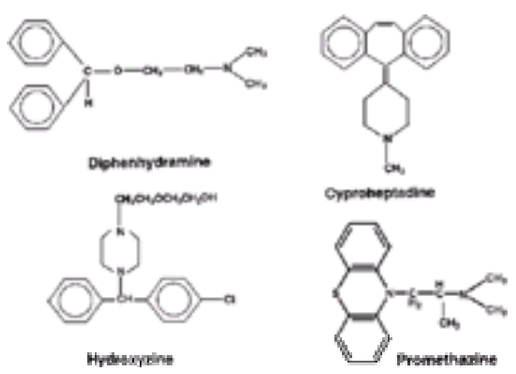

FIGURE 31.8-1 Molecular structures of antihistamines used in psychiatric practice.

PHARMACOLOGICAL ACTIONS

Most H_1 antagonists have similar pharmacological properties and can be discussed together.

Pharmacokinetics

Absorption The first-generation antihistamines are well absorbed from the gastrointestinal tract. Following oral administration, effects begin within 15 to 30 minutes and maximal blood concentrations are reached in 1 to 3 hours. Duration of action is generally 4 to 6 hours, but some compounds are much longer acting. Parenteral injection produces a more rapid onset of action but may cause hypotension, particularly with rapid intravenous administration.

Distribution Antihistamines such as diphenhydramine are widely distributed throughout the body and are contraindicated in nursing mothers. These drugs cross the blood-brain barrier and have both central and peripheral effects.

Metabolism and Elimination The first-generation antihistamines are extensively metabolized by the liver, with most eliminated as metabolites in the urine; little, if any antihistamine is excreted unchanged. Elimination is more rapid in children and slower in patients with severe hepatic disease. H_1 receptor antagonists induce hepatic microsomal enzymes and therefore may facilitate their own metabolism.

Pharmacodynamics

Mechanism of Action The clinical effects of antihistamines are the result of their blockade of histamine receptors. H_1 receptors are present throughout the CNS, with dense concentrations found in the hypothalamus. Histamine increases wakefulness via H_1 receptors, which may explain the sedative potential of the traditional antihistamines.

Many first-generation H_1 antagonists, including diphenhydramine, hydroxyzine, promethazine, and cyproheptadine, also block responses to acetylcholine mediated by muscarinic receptors. In addition to its antihistaminic and anticholinergic effects, cyproheptadine is a potent serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT_2) receptor antagonist.

Blood Levels Blood levels of antihistamines are not routinely obtained in clinical practice.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

There are no recent studies clearly demonstrating the safety and efficacy of traditional antihistamines in psychiatric disorders. The original literature addressing the sedative and hypnotic uses of these agents is decades old, limiting comparison to research using current diagnostic criteria. More recent studies of antihistamines as sleep aids demonstrated significantly more improvement in several sleep parameters compared with placebo, but these effects were less pronounced than the effects of the benzodiazepines.

An open clinical trial has indicated that cyproheptadine may be useful in the treatment of neuroleptic-induced akathisia. A double-blind, placebo-controlled study of the treatment of chronic schizophrenia with cyproheptadine showed no improvement in negative symptoms and exacerbation of some positive symptoms. Preliminary findings from open-label studies and case reports suggest that famotidine (Pepcid), an H_2 receptor antagonist, may be beneficial as an adjunctive treatment for schizophrenia.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Target organ effects of the traditional antihistamines result from the direct action of their blockade of histamine receptors or their associated anticholinergic activity; they are associated with both CNS depression and excitation. Sedation is common at therapeutic dosages, but these agents vary in their ability to cause CNS depression and patients vary in their response to individual drugs. The ethanolamines, such as diphenhydramine, are particularly sedating. Stimulation occasionally occurs in patients at therapeutic dosages, and central excitation may be a dramatic feature of poisoning. Some H_1 antagonists, particularly promethazine, also have antiemetic effects and local anesthetic activity.

H_1 antagonists block the action of histamine on capillary permeability and respiratory and vascular smooth muscle, which helps to suppress the vasodilation, edema, and pruritis associated with various allergic responses. These drugs inhibit histamine-mediated bronchoconstriction in challenge tests but, at usual dosages do not inhibit bronchoconstriction in patients with asthma or other hypersensitivity reactions.

Unlike the H_2 antagonists, the H_1 antagonists do not inhibit gastric secretion at all; they suppress histamine-mediated salivary, lacrimal, and other exocrine secretions to varying degrees. The anticholinergic properties of these agents may reduce secretions in cholinergically innervated glands and in tissues such as the respiratory system.

THERAPEUTIC INDICATIONS

Historically, H_1 antagonists have been widely used for nonspecific sedation and as mild hypnotics, particularly in over-the-counter sleep aids. They have largely been replaced in psychiatric practice by benzodiazepines, which have fewer side effects and are more effective for the treatment of anxiety and for the induction and maintenance of sleep. Antihistamines may have a role in the treatment of patients with histories of benzodiazepine abuse or other contraindications to benzodiazepine use. Although antihistamines are prescribed for the treatment of childhood behavioral problems, a recent review of the literature found no clear indication for their use in the treatment of child and adolescent anxiety disorders. They may have some anxiolytic effect, but their use is limited by lowered seizure threshold, sedation, anticholinergic adverse effects, and the potential for abuse in adolescents.

Diphenhydramine Diphenhydramine is indicated for the treatment of allergic reactions and motion sickness. It is also indicated for treating parkinsonism (including neuroleptic-induced parkinsonism) in elderly patients unable to tolerate more potent agents, other age groups with mild parkinsonism, or patients requiring treatment in combination with centrally acting anticholinergic agents. The injectable form of diphenhydramine is effective when oral treatment is impractical (e.g., acute allergic or dystonic reaction). Although probably not as effective as the more specific anticholinergic agents in the treatment of drug-induced extrapyramidal side effects, diphenhydramine could be useful to treat extrapyramidal adverse effects in patients with acute psychotic agitation when additional sedation may be desirable. When administered intravenously, diphenhydramine is the drug of choice for the treatment of dystonic reactions induced by dopamine-blocking agents; however, it is not effective in relieving akathisia. Diphenhydramine is also found in a variety of nonprescription cold and allergy preparations and in sleep-inducing aids.

Hydroxyzine Hydroxyzine is the only antihistamine with Food and Drug Administration (FDA) approval for use in the symptomatic relief of anxiety and tension associated with psychiatric and medical conditions. Its effectiveness as an antianxiety agent for periods exceeding 4 months has not been systematically assessed. It is also indicated for the management of pruritis caused by allergic conditions, and it is used as a premedication sedative and following general anesthesia.

Promethazine As one of the more sedating and anticholinergic H_1 antagonists, promethazine is indicated in the treatment of a variety of conditions, including allergic reactions and motion sickness. It is used in the surgical setting as an antiemetic; as an adjunct to analgesics for postoperative pain control; and as a preoperative, postoperative, or obstetric sedative. It is also indicated for sedation, relief of apprehension, and production of light sleep in both children and adults.

Cyproheptadine Cyproheptadine has FDA approval for use in the treatment of vasomotor rhinitis and a variety of allergic reactions. Because of its serotonin-blocking effects in addition to its H_1–histamine-receptor antagonism, cyproheptadine has been used in the treatment of antidepressant-induced sexual dysfunction; however, adverse effects have been reported and results have been inconsistent. Systematic studies in this area are lacking.

An open clinical trial of 4 mg of cyproheptadine four times a day by mouth reported improvement in 15 of 17 patients with neuroleptic-induced akathisia. Case reports

of other conditions indicating improvement following cyproheptadine treatment include recurrent nightmares with posttraumatic themes and one case of suspected serotonin syndrome.

PRECAUTIONS AND ADVERSE REACTIONS

The most common adverse effects of first-generation H_1 antagonists involve the nervous system and the gastrointestinal tract. These drugs have a high incidence of sedation, which may be a desirable effect in some patients but may interfere with the patient's daily activities. Other nervous system reactions include dizziness, tinnitus, incoordination, fatigue, blurred vision, insomnia, and tremors. Promethazine, a phenothiazine derivative, can cause extrapyramidal symptoms. Antihistamines may be associated with CNS-related emotional reactions such as lassitude, nervousness, and euphoria. Gastrointestinal effects, which may be reduced by giving the drug with meals, include loss of appetite, epigastric distress, nausea, vomiting, and constipation or diarrhea. Untoward anticholinergic effects include dryness of the mouth, thickening of respiratory secretions, urinary frequency, dysuria, and urinary retention.

Because of their anticholinergic actions, these antihistamines should be used with great caution in patients with narrow-angle glaucoma, stenosing peptic ulcer, pyloroduodenal obstruction, symptomatic prostatic hypertrophy or bladder neck obstruction. Caution should also be exercised in the treatment of patients with hyperthyroidism, cardiovascular disease, hypertension, increased intraocular pressure, and history of bronchial asthma. Elderly patients may be more likely to experience sedation, confusion, dizziness, and hypotension; young children may experience paradoxical excitation.

Although uncommon, first-generation H_1 antagonists have the potential for abuse and dependence. They may be fatal in overdose, with excitatory effects posing the greatest danger in acute poisoning. The syndrome includes hallucinations, excitement, ataxia, incoordination, and seizures. Along with dilated pupils, sinus tachycardia, urinary retention, and fever, there may be deepening coma progressing to cardiorespiratory collapse and death; treatment is generally symptomatic and supportive.

There are no adequate and well-controlled studies of these antihistamines in pregnant women. The drugs fall into the FDA's Pregnancy Categories B (no evidence of risk in humans) and C (risk cannot be ruled out). Results are similarly lacking regarding the excretion of these drugs in breast milk, but their use is generally contraindicated in nursing mothers. Clinical studies and experience with these antihistamines do not suggest carcinogenicity or teratogenicity in humans.

Despite not being clinically used in psychiatry, it is important to note that H_2 antagonists, widely prescribed for the treatment of upper gastrointestinal disorders, have all been associated with CNS toxicities. Reactions reported have included psychosis, agitation, hallucinations, delirium, disorientation, confusion, obtundation, and hostility. A review of the literature indicated that the symptoms usually emerged during the first 2 weeks of treatment and most resolved within 3 days of discontinuing therapy; all the reviewed reactions resolved within 7 days. Cimetidine (Tagamet) was most associated with CNS reactions, but there was no clear evidence to indicate that one H_2 blocker was more likely than another to cause these symptoms. Although the estimated incidence of CNS toxicities was low (0.2 percent in outpatients versus 1.6 to 1.9 percent in hospitalized patients), consulting psychiatrists should be aware of the potential CNS toxicities of these widely used medications.

DRUG INTERACTIONS

Monoamine oxidase inhibitors intensify and prolong the anticholinergic effects of antihistamines, so these drugs should be used with caution. The sedative effects of traditional H_1 antagonists are additive with those of alcohol and other CNS depressants. Hydroxyzine and promethazine may potentiate the actions of narcotics, nonnarcotic analgesics, and barbiturates, necessitating dosage reductions of these CNS depressants during coadministration. In case reports, the antidepressant and antibulimic effects of fluoxetine (Prozac) were reversed in a few patients when cyproheptadine was added to treat fluoxetine-induced anorgasmia.

The second-generation H_1 antagonists astemizole (Hismanal) and terfenadine (Seldane) have the potential to cause prolongation of the QTc interval, resulting in polymorphic ventricular tachycardia (*torsades de pointes*). This can occur when these drugs are taken in higher-than-recommended doses, in patients with liver disease, or by coadministration of drugs that inhibit the hepatic cytochrome P_{450} (CYP) 3A4 isoenzyme, thought to be primarily responsible for terfenadine and astemizole metabolism. Of importance to psychiatrists is the fact that the serotonergic antidepressants nefazodone (Serzone) and fluvoxamine (Luvox), inhibitors of CYP 3A4, should not be used with terfenadine and astemizole because of potentially fatal cardiac arrhythmias. The manufacture of terfenadine (Seldane) in the U.S. was stopped in early 1998 because of cardiac risks. The drug fexofenadine (Allegra) provides essentially the same antihistaminic effects without apparent cardiac risks.

Because of minor metabolic pathways of astemizole (Hismal) involving CYP 1A2 and 2D6, the list of substances not recommended for coadministration with astemizole has been expanded to include all of the serotonin selective reuptake inhibitors as well as nefazodone. Loratadine (Claritin), cetirizine (Zyrtec), and fexofenadine, nonsedating antihistamines not associated with this cardiotoxic interaction, are considered safer choices for patients taking these antidepressants. However, levels of these antihistamines can be increased in the presence of CYP 3A4 inhibitors, and recent reports have suggested closer inspection of their safety profiles.

Clinicians should inquire about the use of over-the-counter sleep preparations, many of which contain antihistamines and may be involved in interactions with other medications.

LABORATORY INTERFERENCES

H_1 antagonists can interfere with allergy skin tests and should be discontinued at least 1 week before any such testing is performed. Promethazine has been reported to interfere with pregnancy tests and increase blood glucose levels. When taken within 2 weeks of delivery, promethazine may inhibit platelet aggregation in the newborn. One report found that large quantities of diphenhydramine resulted in a false-positive urine screen for phencyclidine.

DOSAGE AND ADMINISTRATION

The recommended preparations and dosages for children and adults for the antihistamines most commonly used in psychiatry are listed in Table 31.8-3.

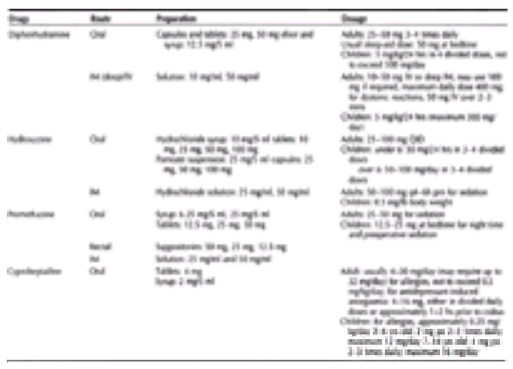

Table 31.8-3 Dosage and Administration of Traditional Antihistamines

SUGGESTED CROSS-REFERENCES

Treatment of extrapyramidal side effects is discussed in Section 31.4, benzodiazepines are discussed in Section 31.9, treatment of anxiety and anxiety disorders is discussed in Section 15.7 and Section 15.8, hypnotic medications and the treatment of insomnia are discussed in Chapter 21, pharmacotherapy in children is discussed in Section 48.6, antidepressant-induced sexual dysfunction is discussed in Section 19.1a, and antidepressant-related metabolic effects and drug

interactions are discussed in Section 31.2.

31.9 BARBITURATES AND SIMILARLY ACTING SUBSTANCES

LAWRENCE A. LABBATE, M.D., GEORGE W. ARANA, M.D., AND JAMES C. BALLENGER, M.D.

Adolph von Baeyer discovered the precursor to the barbiturates, barbituric acid, in 1864. Barbituric acid was the product of urea and malonic acid. Although various hypotheses exist regarding the origin of the name “barbituric,” it was likely derived from the word “urea” and the name “Barbara,” though to whom it refers is uncertain. Barbital, the first drug of the class with hypnotic action, was discovered in Berlin, Germany, in 1892 by Josef von Mering and Emil Fisher. Barbital was introduced to clinical practice as Veronal in 1903 and became widely used for its sedative and hypnotic properties. Numerous other barbiturates were subsequently synthesized, including phenobarbital (Solfoton, Luminel) in 1912.

Although the barbiturates were an improvement over the bromine salts, opium, or ethanol for conditions such as anxiety or insomnia, their usefulness was limited by their narrow therapeutic range and low therapeutic index (LD_{50}/ED_{50}), the ratio of lethal to effective dose. Some barbiturates may cause respiratory compromise or arrest at several times the effective dose. Although many benefited from the sedative and hypnotic qualities, this narrow therapeutic index led to many completed suicides. Several studies in the 1970s found barbiturates to be the most common drugs taken in overdose, and they accounted for a large percentage of suicides and hospitalizations from self-poisoning. Barbiturates have largely been replaced in current practice by the benzodiazepines which have a high therapeutic index and a relatively lower incidence of other complicating features (hepatic enzyme induction, development of life-threatening dependence and tolerance, and others). The primary uses of barbiturates in current psychiatric practice are anesthesia in electroconvulsive therapy (ECT), the differential diagnosis of catatonia, and detoxification of patients dependent on alcohol or other sedative hypnotics. In neurological practice barbiturates are used in the treatment of epilepsy or status epilepticus and to determine cerebral dominance for language (Wada test), discussed below.

CHEMISTRY

The barbiturates are the class of compounds centered on the core molecule barbituric acid (Fig. 31.9-1). Barbiturates in which the oxygen at C2 is replaced by a sulfur molecule are known as thiobarbiturates, the most common of which is thiopental (Pentothal). Compounds with an oxygen at C2 are properly called oxybarbarbiturates, but are commonly called barbiturates. It is, however, common practice to call both groups barbiturates. Although barbituric acid has no effects on the central nervous system (CNS), an alkyl or aryl group at C5 confers sedative-hypnotic properties. Large aliphatic groups at C5 increase lipid solubility and generally decrease latency to onset of action and duration of action. Methohexital (Brevital) is an example of a compound with a large aliphatic side chain.

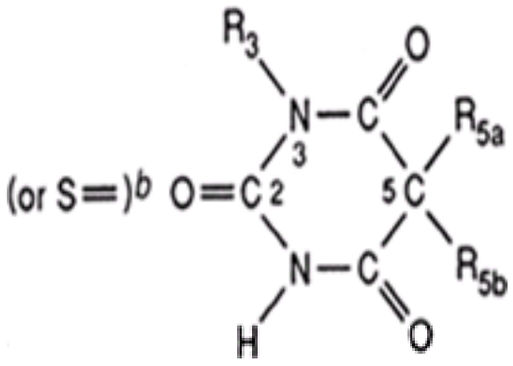

FIGURE 31.9-1 Molecular structure of barbiturates currently available in the United States.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption and Administration The barbiturates are routinely administered orally when used as hypnotic agents but may be given intravenously for seizures or anesthetic use. Intramuscular use is discouraged because soluble preparations cause pain and sometimes necrosis at the injection site. Although food in the stomach may delay absorption of barbiturates, bioavailability is unaffected, with most of the drug absorbed in the small intestine. This class of drugs has a broad range of lipophilicity, an important factor influencing absorption; the more lipophilic compounds are more rapidly absorbed (Table 31.9-1). Certain preparations are available as rectal suppositories, particularly for use in infants.

Barbiturate	Onset (min)	Duration (h)	Elimination Half-Life (h)
Amobarbital	60	10–12	8–42
Aprobarbital	45–60	6–8	14–34
Butabarbital	45–60	6–8	34–42
Mephobarbital	60+	10–12	11–67
Pentobarbital	10–15	3–4	15–48
Phenobarbital	60+	10–12	80–120
Secobarbital	10–15	3–4	14–40

Table 31.9-1 Half-Lives, Onset, and Duration of Action of Selected Barbiturates

Distribution Binding of barbiturates to plasma proteins is based on lipid solubility and ranges from lipophilic compounds with a highly bound fraction (80 percent), such as thiopental or methohexital, to phenobarbital (20 to 45 percent), which is less lipophilic. Weak acids such as warfarin (Coumadin) or aspirin may displace barbiturates from albumin and heighten barbiturate CNS effects. Highly soluble barbiturates such as secobarbital (Seconal) and pentobarbital (Nembutal) are rapidly absorbed into the brain according to vascular distribution and undergo redistribution to less vascular areas of the brain and other tissues within 30 minutes. This rapid

redistribution of barbiturates based on lipophilicity accounts for their relatively brief duration of action, which is predominantly influenced by redistribution of the compound into fat stores rather than the elimination half-life, which determines duration of action in most other classes of drugs. Barbiturates distribute to all tissues, cross the placenta, and are distributed to fetal tissues; they are secreted in breast milk of women treated with these compounds.

Elimination Barbiturates are primarily metabolized in the liver by P450 microenzymes. The barbiturates may undergo oxidation at C5, N hydroxylation, or N alkylation. Although most metabolized barbiturates are inactive, the N-methyl congeners produce active metabolites. For example, mephobarbital (Mebaral) gives rise to phenobarbital. Many inactivated barbiturates also undergo glucuronidation to allow renal elimination. Although most compounds undergo hepatic metabolism, the more water soluble compounds such as phenobarbital and aprobarbital (Alurate) are excreted partly unchanged in the urine. With impaired renal function, concentrations of these drugs will be higher, leading to CNS and cardiovascular depression. More lipophilic barbiturates such as secobarbital or pentobarbital are much less affected by renal function.

The elimination half-lives of select oral-use barbiturates (Table 31.9-1) are long enough that drug will accumulate with repeated daily dosing. Repeated use induces hepatic microenzymes and thus shortens elimination half-life over the initial 2 to 4 weeks of treatment. This calls for caution in the first month of treatment because a dosage that appears adequate in the first week may be insufficient in the fourth week. This increased metabolism affects other drugs that depend on this system, for example, carbamazepine (Tegretol). Elimination half-life is shorter in young persons than in elderly individuals or infants. Half-life may also be increased in chronic liver disease and cirrhosis. Barbiturate dosage should be lowered or the drug avoided completely in cirrhosis.

Pharmacodynamics

Mechanism of Action Although the exact mechanism of action is unknown, barbiturates likely potentiate g-amino butyric acid (GABA)-induced increases in chloride conductance (at postsynaptic GABA Type A [$GABA_A$] receptors) and reduce glutamate-induced depolarization (at a-amino-3-hydroxy-a-methyl-4-isoxazole propionate [AMPA] glutamate receptors) within the CNS. Thus, barbiturates increase the effects of the primary brain inhibitory transmitter, GABA, and decrease the effects of the primary excitatory transmitter, glutamate. $GABA_A$ receptors are a heterogeneous group of receptors composed of five subunits coupled to a chloride ionophore. The variety and heterogeneity of the subunits allow differential effects within the brain and multiple sites of action. Barbiturates resemble benzodiazepines in their mechanism of action, though barbiturates and benzodiazepines act at separate sites on the $GABA_A$-chloride-ionophore complex. Barbiturates do not displace benzodiazepines from their binding sites; they enhance binding of benzodiazepines at the receptor complex, magnifying the effects of the benzodiazepines. The effects of barbiturates depend largely on the presence of chloride or similarly acting anions. Picrotoxin, a drug that limits chloride flow through the ionophore, antagonizes the effects of barbiturates. At anesthetic or toxic doses, however, barbiturates directly increase chloride channel opening, even in the absence of GABA. This is an important difference between barbiturates and benzodiazepines; benzodiazepines do not directly increase chloride channel opening. This difference likely accounts for the relative safety of the benzodiazepines compared with the barbiturates.

Although barbiturates act as depressants at all levels of the neuraxis, the reticular activating system is particularly sensitive to their effects, accounting for their efficacy as sedative-hypnotics. Other brainstem effects of barbiturates are dose dependent and include induction of anticonvulsant effects with respiratory depression at high doses and anesthesia at even higher doses. The mechanism of action for anticonvulsant effects is not certain. It is postulated that barbiturates exert their anticonvulsant effects by decreasing neuronal membrane excitability (primarily by enhancing $GABA_A$ receptor–mediated inhibition) and depressing monosynaptic and polysynaptic transmission.

Blood Concentrations Plasma concentration is directly related to level of CNS depression, though because of neuroadaptation, long-term barbiturate users may have relatively little sedation despite high plasma concentration. On the other hand, naive users may experience toxicity when concentration is in the therapeutic range. The typical therapeutic range for phenobarbital is 10 to 40 µg/mL, though patients may require higher or lower dosages depending on individual differences such as length of treatment, severity of illness, or concurrent use of other anticonvulsants.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

The barbiturates were widely used before the Food and Drug Administration (FDA) established standards for new drugs. Although many barbiturates have been approved for chronic anxiety and short-term treatment of insomnia, few controlled studies have compared barbiturates with placebo or benzodiazepines, and no controlled studies exist for the treatment of syndromes such as anxiety or panic disorders using the currently accepted nosology of the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). The barbiturates, especially amobarbital (Amytal) and secobarbital, appear to be effective hypnotics. One double-blind study found that a combination of amobarbital (100 mg), and secobarbital (100 mg) was more effective than flurazepam (Dalmane) for sleep induction and maintenance and did not lose efficacy after 2 weeks. (Some studies have found loss of efficacy of barbiturates after two weeks.) Although the highly lipid soluble barbiturates may effectively treat insomnia, the authors do not recommend their use. Complications that may arise from the development of tolerance, the narrow therapeutic index, drug-drug interactions, and hepatic microsomal induction render this class of compounds less desirable than benzodiazepines or newer nonbenzodiazepine sedative-hypnotics.

The barbiturates may provide some relief from anxiety, but little evidence from controlled studies or uncontrolled reports suggest that they are useful in the treatment of panic disorder, social phobia, other phobias, posttraumatic stress disorder, or obsessive-compulsive disorder. Barbiturates carry a higher risk for precipitating respiratory or cardiac failure than the benzodiazepines or selective serotonin reuptake inhibitors (SSRIs); their use for the treatment of anxiety or anxiety disorders is limited to patients with known sensitivity to benzodiazepines or SSRIs because of adverse effects or allergic phenomena. Because of their known potential for physical dependence, barbiturates carry a high risk for abuse or addiction and have been classified by the FDA as schedule II, III, or IV compounds.

Two anesthetic agents have been studied in controlled trials. Methohexital appears to be well tolerated and effective in the induction of anesthesia for ECT and is widely used for this purpose. Methohexital was compared with propofol (Diprivan) and found to be equally efficacious, even though seizures last longer with methohexital. Further, depression treatment outcome is equivalent with methohexital or propofol. Thiopental was assessed in controlled studies for the treatment of increased intracranial pressure following head injury and appears to be effective for intracranial hypertension, providing long-term improvement in morbidity and mortality of severely brain injured patients. Thiopental also appears to limit neuropsychiatric sequelae of patients undergoing cardiac surgery.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Central Nervous System Barbiturates depress all levels of the CNS, inhibiting afferent connections from the reticular activating system to the thalamus causing drowsiness; reducing transmission to the cerebral hemispheres; and at sufficiently high doses, inducing dose-dependent anesthesia. The sensitivity of the reticular activating system to this class of medication is responsible for the sedation, and depressed transmission in the cerebellum is thought to cause ataxia. Barbiturates also cause more-subtle effects on learning, memory, and fine motor skills, detectable on neuropsychological tests. Barbiturates reduce rapid eye movement (REM) sleep with short-term use, but tolerance develops. Barbiturates may also cause subtle effects on mood, ranging from depression to euphoria, and long-acting compounds have prolonged effects including irritability and drowsiness.

Respiratory System Barbiturates decrease respiratory drive and depress the rhythmic quality of respiration. Respiratory drive is only slightly diminished at hypnotic doses. At doses only several times higher than that for sleep induction, however, neurogenic drive is nearly eliminated. Higher doses reduce hypoxic and chemoreceptor drive, and doses used for deep anesthesia completely eliminate respiratory drive. The narrow therapeutic window makes barbiturates potentially dangerous to use in any patient with pulmonary insufficiency. Cough and laryngeal reflexes are generally preserved up to doses that limit respiration. Laryngospasm, a troublesome complication of barbiturates, may result from intravenous use of these compounds, and coughing, hiccoughs, and sneezing may also be induced in the early stages of barbiturate-induced anesthesia.

Cardiovascular System In normal subjects only suprapharmacological doses appreciably affect cardiac output or blood pressure. At hypnotic doses there are no significant cardiovascular effects. In patients with heart failure or shock, barbiturates may cause marked reduction in blood pressure. In general, barbiturate anesthesia is less likely to produce cardiac problems than volatile anesthetics. Cardiac decompensation is largely related to barbiturate poisoning. Selective b_1-adrenergic receptor agonists can overcome myocardial depression caused by poisoning.

Intestines Barbiturates used in hypnotic doses have little effect on smooth muscle motility; at higher doses, gastrointestinal motility is slowed. Symptomatic improvement from functional gastrointestinal syndromes is thought to be related to the CNS effects of barbiturates.

Liver The barbiturates increase production of cytochromes and lipid content of the hepatic smooth endoplasmic reticulum. This increases metabolism of steroid hormones, cholesterol, bile salts, vitamin K, and a number of drugs, including barbiturates, warfarin, tricyclic antidepressants, propanolol (Inderal), quinidine (Duraquin), and phenytoin (Dilantin). Barbiturates may also increase the production of other metabolic enzymes, including b-aminolevulinic acid (ALA) synthetase and aldehyde dehydrogenase. The increase in ALA may exacerbate porphyria in patients with intermittent porphyria; thus barbiturates are contraindicated in these patients.

Renal System Renal function and tubular transport may be decreased by very high doses of barbiturates. In general, barbiturates do not affect renal function, nor do they depend on renal function for elimination. Doses of phenobarbital and aprobarbital, drugs excreted through the kidneys, need to be lowered in renal failure.

INDICATIONS AND THERAPEUTIC USES

The following barbiturates have FDA approval for the treatment of anxiety and apprehension or insomnia: amobarbital, secobarbital, pentobarbital, butabarbital (Butisol), and aprobarbital. Amobarbital has also been approved for use in narcoanalysis, though this use is controversial. The FDA has approved methohexital for use in ECT anesthesia.

Electroconvulsive Therapy Methohexital is commonly used as an anesthetic agent for ECT. It has lower cardiac risks than other barbiturate anesthetics. Used intravenously, methohexital produces rapid unconsciousness and because of rapid redistribution has a brief duration of action (5 to 7 minutes). Methohexital, like other barbiturates, provides no analgesia before unconsciousness, so unconsciousness must be ensured before paralytic agents are administered. Typical dosing for ECT is 0.7 to 1.2 mg/kg. A number of studies comparing methohexital with propofol have demonstrated that seizures are shorter with propofol, but efficacy appears equivalent, and cognitive effects may be worse with methohexital. Methohexital may also be used to abort prolonged seizures in ECT or to limit postictal agitation.

Seizures The barbiturates have a long history of use in short-term and prophylactic treatment of seizures. Phenobarbital, the most commonly used barbiturate for seizures has indications for the treatment of generalized tonic-clonic and simple partial seizures. Parenteral barbiturates are used in the emergency management of seizures independent of cause, including meningitis, eclampsia, or tetanus. Intravenous phenobarbital should be administered slowly, 10 to 20 mg/kg for status epilepticus.

Wada Test To localize speech before resection of brain tissue associated with intractable seizures, intravenous barbiturates (most commonly amobarbital, occasionally methohexital) are injected into the carotid artery of the suspected side of interest. Although protocols vary by center, usually 100 to 200 mg of amobarbital is injected intravenously via a transfemoral catheter placed above the level of the carotid bifurcation. Barbiturates injected this way cause temporary contralateral limb paresis and language defects if the injected hemisphere is responsible for language. Memory and naming tests are performed during the Wada test and assessed after neurological function returns to normal. Good memory test results suggest that the unaffected side supports memory function and surgical ablation may leave little deficit. The Wada test may also be used in conjunction with functional neuroimaging studies to study memory and hippocampal perfusion, though this testing is not yet of regular clinical use.

Narcoanalysis Sodium amobarbital has been used historically as a diagnostic aid in a number of clinical conditions including conversion reactions, catatonia, hysterical stupor, and unexplained muteness and to differentiate stupor of depression, schizophrenia, and structural brain lesions. Much of this literature is anecdotal, poorly controlled, and difficult to interpret. Nevertheless, a limited number of these reports present compelling case material, particularly in various differential diagnostic situations. Some of this literature observed that amobarbital decreases arousal and cognitive function in patients with structural brain lesions, facilitates speech in depressed patients, and causes psychotic patients to disclose delusional material. Catatonia was reportedly responsive in patients given 600 to 900 mg intravenously; subjects moved freely and responded appropriately shortly after amobarbital administration.

The “amytal interview” is performed by placing the patient in a reclining position and administering amobarbital intravenously, 50 mg a minute. Infusion is continued until lateral nystagmus is sustained or drowsiness is noted, usually at 75 to 150 mg. Following this, 25 to 50 mg may be administered every 5 minutes to maintain narcosis. Interviews should be gentle, and the patient should be allowed to rest for 15 to 30 minutes after the interview before attempting to walk.

Sleep The barbiturates reduce sleep latency and the number of awakenings during sleep, though tolerance to these effects generally develops within 2 weeks. Slow wave sleep (stages 3 and 4) is shortened in general, and time spent in REM sleep is diminished. Sleep body movements decrease during barbiturate use for sleep induction. On electroencephalograms (EEG), barbiturates decrease low-frequency activity (alpha rhythm) and increase high-frequency activity (beta rhythm). This activation may evoke feelings of euphoria in some patients. Discontinuation of barbiturates for insomnia often leads to rebound increases on EEG measures.

Withdrawal From Sedative Hypnotics Barbiturates are sometimes used to determine extent of tolerance to barbiturates or other hypnotics to guide detoxification. Once intoxication has resolved, a test dose of pentobarbital (200 mg) is given orally. An hour later the patient is examined. Tolerance and dose requirement are determined by the degree to which the patient is affected. Unaffected patients have marked tolerance; patients with mild cognitive or cerebellar impairment have moderate tolerance; and patients who are put to sleep have minimal or no tolerance. If the patient is not sedated, another 100 mg of pentobarbital may be administered every 2 hours, up to three times (maximum, 500 mg over 6 hours). The amount needed for mild intoxication corresponds to the approximate daily dose of barbiturate used. Phenobarbital (30 mg) may then be substituted for each 100 mg of pentobarbital. This daily dose requirement may be administered in divided doses and gradually tapered by 10 percent a day, with adjustments made according to withdrawal signs.

PRECAUTIONS AND ADVERSE REACTIONS

Overdose Barbiturates depress the CNS. In overdose or in combination with other CNS depressants (especially alcohol or benzodiazepines), barbiturates may be lethal. Overdose may lead to respiratory depression or arrest, absent deep tendon reflexes, hypothermia, coma, and death. EEG may reveal loss of electrical activity in severe overdose, which may be reversible with detoxification. One case report noted 28 hours of isoelectric recording with subsequent full recovery.

Gastrointestinal and Nutritional Barbiturates may be toxic or lethal in patients with cirrhosis or acute intermittent porphyria and should not be used in these patient groups. Long-term barbiturate use may interfere with vitamin D metabolism and result in osteopenia or rickets. Patients may require vitamin D supplements.

Pregnancy Some evidence indicates that barbiturates cause fetal malformations, and use in the first trimester of pregnancy is contraindicated. A recent study also suggests that in utero exposure to phenobarbital is associated with intelligence deficits in adult men. Caution should be taken with barbiturates at any time in pregnancy. Barbiturate use late in pregnancy may result in neonatal dependence and a withdrawal syndrome upon delivery. Use during pregnancy has been associated with neonatal coagulopathy because barbiturates accelerate metabolism of vitamin K. Barbiturates pass into breast milk and cause CNS depression in breast-feeding newborns.

CNS Excitement Some patients exhibit paradoxical excitement rather than sedation; phenobarbital has been most often implicated. Pediatric, geriatric, or medically ill patients are at greatest risk for this phenomenon.

Addiction Potential Highly lipid soluble, short-acting agents such as pentobarbital (“yellow jackets”) or secobarbital (“red devils”) may have greater abuse potential than the other barbiturates. Barbiturates may also be used by drug addicts dependent on cocaine, opioids, or alcohol. Barbiturates should be avoided in patients with a history of alcohol or drug dependence. Moreover, because of the low therapeutic index, accidental poisoning is not uncommon. It was once thought that persons taking barbiturates took them automatically, their memory clouded by intoxication, but this seems not to be the case. Rare overdose attempts were unintentional in studies examining this so-called automatism phenomenon. These drugs should not be used in suicidal patients. Barbiturates may be lethal when used in combination with alcohol or other sedative hypnotics. Severe barbiturate addicts may use up to 2 or 3 grams of pentobarbital a day, and these patients commonly experience severe withdrawal following abrupt discontinuation, including seizures, delirium, and autonomic arousal similar to that with alcohol withdrawal.

Hypersensitivity Allergic reactions may occur, especially in patients with a history of atopy or asthma. They may include hives, wheezing, facial swelling, and (rarely) exfoliative dermatitis or the Stevens-Johnson syndrome, for which fatalities have been reported with phenobarbital. Maculopapular rashes are common, and some reports note an incidence of 1 to 3 percent among patients treated with phenobarbital.

Cardiopulmonary Rapid intravenous use of barbiturates may cause a catastrophic drop in blood pressure, even before CNS depression. Hypotension may be

reversed by dopamine. Pulmonary complications and renal failure account for most poisoning deaths. Patients with preexisting pulmonary compromise are at risk for respiratory embarrassment. Rapid intravenous use may cause laryngospasm or bronchospasm. Intravenous use may cause local irritation or thrombosis. Using large veins and administering drugs slowly may ameliorate this problem.

Hematopoietic Rarely, megaloblastic anemia, thrombocytopenia, or agranulocytosis may occur. Barbiturates may increase folate metabolism, and patients may need folate supplements.

DRUG INTERACTIONS

Use of barbiturates in conjunction with other medications may be complicated by additive effects with CNS depressants or compounds known to cause hepatic microsomal enzyme induction. Barbiturates used in combination with ethanol, opiates, benzodiazepines, or monoamine oxidase inhibitors may increase CNS depression. Drug interactions result from barbiturate-induced microsomal enzyme activity with induction related to long-term use rather than single doses or use for short periods (fewer than 7 days). Many drugs may be affected by this nonspecific increase in metabolism, which may cause loss of efficacy of the metabolized drug, though patients vary in the degree to which other agents are affected. If barbiturates are added to a drug regimen, the clinician must be alert to decreased efficacy of other compounds and make appropriate dosage adjustments. The tricyclic antidepressants carbamazepine, haloperidol (Haldol), or paroxetine (Paxil) may require dosage increases if barbiturates are added. Table 31.9-2 list drugs that may be affected by chronic barbiturate use. Plasma concentrations of other drugs that are unstudied may also be reduced. On the other hand, phenobarbital concentration may be increased by concurrent use of valproic acid (Depakene) or methylphenidate (Ritalin), and limited data suggest that fluoxetine (Prozac) and possibly other serotonin reuptake antidepressants may inhibit barbiturate metabolism. Chronic barbiturate use induces metabolism of gaseous anesthetics, and the increased metabolism may increase hepatotoxicity risk associated with enflurane or halothane.

The metabolism of the following drugs has been reported to be increased with long-term use of barbiturates. Others unlisted may also be affected
Analgesics—acetaminophen, fenoprofen
Antiarrhythmics—digitalis, lidocaine, mexiletine
Antibiotics—chloramphenicol, metronidazol, rifampin, tetracycline, griseofulvin
Anticoagulants—warfarin
Anticonvulsants—carbamazepine, phenytoin
Antidepressants—amitriptyline, desipramine, paroxetine, protriptyline
Antihypertensives—methyldopa
Antipsychotics—haloperidol, thioridazine, loxapine
β-Adrenergic receptor antagonists—labetalol, propranolol, metoprolol
Benzodiazepines—clonazepam, diazepam
Contraceptives—all containing estrogens
Immunosuppressants—corticosteroids, cyclophosphamide, cyclosporin, dacarbazine
Xanthines—aminophylline, caffeine, theophylline

Table 31.9-2 Drug Interactions

LABORATORY INTERFERENCES

Barbiturates may interfere with the metyrapone test by increasing metyrapone metabolism and decreasing the response to the metyrapone test. Bilirubin concentration may be reduced in neonates or patients treated with chronic barbiturates because barbiturates induce glucuronyl transferase, the enzyme responsible for bilirubin conjugation. Barbiturates may cause a false positive phentolamine (Regitine) test result or interfere with absorption of radioactive cyanocobalamin.

DOSAGE AND ADMINISTRATION

Dosage and routes of administration are shown in Table 31.9-3. Table 31.9-4 lists barbiturates contained in mixed preparations.

Drug	Available Preparations	Daily Dosage Range[a] (sedative[b]/hypnotic)	Anticonvulsant	Pediatric
Amobarbital	200 mg	100–200 mg/50–300 mg	65–500 mg IM	2 to 6 mg/kg up to 100 mg
Aprobarbital	40 mg/5 ml oral	40–160 mg/40–120 mg	not established	not established
Butabarbital	30 mg/5 ml oral; 15, 30, 50, 100 mg	45–120 mg/50–100 mg	not established	2–6 mg/kg (max 100 mg)
Mephobarbital	32, 50, 100 mg	64–300 mg/100 mg	200–600 mg	16–32 mg three to four times daily (1 mo–age 5); 32–64 mg three to four times daily (> age 5)
Methohexital	500 mg/50 cc (i)	0.7–1.2 mg/kg for ECT	not established	not established
Pentobarbital	30, 100 mg; 50 mg/ml (i); 20 mg/ml (e); 50, 60, 120, 200 mg (r)	60–100 mg/100–150 mg	100 mg intravenous at one minute intervals up to 500 mg	2 to 6 mg/kg up to 100 mg
Phenobarbital	8, 15, 30, 60, 100 mg; 30, 60, 65, 130 mg/ml (i); 20 mg/5 ml (e)	30–120 mg/100–300 mg	100–300 mg intravenous, up to 600 mg/day; 60–250 mg/d oral	1–3 mg/kg
Secobarbital	100 mg; 50 mg/ml (i)	100–300 mg/100 mg	5.1 mg/kg intravenous, may repeat every 1–4 hours	3–3 mg/kg

[a] Dosages are oral form unless specified: (i)=injection, (r)=rectal suppository.
[b] Sedative dosage is equal to the hypnotic dosage, but should be given 3 to 4 times daily.

Table 31.9-3 Barbiturates Dosages

Product Name	Barbiturate	Other Content
Fioricet with Codeine	Butalbital, 50 mg	Caffeine, 40 mg; codeine, 30 mg; acetaminophen, 325 mg
Fiorinal with Codeine	Butalbital, 50 mg	Caffeine, 40 mg; codeine, 30 mg, aspirin, 325 mg
Cafatine-PB	Phenobarbital, 30 mg	Caffeine, 100 mg; ergotamine tartate, 1 mg; alkaloid of belladona, 0.125 mg
Barbidonna	Phenobarbital, 32 mg	Atropine sulfate 0.025 mg; scopolamine, 0.0074 mg; hyoscyamine, 0.1286 mg
Butibel	Butabarbital, 15 mg	Belladonna extract, 15 mg
Donnatal Extentabs	Phenobarbital, 48.6 mg	Atropine sulfate 0.0582 mg; scopolamine, 0.0195; hyoscyamine, 0.311 mg
Phenerbel-S	Phenobarbital, 40 mg	Alkaloid of belladona, 0.2 mg; ergotamine tartate, 0.6 mg

Table 31.9-4 Barbiturates Contained in Combination Products

NONBARBITURATE, NONBENZODIAZEPINE SEDATIVE-HYPNOTIC AGENTS

A number of agents were widely used after the advent of the barbiturates and before the use of benzodiazepines in the treatment of anxiety and insomnia. Four such available drugs are paraldehyde, ethchlorvynol (Placidyl), meprobamate (Miltown) and glutethimide (Doriden). These drugs are not advised for use because of their low therapeutic index. Unfortunately, following the requirement of triplicate copy prescriptions for benzodiazepines in New York state, two studies found marked increases in several of these drugs.

Paraldehyde Paraldehyde is a cyclic ether, first used in 1882 as a hypnotic. It has also been used historically to treat epilepsy or delirium tremens. Because of its low therapeutic index it has been supplanted by the benzodiazepines and other anticonvulsants. Its malodorous scent is remembered by all practitioners who prescribed

it.

Chemistry The chemical name is 2,4,6 trimethyl-1,3,5-trioxane. The structure is shown in Figure 31.9-2.

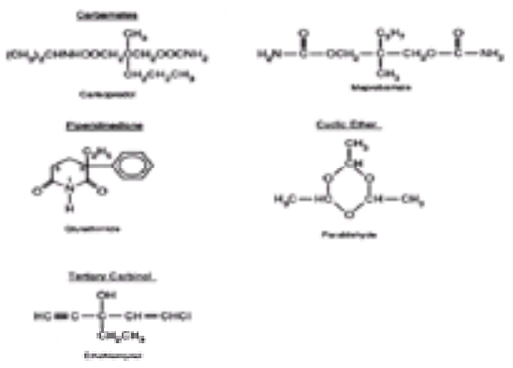

FIGURE 31.9-2 Molecular structures of other, similarly acting drugs.

Pharmacological Actions

PHARMACOKINETICS Paraldehyde is rapidly absorbed from the gastrointestinal tract and from intramuscular injections. It is primarily metabolized to acetaldehyde by the liver, and unmetabolized drug is expired by the lungs. Reported half-lives range from 3.4 to 9.8 hours. Onset of action is 15 to 30 minutes.

PHARMACODYNAMICS The mechanism of action is unknown.

Clinical Drug Studies Paraldehyde was commonly used before controlled studies were required for regulatory approval. No placebo-controlled studies exist.

Effects on Specific Organ Systems Paraldehyde may cause CNS depression, respiratory depression in the newborn, and hepatitis with long-term use. The drug passes into the fetus, but there are no studies in humans or animals regarding teratogenicity.

Therapeutic Indications Although paraldehyde is indicated by the FDA in the treatment of seizures induced by tetanus or eclampsia or status epilepticus, it should be used only when safer agents fail. Paraldehyde is not indicated as an anxiolytic or hypnotic and has little place in current psychopharmacology.

Precautions and Adverse Reactions Paradehyde frequently causes foul breath because of expired unmetabolized drug. It may inflame pulmonary capillaries and cause coughing. It may also cause local thrombophlebitis with intravenous use. Patients may experience nausea and vomiting with oral use. Overdose leads to metabolic acidosis and decreased renal output. There are no specific studies in children or elderly patients. There is risk of abuse among drug addicts.

Drug Interactions Disulfiram (Antabuse) inhibits acetaldehyde dehydrogenase and reduces metabolism of paraldehyde, leading to possible toxic concentration of paraldehyde. Paraldehyde has additive sedating effects in combination with other CNS depressants such as alcohol or benzodiazepines.

Laboratory Interferences Paraldehyde, like the other agents in this section, may interfere with the metyrapone, phentolamine, or urinary 17-hydroxycorticosteroid tests.

Dosage and Administration Paraldehyde is available in 30-mL vials for oral or intravenous use. It should not be placed in plastic containers. Unused drug exposed to the air rapidly deteriorates to acetaldehyde and acetic acid and should be discarded after 24 hours. For seizures in adults, up to 12 mL (diluted to a 10 percent solution) may be administer by gastric tube every 4 hours. For children the oral dose is 0.3 mg/kg.

Meprobamate Meprobamate, a carbamate, was introduced shortly before the benzodiazepines specifically to treat anxiety. It is uncommonly used today, though it once had great popularity. Following a triplicate benzodiazepine prescription requirement in New York, however, meprobamate use more than doubled. There is little rationale for meprobamate use in current psychopharmacology.

Chemistry The chemical name is 2-methyl-2-propyl-1,3-propanediol dicarbamate. The structure is shown in Figure 31.9-2.

Pharmacological Actions

PHARMACOKINETICS Meprobamate is rapidly absorbed from the gastrointestinal tract and from intramuscular injections. It is primarily metabolized by the liver, and a small portion is excreted unchanged in urine. Plasma half-life is approximately 10 hours.

PHARMACODYNAMICS The mechanism of action is unknown, though it appears to affect the limbic and reticular activating systems.

Clinical Drug Studies Meprobamate was approved for use before controlled clinical trials examined efficacy and safety in specific diagnoses. Meprobamate has been compared with barbiturates, diazepam (Valium), and chlordiazepoxide (Librium) for the treatment of anxiety. In mixed groups of patients with anxiety, meprobamate has only rarely fared better than placebo or barbiturates. These studies were performed before the currently accepted diagnoses of panic disorder, social phobia, obsessive-compulsive disorder, generalized anxiety disorder, or posttraumatic stress disorder, and no data exist about treating these conditions with meprobamate. One study found that patients with drug addiction preferred meprobamate to lorazepam (Ativan), suggesting that this preference would give meprobamate a high risk for abuse by patients with drug abuse histories.

Effects on Specific Organ Systems Meprobamate may cause CNS depression, especially when combined with other CNS depressants, and because it passes into breast milk, infants may be sedated by mothers using meprobamate and breast-feeding. Limited data suggest that higher rates of fetal malformations result from meprobamate use in the first trimester of pregnancy. Prolonged use may decrease saliva production and lead to dental caries, oral candidiasis, or periodontal disease. Elderly patients are more sensitive than younger adults to effects of meprobamate.

Therapeutic Indications Meprobamate is indicated for short-term treatment of anxiety disorders. This indication, however, is not based on current diagnoses or controlled trials. The drug has been supplanted by the benzodiazepines and antidepressants in the treatment of anxiety. It has been used as a hypnotic, but it is not approved for this use.

Precautions and Adverse Reactions Meprobamate may cause CNS depression and death in overdose and carries the risk of abuse by patients with drug or alcohol dependence. Abrupt cessation following long-term use may lead to a withdrawal syndrome including seizures and hallucinations. Meprobamate may exacerbate acute intermittent porphyria. Hypersensitivity reactions including wheezing and hives are uncommon. Paradoxical excitement or leukopenia is rare. It should not be used in patients with hepatic compromise.

Drug Interactions Meprobamate has additive sedating effects in combination with other CNS depressants such as alcohol, barbiturates, or benzodiazepines.

Laboratory Interferences Meprobamate, like the other agents in this section, may interfere with the metyrapone, phentolamine, or urinary 17-hydroxycorticosteroid tests.

Dosage and Administration Meprobamate is available in 200-, 400-, and 600-mg tablets as well as in a combination of aspirin, 325 mg, and 200 mg of meprobamate

(Equagesic) for oral use. For adults, the usual dosage is 400 to 800 mg twice daily. Elderly patients and children, age 6 to 12, require half the adult dose. The authors do not recommend use of meprobamate in any age group.

Ethchlorvynol Ethchlorvynol, a tertiary carbinol, was historically widely used to treat insomnia and anxiety. It has since been replaced by the benzodiazepines and other safer agents in the treatment of anxiety and sleep disturbance. It has a low therapeutic index. There is no rational use for ethchlorvynol in current psychopharmacology.

Chemistry The chemical name is 1-chloro-3-ethyl-1-penten-4-yn-3-ol. It is a liquid. The structure is shown in Figure 31.9-2.

Pharmacological Actions

PHARMACOKINETICS Ethchlorvynol is rapidly absorbed from the gastrointestinal tract. It is primarily metabolized by the liver, and a small portion is metabolized by the kidney. Metabolites are excreted in the urine. Elimination half-life is approximately 10 to 20 hours.

PHARMACODYNAMICS The mechanism of action is unknown, though it is a potent CNS depressant.

Clinical Drug Studies Ethchlorvynol was approved for use before controlled clinical trials examined efficacy and safety in specific diagnoses. It has anecdotal effectiveness for brief treatment of insomnia.

Effects on Specific Organ Systems Ethchlorvynol may cause CNS depression. Overdose may cause respiratory depression, bradycardia, or death. It passes into the placenta, and while there are no human studies of teratogenicity, animal studies suggest higher rates of stillbirth. It should not be used in pregnancy. Use late in pregnancy may result in neonatal CNS depression or a withdrawal syndrome. Higher rates of lung tumors have been reported in mice; and there are no human studies regarding carcinogenicity. Abuse of ethchlorvynol may cause pulmonary edema or effusions. Elderly patients are more sensitive than younger adults to effects of ethchlorvynol for treatment of anxiety.

Therapeutic Indications Ethchlorvynol is indicated for up to 1-week treatment of insomnia. It has been used to treat anxiety in the past, but it has no FDA indication.

Precautions and Adverse Reactions Ethchlorvynol may cause CNS depression, slurred speech, double vision, confusion, and death in overdose. There is risk of abuse by patients with drug or alcohol dependence. Abrupt cessation following long-term use may lead to a withdrawal syndrome including seizures and hallucinations. Ethchlorvynol may exacerbate acute intermittent porphyria or cause cholestatic jaundice. Hypersensitivity reactions are uncommon. Paradoxical excitement is rare. It should not be used in patients with hepatic compromise.

Drug Interactions In combination with other CNS drugs including tricyclic drugs, alcohol, barbiturates or benzodiazepines, ethchlorvynol has additive sedating effects. Ethchlorvynol stimulates hepatic microenzymes and may increase metabolism of many drugs, most notably warfarin.

Laboratory Interferences Ethchlorvynol may cause a false-positive phentolamine test result.

Dosage and Administration Ethchlorvynol is available in 200-, 500-, and 750-mg capsules. For adults, the usual dose is 500 to 750 mg at bedtime. It is best taken with food to limit rate of onset for patients in whom ataxia is of concern. Patients requiring withdrawal should be switched to a barbiturate such as phenobarbital and gradually tapered. Safety and efficacy in children or elderly patients has not been established. The authors do not recommended ethchlorvynol use in any age group.

Glutethimide

Chemistry The chemical name is 3-ethyl-3-phenyl-2,6-piperidinedione glutarimine. The structure is shown in Figure 31.9-2.

Pharmacological Actions

PHARMACOKINETICS Glutethimide is absorbed erratically from the gastrointestinal tract, is metabolized by the liver, and has an onset of action of 30 minutes. Its elimination half-life is 10 to 12 hours, and it is known to induce hepatic microsomal enzymes.

PHARMACODYNAMICS The mechanism of action is unknown, though it has potent anticholinergic activity.

Clinical Drug Studies Glutethimide has anecdotal effectiveness for brief treatment of insomnia but is not FDA approved for this use.

Effects on Specific Organ Systems Glutethimide may cause CNS depression. Overdose may cause respiratory depression, bradycardia, or death. It passes into the placenta and breast milk. There are no human or animal pregnancy studies. Use late in pregnancy may result in neonatal CNS depression or a withdrawal syndrome. There are no human studies regarding carcinogenicity. Elderly patients are more sensitive than younger adults to sedative and anticholinergic effects of glutethimide.

Therapeutic Indications Glutethimide has been used to treat insomnia but without FDA indication.

Precautions and Adverse Reactions Glutethimide may cause CNS depression, slurred speech, double vision, confusion, and death in overdose. There is risk of abuse by patients with drug or alcohol dependence. Abrupt cessation following long-term use may lead to a withdrawal syndrome including seizures and hallucinations. Glutethimide may exacerbate acute intermittent porphyria. Because of its potent anticholinergic effects it should be used cautiously in patients with prostatic hypertrophy or narrow-angle glaucoma. Hypersensitivity reactions are uncommon. Paradoxical excitement is rare. It should not be used in patients with hepatic compromise.

Drug Interactions Glutethimide has additive sedating effects in combination with other CNS drugs including alcohol, barbiturates, and benzodiazepines. Glutethimide induces hepatic microenzymes and may increase metabolism of many drugs, most notably warfarin.

Laboratory Interferences Glutethimide may cause a false-positive phentolamine test result or interfere with urine assays for 17-ketosteroids.

Dosage and Administration Glutethimide is available in 500-mg tablets. For adults, the usual dose for insomnia is 250 to 500 mg at bedtime. For elderly patients the recommended dose is 250 mg. Safety and efficacy in children has not been established. Patients requiring withdrawal should be switched to a barbiturate such as phenobarbital and gradually tapered. The authors do not recommend using glutethimide in any age group.

SUGGESTED CROSS-REFERENCES

Anxiety disorders are discussed in Section 15, substance-related disorders in Chapter 11. Chloral hydrate is covered in Section 31.14. Sleep disorders are discussed in Chapter 21.

31.10 BENZODIAZEPINE RECEPTOR AGONISTS AND ANTAGONISTS

JAMES C. BALLENGER, M.D.

INTRODUCTION AND HISTORY

In the mid-1950s Roche Laboratories synthesized two compounds with anxiolytic and sedative properties, which in laboratory tests appeared to be superior to meprobamate (Miltown) and chlorpromazine (Thorazine), the principal agents available at that time. The work of Leo Sternbach and Earl Reeder led to development of the first benzodiazepine, chlordiazepoxide (Librium), in 1959. This was followed in 1963 by the release of an even more potent agent, diazepam (Valium). Since then, this class of medications has become one of the most popular in the world because of its effectiveness and safety. There are now more than three dozen benzodiazepines on the market. They have become the mainstay of treatment for anxiety, insomnia, alcohol withdrawal, and several other conditions and have largely replaced meprobamate and the barbiturates because of their increased efficacy and safety.

Various studies have documented that approximately 10 to 15 percent of the populations of developed nations have taken a benzodiazepine in the past year. However, between 2 and 8 percent have taken them on a daily basis for a month. Those using benzodiazepines appear to need them: they generally have several medical conditions as well as psychiatric conditions, are distressed and older, and appear to benefit from them. Despite worry in the general public that the benzodiazepines are overused, most patients who would probably benefit from treatment do not receive it. The evidence suggests that, in fact, undertreatment is much more frequent than overtreatment.

Some have suggested that more is known about how benzodiazepines work than perhaps any other medications used in neuropsychiatry. This area continues to evolve rapidly with new molecular biological techniques elucidating a tremendous heterogeneity of receptors involved in the action of the benzodiazepines. There is considerable promise that even more effective agents will be developed from this increased understanding.

Ligands of Benzodiazepine Receptor There are a series of ligands that interact with the g-aminobutyric acid–benzodiazepine (GABA-BZ) receptor but which have quite differing, even opposing, effects (i.e., either reducing or increasing chloride channel openings). The traditional agonists increase the frequency of the chloride ionophore openings and are anxiolytic, sedating, and anticonvulsant. Compounds with essentially the opposite action (i.e., decreasing the chloride ionophore openings and producing anxiety and convulsions) have also been recognized, and these have been termed *inverse* agonists. The third type, classified benzodiazepine antagonists, block the action of agonists and inverse agonists but have, in the main, no intrinsic activity themselves.

Other benzodiazepine direct agonists include zopiclone (Imovane), some triazolopyridazines, zolpidem (Ambien), and some b-carbolines. Although some bind to specific receptor subtypes (e.g., zolpidem), they all have the basic action of increasing the opening of the chloride channel.

Inverse agonists do the opposite and decrease the frequency of the opening of the chloride channel. They include other b-carboline derivatives and a compound named the diazepam-binding inhibitor (DBI). These agents have been observed to create anxiety in humans as well as the secondary physiological effects of anxiety (increased heart rate, blood pressure, cortisol, etc.).

The benzodiazepine antagonists block or reverse the effect of agonists or inverse agonists. The imidazobenzodiazepine derivative flumazenil (Romazicon) was the first and most widely studied benzodiazepine antagonist. In animals and humans, flumazenil can reverse all benzodiazepine actions and is marketed to reverse benzodiazepine overdose.

Partial Agonists Recently, agents that have less-functional effects, despite occupying most or all of their receptors have been termed *partial agonists*. Partial agonists have been synthesized not only for agonists, but also for inverse agonists and even antagonists. Some compounds can function as partial agonists at some receptors and full agonists at others.

The discovery of partial agonists has stimulated the search for an agent that would not be as sedating, amnestic, or prone to withdrawal symptomatology but would still have sufficient anxiolytic properties. The medication most extensively studied has been abecarnil in generalized anxiety disorder. Partial agonism may also explain certain features of the traditional benzodiazepines. Clonazepam (Klonopin) has been recognized to function as a partial agonist at certain receptors. This may explain why clonazepam use is apparently associated with fewer withdrawal difficulties.

Endogenous Ligands As with the opioids, the presence of a receptor suggests that endogenous ligands may exist for the benzodiazepine receptor. Such an endogenous compound could, theoretically, be either an anxiogenic inverse agonist or an anxiolytic agonist. Although no ligands have been found in living humans, several candidates have been put forward, including DBI, thought to have anxiogenic properties. Interestingly, desmethyldiazepam, the metabolite of diazepam and chlordiazepoxide, was isolated from brains of rats never exposed to benzodiazepines. Similarly, Sandra File and colleagues have found these same metabolites in human brains stored in the 1940s, long before the chemical synthesis of benzodiazepines two decades later. This also could have come from dietary sources, in that diazepam and lorazepam (Ativan) have been found in various foods.

BENZODIAZEPINES

Chemistry The basic structure of all benzodiazepines involves 2-aminobenzodiazepine-4-oxidates. Modifications to the structure at the R1 position increase the potency as attachments to R1 with greater electron properties increase potency (Fig. 31.10-1). Other modifications leading to drugs with differing properties have primarily been to the ring systems. Although controversial, it is thought that the fused triazolo ring in positions 1 and 2 in the diazepine ring is what confers special potency on the triazolobenzodiazepines such as triazolam (Halcion), alprazolam (Xanax), and estazolam (Prosom). In a similar fashion, a fused imidazo ring at the 1 and 2 position confers considerable potency on the preanesthetic midazolam (Versed).

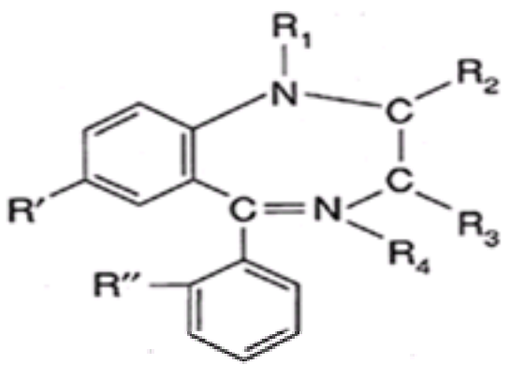

FIGURE 31.10-1 Molecular structure of benzodiazepine nucleus.

Pharmacological Actions

Pharmacokinetics

ABSORPTION AND DISTRIBUTION Benzodiazepines are readily absorbed from the gastrointestinal tract, reaching peak levels within 30 minutes to several hours. Clorazepate (Tranxene) is metabolized to its active metabolite in the stomach and then absorbed. Onset of action is primarily related to differences in lipid solubility, which affects both absorption and movement into the brain. Only lorazepam and midazolam are reliably absorbed after intramuscular injection.

Most of the benzodiazepines are highly protein bound, although this does vary somewhat. Benzodiazepines like diazepam with high lipid solubility are both quickly absorbed and quickly pass into the brain. Conversely, benzodiazepines with lower lipid solubility (e.g., lorazepam) are less rapidly absorbed and thus have a slower onset of action. Lipid solubility also obviously affects duration of action, in that their action depends not only on entry to the brain, but also clearance from the brain and other areas. Drugs with lower lipid solubility will be cleared more slowly and thus have a longer duration of action.

The varying half-lives of the benzodiazepines are also responsible for differences in duration of action and other clinical features, but this often depends more on the half-life of active metabolites. For instance, the half-life of lorazepam is 2 hours, but that of its principal metabolite, desalkyllorazepam, is more than 25 times that. Also, the principal metabolite of diazepam has a half-life of almost 100 hours. For the hypnotic flurazepam (Dalmane), this can be a negative feature in that it can lead to drowsiness the day after it is taken for insomnia. When diazepam is used for anxiety, this may be a positive feature in that missed doses are less important and discontinuation is perhaps easier. Conversely, benzodiazepines with a shorter half-life require more-frequent dosing (e.g., three or four times a day). This can be reassuring to many anxious patients but can have negative connotations for some patients and pose practical problems for others. Also, anxiety symptoms return in some patients using benzodiazepines with a shorter duration of action (e.g., alprazolam).

Most benzodiazepines cross the placental barrier and are also found in breast milk. Newborns of mothers who have been receiving benzodiazepines can be lethargic, have breathing problems, or even withdrawal symptoms postnatally.

METABOLISM Almost all benzodiazepines are metabolized primarily through the liver, and although some are excreted without being metabolized, most undergo multiple biotransformations and form active metabolites. Most are biotransformed by oxidation (also known as phase 1 metabolism), including diazepam, chlordiazepoxide, and chlorazepate, each forming multiple active metabolites. A smaller number of benzodiazepines undergo biotransformation by glucuronidation (phase 2) to inactive glucuronides or other sulfated or acetylated substances. Some agents such as diazepam are metabolized through both phase 1 and 2 processes.

The type of metabolism has some clinical importance in that patients with impaired liver function or elderly patients (at least theoretically) better tolerate those metabolized by phase 2, which involves simpler biotransformation to inactive metabolites. This is most important in elderly persons, especially those who smoke, both of which increase half-life, or those with significant hepatic impairment (e.g., alcoholics with cirrhosis).

Pharmacodynamics

Mechanism of Action Recent research has demonstrated that the action of the benzodiazopines is intimately connected to the g-aminobutyrate (GABA) system, which represents 30 percent of the cortical and thalamic inhibitory system. Specific benzodiazepine binding in the central nervous system (CNS) was first found in 1977. Further research has demonstrated that benzodiapine binding to these sites increases the activity of the GABA receptor, but only in the presence of GABA. This occurs at some, but not all, CNS GABA receptors. This has led to this receptor being referred to as the BZ-GABA receptor, although it is clear that other agents bind to this receptor as well, including picrotoxin, barbiturates, anesthetic-derivatives, alcohol, and penicillin.

Benzodiazopines and GABA both increase the propensity of the other to bind to their receptor sites. Benzodiazepines do not have any direct effect on the action of the receptor unless GABA is present. GABA's principal action is to open the chloride ionophore permitting chloride ions to move inward. Benzodiazepines increase the frequency and number of openings of the chloride channel, thus decreasing cellular excitability. This is thought to be the principal mechanism, although others have been suggested (e.g., increase in calcium-dependent potassium conductance).

The discovery of high-affinity, saturable, and stereo-specific benzodiazepine receptors by several groups in 1977 allowed the understanding of the various actions of benzodiazepine. Ataxia could be understood via the effects of GABA neurons in the cerebellum, sedation in the reticular formation, memory effects in the hippocampus, and muscle relaxant properties in the spinal cord. The potency of benzodiazepines also closely paralleled their ability to displace tritiated benzodiazepines in vitro.

The GABA-BZ receptor is an oligomeric glycoprotein with four membrane-expanding regions with 20 to 30 hydrophobic amino acids in each subunit. More recently, molecular biological studies have demonstrated at least 15 different proteins in this receptor, with at least 5 units each of 1 to 6 variants. Other studies suggest 15 subunits. Theoretically, there could be more than 500 variations in the benzodiazepine receptor, with differing pharmacology depending on the makeup of the subunits.

These receptors are localized throughout the brain, with some types clustering in one region and others in differing regions. Although some controversy remains, benzodiazepine receptors have been classified as type 1 (BZ_1) (with a high affinity for the triazolopyridazines) or type 2 (BZ_2) (with low affinities for the triazolopyridazines). Type I receptors are the most common and are found in the cerebellum and cortex. There are high numbers of type 2 receptors in the hippocampus, striatum, and spinal cord. Both groups are found in high concentrations in the cortex.

This is a highly promising area for future drug development, given the remarkable heterogeneity of the subunits. Because these receptors are also differentially localized in various parts of the CNS with differing projection patterns and differing functional effects, a variety of potential new compounds that interact with the GABA-BZ receptor is possible.

Therapeutic Indications As mentioned, because of their widespread efficacy and minimal adverse effects, as well as their rapid onset of action, the benzodiazepines have replaced predecessors for multiple indications.

Insomnia The most common use of benzodiazepines, certainly in primary care and general medicine, is for insomnia. Flurazepam is one of the most frequently prescribed hypnotics, with few adverse effects. The very short half-life benzodiazepine triazolam enjoyed transient popularity because its short half-life allowed it to be cleared before morning, and it was not associated with daytime drowsiness. However, serious concern and controversy have arisen concerning its apparent potential for serious adverse effects at higher doses (see below).

Seizures Benzodiazepines, particularly clonazepam, have anticonvulsant properties and are used for that indication. Clonazepam is used for petit mal in children.

Alcohol Withdrawal The benzodiazepines have become the treatment of choice for alcohol withdrawal in most countries, certainly in the United States. Traditionally, they are first given in higher doses (40 to 60 mg per day), and then tapered over several days.

Anxiety Disorders Generalized anxiety disorder, adjustment disorder with anxiety, but not necessarily pathological anxiety associated with life events (for example, after an accident) are the major clinical applications for benzodiazepines in psychiatry and general medical practice. Most patients should be treated for a predetermined, specific, and relatively brief period. Some patients with generalized anxiety disorder may warrant maintenance treatment with benzodiazepines. The serotonin-specific reuptake inhibitors are effective antianxiety agents that lack abuse potential, although their antianxiety effects require 2 to 4 weeks to develop.

For two anxiety disorders, panic disorder with or without agoraphobia and social phobia, the two high-potency benzodiazepines, alprazolam and clonazepam, are effective. The Food and Drug Administration (FDA) has approved the use of alprazolam for the treatment of panic disorder. The dosage guidelines for the use of alprazolam in panic disorder are similar to those for depression, as already discussed. Paroxetine (Paxil) and sertraline (Zoloft) have also been approved by the FDA for treatment of panic disorder. Because paroxetine and sertraline may not be fully effective for 2 to 4 weeks after initiation, coadministration of a high-potency

benzodiazepine for the first 2 to 4 weeks of use of paroxetine or sertraline can provide rapid control of anxiety, before the long-term benefits of paroxetine or sertraline emerge.

Benzodiazepines, especially clonazepam, which has serotonergic properties, may treat the anxiety component of obsessive-compulsive disorder. Clonazepam may be effective for certain patients who do not respond to clomipramine. Benzodiazepines may also be used to augment clomipramine or the serotonin-specific reuptake inhibitors. Benzodiazepines may help reduce hyperarousal in posttraumatic stress disorder.

Depression Unique among the benzodiazepines, alprazolam has antidepressant effects equal to those of the tricyclic drugs, but alprazolam is not effective with seriously depressed inpatients. The efficacy of alprazolam in depressive disorders may reflect its potency; the antidepressant effects of other benzodiazepines may be evident only at doses that also induce sedation or sleep.

Other Conditions They are also widely used by nonpsychiatrists to treat situational anxiety, especially that associated with medical treatment, and as muscle relaxants. Lorazepam and clonazepam are often used alone or adjunctively in the treatment of mania. The benzodiazepines (especially intramuscularly lorazepam) are used to manage both substance-induced (except amphetamine) and psychotic agitation in the emergency room. A few studies report the use of high dosages of benzodiazepines in patients with schizophrenia who had not responded to antipsychotics or who were unable to take the traditional drugs because of adverse effects. The successful use of lorazepam intramuscularly for the transient resolution of catatonia has been reported. Benzodiazepines have also been used instead of amobarbital (Amytal) for drug-assisted interviewing. Several studies have found that benzodiazepines are also effective in treating some cases of akathisia.

Precautions and Adverse Effects

Central Nervous System Certainly, the most prominent and common adverse effects of benzodiazepines are those related to their principal actions in the CNS. Almost all benzodiazepines are significantly sedating, although most patients develop rapid tolerance to this side effect within several days. Patients can experience significant daytime sleepiness, even falling asleep during daytime activities or exhibiting other signs of overdosage (e.g., ataxia or slurred speech). The ataxia associated with the benzodiazepines has particular importance for elderly persons, who are more at risk for overdose because of the reduced metabolic rate associated with aging. This has particular importance with the increased risks in elderly persons for ataxia, falls, and hip fractures. In a related fashion, younger individuals have always been cautioned about operating heavy machinery during benzodiazepine use. More recently, benzodiazepine interference with the ability to drive automobiles has been studied. This bears close following, as research suggests significant impairment of driving ability.

Certainly, the cognitive effects of benzodiazepines have been and continue to be an important issue. The anterograde amnestic effects of benzodiazepines are used widely in anesthesia induction to produce anterograde amnesia. Intravenous administration appears to be required to produce this effect, but it also has been reported with oral dosing, especially with triazolam. This effect may be increased if alcohol is also consumed.

Probably more important are the observations that long-term benzodiazepine therapy interferes with concentration and memory of new material. However, it does appear that the ability to remember and recall information learned prior to benzodiazepine therapy is not compromised. Although this can be a particular problem in elderly patients and may even lead to confusional, delirious, and even pseudodementia-type pictures, these effects on memory are generally subtle. These adverse effects, in particular, must be monitored with each individual patient to balance these relatively minor memory disturbances (if they occur) with clinical efficacy.

An important issue has been the use of benzodiazepines to induce amnesia in date rape. Although it is generally believed that flunitrazepam (not sold legally in the United States) is especially effective in inducing amnesia, all full agonist benzodiazepines are, essentially, equally capable of inducing anterograde amnesia.

A further issue is whether behavioral disinhibition occurs with the benzodiazepines. This has been reported as an increase in anxiety and, more commonly, in hostility, impulsive thefts, acts of aggression, and (particularly) verbal hostility. It is unclear how common these reactions are, and some patients believably describe that they had meant to say certain angry things for many years, but were too anxious to do so. Therefore, it is unclear whether this represents disinhibition or not.

Rarely, incontinence has been reported with patients receiving benzodiazepines. Also, certain benzodiazepines, especially at higher doses, have been associated with sexual dysfunction (primarily decreased libido or inability to maintain an erection) and are common enough that clinicians should inquire about changes in sexual function.

Certainly, intravenous benzodiazepines can lead to pulmonary depression or even arrest. This can even occur with oral doses in patients with chronic obstructive pulmonary disease or sleep apnea.

There is some concern that benzodiazepine use is associated with the emergence of depression. This is theorized to occur by either direct action of the drug or by treating anxiety in a mixed anxiety-depressive disorder and thereby uncovering the depression.

Flumazenil has been associated with seizures in epileptic patients who have been treated with benzodiazepine anticonvulsants, in patients on long-term treatment with benzodiazepines, and in patients who have also overdosed with tricyclic drugs. Occasionally, cardiac arrhythmias have also been observed with flumazenil use.

Abuse Liability In this author's experience, concern over the so-called abuse liability of the benzodiazepines in the general public and even the medical profession is the most controversial area of clinical medicine. Despite considerable scientific evidence that the risk of drug abuse with benzodiazepines is low, there is tremendous prejudice against their use in many individuals, in certain treatment settings, and even countries (e.g., United Kingdom). This area has had excellent review, and it is actually much more common for anxious patients to take lower doses than prescribed, and routinely they do not escalate dosage, even over prolonged use. Dose increases are generally appropriate and are not an indication of abuse.

Despite this research literature and clinical experience, many people and certainly the media believe that benzodiazepines are widely and routinely associated with abuse. This seems to stem from at least two sources. First, there is a general belief that patients who have abused other drugs are at high risk for abusing benzodiazepines. Although some data support this view and there are certainly patients who abuse benzodiazepines in context with other illegal drugs of abuse or even by themselves, this is a controversial area. Second, conventional wisdom suggests that benzodiazepine use by alcoholics be generally avoided. However, recent analyses of even these data suggest that abuse of benzodiazepines (even by alcoholic individuals) may not be as certain in all alcoholics as believed.

Certainly, primary abuse of benzodiazepines does occur. Abuse of oral benzodiazepines has been relatively infrequent, but there has been a sharp increase in other abuse of benzodiazepines, particularly in Britain. Temazepam (Restoril) is being increasingly abused through intravenous use, with extraordinary vascular side effects, even resulting in loss of limbs, and some evidence suggests that flunitrazepam has been abused by heroin addicts more than other benzodiazepines.

Confusion over the meaning of the terms *addiction, dependence*, and *abuse* has significantly contributed to the continued confusion and controversy in this area. Recent efforts to clarify the semantic confusion, especially differentiating the routine withdrawal symptom liability observed in 30 to 90 percent of patients from terms such as *addiction* and *abuse* have been helpful.

Pregnancy Complications from use of benzodiazepines during pregnancy are somewhat unclear. However, some data suggest palate abnormalities; although in general, use during pregnancy is relatively safe if clinical issues outweigh the risks. If a mother is taking a benzodiazepine at birth, children can have difficulties with the drug in their bloodstream.

Discontinuation of Treatment One of the more important areas of benzodiazepine use centers around the discontinuation of effective or ineffective treatment. Pressure to discontinue often arises from the patient, patient's family, or even the medical professional. This is often related to exaggerated fears of becoming addicted or an attitude that use of benzodiazepines is a sign of weakness rather than a treatment for a medical condition. There are some good reasons to discontinue effective pharmacotherapy, including determining if the patient still needs the medication as mentioned above. Others include serious adverse effects or the wish to conceive a child.

Successful discontinuation involves several activities that although simple are often not performed. Patients and their families need to be told what to expect with discontinuation, because it is often associated with anxiety before (and certainly if) withdrawal symptomatology occurs.

Withdrawal symptoms occur in 30 to 90 percent of patients, depending on the definition of symptoms, length and dosage of previous treatment, and (most importantly) the rate of taper. Most of the symptoms are mild to moderate and easily tolerated, although abrupt discontinuation of a relatively high dose of benzodiazepines has been (rarely) associated with convulsions. Although benzodiazepines, particularly those with a long half-life, can be abruptly discontinued, this is not recommended in any case. In fact, recent clinical experience suggests that the withdrawal syndrome can be largely avoided with an appropriately slow taper. In generalized anxiety disorder patients, this might well be 3 to 6 weeks, and in panic disorder patients 8 to 24 weeks. This is less necessary with shorter periods of treatment or low doses of benzodiazepines.

When patients discontinue taking benzodiazepines, several types of symptoms occur. First, patients can relapse with return of their original symptoms. Second, patients can experience withdrawal symptoms, which generally occur within several days of discontinuation but generally decrease and disappear within 2 to 3 weeks. With high-potency benzodiazepines, withdrawal symptoms can be observed even with decreases from one dosage level to another. *Rebound* refers to the sudden onset of more severe symptoms than those in the original anxiety syndrome within days of decreasing or discontinuing benzodiazepine use. These generally clear very rapidly. *Relapse* refers to the return of the original anxiety syndrome. Since all of these syndromes overlap considerably and are often difficult to distinguish, the term *relapse* is generally reserved for stable or increasing symptoms present 3 to 4 weeks after medication use is discontinued that represent return of the original syndrome.

Proper management of discontinuation includes educating patients and their family, support, easy availability of the clinician, providing other strategies for dealing with anxiety or sleep difficulties, and the passage of time. Some recent studies suggest that formal cognitive-behavioral group treatment is also helpful in helping patients discontinue long-term benzodiazepine use (Table 31.10-1).

Anxiety
Irritability
Insomnia
Fatigue
Headache
Muscle twitching or aching
Tremor, shakiness
Sweating
Dizziness
Concentration difficulties
Nausea, loss of appetite*
Observable depression*
Depersonalization, derealization*
Increased sensory perception (smell, sight, taste, touch)*
Abnormal perception or sensation of movement*

* Symptoms likely to represent true withdrawal, rather than an exacerbation or return of original anxiety.

Table 31.10-1 Commonly Observed Withdrawal Symptoms (Benzodiazepine Withdrawal Syndrome)

DRUG INTERACTIONS

The most common drug-drug interaction occurs when benzodiazepines are combined with other CNS depressants (e.g., alcohol, barbiturates, opioids and antihistamines). Patients should be cautioned about potential potentiation of the depressant effects (Table 31.10-2).

Decrease absorption		
Antacids		
Increase CNS depression		
Antihistamines		
Barbiturates and similarly acting drugs		
Cyclic antidepressants		
Ethanol		
Increase benzodiazepine levels (compete for microsomal enzymes; probably little or no effect on lorazepam, oxazepam, temazepam)		
Cimetidine	Erythromycin	Fluoxetine
Disulfiram	Estrogens	Isoniazid
Decrease benzodiazepine levels		
Carbamazepine (possibly other anticonvulsants)

Table 31.10-2 Interactions of Benzodiazepines With Other Drugs

Cimetidine (Tagamet) and disulfiram (Antabuse) decrease metabolism of benzodiazepines, prolonging their effects. This can be clinically important with estrogen and oral contraceptives. Diazepam and gallamine or succinylcholine can result in paralysis. Fluvoxamine (Luvox) and other inhibitors of the cytochrome P450 enzyme CYP 3A4 can also inhibit metabolism of benzodiazepines and greatly increase their effects. The half-life of digoxin (Lanoxin) is increased by benzodiazepines by an unknown mechanism. With the resurgence of tuberculosis, particularly in acquired immune deficiency syndrome (AIDS)-related problems, antibiotics can also affect benzodiazepine metabolism. Rifampin (Rifadin) increases hepatic metabolic enzymes, and isoniazid decreases them.

Relationship of Blood Concentration to Clinical Efficacy The clinical effects of the benzodiazepines depend on the time course of receptor occupancy, which itself depends on dose and plasma concentration. However, controversy continues about whether significant correlations exist between dose and plasma concentration and clinical effects, because research results are mixed. Several early studies failed to find a correlation, although others did find positive correlations between plasma concentration and clinical improvement.

More recently, positive correlations between alprazolam plasma concentration and clinical response were observed in panic disorder patients. Although there was wide variability between patients given identical doses of alprazolam, reductions in panic and phobic symptomatology and drug concentration in blood were observed. Adverse effects also increased with increased plasma concentration at a certain point, and both studies suggested a range of plasma concentration that were associated with positive clinical response and relatively few adverse effects.

Dosage and Administration Table 31.10-3 summarizes the benzodiazepine receptor agonists and antagonists and presents dosage and preparations.

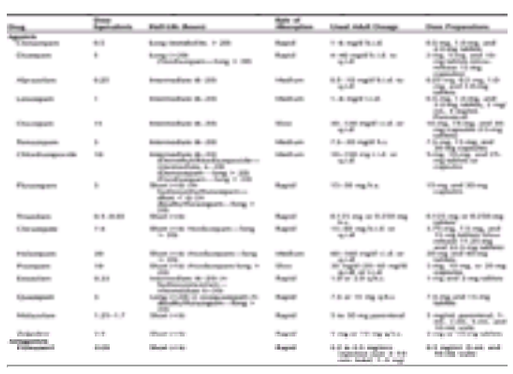

Table 31.10-3 Half-Lives, Doses, and Preparations of Benzodiazepine Receptor Agonists and Antagonists

The starting dosage of alprazolam for the treatment of depression should be 0.5 mg two or three times a day and should be raised in 0.5 mg a day intervals every 3 or 4 days. The maximal dosage is usually 4 mg a day, although some investigators and clinicians have used dosages as high as 10 mg a day. The use of high dosage is controversial because of the possibility of withdrawal symptoms. Clinicians must taper, rather than abruptly stop, alprazolam use, usually at the rate of 0.5 mg a day every 3 to 4 days or slower.

Length of Treatment Much of the formal research with benzodiazepines has involved short-term use, and they are generally labeled as such. However, accumulated clinical experience and recent research has demonstrated that, in fact, most anxiety conditions are quite long term. The long-term nature of panic disorder has recently been established. In the early trials when benzodiazepines were discontinued blindly after 6 weeks, approximately half of the patients relapsed with return of anxiety. It would seem prudent for clinicians to taper and try to discontinue benzodiazepines in generalized anxiety disorder patients after 6 weeks to see whether they can remain off medications. Current practice with panic disorder patients is to continue treatment for 6 to 18 months before tapering and attempting discontinuation. Although longer treatment has become commonplace in anxiety, benzodiazepine use in the treatment of insomnia should be restricted to the short term in most cases.

ZOLPIDEM

Zolpidem is a hypnotic that acts at the g-aminobutyric acid (GABA)-benzodiazepine complex as the benzodiazepines do, but it is not itself a benzodiazepine. The only indication for zolpidem at this time is as a hypnotic. The drug lacks the muscle-relaxant effects that are common to the benzodiazepines. Zolpidem is an imidazopyridine, and its chemical structure is shown in Figure 31.10-2.

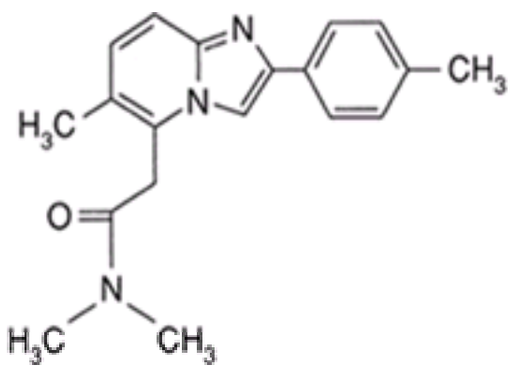

FIGURE 31.10-2 Molecular structure of zolpidem.

Pharmacological Actions Zolpidem is rapidly and well absorbed after oral administration, and it reaches peak plasma levels in about 2 to 3 hours. Zolpidem has a half-life of about 2½ hours and is metabolized primarily by conjugation. Zolpidem does not have any active metabolites. Zolpidem has a much higher affinity for BZ_1 receptors than for BZ_2 receptors. Zolpidem is also more specific for the CNS benzodiazepine receptors than for the peripheral benzodiazepine receptors. These pharmacodynamic properties are consistent with the drug's efficacy as a hypnotic in the absence of significant anticonvulsant or muscle-relaxant properties. The binding site of zolpidem is likely to be similar to that of the benzodiazepines, as the effects of zolpidem can be prevented or reversed by the benzodiazepine receptor antagonist flumazenil.

Therapeutic Indications The sole indication at the time for zolpidem is as a hypnotic. Several studies have found an absence of rebound REM after the use of the compound for the induction of sleep. The comparatively few data available indicate that zolpidem may not be associated with rebound insomnia after the discontinuation of its use for short periods.

Precautions and Adverse Reactions Because of the short half-life of zolpidem, clinicians may reasonably evaluate a patient for the possibility of anterograde amnesia and anxiety the day after its administration, although neither of these adverse effects has been reported. Emesis and dysphoric reactions have been reported as adverse effects. Tolerance and dependence have been reported in less than 1 percent of patients, and the withdrawal symptoms are similar to those described for benzodiazepines. Zolpidem is secreted in breast milk and is, therefore, contraindicated for use by nursing mothers. The dosage of zolpidem should be reduced in patients with renal and hepatic impairment.

Drug Interactions and Laboratory Interferences Information on drug interactions and laboratory interferences is limited. Therefore, clinicians should consider the possibility of such an interaction or interference in a patient who is being treated with zolpidem.

Dosage and Administration A single 10 mg dose is usual for the treatment of insomnia. For patients under age 65, the initial dose of 10 mg can be increased to 15 to 20 mg if necessary. For patients over age 65, an initial dose of 5 mg may be advised. Prolonged use of zolpidem or any hypnotic is not recommended.

FLUMAZENIL

Flumazenil is a benzodiazepine receptor antagonist. It reverses the psychophysiological effects of the benzodiazepine agonists (for example, diazepam). The use of flumazenil is limited to emergency rooms and other emergency settings. The molecular structure of flumazenil is based on a benzodiazepine nucleus (Fig. 31.10-3).

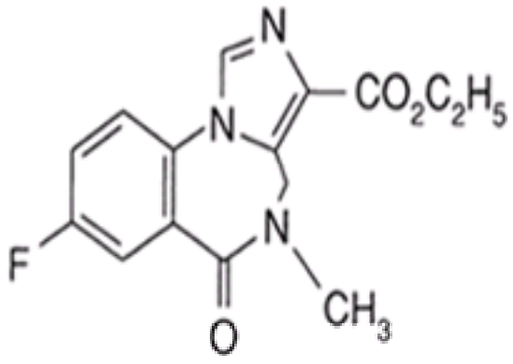

FIGURE 31.10-3 Molecular structure of flumazenil.

Pharmacological Actions After intravenous administration, flumazenil has a half-life of 7 to 15 minutes. Protein binding is about 50 percent. Clearance of flumazenil occurs primarily by hepatic metabolism. The major metabolites of flumazenil are the deethylated free acid and its glucuronide conjugate, which are excreted in the urine. Elimination of the drug is essentially complete in 72 hours. The pharmacokinetics of flumazenil are not significantly affected by gender, age, renal failure, or hemodialysis but are affected by hepatic impairment, which prolongs the half-life.

Flumazenil antagonizes sedation, impairment of recall, and psychomotor retardation produced by benzodiazepine receptor agonists. But flumazenil does not reverse the effects of other CNS depressants, even if they also act partly on the $GABA_A$ receptor (for example, ethanol and barbiturates). Flumazenil is also ineffective in

reversing the effects of opioids.

Therapeutic Indications Flumazenil is used to reverse the effects of benzodiazepine receptor agonists that have been used for clinical indications (for example, sedation and anesthesia) or in overdose.

Precautions and Adverse Reactions The most common adverse effects of flumazenil are nausea, vomiting, dizziness, agitation, emotional lability, cutaneous vasodilation, injection-site pain, fatigue, impaired vision, and headache. The most common serious adverse effect of the use of flumazenil to reverse benzodiazepine overdose is the precipitation of seizures, which is especially likely to occur in patients with seizure disorders, those who are physically dependent on benzodiazepines, or those who have ingested very large quantities of benzodiazepines. Flumazenil alone may impair memory retrieval.

Drug Interactions and Laboratory Interferences No deleterious drug interactions have been noted when flumazenil is administered after narcotics, inhalation anesthetics, muscle relaxants, and muscle-relaxant antagonists administered in conjunction with sedation or anesthesia. In mixed-drug overdose the toxic effects (for example, seizures and cardiac arrhythmias) of other drugs (for example, tricyclic drugs) may emerge with the reversal of the benzodiazepine effects of flumazenil. For example, seizures caused by an overdose of tricyclic drugs may have been partially treated in a patient who had also taken an overdose of benzodiazepines. With flumazenil treatment, the tricyclic-induced seizures or cardiac arrhythmias may appear and may result in a fatal outcome.

No laboratory interferences have been associated with the use of flumazenil.

Dosage and Administration For the initial management of a known or suspected benzodiazepine overdose, the recommended initial dose of flumazenil is 0.2 mg (2 mL) administered IV over 30 seconds. If the desired level of consciousness is not obtained after waiting 30 seconds, a further dose of 0.3 (3 mL) can be administered over 30 seconds.

Most patients with a benzodiazepine overdose respond to a cumulative dose of 1 to 3 mg of flumazenil; doses beyond 3 mg of flumazenil do not reliably produce additional effects. If a patient has not responded 5 minutes after receiving a cumulative dose of 5 mg flumazenil, the major cause of sedation is probably not due to benzodiazepine receptor agonists, and additional flumazenil is likely to have no effect.

SUGGESTED CROSS-REFERENCES

Disorders for which benzodiazepine therapy may be considered are discussed in Section 11.2 on the treatment of alcohol-related disorders, Chapter 15 on anxiety disorders, and Chapter 21 on sleep disorders. Section 3.1 takes up perception and cognition; Section 3.4 is devoted to the biology of memory. Section 31.12 discusses buspirone, and Section 31.25 discusses the selective serotonin reuptake inhibitors.

31.11 BUPROPION

ROBERT N. GOLDEN, M.D., AND LINDA M. NICHOLAS, M.D.

HISTORY

Thirty years ago, a group of pharmacologists decided to develop a novel antidepressant compound. They devised a research plan in which they would create a molecule that was active in conventional antidepressant screening models yet differed from the current available antidepressants in five specific ways: (1) it would possess different chemical, pharmacological, and biochemical properties from tricyclic drugs; (2) it would not inhibit monoamine oxidase (MAO) activity; (3) it would not possess sympathomimetic activity; (4) it would not exhibit anticholinergic effects; and (5) it would not depress myocardial activity. The group believed that the first two of these properties would enhance their chances of developing a unique approach to treating depression, while the other three properties would evoke an adverse-effect profile that was far superior to that of existing antidepressant medications. Their approach led to the discovery of bupropion (Wellbutrin).

As predicted, early clinical trials demonstrated that bupropion had efficacy comparable to that of conventional antidepressants and an apparently more benign side-effect profile, with a striking lack of significant anticholinergic toxicity and minimal effect on cardiovascular systems. However, shortly after the drug was shipped to pharmacies in 1986, seizures were reported in a small number of nondepressed, bulimia nervosa patients treated with bupropion. The manufacturer immediately withdrew the drug and launched extensive clinical investigations focusing on bupropion's effects on seizure threshold. Finally, in 1989, bupropion was released for clinical use in this country. In 1996, a slow-release preparation (Wellbutrin-SR) became available for clinical use, and bupropion (Zyban) was recognized by the Food and Drug Administration as a safe and effective aid, in combination with a behavioral modification program, in smoking cessation treatment.

CHEMISTRY

Bupropion is a unicyclic aminoketone (Fig. 31.11-1), with a chemical structure that is unique among antidepressants. The lack of certain common functional groups (e.g., *N*-methylpiperazine) often found in neuroleptics and the absence of complex heterocyclic fused rings probably contribute to bupropion's lack of the type of adverse-effect profile often seen in tricyclic and tetracyclic drugs. Bupropion's chemical structure is similar to that of psychostimulants, including amphetamines and diethylpropion (Tenuate), which may account for certain shared characteristics.

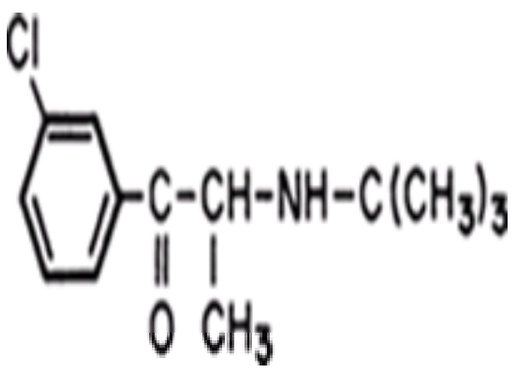

FIGURE 31.11-1 Molecular structure of bupropion.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption The bupropion is rapidly absorbed following oral administration, with peak blood concentrations reached within 2 hours. Mean protein binding in healthy subjects is 85 percent. The elimination is biphasic, with an initial phase of approximately 1.5 hours and a second phase of about 14 hours.

The sustained-release formulation of bupropion is bioequivalent to the immediate-release formulation with respect to the parent compound, active metabolites, and a pharmacological activity–weighted composite. Peak plasma concentrations of bupropion are reached approximately 3 hours after oral administration of the sustained-release form, followed by a biphasic decline, that is less pronounced than that seen following administration of the immediate-release formulation. At equal doses, the total amount of bupropion absorbed from the immediate-release and sustained-release formulations is about the same. Peak and trough steady-state plasma concentrations of bupropion following oral administration of 150 mg of the sustained-release formulation twice a day are about 85 and 107 percent respectively, of the concentrations achieved following 100 mg of the immediate-release formulation thrice daily. Bupropion areas under the concentration time curve (AUCs), peak plasma concentration, and AUCs for all three of the detectable active metabolites are equivalent for the immediate-release and sustained-release formulations.

Distribution Protein binding for bupropion ranges from 82 to 88 percent at concentrations of 84 to 239 ng/mL. It is widely distributed to tissues. The cerebrospinal fluid to plasma ratio of bupropion is 0.43, and the ratios for the three active metabolites range from 0.04 to 0.50. Bupropion crosses the placental barrier, although fetal tissue concentrations are lower than those in placental and other maternal tissues. Bupropion is excreted in breast milk.

Metabolism and Elimination Bupropion undergoes extensive hepatic metabolism, including a pronounced first-pass effect. At steady state, the three active metabolites, hydroxybupropion, erythyrohydrobupropion, and threohydrobupropion, predominate over the parent compound in plasma and cerebrospinal fluid and may play an important role in determining clinical response. Less than 1 percent of the drug is excreted unchanged, and approximately 87 and 10 percent of radioactively labeled drug dose is recovered in the urine and feces, respectively.

Pharmacodynamics

Mechanism of Action The mechanism of action of bupropion remains unclear. Early investigations focused on enhanced dopaminergic activity because of reuptake inhibition by the parent compound as a likely mechanism of action. Some of the behavioral effects of bupropion in classical animal models of antidepressant activity, including stimulation of locomotor activity and effects on the Porsolt forced swim test, are abolished by destruction of dopaminergic neurons by 6-hydroxydopamine. Also, bupropion-induced behavioral sensitization in the rat is accompanied by a selective potentiation of the effects of the compound on interstitial dopamine concentrations in the nucleus accumbens. In a clinical study, plasma concentrations of the major metabolite of dopamine, homovanillic acid, increased in patients who

failed to respond to bupropion treatment but not in those who achieved clinical response.

More recently, the role of norepinephrine in the mechanism of action of bupropion has received considerable attention. In hospitalized depressed patients, bupropion, along with the norepinephrine reuptake inhibitor desipramine and MAO inhibitors, enhanced noradrenergic function, as measured by 24-hour excretion of 6-hydroxymelatonin, a physiological gauge of noradrenergic activity. At the same time, these antidepressants reduced “whole body norepinephrine turnover,” that is, the 24-hour excretion of norepinephrine and its metabolites. These observations suggest that bupropion increases the functional efficiency of noradrenergic systems. This effect may be mediated by bupropion's active metabolites, including hydroxybupropion, which inhibit the reuptake of norepinephrine into rat cortical tissue.

The three known active metabolites, hydroxybupropion, erythyrohydrobupropion, and threohydrobupropion, may play important roles in the mechanism of bupropion's antidepressant activity. In animal models, hydroxybupropion possesses more-potent antidepressant properties than the parent compound, and threohydrobupropion also demonstrates some antidepressant activity. In depressed patients, the steady-state plasma and cerebrospinal fluid concentrations of the active metabolites actually exceed those of bupropion itself.

Blood Levels and Relation to Action No consistent, clear relationship between steady-state bupropion plasma concentrations and clinical response has emerged. One study reported a curvilinear relation between antidepressant efficacy and trough bupropion plasma concentrations, with greatest efficacy associated with bupropion plasma concentrations between 25 and 100 ng/mL. In contrast, another study found greater clinical response associated with trough levels below 30 ng/mL. A study examining both parent and metabolite concentrations found no relation between steady-state plasma bupropion concentrations and clinical response, but a significant relation between metabolite concentrations and clinical outcome. For each of the three active metabolites, higher concentrations were significantly related to poor clinical outcome; this effect was most striking for hydroxybupropion. The interpretation of this observation is unclear. It may indicate toxic effects that emerge at higher metabolite concentrations. On the other hand, the metabolites may be responsible for bupropion's therapeutic effects, and a curvilinear plasma concentration-response relation (like that seen with nortriptyline) may exist.

CLINICAL DRUG STUDIES

Double-blind, placebo-controlled studies have clearly demonstrated that bupropion is superior to placebo and comparable to conventional tricyclic drugs in the treatment of major depressive disorder. In four multicenter studies, bupropion was consistently superior to placebo in treating depressed outpatients and inpatients, with 60 to 70 percent efficacy, compared with 30 percent with placebo. At the same time, bupropion's side-effect profile did not differ substantially from that associated with placebo treatment, with minimal cardiovascular changes. In controlled comparisons to standard antidepressants, including amitriptyline (Elavil), imipramine (Tofranil), doxepin (Sinequan), and nortriptyline (Aventyl), bupropion has generally demonstrated similar efficacy. When a sedating tricyclic drug such as doxepin or amitriptyline is used as the gold standard treatment, greater or more rapid improvement in sleep or both can yield more impressive results in the insomnia component of depression rating scales. On the other hand, in such comparisons bupropion appears superior in terms of diminished anticholinergic adverse effects and unwanted weight gain.

A few studies have compared bupropion with other second-generation antidepressants. In a two-center double-blind study, outpatients with major depressive disorder were treated with either 225 to 450 mg of bupropion (N = 63), or 150 to 400 mg of trazodone (Doseryl) (N = 61). Following 6 weeks of treatment 58 percent of bupropion-treated patients were considered much or very much improved compared with 46 percent of trazodone-treated patients. In another study, fluoxetine (Prozac) and bupropion demonstrated similar efficacies in treating major depressive disorder and accompanying anxiety symptoms in a double-blind controlled trial. Both drugs provoked minimal adverse effects.

Psychiatrists are increasingly called upon to treat depressed patients who have been refractory to one or more antidepressant treatments. Under double-blind conditions, bupropion was superior to placebo in treating hospitalized patients who were refractory to tricyclic drugs. In an open-label study, depressed outpatients with histories of either nonresponse or nonresponse plus intolerance to tricyclic drugs showed marked improvement on bupropion. In a recently published open study of 41 depressed patients who had failed to respond to well-documented tricyclic treatment, about half responded to bupropion.

Bupropion's adverse-effect profile is relatively mild and benign, and the medication is generally better tolerated than tricyclic drugs. While considerable attention has been focused on the issue of treatment-associated seizures, when bupropion is prescribed according to the current recommended guidelines regarding patient selection and dosage, the risk is similar to that of tricyclic and tetracyclic antidepressants. In contrast to serotonin selective reuptake inhibitors (SSRIs), bupropion does not appear to impair psychosexual function.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Central Nervous System Bupropion pharmacotherapy has been linked to seizures, although the relative risk is probably not substantially greater than that with other antidepressants when the current prescribing guidelines are followed. Other, more common adverse effects include agitation, insomnia, and restlessness. Psychosis, confusion, delirium, and other altered mental status effects have been described but probably occur in a very small minority of patients.

Cardiovascular System Clinical trials of potential new antidepressants exclude patients with substantial coexistent medical conditions, for obvious safety and ethical considerations. In this population, bupropion did not demonstrate cardiac adverse effects, and in contrast to tricyclic drugs, it did not affect cardiac conduction or induce orthostatic hypotension. Since becoming available for clinical use, bupropion has demonstrated a lack of impairment on cardiac output in patients with preexisting heart failure, and its benign profile in terms of orthostatic blood pressure effects has been confirmed in patients with preexisting cardiac disease. Bupropion has been well tolerated by patients who had previously developed orthostatic hypotension in conjunction with tricyclic antidepressant pharmacotherapy. Occasional patients with preexisting hypertension may exhibit increased blood pressure following initiation of bupropion treatment. Because of a lack of reported clinical experience in patients with a history of recent myocardial infarction or unstable heart disease, the manufacturer recommends exercising care in prescribing bupropion to these patient populations.

Blood Bupropion does not appear to affect the hematopoetic system. Rare instances of lymphadenopathy, anemia, and pancytopenia have been reported but without clear causal relationship to bupropion exposure.

Liver Although scattered abnormalities in liver function test results were reported during the premarketing clinical trials, there is no clinical evidence that bupropion has hepatotoxicity in humans. Because bupropion and its active metabolites undergo hepatic metabolism, patients with substantial liver disease and impairment should receive reduced dosages and should be carefully supervised and monitored for possible toxic effects from elevated blood concentrations of the parent compound and active metabolites.

Sexual Functioning In sharp contrast to SSRIs and some other antidepressants, bupropion does not appear to be associated with psychosexual dysfunction, including decreased libido, anorgasmia, and erectile problems. In fact, several published reports describe successful use of bupropion in patients who had stopped treatment with other antidepressants because of psychosexual adverse effects.

Weight In contrast to tricyclic drugs and several other antidepressants, bupropion causes appetite suppression more often than appetite enhancement. Weight loss of more than 5 pounds occurred in 28 percent of patients treated with bupropion, about twice that seen with placebo or tricyclic antidepressants. In addition, less than 10 percent of bupropion-treated patients gained weight versus nearly 35 percent of patients receiving tricyclic drugs.

Skin Bupropion has been associated with rashes and pruritis in a small minority of patients.

THERAPEUTIC INDICATIONS

The primary indication for bupropion is the treatment of major depression. Bupropion has been shown superior to placebo and as effective as both standard tricyclic antidepressants and the SSRIs in treating both ambulatory and hospitalized depressed patients. Under double-blind conditions, bupropion was superior to placebo in treating hospitalized patients who were refractory to tricyclic pharmacotherapy. In an open-label study, outpatients with a history of either nonresponse or nonresponse coupled with intolerance to tricyclic drugs showed marked improvement when switched to bupropion treatment. Additionally, in a recent open study of 41 depressed patients who had failed to respond to well-documented tricyclic treatment, about half responded to bupropion.

The role of bupropion in the treatment of bipolar disorder depression is unclear. Most clinicians recognize the potential danger of switching a depressed bipolar disorder patient into a manic state or inducing a rapid-cycling pattern associated with the use of antidepressants alone without concurrent mood-stabilizing agents. Initially, bupropion was considered especially helpful in these situations, with a putatively lower propensity for inducing the switch process. However, the past several years have seen several case reports of possible bupropion precipitation of mania and a mixed affective state. In addition, in a published series of 11 consecutive bipolar disorder patients, 6 experienced hypomanic or manic symptoms when bupropion was added to their treatment regimen. On the other hand, a recent report suggests that bupropion may be particularly promising in treating rapid-cycling bipolar II disorder patients. In that case series, all six patients showed improvement, with “dramatic” improvement in four that was sustained after an average of 2 years of treatment. In addition, none of the patients developed hypomania or rapid cycling, in contrast to the experience with conventional antidepressants. Furthermore, a recent prospective, double-blind trial found bupropion to be less likely to induce hypomania or mania in depressed bipolar disorder patients than desipramine (Norpramin). Thus, the most valid data suggest that bupropion may be quite useful in the treatment of bipolar disorder depression, but caution is still advised.

Because bupropion enhances dopaminergic neurotransmission, it makes sense that its potential efficacy has been examined in other psychiatric illnesses in which psychostimulant-like properties could be useful. Bupropion has been found effective in the treatment of attention-deficit disorders in two double-blind, placebo-controlled trials in children and one open trial in adults. In a double-blind crossover study, bupropion and methylphenidate had similar efficacies (Ritalin) in children with attention-deficit/hyperactivity disorder. However, bupropion may exacerbate tics in children with comorbid Tourette's disorder and attention-deficit disorders. Bupropion's activating properties have encouraged open trials of its potential use in the treatment of chronic fatigue syndrome and fatigue associated with multiple sclerosis.

In a placebo-controlled, double-blind trial, bupropion was superior to placebo in reducing episodes of binge eating and purging in patients with bulimia nervosa. However, because four subjects experienced grand mal seizures during treatment, the use of bupropion in the treatment of bulimia nervosa should be avoided. In a recent double-blind comparison, the efficacy of bupropion was intermediate between that of fluoxetine and placebo in the treatment of premenstrual dysphoric disorder but not significantly different from either. Uncontrolled case reports have described the use of bupropion in the treatment of social phobia.

In a recent randomized, double-blind study, 42 male veterans who smoked at least one pack of cigarettes daily received either bupropion (300 mg daily) or placebo for 3 months as an adjunct to group smoking-cessation counseling. Using salivary nicotinine concentrations to confirm smoking cessation, bupropion was significantly superior to placebo on all a priori defined measures of smoking cessation. A second study, examining 160 nondepressed male subjects and 30 female subjects, the sustained-release preparation of bupropion was again found superior to placebo as an adjunct for smoking cessation in patients who had failed multiple prior attempts to stop smoking. In a 3-month double-blind controlled trial of group smoking-cessation counseling, smoking abstinence of at least 1 week was achieved by 60 percent of the patients in the bupropion group, compared with 35 percent of patients in the placebo group.

In the largest published study to date, 615 cigarette smokers were assigned, under double-blind conditions, to treatment with either placebo or 100, 150, or 300 mg of sustained-release bupropion as an adjunct to brief counseling sessions for smoking cessation. After 7 weeks of treatment, the rates of smoking cessation (confirmed by carbon monoxide measurements in expired air) were 19 percent in the placebo group, 29 percent in the 100-mg bupropion group, 39 percent in the 150-mg bupropion group, and 44 percent in the 300-mg bupropion group. At 1-year follow-up, the respective cessation rates had dropped to 12, 20, 23, and 23 percent. Subjects who were continuously abstinent through the end of treatment exhibited a mean absolute weight gain that showed a significant inverse correlation with bupropion dose.

PRECAUTIONS AND ADVERSE REACTIONS

Much attention has understandably focused on the rare, but serious, adverse effect of bupropion-induced seizure. A careful retrospective review found that the incidence of seizures in patients receiving bupropion at dosage of 450 mg a day or less ranged from 0.33 to 0.44 percent, depending on the method used to complete this calculation. The cumulative 2-year risk in patients receiving 450 mg a day or less was 0.48 percent. This is comparable to the risk of seizures associated with other tricyclic or tetracyclic drugs. For example, the estimated frequency of seizures in outpatients with no predisposing factors, receiving tricyclic drugs at modest dosages (e.g., 150 mg a day or less) is 0.1 percent, and the frequency increases to 0.6 to 0.9 percent at higher dosages (e.g., 200 mg a day or more). In a prospective study of 3100 patients receiving the sustained-release formulation of bupropion, the incidence of seizures was 0.1 percent at dosages of 300 mg a day or less. To minimize the risk of seizure induction, patients should be carefully evaluated for potential risk factors, including past history of seizures, recent withdrawal from alcohol or anxiolytic drugs, concomitant therapy with other drugs that lower the seizure threshold, and history of organic brain disease or abnormal electroencephalogram (EEG). In addition, conservative dosage titration with a maximum dose of 400 to 450 mg a day and use of divided-dose schedules (e.g., thrice daily for the immediate-release formulation and twice daily for the sustained-release formulation) should further minimize the risk for bupropion-related seizures.

Bupropion's profile of common adverse reactions and side effects is strikingly different from that of conventional tricyclic drugs. It lacks anticholinergic effects, is clearly not sedating, and suppresses appetite in some patients. Unlike several other second-generation antidepressants, including the serotonin selective reuptake inhibitors, bupropion does not cause psychosexual dysfunction. A recent report documents that patients who experience psychosexual dysfunction in conjunction with fluoxetine treatment report substantially greater satisfaction with their sexual function while receiving bupropion.

Bupropion's cardiovascular profile is especially favorable. It does not appear to cause electrocardiographic ECG changes, and orthostatic hypotention is rare, even in patients with preexisting heart disease. In a direct comparison, bupropion was found safer than nortriptyline in regard to cardiovascular adverse effects.

Bupropion appears to be relatively less lethal following overdose than tricyclic drugs and certain other antidepressants. However, as with all medications, it should be distributed with care to patients who are at risk for suicide attempt. In a review of 58 cases of bupropion overdose and 9 cases of combined bupropion-benzodiazepine ingestion, bupropion did not appear to possess major cardiovascular toxicity. Neurological toxicity was described in that case series, including tremors, lethargy, and seizures; the seizures responded well to treatment with either benzodiazepines or phenytoin (Dilantin). Two fatal overdoses have been reported, associated with peripheral blood bupropion concentrations of 4.0 to 4.2 mg/L and total metabolite concentrations of 15 and 16.6 mg/L. By history, the estimated lethal doses were less than 10 grams.

Bupropion is associated with side effects that are linked to its pharmacological profile of enhanced dopaminergic neurotransmission. Bupropion can have activating effects similar to those seen with conventional psychostimulants, which are often helpful in patients with psychomotor retardation. On the other hand other patients can experience such effects as troubling agitation or insomnia. Appetite suppression is also perceived as an advantage in some clinical situations but a disadvantage in others. Psychotic symptoms, including hallucinations and delusions, have been associated with bupropion treatment. Since the initial description of bupropion-related psychoses, numerous case reports have described similar toxic reactions, including organic mental disorders, delirium, and catatonia. These relatively rare psychotic reactions may reflect overstimulation of dopaminergic systems, since one series of patients with bupropion-associated psychoses displayed increased plasma concentrations of homovanillic acid, a major metabolite of dopamine.

DRUG INTERACTIONS

Since bupropion undergoes extensive hepatic metabolism, other medications that inhibit or induce hepatic microsomal enzyme systems may affect its metabolism. The combined use of bupropion with MAO inhibitors should be avoided because of the risk of a hypertensive reaction if bupropion is added to ongoing MAO inhibitor. Treatment with MAO inhibitors should be discontinued at least 2 weeks prior to initiating bupropion pharmacotherapy.

Because bupropion increases synaptic availability of dopamine by blocking its reuptake, patients with coexisting Parkinson's disease and depression can often decrease their dose of antiparkinsonian medication when bupropion is added to their regimen. However, the combination of bupropion and antiparkinsonian medication should be administered cautiously, since the emergence of hallucinations, confusion, and dyskinesia has been described following the addition of bupropion to previously therapeutic dosages of levodopa (Larodopa).

Case reports have described the onset of delirium and a grand mal seizure following the addition of bupropion to fluoxetine treatment. Although the combination of lithium (Eskalith) and bupropion has been generally safe and well tolerated in a small number of published studies, a case report suggests that bupropion may affect lithium serum concentrations, and combined bupropion-lithium therapy has been linked to seizures in three patients. Two case reports suggest that carbamazepine (Tegretol) may decrease bupropion blood concentration and increase hydroxybupropion concentrations, while bupropion may increase valproate (Depakene) concentration.

LABORATORY INTERFERENCES

Bupropion pharmacotherapy may be associated with false positive test results for amphetamine in urine toxicology screening tests. In one report, the white blood cell count decreased by 10 to 14 percent during the first 2 months of therapy. However, there is no need to monitor hematological indexes routinely during bupropion therapy.

DOSAGE AND ADMINISTRATION

Bupropion is available in 75- and 100-mg tablets; the sustained-release formulation is available in 100- and 150-mg tablets. For the immediate-release preparation, the usual adult dosage is 100 mg thrice daily. Dosing should begin, in a healthy adult, at 100 mg twice a day and may be increased to 100 mg thrice daily after a minimum of 3 days. An increase in dosage, up to a total of 450 mg a day, in divided doses that do not exceed 150 mg each, can be pursued for patients who fail to respond to lower doses.

The usual target adult dosage of the sustained-release formulation is also 300 mg, but given as 150 mg twice a day. Dosing with the sustained-release formulation, in a healthy adult, is recommended to begin at 150 mg a day, given as a single daily dose in the morning. If the 150-mg dose is well tolerated, the 150-mg twice-daily target dose can be administered as early as the fourth day of treatment. At least 8 hours should elapse between successive doses. When indicated, the total dosage may be increased to a maximum of 400 mg a day, given as 200 mg twice a day.

The manufacturer recommends close adherence to the recommended dosing guidelines to minimize the risk of seizure. As with other psychotropic medications, particular attention should be given to dosage for elderly adults, children and adolescents, and patients with coexistent liver or renal disease.

31.12 BUSPIRONE

OLGA BRAWMAN-MINTZER, M.D., R. BRUCE LYDIARD, FH.D., M.D., AND JAMES C. BALLENGER, M.D.

Buspirone (BuSpar) is one of the azaspirone class of clinical compounds and differs both structurally and pharmacologically from benzodiazepines, barbiturates, or other sedative-anxiolytic compounds. Unlike benzodiazepines, buspirone does not exert anticonvulsant, muscle-relaxant, or hypnotic effects. The precise mechanism of action of buspirone is not known but appears to be complex, probably involving several brain neurotransmitter systems. Pharmacologically, buspirone exhibits a high affinity for serotonin (5-hydroxytryptamine [5-HT]) subtype in (5-HT_{1A}) receptors and moderate affinity for dopamine type 2 (D_2) receptors in vitro. The main active metabolite, 1-pyrimidinylpiperazine (1-PP), posesses a $_2$adrenergic receptor antagonism. Buspirone has no appreciable affinity for the g-aminobutyric acid (GABA)-benzodiazepine-chloride receptor complex and does not affect binding of benzodiazepines at the receptor complex in vitro.

CHEMISTRY

Buspirone (Fig. 31.12-1) is chemically designated 8-[4-[4-(2-pyrimidinyl)-1-piperazinyl]butyl]-8-azaspiro[4,5]decane-7,9-dione monohydrochloride. The heteroaryl piperazine nature of buspirone appears to be important for the anxiolytic activity, serotonergic effects, and dopamine antagonist properties.

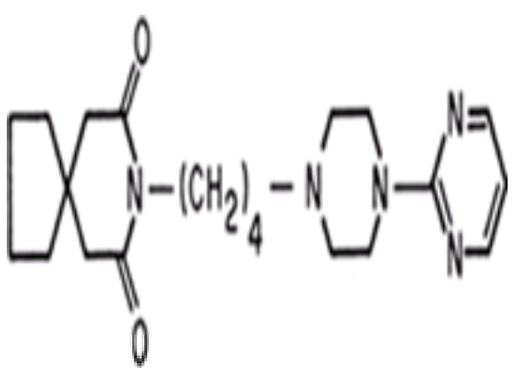

FIGURE 31.12-1 Molecular structure of buspirone.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption Buspirone is rapidly and almost completely absorbed after oral administration. However, the drug undergoes extensive first-pass metabolism, with approximately 4 percent of the parent drug reaching the systemic circulation. Peak plasma buspirone levels of 1 to 6 ng/mL occur within 40 to 90 minutes after a single oral dose of 20 mg. In healthy adult volunteers, the relation between plasma buspirone concentration and the oral dose appeared linear at single doses ranging from 10 to 40 mg. Following a multiple-dose oral administration, buspirone may have nonlinear pharmacokinetics, that is, dose increases, multiple doses, or both may lead to higher plasma concentrations than those predicted from single-dose studies. Ingestion of food delays gastrointestinal absorption of buspirone and increases the amount of unchanged buspirone reaching the systemic circulation. However, neither its efficacy nor the incidence of adverse effects appear to be affected by whether buspirone is administered with or without food.

Distribution At present, data regarding distribution of buspirone into body tissues and fluids are available primarily from animal models. In animals, buspirone is extensively distributed following intravenous administration, achieving higher concentrations in lung, kidney, and adipose tissue than in plasma. The concentration of buspirone in the brain parallels that in the plasma, but the active metabolite (1-PP) accumulates in the brain at concentrations 4 to 5 times higher than those in plasma. The volume of distribution of buspirone after intravenous administration averages 5.3 L/kg in healthy adults.

Approximately 95 percent of buspirone is bound to plasma proteins (albumin and a $_1$-acid glycoprotein). However, buspirone does not displace other highly protein bound drugs such as phenytoin (Dilantin), propranolol (Inderal), and warfarin (Coumadin). In vitro, buspirone does displace digoxin (Lanoxin).

Metabolism and Elimination After undergoing extensive hepatic metabolism, buspirone and its metabolites are excreted primarily in the urine (29 to 63 percent) and to a lesser extent in feces (18 to 38 percent). The major metabolites of buspirone are the inactive 5-hydroxybuspirone (5-HB) (via hydroxylation) and the pharmacologically active metabolite 1-PP (via oxidative dealkylation). The oxidation process has been shown to be mediated by cytochrome P450 isoenzyme 3A4 (CYP 3A4) in vitro. In animals, 1-PP is 20 to 25 percent less potent than buspirone, but brain concentrations are 15- to 30-fold greater than those of buspirone despite relatively lower blood concentrations.

The elimination half-life of unchanged buspirone following a single dose of 10 to 40 mg ranges from 2 to 11 hours. The average elimination half life of 1-PP following 20 mg of buspirone is 6 hours. The average elimination half life of 1-PP following 20 mg of buspirone is 6 hours. The elimination half-life of buspirone may be prolonged in patients with renal impairment and those with cirrhosis. Such patients may require lower doses of buspirone. The extent of secretion of buspirone and metabolites in human milk is unknown. However, in animal models buspirone and its metabolites appear in measurable amounts.

Pharmacodynamics

Mechanism of Action The precise mechanism of pharmacological action of buspirone is not known but probably involves several brain neurotransmitter systems.

BENZODIAZEPINE-GABA SYSTEM Unlike benzodiazepines, buspirone has no affinity for the GABA-benzodiazepine-chloride receptor complex. Buspirone does not appear to stimulate or inhibit binding of benzodiazepines at the receptor complex in vitro, although binding may be enhanced in vivo. Buspirone does not directly affect GABA binding. Further, benzodiazepine antagonists (such as flumazenil [Romazicon]) do not block the anxiolytic activity of buspirone. However, it has been suggested that buspirone may possibly indirectly affect GABA transmission via other mechanisms.

DOPAMINE SYSTEM Buspirone has a moderate affinity for dopamine D_2 receptors in the central nervous system (CNS). Buspirone appears to function as an antagonist of D_2 presynaptic autoreceptors, thus increasing dopaminergic neurotransmission and dopamine turnover. Some evidence in animal models indicates that buspirone may, in a limited fashion, block the postsynaptic D_2 receptors. It may also possess some dopamine agonist activity. However, the clinical significance of

these dopamine-related effects of buspirone has not been established, and they are probably clinically unimportant.

SEROTONIN SYSTEM Serotonin function has been thought to be important in various psychiatric disorders including anxiety and depression. Thus, it has been suggested that buspirone's effects on the serotonin system may contribute to its anxiolytic and possibly antidepressant effects. Specifically, buspirone was found to have high affinity for the 5-HT_{1A} receptor subtype in the CNS. The 5-HT_{1A} receptors are present in high concentrations in the dorsal raphe nucleus, which contains the cell bodies of the ascending serotonin neurons (i.e., somatodendritic-presynaptic receptors), and in the hippocampal and cortical regions, where the ascending 5-HT neurons terminate (i.e., postsynaptic receptors). Buspirone acts as a partial agonist or mixed agonist/antagonist at the 5-HT_{1A} receptor. The agent appears to have predominantly agonistic activity at the presynaptic 5-HT_{1A} receptors and partial agonistic activity at the postsynaptic receptors. Buspirone's ability to inhibit spontaneous firing of serotonergic neurons in the dorsal raphe nucleus, which probably accounts for its anxiolytic activity, has be suggested to be mediated through the somatodendritic serotonin autoreceptors. It has also been suggested that the agonist activity of buspirone at the postsynaptic 5-HT_{1A} receptors may be associated with its antidepressant activity.

NORADRENERGIC SYSTEM Buspirone was initially reported to be inactive at CNS adrenergic receptor sites. However, both preclinical and human data indicate that 1-PP, the main metabolite of buspirone, has central and peripheral a_2-adrenergic receptor blocking activity. Buspirone and 1-PP increase neuronal activity in the locus ceruleus and increase norepinephrine metabolism. Buspirone also decreases striatal concentrations of norepinephrine and increases the concentrations of 3-methoxy-4-hydroxyethylenephenylglycol (MHPG). Buspirone may also downregulate b_1-adrenoreceptors.

CHOLINERGIC SYSTEM The effects of buspirone on the cholinergic neurotransmitter system have not been fully elucidated. However, buspirone does not seem to interact directly with cholinergic receptors. In animal models buspirone administration increases the acetylcholine efflux in hippocampal neurons. Buspirone also decreases acetylcholine concentrations in the striatum.

Relation of Clinical Effects and Blood Concentrations No clear relation exists between plasma buspirone concentrations and clinical efficacy. Thus, there are no clinical indications for determining buspirone plasma concentrations.

CLINICAL STUDIES

Generalized Anxiety Disorder The efficacy of buspirone as an anxiolytic has been established in several multicenter, double-blind placebo-controlled trials, primarily for the treatment of generalized anxiety disorder. The published studies compared buspirone with another anxiolytic agent, placebo, or both. Buspirone has been compared with diazepam (Valium), clorazepate (Tranxene), alprazolam (Xanax), lorazepam (Ativan), and oxazepam (Serax). Most studies had a 1-week placebo run-in phase followed by double-blind randomization to a 4-week treatment phase (buspirone, a benzodiazepine, or placebo). The Hamilton Rating Scale for Anxiety (HAM-A) was the most widely used rating scale for clinical assessments. The mean doses of buspirone ranged from 7.5 to 42.3 mg daily.

Most of the available studies used the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) criteria for generalized anxiety disorder, which required only a 1-month duration of anxiety symptoms. Three studies used the revised third edition (DSM-III-R) or the fourth edition (DSM-IV) diagnostic criteria, which extended the required duration of anxiety symptoms to a minimum of 6 months. Thus, fewer data are available on the efficacy of buspirone in subjects with chronic symptoms of anxiety. Of the 13 peer-reviewed, placebo-controlled studies, 6 showed no benefit of buspirone over placebo following 4 to 6 weeks of treatment. In 6 of the 10 peer-reviewed, placebo-controlled studies that compared buspirone with a standard benzodiazepine, buspirone was statistically significantly better than placebo and comparable to diazepam, alprazolam, and lorazepam. However, 2 of those 10 showed no benefit for diazepam and buspirone over placebo, and 2 showed no benefit of buspirone over placebo. The therapeutic response to buspirone was usually evident by 2 to 3 weeks, compared with a more rapid (e.g., 1 to 2 weeks) response with benzodiazepines. Benzodiazepines may also be slightly more effective in the treatment of somatic symptoms of anxiety, but no significant differences appear to exist between buspirone and benzodiazepines in measures of psychic anxiety. Buspirone may be more effective in the treatment of anger and hostility symptoms than benzodiazepines. Finally, some investigators suggested that prior treatment with benzodiazepines may decrease the efficacy of buspirone. However, available data indicate that only very recent (i.e., within 4 weeks) treatment with benzodiazepines tends to reduce the anxiolytic benefit of buspirone.

One study examined the effects of long-term treatment (6 months) of generalized anxiety disorder symptoms with buspirone or clorazepate. Results suggest that buspirone was as effective as chlorazepate in the treatment of anxiety after the second week of treatment. Further, in contrast to clorazepate, abrupt discontinuation of buspirone treatment was not accompanied by withdrawal symptoms. At 40-month follow-up, 30 percent of patients who received 6-months of clorazepate treatment but none of patients who received buspirone had returned to regular use of anxiolytic medications (benzodiazepines in most cases). The authors concluded that long-term buspirone therapy for generalized anxiety disorder may have produced more lasting improvement than therapy with the benzodiazepines.

The efficacy and tolerability of buspirone in the treatment of anxiety symptoms was also evaluated in elderly patients. One 4-week, placebo-controlled trial examined the effects of buspirone (at doses ranging from 15 to 30 mg a day) in the treatment of anxiety symptoms in 40 elderly patients who had both anxiety and depressive symptoms. Patients receiving buspirone exhibited significantly lower scores in the HAM-A, Hamilton Rating Scale for Depression (HAM-D), and Clinical Global Impression (CGI) rating scales than to placebo recipients. Buspirone treatment was generally well tolerated by elderly patients at doses similar to those used to treat younger patients; in fact, most (75 percent) buspirone-treated patients reported no adverse experiences.

Other Anxiety Disorders The effects of buspirone have been evaluated in the treatment of panic disorder, social phobia, obsessive-compulsive disorder, and posttraumatic stress disorder. In two double-blind, placebo-controlled studies (one with imipramine [Tofranil] and another with alprazolam), buspirone did not differ from placebo in the treatment of patients with panic disorder, but the active agents did. In a recent controlled study in patients with panic disorder, buspirone enhanced the effects of cognitive behavioral therapy on measures of generalized anxiety and agoraphobia; however this enhanced effect did not persist at follow-up.

Two open trials found buspirone only modestly effective in the treatment of patients with social phobia (predominantly the generalized subtype). One double-blind, placebo-controlled study evaluating the effects of buspirone and cognitive-behavioral therapy in the treatment of musicians with performance anxiety who met DSM-III-R criteria for social phobia found buspirone ineffective in the treatment of performance anxiety. Finally, in a recent double-blind, placebo-controlled study in the treatment of patients diagnosed with DSM-IV social phobia patients, buspirone did not differ from placebo.

Several case reports or series and one open trial suggest that buspirone may have some efficacy in the treatment of posttraumatic stress disorder symptoms, such as increased arousal and reexperiencing of the traumatic event.

The existing data regarding the efficacy of buspirone in the treatment of obsessive-compulsive disorder are limited and conflicting. For example, in one open trial buspirone was ineffective in the treament of obsessive-compulsive disorder symptoms. Conversely, in the only controlled study comparing the effects of buspirone, clomipramine (Anafranil), and placebo in the treatment of 18 patients with obsessive-compulsive disorder, buspirone and clomipramine produced significant and comparable improvement. Buspirone is also the most studied augmenting agent in obsessive-compulsive disorder patients. Adding buspirone to ongoing fluoxetine (Prozac) treatment was reported to diminish obsessive-compulsive disorder symptoms in open trials, but controlled studies examining the usefulness of adding buspirone to fluoxetine, fluvoxamine (Luvox), and clomipramine treatment in obsessive-compulsive disorder patients reported that buspirone was ineffective in enhancing the therapeutic outcome in most patients. Patients who do benefit appear to be those with a partial response; patients with no response appear to obtain no further benefit from the addition of buspirone.

Major Depressive Disorder Following an early open-label study that suggested the possible effectiveness of buspirone in the treatment of nonmelancholic major depression three placebo-controlled studies (varying considerably in their diagnostic/severity criteria), one meta-analysis of eight studies, and one composite of five parallel group placebo-controlled studies, examined the effects of buspirone treatment in patients with major depression and anxiety symptoms or primary generalized anxiety disorder with depressive symptoms. Overall, these studies found buspirone (at relatively high mean dosages ranging from 30 to 56 mg daily) to be superior to placebo in the treatment of depressive and anxiety symptoms (as measured by the HAM-D and HAM-A rating scales and CGI ratings). In some studies patients with more-severe depressive symptoms or melancholic subtype appeared to respond better to buspirone than patients with mild or nonmelancholic depression. In several studies a considerable number of patients (up to 64 percent of buspirone-treated patients and up to 74 percent of placebo-treated subjects) discontinued the study before 8 weeks.

Open trials have tested buspirone augmentation in patients with major depression who had failed to respond to standard trials of antidepressants. For example, in one open trial, seven of eight nonresponders (six patients receiving fluoxetine and one patient receiving imipramine) reported a full or partial antidepressant response after the addition of buspirone, 30 mg daily. In another open trial, 17 of 25 patients initially receiving fluoxetine or fluvoxamine were reported to improve (using

four-point CGI ratings) following the addition of buspirone (at doses of 20 to 50 mg daily). However, in a recent double-blind, placebo-controlled study that evaluated the efficacy and safety of buspirone augmentation in the management of depressed patients who failed to respond to the selective serotonin reuptake inhibitors (SSRIs) paroxetine or citalopram, no significant between-group differences in response rates were found. It should be noted that study results may be inconclusive due to the high placebo response rates observed (47 percent for placebo versus 51 percent for buspirone). In summary, the efficacy of buspirone in the treatment of depression remains uncertain at this time.

Other Uses

Alcohol Use Disorders The effects of buspirone in treating relapsed alcoholics with concurrent anxiety symptoms have been mixed. Four double-blind, placebo-controlled studies examined the effects of buspirone treatment of anxious alcoholics. In one study buspirone treatment was associated with significantly greater treatment retention and greater decreases in alcohol craving, anxiety, and depression than placebo. A study of alcoholics with comorbid generalized anxiety disorder reported a similar advantage of buspirone over placebo treatment. Another study found buspirone therapy to be associated with reduced anxiety, a slower return to heavy alcohol consumption, and fewer drinking days during the follow-up period. In contrast, one study of male alcoholic veterans in aftercare showed no differences between groups of patients treated with buspirone or placebo on measures of anxiety and alcohol consumption.

Psychosis Its activity at the D_2 receptor created some interest in the potential antipsychotic effects of buspirone. Although buspirone exhibited some evidence of antipsychotic potential in several animal models and reportedly has transient antipsychotic effects when administered in large dosages (mean dosage of 1470 mg daily) to patients with schizophrenia, the drug has no established antipsychotic activity in humans at usual dosages when administered alone. Several open trials that evaluated the efficacy of buspirone as an adjunct to antipsychotics in schizophrenia patients found no clear efficacy in decreasing psychosis or negative symptoms.

Aggression Some data indicate that buspirone may be an effective antiaggressive agent. Several animal studies have demonstrated potential anticonflict properties for buspirone. In humans, a small, placebo-controlled trial found buspirone to be effective in reducing aggression and anxiety in five of six developmentally disabled and mentally retarded subjects. Others have also suggested that buspirone may be effective in the treatment of agitation in brain-injured and demented patients. For example, buspirone treatment decreased scores on the Neurobehavioral Rating Scale in seven traumatically injured patients with behavioral problems. In a retrospective evaluation of the effects of buspirone treatment (for at least 3 months) in 10 patients with organically related psychiatric diagnosis and aggressive behaviors, 9 of the 10 patients treated with buspirone showed some improvement in their behavioral target symptoms. Patients with at least 50 percent reduction in their symptoms (6 of 10 patients) received relatively high doses of buspirone (an average dosage of 50 mg a day). Buspirone was well tolerated and caused minimal sedation and cognitive changes in these reports. In a recent open trial, buspirone was effective as an adjunct in the pharmacotherapy of oppositional defiant disorder symptoms in children with comorbid DSM-III-R defined attention-deficit hyperactivity disorder and oppositional defiant disorder whose attention-deficit disorder symptoms were significantly helped by standard treatments.

Pervasive Developmental Disorders A case report described improvement of hyperactive behaviors in two or four autistic disorder children receiving buspirone treatment. Additional open-label study reported moderate to marked improvement in 16 of 22 children diagnosed with pervasive developmental disorders who received buspirone 15 to 45 mg daily for 6 to 8 weeks.

Premenstrual Disorder Buspirone has also been investigated in the treatment of premenstrual syndrome. Two controlled studies (one using parallel design and one using crossover design) found buspirone to be more effective than placebo in reducing physical and psychic symptoms associated with premenstrual syndrome.

Somatoform Disorders Augmentation with buspirone had modest therapeutic effects in nonresponders and partially responsive patients with body dysmorphic disorder receiving fluoxetine or clomipramine.

Sexual Dysfunction Finally, limited data indicate that buspirone improved sexual function in generalized anxiety disorder patients, which was not correlated with anxiety reduction. Further, in one retrospective study, buspirone was found to alleviate SSRI-induced sexual dysfunction in 11 of 16 patients who received treatment with SSRIs. Failure to respond to buspirone treatment was most common among patients who received either high dosages of SSRIs or low dosages of buspirone (15 mg daily).

Nicotine Dependence The effects of buspirone in smoking cessation have been evaluated. The results of the available studies have been inconsistent and contradictory. The rate of smoking abstinence has been reported to range from 36 to 88 percent and 16 to 89 percent in buspirone and placebo treatment groups respectively. A controlled trial using strict methodology is needed to further evaluate buspirone efficacy in smoking cessation and the reduction of nicotine withdrawal symptoms.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Nervous System The most frequent adverse effects associated with buspirone treatment are CNS effects. The most common effects include dizziness, drowsiness, headaches, and light-headedness. Adverse effects associated with CNS depression, such as sedation, psychomotor dysfunction, or fatigue, occur less frequently with buspirone than with benzodiazepines. The potential of buspirone for causing adverse effects associated with its activity in the dopaminergic system is minimal. However, symptoms such as akathisia, dystonia, tremor, muscle stiffness/rigidity, or involuntary movements have occasionally been associated with buspirone treatment.

Gastrointestinal System Nausea has been reported in patients receiving buspirone. Less frequent adverse gastrointestinal effects include dry mouth, abdominal distress, diarrhea, constipation, and vomiting.

Cardiovascular System Although tachycardia, palpitations, and nonspecific chest pain have been reported in some patients receiving buspirone, the frequency of these symptoms does not appear to differ from that in patients receiving placebo. Buspirone has minimal, if any, effect on blood pressure.

Dermatological Effects Adverse dermatological effects such as rash or pruritus occur occasionally in patients receiving buspirone.

Endocrine System Buspirone produces a dose-dependent stimulation of prolactin secretion. Menstrual irregularities, galactorrhea, and thyroid abnormalities have occurred occasionally in patients receiving buspirone, but no causal relationship has been established.

Other Systems Although some side effects or adverse events have been reported in other organ systems, buspirone has little, if any, effect on the respiratory system, platelets, smooth muscles, or autonomic nervous system function.

THERAPEUTIC INDICATIONS

Buspirone is indicated by the Food and Drug Administration (FDA) for the treatment of “anxiety disorders or the short-term relief of the symptoms of anxiety,” a description that corresponds roughly to generalized anxiety disorder. No FDA approval for other indications has been granted.

PRECAUTIONS AND ADVERSE REACTIONS

The main contraindication to buspirone therapy is a history of a hypersensitivity reaction to buspirone. Buspirone should be used with caution in patients with impaired renal function, since the drug and its metabolites are excreted primarily by the kidneys. It should also be used cautiously in patients with hepatic dysfunction.

The combined use of monoamine oxidase inhibitors (MAOIs) and buspirone is not recommended because of the potential for hypertensive crisis. A seizure was reported in one obsessive-compulsive disorder patient who received buspirone augmentation of SSRI treatment. Hypomania was reported in a patient with a bipolar disorder who was receiving buspirone, lithium (Eskalith) tranylcypromine (Parnate), and alprazolam. Buspirone does not exhibit cross-tolerance with benzodiazepines, other sedative-hypnotic drugs, or alcohol. Some studies found that concomitant administration of buspirone during benzodiazepine taper may reduce the development of rebound anxiety or benzodiazepine-withdrawal symptoms. However, abrupt substitution of buspirone for benzodiazepines in chronic benzodiazepine users is not recommended.

Animal studies have found no evidence of buspirone-induced mutagenicity, carcinogenicity, or teratogenicity. The FDA has designated buspirone as a category B (no evidence of risk in humans) agent for pregnancy. Buspirone is secreted in the milk of rats, and it is recommended that buspirone be avoided in lactating women.

DRUG INTERACTIONS

Administration of buspirone to patients receiving MAOIs has been reported to be associated with hypertensive crisis. Concomitant administration of buspirone and haloperidol (Haldol) has resulted in increased serum haloperidol concentrations, suggested to be due to competitive inhibition of the oxidative dealkylation of haloperidol. Because buspirone is highly protein bound, it could theoretically displace other protein-bound drugs. Although in vivo studies failed to reveal substantial evidence of displacement by buspirone of phenytoin, propranolol, or warfarin, in vitro evidence suggests that buspirone may displace less firmly bound drugs such as digoxin. However, those effects have not been reported to be clinically important. Concurrent use of buspirone and cimetidine (Tagamet) is unlikely to result in a clinically important interaction. Buspirone does not appear to alter blood alcohol concentrations nor to potentiate alcohol-induced impairment of psychomotor and cognitive performance.

Although drug interaction studies suggest that buspirone does not potentiate benzodiazepine-induced CNS depression to a clinically important degree, the effects of combined therapy have not been fully evaluated. Buspirone potentiated the effects of diazepam on several tests of psychomotor function and has subjectively potentiated diazepam-induced sedation, but it also counteracted some diazepam-induced attention and learning acquisition impairments. Buspirone did not substantially alter hypnotic or psychomotor effects of flurazepam (Dalmane) and triazolam (Halcion). In general buspirone can be safely combined with benzodiazepines if it is indicated. Other CNS depressants such as analgesics, antihistamines, and sedative-hypnotics generally have little or no effect on the frequency or severity of adverse effects associated with buspirone administration.

Buspirone may interact with drugs that inhibit CYP 3A4. For example, it has been shown that potent CYP 3A4 inhibitors, such as erythromycin, itraconazole (Sporanox), nefazodone (Serzone), and grapefruit juice, increase buspirone plasma concentrations. Thus, lower dosages of buspirone are recommended, if the drugs are to be used in combination.

LABORATORY TESTS

Buspirone has not been reported to interfere with clinical laboratory values.

DOSAGE AND ADMINISTRATION

Buspirone is prepared as buspirone hydrochloride and is available in 5-, 10-, and 15-mg (Dividose) tablets. The usual initial adult dosage is 10 to 15 mg daily in three divided doses. Recently, the manufacturer recommended use of a twice-a-day dosing schedule (i.e., 7.5 mg two times a day), which appears to be equally effective and well tolerated. To achieve an optimal therapeutic response, the dosage may be increased by 5 mg a day at 2- to 3-day intervals. Patients may benefit from dosage titration (using twice-a-day dosing) to 30 to 60 mg a day. A lower initial dose of 5 mg twice a day may be necessary to avoid adverse effects in some patients.

SUGGESTED CROSS-REFERENCES

Anxiety disorders are discussed in Chapter 15, mood disorders in Chapter 14, and benzodiazepines in Section 31.9.

ROBERT M. POST, M.D.

HISTORY

Calcium dysregulation has been linked to psychiatric illness and to mood disorders in particular, with a high incidence of mood disorders accompanying calcium dysregulation in hyperparathyroidism and hypoparathyroidism. A high incidence of depression accompanies the increases of serum calcium in hyperparathyroidism and mood instability accompanies the decreases in calcium in hypoparathyroidism as well. Early preclinical work identified major disruptions in motor activity and other physiological endpoints with specific alterations of the parathyroid glands.

Whereas evidence of alterations in plasma and cerebrospinal fluid (CSF) calcium in patients with primary mood disorder has remained inconsistent and controversial, more recent evidence of increased intracellular calcium in blood elements (both platelets and lymphocytes) has been widely documented and multiply replicated. This increased intracellular calcium occurs in both the basal condition and following stimulation with serotonin, thrombin, or related agents. Steven Dubovsky, who pioneered these initial investigations, has also gone on to study the potential therapeutic implications of the calcium channel inhibitors, particularly their ability to act as antimanic agents (Table 31.13-1). Bolstering this empirical and theoretical framework implicating calcium dysregulation in affective illness are the data showing that many of the other mood-stabilizing agents effective in the treatment of bipolar I disorder, such as lithium (Eskalith), carbamazepine (Tegretol), divalproex (Depakote) or valproate (Depakene), and perhaps lamotrigine (Lamictal), also appear to exert major effects on different aspects of intracellular calcium metabolism.

Table 31.13-1 Calcium Channel Inhibitors in Mood Disorders

Because calcium is a critical intracellular transduction mechanism and is highly regulated this system becomes a key target for therapeutics (Fig. 31.13-1). Moreover, the 50 to 100 nanomolar intracellular calcium concentrations are at risk from the 10,000 times greater concentration of calcium in the extracellular fluid. With neuronal depolarization and firing, not only is there a major sodium influx but also a rapid calcium influx through voltage-gated calcium channels as well as through the ligand-gated *N*-methyl-D-aspartate (NMDA) receptor. Thus, restoring calcium homeostasis requires active calcium extrusion mechanisms, and a variety of calcium buffering and intracellular sequestration mechanisms, including those of mitochondria and endoplasmic reticulum. Recent data suggest that the mood stabilizers lithium, carbamazepine, and perhaps valproate and lamotrigine may block calcium cation (Ca^{++}) influx through the NMDA receptor.

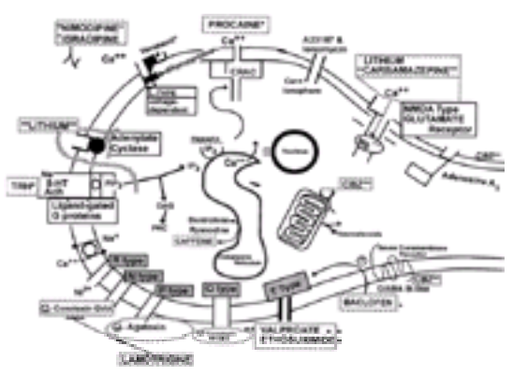

FIGURE 31.13-1 Calcium channel diversity and drug targets. This figure outlines the multiple extracellular and intracellular membrane effects of different agents (** = commonly used drugs; * = drugs explored in some psychiatric patients) and the diversity of other calcium channel regulatory sites that could be amenable to new drug development. Carbamazepine is shown to have four putative actions on different aspects of cellular biochemistry; two of lithium's many actions are highlighted, including adenylate cyclase and PI turnover.

CHEMISTRY

The L-type (long-lasting) calcium channel inhibitors have been most widely studied and have the greatest current potential for therapeutics. This channel requires neuronal depolarization for calcium entry. However, it should be noted that a variety of other calcium channels have been identified and these may ultimately also be differentially targeted for clinical therapeutics (Fig. 31.13-1). The N-type (neither L nor T) calcium channel is blocked by omega-conotoxin GVIA, the P-type (Purkinje cell) by omega-agatoxin, and the Q-type by omega-conotoxin MVIIC. T-type (transient) calcium channels have been implicated in the therapeutic action of ethosuximide and potentially of valproate in their actions on spike-and-wave absence epilepsy. Ligands acting at G-proteins hydrolyze phosphatidylinositol 4,5-bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3), the latter of which acts at a heparin-sensitive calcium channel on the endoplasmic reticulum. This action is different from the calcium-related ranodyne receptor, at which caffeine and dantrolene (Dantrium) act. Dantrolene is also used as a part of the emergency medical regimen for the treatment of malignant hyperthermia.

As noted in the *Physicians' Desk Reference* for the L-type calcium channel inhibitors, verapamil (Calan) is an almost white, crystalline powder that is practically free of odor and has a bitter taste. It is soluble in water, chloroform, and methanol and is not chemically related to other cardioactive drugs. Chemically, verapamil is

benzeneacetonitrile, a-[3-[[2-(3,4-dimethoxyphenyl)ethyl]-methylamino]propyl]-3,4-dimethoxy-a-(1-methyl-ethyl)hydrochloride. The chemical formula of the phenylalkylamine is $C_{27}H_{38}N_2O_4$ (Fig. 31.13-2) and its molecular weight is 454.59.

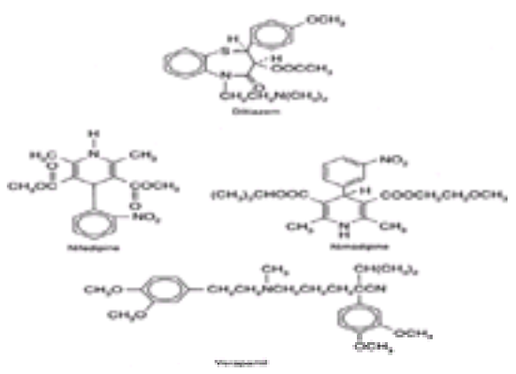

FIGURE 31.13-2 Molecular structures of calcium channel inhibitors

Diltiazem (Cardizem) is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. Chemically, diltiazem is 1,5-benzothiazepin4(5H)-one,3-(acetyloxy)5 - [2 - (dimethylamino) - ethyl] - 2,3 - dihydro - 2 - (4-methoxy-phenyl) - , monohydrochloride,(+)- *cis*. Its chemical formula is $C_{22}H_{27}ClN_2O_4S$ (Fig. 31.13-2). This benzothiazepine has a molecular weight of 450.98.

Nifedipine (Procardia) is 3,5-pyridinedicarboxylic acid, 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-, dimethyl ester. The chemical formula is $C_{17}H_{18}N_2O_6$ (Fig. 31.13-2). It is a yellow crystalline substance that is practically insoluble in water, but soluble in ethanol. It has a molecular weight of 346.34.

Nimodipine (Nimotop) is isopropyl (2-methoxyethyl) 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)-3,5-pyridine-dicarboxylate. It has a molecular weight of 418.5, and its chemical formula is $C_{21}H_{26}N_2O_7$ (Fig. 31.13-2). Nimodipine is a yellow crystalline substance that is practically insoluble in water. Its closely related dihydropyridine congeners include isradipine (DynaCirc) and amlodipine (Norvasc).

Amlodipine is (RS) 3-ethyl-5-methyl-2-(2-amino-ethoxymethyl)-4-(2-chlorophenyl)-1,4-dihydro-6-methyl-3,5-pyridine dicarboxylate benzenesulphonate. It has a molecular weight of 567.1, and its chemical formula is $C_{20}H_{25}ClN_2H_6O_3S$. Amlodipine is a white crystalline powder, slightly soluble in water, and sparingly soluble in ethanol.

Flunarizine is (E)-1-[bis (4-fluorophenyl)methyl]-4-(3-phenyl-2-propenyl)-piperazine. Its chemical formula is $C_{26}H_{26}F_2N_2$ (Fig. 31.13-2) and its molecular weight is 404.51.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption Calcium channel inhibitors are well absorbed by the gastrointestinal tract, each being substantially metabolized by a hepatic first-pass effect.

Distribution As with all hepatically metabolized drugs, there are considerable intraindividual and interindividual variations in the plasma concentrations of the calcium channel inhibitors. Verapamil crosses the placenta and can be detected in umbilical vein blood at delivery.

Studies in rats have shown significant concentrations of calcium channel blockers in maternal milk following oral administration. It is recommended that women who wish to breastfeed should not take these drugs.

Elimination The half-life of verapamil after the first dose is 2 to 8 hours, but it increases to 5 to 12 hours after the first few days of therapy. Verapamil enters the central nervous system (CNS) poorly and attains concentrations approximately 0.05 percent those in plasma. The half-lives of the dihydropyridines are short for nimodipine (1 to 2 hrs) and isradipine (DynaCirc) (1½–2 hrs), but longer for amlodipine (30 to 50 hrs), making once-daily or twice-daily dosing more feasible with the latter compound (Table 31.13-2).

	Phenylalkylamine (on outside of Ca^{++} channel)	Dihydropyridines (inside Membrane and Ca^{++} Channel)		
	Verapamil (Calan, Isoptin)	Nimodipine (Nimotop)	Isradipine (DynaCirc)	Amlodipine (Norvasc)
Half-life	Short (5–12 hr)	Short (1–2 hr)	Short (1 1/2–2 hr)	Long (30–50 hr)
Starting dosage	30 mg t.i.d.	30 mg t.i.d.	2.5 mg b.i.d.	5 mg q.a.

Table 31.13-2 Half-Lives, Dosages, and Effectiveness of L-Type Calcium Channel Inhibitors in Mood Disorders

Pharmacodynamics

Mechanism of Action There are several subtypes of these voltage-dependent blockers of calcium influx that modulate the relatively long opening times of these channels. These compounds include the widely recognized phenylalkylamine type characterized by verapamil, the benzothiazepine type characterized by diltiazem, and the dihydropyridine type characterized by nifedipine, nimodipine, isradipine, amlodipine, nicardipine (Cardene), and nitrendipine. Even though these agents all potently bind to this voltage-dependent calcium channel and act to inhibit calcium influx, their biochemical and physiological effects are remarkably different (Table 31.13-3). In addition, not all dihydropyridines are equivalent. For example, nimodipine, but not nifedipine, abolishes calcium oscillations in hypothalamic neurons, and amlodipine, but not nimodipine, has prominent antioxidant properties.

Table 31.13-3 Effects of Dihydropyridine L-Type Calcium Channel Blockers Versus Verapamil

Verapamil and the phenylalkylamines are charged and gain access to the inside of the calcium channel less readily than most of the dihydropyridines, which are uncharged (except amlodipine). These different membrane properties and binding characteristics result in a profile of effects for the dihydropyridines compared with the phenylalkylamines, including increased lipid solubility; anticonvulsant effects on kindling and hyperfusion models and clinical seizures; the ability to block cocaine hyperactivity, behavioral sensitization, and its associated dopamine overflow in the nucleus accumbens (whereas verapamil is inactive); positive effects in two animal models of depression, including the forced swim test and learned helplessness model; decreased glycine inhibition of ^{3}[H] 5,7-DCKA binding similar to that of other antidepressant modalities; and possibly a different effectiveness on mood in some patients with bipolar disorder. Blood concentration and relation to action have not been clearly established.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Design Verapamil has been reported effective in the treatment of acute mania. Open case studies were followed with a small series of double-blind studies as well as seven studies comparing verapamil to placebo or to lithium. The early studies were generally positive in acute mania, showing effects equal to those of lithium, and in several studies, better than placebo. However, more recent studies have revealed more equivocal results, and despite the generally positive controlled literature, verapamil remains rarely used in the general therapeutics of bipolar disorders. Moreover, in a placebo-controlled study, verapamil (like placebo) was distinctly less effective than either standard antidepressant treatment or amitriptyline (Elavil) in acute depression.

Given continuing uncertainties regarding verapamil's place in the clinical therapeutics of the mood disorders, other groups have begun to study the dihydropyridines more intensively because of their potentially different pharmacological and therefore therapeutic profiles. One study at the National Institute of Mental Health (NIMH) reported improvement in six mania patients in an open trial, and another study reported improvement in approximately one-third of a heterogeneous group of treatment refractory patients with recurrent mood disorders using double-blind, placebo substitution in B-A-B-A trials to reconfirm responsiveness. In the latter study, several of the best responders had ultra–ultra-rapid (or “ultradian”) fluctuations in mood (i.e., multiple switches within a 24-hour period).

Interpretation In an updated series of the previous NIMH study, 10 of 30 patients were reported to show a clinically relevant degree of response to nimodipine monotherapy, as rated by a marked or moderate response on the Clinical Global Impressions (CGI) scale. One such patient is illustrated in Figure 31.13-3A in which prospective daily life chart ratings of mild, moderate, and severe mania and depression are illustrated by nursing ratings blind to treatment with nimodipine or placebo. As illustrated, gradual titration of nimodipine to average dosages of 630 mg a day resulted in the complete amelioration of a moderate to severe depressive episode. Response was verified with placebo substitution, which resulted in a pattern of ultra-rapid mood fluctuations that were again ameliorated by the institution of nimodipine on a blind basis. The patient was able to be transferred from one dihydropyridine to another (nimodipine to isradipine) without loss of efficacy.

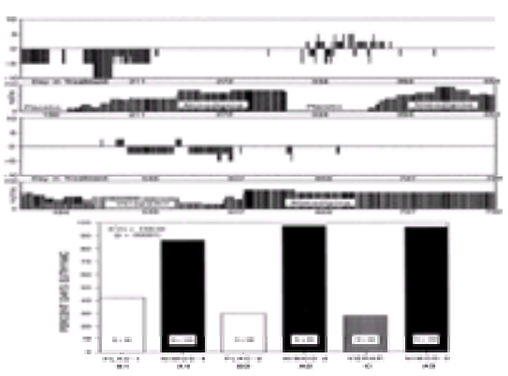

FIGURE 31.13-3 A. Prospective daily life chart ratings of mood (above) by nurses blind to medication status (below). Boxes above the horizontal line (euthymia) represent mild, moderate, or severe mania. Boxes below the line represent mild, moderate, or severe depression. A complete record of all her medications for each day of the study is depicted below each life chart line. Each line represents 1 day. Numbers indicating the day of the patient's clinical trial are in 2-month intervals. **B**. Efficacy of nimodipine in a female with bipolar II disorder. Daily life chart ratings of the same patient as illustrated in **A**. The numbers in each bar are the number of days during that phase of the study that were included in data analyses. For example, medication phases did not include periods of titration or overlap with another psychotropic medication. The statistic represents the percentage of days euthymic during each of the three double-blind nimodipine phases compared to the percentage of days euthymic during the two placebo phases as well as the blind verapamil phase.

Also demonstrated in this patient was the inability of verapamil at maximally tolerated dosages of 320 mg a day to maintain clinical improvement, which was reestablished with the third institution of nimodipine treatment on a blind basis. This patient was euthymic 85 to 95 percent of her days on full dosages of nimodipine compared with being euthymic 30 to 40 percent of her days during periods of placebo or verapamil administration (Fig. 31.13-3B). The patient had previously received multiple clinical trials with a variety of antidepressant agents and lithium without success; her depression had been complicated by comorbid symptoms of generalized anxiety and panic disorder. Her mean Hamilton Depression ratings decreased from 28 during the placebo phase to the 10 to 15 range during the latest nimodipine phase. Similarly, on this blind therapy, her Beck Depression Inventory scores were halved, from approximately 10 to under 5. The patient has continued to remain markedly improved on isradapine 3 years after discharge from the inpatient and outpatient programs at the NIMH.

This patient's detailed case response, performed on a blind basis, as well as the second patient described below, suggest the possibility that the same degree of clinical responsivity achieved by the dihydropyridine L-type calcium channel blockers may not be readily substituted for by the more widely used phenylalkylamine L-type calcium channel blocker, verapamil.

Figure 31.13-4A illustrates a patient with marked ultradian mood fluctuations in whom significant amplitude decreases in manic and depressive oscillations were observed when placebo (B) was substituted for nimodipine (A). This decrease was verified as not being attributable to spontaneous improvement in the course of illness because a second phase of placebo substitution resulted in a renewal of both manic and depressive severity, which again improved with the blind reintroduction of nimodipine. Only a 1-month sampling of the last ratings in the trial is illustrated in the figure, and a more complete picture of the entire trial is summarized in Figure 31.13-4B.

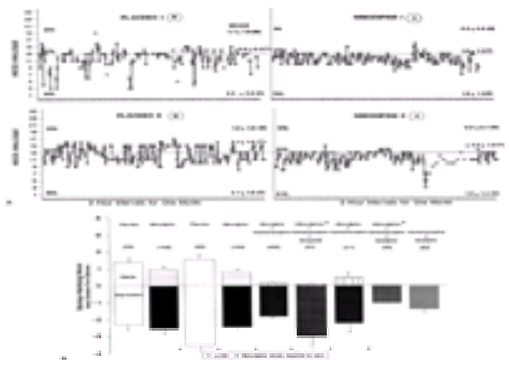

FIGURE 31.13-4 A. Effect of nimodipine in an ultra–ultrarapid (ultradian) cycling patient. Twice-daily to two-hourly mood analogue ratings show a partial response to nimodipine, relapse after placebo substitution, and renewed response in this female with bipolar II disorder. Only the last month of each double-blind phase is illustrated. Mean depression and mania ratings (as a difference from euthymia) are given for mania (M) above the euthymia mood line or for depression (D) below the line. **B**. Efficacy of dihydropyridine L-type calcium channel inhibitors in a female with bipolar II disorder (the same patient illustrated in **A**). Mean deviation from euthymia ratings (number of days in parentheses) in a bipolar II ultra–ultra-rapid cycling patient showing efficacy of nimodipine monotherapy; efficacy of nimodipine-carbamazepine combination therapy; unsuccessful transition from nimodipine to verapamil; successful reinstitution of nimodipine-carbamazepine combination therapy; and finally, successful transition to isradipine-carbamazepine combination therapy.

This figure not only demonstrates the improvement in mania and depression observed during the trial, but also additional improvement when carbamazepine (Tegretol) was added to the incomplete response to nimodipine. At this time, the patient was able to resume her full-time employment as an artist and teacher whereas she had been unable to do so in the prior 4 years, during which time she was treated with lithium as well as the lithium-carbamazepine combination.

Interactions In an attempt to ascertain whether this patient would respond equally well to the related phenylalkylamine L-type calcium channel inhibitor verapamil, a slow, blind crossover was attempted to achieve maximally tolerated doses of this agent (320 mg a day). This crossover resulted in mood destabilization, and the patient was again successfully reintroduced to nimodipine in combination with carbamazepine on a blind basis (Fig. 31.13-4B). The substitution of nimodipine for another dihydropyridine L-type calcium channel inhibitor, isradipine, was successful and the patient was discharged on this combination. This patient's clinical response indicates a partial amelioration of ultradian cycling amplitude with the dihydropyridine L-type calcium channel inhibitor and the need for further augmentation with another mood stabilizer, such as carbamazepine. However, such augmentation with carbamazepine was effective in only 4 of 14 patients overall.

Carbamazepine blocks calcium influx through the NMDA receptor, and it remains to be determined whether two different mechanisms converge on calcium dysregulation or whether some other mechanism of action of carbamazepine could account for its additive effects in this patient. An open prophylactic study reported that patients with bipolar disorders responded better to the combination of nimodipine plus lithium than either agent alone. Which of lithium's panoply of actions account for this additive effect also remains to be determined.

Recurrent Brief Depressive Disorder Recent studies have described a syndrome, recurrent brief depressive disorder characterized by severe, rapidly recurring, brief episodes of depression that do not meet the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) criteria for major depressive disorder because of their brevity. These episodes average 3 days or less, are associated with considerable morbidity and some mortality through suicide, and appear more common in women than men (although they are not linked to the menstrual cycle). The incidence of recurrent brief depression in the general population has been reported to be as high as 8 to 10 percent, although the interpretation of this number is obscured by the fact that the pattern of recurrent brief depression can be to some extent interchangeable with the pattern of more consistent periods of major depressive disorder. Nonetheless, initial clinical trials suggest the lack of adequate responsivity of the recurrent brief depression pattern to standard antidepressant treatments, including the tricyclics, monoamine oxidase inhibitors (MAOIs), selective serotonin reuptake inhibitors (SSRIs), and lithium.

Several patients with recurrent brief depression studied appeared to show an excellent response to nimodipine. One such patient is illustrated in Figure 31.13-5, and her clinical response at average maintenance doses of 270 mg a day was confirmed by exacerbation of her recurrent brief depression pattern upon placebo substitution and then renewed responsivity to blind reinstitution of nimodipine. It is particularly noteworthy, however, that in contrast to the bipolar I disorder patients illustrated in Figure 31.13-3 and Figure 31.13-4, this patient with recurrent brief depression did sustain her clinical responsivity during a blind crossover to verapamil and was able to be discharged on this compound. These preliminary but double-blind controlled observations suggest the potential utility of L-type calcium channel inhibitors in recurrent brief depressive disorder and large, controlled clinical trials are clearly indicated.

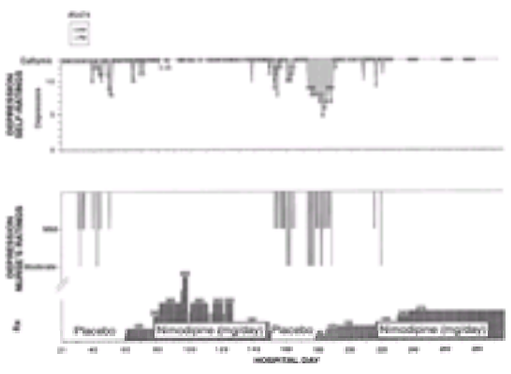

FIGURE 31.13-5 Response to nimodipine in recurrent brief depression. Patient's depression rating (**top**) and nurse's rating (**bottom**) reflect improvement in recurrent brief depression from placebo to nimodipine, with a recurrence of symptoms upon placebo substitution and re-response in the last phase.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Although no well-controlled studies of the calcium channel inhibitors in large numbers of pregnant women exist, no clearcut teratological effects on the human fetus have been reported, and their relative safety in pregnancy has been suggested. The ultimate role for the dihydropyridines and other L-type calcium channel inhibitors as alternatives to lithium (with its low risk for Ebstein's anomaly) or the mood-stabilizing anticonvulsant drugs carbamazepine and valproate (with their risk of spina bifida) during pregnancy remains to be systematically investigated.

THERAPEUTIC INDICATIONS

Calcium channel blockers are effective antihypertensive agents and are widely used for that purpose as well as in the treatment of ischemic heart disease and migraine. However, nimodipine is approved for use only in subarachnoid hemorrhage. The major use of the calcium channel inhibitors in psychiatry is currently in the area of treatment of bipolar disorders with limited use in depression and recurrent brief depressive disorder.

PRECAUTIONS AND ADVERSE REACTIONS

The most common adverse effects associated with calcium channel inhibitors are associated with vasodilation and include dizziness, headache, skin flushing, tachycardia, nausea, dysaesthesias, and peripheral edema. Verapamil and diltiazem in particular can induce bradycardia and atrioventricular heart block. In older patients the hypotensive, bradycardic, and conduction effects of calcium channel inhibitors require careful monitoring by the clinician. Other symptoms commonly reported include constipation, fatigue, rash, coughing, and wheezing. Rare adverse effects that have been reported with diltiazem include hyperactivity, akathisia, and

parkinsonism; with nifedipine (Procardia), depression; with verapamil, delirium, hyperprolactinemia, and galactorrhea; and with flunarizine (Sibelium), parkinsonism.

The calcium channel inhibitors are relatively well tolerated and considerable clinical experience has been gained by using them in the treatment of hypertension, arrhythmias, and other medical syndromes. The most common dose-limiting adverse effects of nimodipine include lightheadedness, gastrointestinal upset, subjective sense of tightness in the chest (unaccompanied by electrocardiographic changes), and flushing. The sense of warmth associated with erythema has not been uncommon with nimodipine treatment, particularly on the anterior aspects of the lower extremities.

Some investigators have advocated the potential use of the calcium channel blockers as a substitute for lithium in pregnancy in light of the lack of evidence for calcium channel inhibitor teratogenicity. Lithium has a potential for major cardiac anomalies such as Ebstein's anomaly in pregnancy, and valproate and carbamazepine have risks for spina bifida. There is recent evidence that an increased incidence of Ebstein's anomaly with lithium may have been overestimated, and the safety of continued use of lithium during pregnancy is being re-evaluated.

Recent evidence widely cited in the lay press has suggested some reasons for caution in routinely using L-type calcium channel inhibitors for hypertension and other indications, because of the potential for increasing the risk for reinfarction compared with b-adrenergic receptor antagonists, and increasing the risk of a variety of malignancies. Others argue that the data are far from conclusive and in many instances opposing views have been suggested that calcium channel inhibitors are able to decrease cancer-inducing mechanisms. Much of the initial work used case-control methods, not prospective randomized studies. Moreover, the general perspective in cardiology is that the short-acting nifedipine compounds should be relatively avoided, but not necessarily the longer-acting preparations. In support of this view is a recent positive study of the efficacy of the longer-acting amilodipine on blood pressure and on increased long-term survival. Thus, many patients continue to remain on calcium channel inhibitors for blood pressure and various other cardiological purposes, and it would appear reasonable to continue to pursue these agents for their potential role in the mood disorders, both as lithium substitutes and as alternatives with a different potential range of therapeutic effects.

DRUG INTERACTIONS

b-adrenergic receptor antagonists in combination with verapamil and diltiazem have been reported to cause cardiac depression. Caution should also be used with inhaled anesthetics, digoxin (Lanoxin), quinidine (Duraquin), cimetidine (Tagamet), and other antihypertensive agents. Neurotoxicity, choreoathetosis, parkinsonism, and bradycardia have been reported with use in combination with lithium.

LABORATORY INTERFERENCES

Verapamil and diltiazem (but not the dihydropyridines) increase carbamazepine concentrations and potential resultant neurotoxicity.

DOSAGE AND ADMINISTRATION

Verapamil is available in 40-, 80-, and 120-mg tablets. The starting dosage is 80 mg given orally three times a day; it can be raised in increments every 4 to 5 days, up to 80 to 120 mg three to four times a day. The patient's blood pressure, pulse, and electrocardiogram (in patients over 40 years old or with a history of cardiac illness) should be followed routinely. Diltiazem is available in 30-, 60-, 90-, and 120-mg tablets. The starting dosage is 30 mg given orally four times a day and can be increased to a maximum of 360 mg a day. Nifedipine is available in 10-, 20-, 30-, 60-, and 90-mg tablets. The starting dosage is 10 mg given orally three or four times a day and can be increased to a maximum dosage of 180 mg a day. Nimodipine is available in 30-mg capsules. The oral dosage is 30 mg three times a day with slow increases in dosage to 60 mg given every 4 hours or higher if tolerated. Isradipine is available in 2.5-, 5-, and 10-mg capsules or tablets. The starting dosage is 2.5 mg a day and can be increased to a maximum dosage of 15 mg a day in divided doses. Amlodipine is available in 2.5-, 5-, and 10-mg tablets. The starting dosage is 5 mg a day at night with a maximum dosage of 10 to 15 mg a day.

Investigational Approaches and Prediction of Response With the panoply of drugs now available for the short-term and long-term treatment of bipolar disorders, one major problem is determining how to sequence these drugs in the absence of clinical and biological markers that might enhance the rapidity with which a given drug is optimally matched to a given patient. There are few clinical or biological markers of response to the calcium channel blockers. Case series have suggested that lithium responders were most likely to also respond to verapamil, but some patients have responded to nimodipine after failing lithium. Among the nimodipine responders were patients with patterns of illness that are often refractory to conventional treatment, including those with rapid, ultra-rapid, and ultradian presentations as well as recurrent brief depression.

A promising area of investigation is work using brain imaging that found that patients with mood disorders with the classical pattern of relative frontal hypometabolism in major depressive disorder were among those who responded to nimodipine whereas equally depressed patients with hypermetabolism, particularly in frontal areas and the left insula, responded to carbamazepine. These data raise the possibility that regional topographies of blood flow or metabolism might ultimately help to identify a subgroup of patients who are more responsive to the calcium channel inhibitors. Responders to nimodipine had significantly lower concentrations of somatostatin in their cerebrospinal fluid (CSF) compared with nonresponders. Since nimodipine significantly increases somatostatin in the CSF, it is possible that those who have low basal concentrations are helped more by this drug action than those with normal or high concentrations.

Given the substantial percentage of depressed patients who show increased intracellular calcium alterations during or in bipolar disorder patients even between depressive episodes, it remains to be seen whether this neurobiological alteration, consistently observed on a statistical basis across many studies compared with normal volunteers, will provide a basis for helping to select those patients who respond to interventions that block calcium influx such as that of the L-type calcium channel inhibitors. In addition, exploring the molecular basis for the increased intracellular calcium in depressed patients may also help to locate new targets for therapeutic medications.

SUGGESTED CROSS-REFERENCES

Basic science discussions of electrophysiology are found in Section 1.8 and Section 1.9; the biochemical and clinical aspects of the mood disorders are discussed in Section 14.3 and Section 14.6 respectively. Section 2.1 addresses the clinical aspects of neuropsychiatric disorders.

CHAPTER 31. BIOLOGICAL THERAPIES

31.14 CHLORAL HYDRATE

LAWRENCE A. LABBATE, M.D., GEORGE W. ARANA, M.D., AND JAMES C. BALLENGER, M.D.

HISTORY

Chloral hydrate was discovered by Justus von Liebig in 1831 and was determined to have hypnotic properties by Rudolph Buchheim in 1861. It was introduced into clinical use in the late nineteenth century, at first as an anesthetic and subsequently as a hypnotic, for which it had widespread use. Although initially thought to induce its effects by metabolism to chloroform, chloral hydrate's active metabolite turned out to be trichloroethanol. Until the recent common use of benzodiazepines it was often used as a hypnotic in medical and surgical practice. Further, until more effective and specific agents were developed, it was also used to treat many psychiatric conditions including anxiety, psychosis, mania, and delirium. Chloral hydrate has been largely replaced by the benzodiazepines and zolpidem (Ambien) in the clinical treatment of insomnia. The benzodiazepines have a much higher therapeutic index and are therefore preferred. Chloral hydrate is sometimes used as a hypnotic agent, although it is not the standard of care in psychiatric practice. It is currently used more commonly in pediatrics as a sedative for procedures, including imaging studies or dental work.

Chemistry Chloral hydrate is formed by adding water to the carbonyl group of chloral, 2,2,2-trochloroacetaldehyde. Chloral hydrate serves largely as a pro-drug. It is metabolized by alcohol dehydrogenase to its active metabolite trichloroethanol (CCl_3CH_2OH).

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption Chloral hydrate is completely absorbed in the small intestine, rapidly reduced to trichloroethanol, and effects are generally manifest in 30 to 60 minutes. Food in the stomach slows onset of action.

Distribution Chloral hydrate and trichloroethanol are lipid soluble and enter all tissues, including breast milk, although concentration in breast milk is usually low and not clinically significant.

Elimination Chloral hydrate is rapidly metabolized in the liver by alcohol dehydrogenase. Ethanol accelerates metabolism because its oxidation reduces chloral hydrate and thus leads to more rapid central nervous system (CNS) effects. The active drug, trichloroethanol, has a plasma half-life ranging from 4 to 8 hours. Trichloroethanol is primarily metabolized in the liver by conjugation with glucuronic acid to form urochloralic acid and is then excreted into urine and bile. To a lesser extent, trichloroethanol and chloral hydrate are oxidized to trichloroacetic acid and excreted in urine. Trichloroacetic acid is not an active drug and has a half-life of approximately 4 days.

Pharmacodynamics

Mechanism of Action Pharmacological effects are attributable to trichloroethanol. Limited study in animals suggests that, like the barbiturates trichloroethanol exerts g-aminobutyric acid A (GABA) receptor channel, and potentiates GABAergic transmission. Chloral hydrate thus serves to increase chloride ion flow and depress excitable cells.

Blood Levels Because chloral hydrate is a prodrug, plasma level of trichloroethanol are measured. Typical clinical doses, 500 to 1500 mg in adults or 15 mg/kg in children, are associated with peak plasma concentrations of trichloroethanol of 7 to 12 µg/mL.

CLINICAL DRUG STUDIES

Interpretation and Design Chloral hydrate was introduced to clinical practice long before Food and Drug Administration (FDA) requirements were in place for new drugs. As a result there were no placebo-controlled studies for its use, even though it has historically been used as an antianxiety or hypnotic agent or in the treatment of alcohol withdrawal. Long after its introduction a number of double-blind studies compared the use of benzodiazepines with chloral hydrate for the treatment of insomnia. A number of open-label studies have also evaluated chloral hydrate in children undergoing imaging, medical, or surgical procedures. Chloral hydrate, however, does not have an FDA indication for pediatric sedation.

Double-blind studies find that chloral hydrate is as effective as the benzodiazepines in the short-term treatment of insomnia. However, people may become tolerant to these effects after 2 weeks. Chloral hydrate appears in this respect similar to the barbiturates clinically and is not an effective agent for chronic insomnia. It also appears to be an effective agent for sedation in young children undergoing minor surgery and imaging studies (computerized tomography, magnetic resonance imaging, electroencephalography [EEG], vesicoureterogram). Respiratory compromise limits its use. Chloral hydrate may have some utility as an adjunct in the treatment of alcohol withdrawal, and a few controlled studies have found it effective for this purpose.

Effects on Specific Organ Systems

Central Nervous System Chloral hydrate has little if any analgesic properties and may induce excitement or agitation in the presence of pain. It also has anticonvulsant properties, although the ratio of anticonvulsant to sedative properties is low. Because of its anticonvulsant properties chloral hydrate has been used historically in the treatment of eclampsia or tetanus. The benzodiazepines or barbiturates are far superior to chloral hydrate as anticonvulsants. Chloral hydrate's most common CNS effects are due to depression at all levels of the neuraxis associated with high dose or abuse. High doses (over 4 grams) may be associated with stupor, confusion, ataxia, falls, or coma. Some individuals have survived doses over 30 grams. In general, appropriate doses are not associated with day-after hangover effects.

Respiratory System In typical clinical doses chloral hydrate has little effect on respiration. Toxic doses, however, may cause respiratory compromise and the drug should be used cautiously in patients who have obstructive pulmonary disease or asthma.

Cardiovascular System In oral therapeutic doses there are no effects on blood pressure, although higher doses or overdoses may result in lowered blood pressure because chloral hydrate depresses cardiac contractility. Patients with cardiac disease should probably not be given chloral hydrate.

Gastrointestinal System Chloral hydrate does not have specific effects on smooth muscle and does not induce hepatic microsomal enzymes the way the barbiturates do. The drug is irritating to mucous membranes and may cause unpleasant taste, epigastric distress, vomiting, or diarrhea.

Pregnancy There are no studies on the effects of chloral hydrate on the fetus. Use during pregnancy may precipitate a withdrawal syndrome in the newborn. Chloral hydrate crosses into breast milk and may cause drowsiness in nursing infants.

Therapeutic Indications

Insomnia Relatively less costly than other sedative-hypnotics, chloral hydrate is as an inexpensive drug for the treatment of insomnia although it is seldom prescribed for this purpose. Effective doses range from 500 to 1500 mg, although some patients require 2 grams. It has largely been supplanted by the benzodiazepines and zolpidem in the treatment of insomnia. Chloral hydrate is sometimes helpful for patients who do not benefit from benzodiazepines or for elderly patients with agitation associated with insomnia. The benzodiazepines, however, appear superior to chloral hydrate for sedation and sleep as reported in various studies that compare them directly.

Sedation for Pediatric Procedures Oral administration or rectal suppositories are used for children undergoing minor procedures or imaging studies. This is not an FDA-approved indication, although it is commonly used in pediatrics. The indicated dose is 50 mg per kg of body weight for oral or rectal use, with usual dose not higher than 1 gram; however, to ensure sedation, some practitioners use 80 to 100 mg per kg of body weight and up to 3 grams. Several recent controlled clinical trials evaluating chloral hydrate for various tests, especially imaging studies, have supported the clinical practice of using higher than the recommended dose of 50 mg per kg, and the dose of 80 to 100mg per kg may be optimal. Higher doses are more likely to ensure completion of the study without awakenings, and complications are uncommon even at doses of 100 mg per kg. Doses should not be repeated, and children should be monitored and not released until they are awake and appropriate for discharge.

Preoperative Use Chloral hydrate may be used preoperatively, 1 gram orally, to allay anxiety or produce sleep even though the benzodiazepines are preferable in this setting.

Alcohol Withdrawal Chloral hydrate has historically been used to treat alcohol withdrawal although it is rarely used now and has been replaced by the benzodiazepines, which are safer.

Precautions and Adverse Effects

Central Nervous System Like other CNS depressants, use of chloral hydrate may be associated with sedation; tiredness the morning after use; dizziness or lightheadedness; slurred speech; and less commonly confusion, hallucinations, or paradoxical excitement.

Abuse and Dependence Like the barbiturates, chloral hydrate has abuse potential, primarily by individuals with a history of alcohol or other drug abuse. Because tolerance can develop, addicts may take large doses to maintain their addiction. Sudden cessation of chloral hydrate in addicts leads to a withdrawal syndrome similar to barbiturate withdrawal, including autonomic instability, seizures, delirium, and possibly death if untreated.

Overdose Toxic doses generally result from use of 10 grams or more in adults, although elderly patients may be more sensitive. Poisoning resembles barbiturate poisoning, including loss of respiration, pinpoint pupils, and loss of deep tendon reflexes. Supportive treatment is the same as for other CNS depressants, and hemodialysis or hemoperfusion may promote trichloroethanol clearance. Deaths have been reported in children being sedated for procedures, and repeated doses should not be used for procedure sedation. Accumulation of trichloroethanol may cause excessive CNS depression and respiratory arrest.

Allergic Reactions Patients occasionally develop rash, erythema, urticaria, eosinophilia, or leukopenia.

Gastrointestinal Tract Because of its irritating properties, oral chloral hydrate should be avoided in patients with esophagitis, gastritis, gastric or duodenal ulcers, proctitis, or colitis. Chloral hydrate has been reported to precipitate attacks of intermittent porphyria and should not be used in patients with advanced liver disease.

DRUG INTERACTIONS

Patients receiving intravenous furosemide (Lasix) with chloral hydrate may experience vasodilation and flushing, tachycardia, hypertension or hypotension, and sweating. The symptoms are thought to be caused by displacement of thyroxine from the bound state. Similarly, chloral hydrate may displace oral anticoagulants from plasma proteins and increase the effects of a stable dose of warfarin (Coumadin) for several weeks. Monitoring of coagulation must be frequent if the combination is to be used, but because many other hypnotic agents are available patients taking warfarin should not be given chloral hydrate. Chloral hydrate combined with alcohol is known popularly as a “Mickey Finn.” The combination causes a combined and possibly synergistic effect of these two CNS depressants. Possible synergistic effects may be explained by the inhibition of metabolism of alcohol by chloral hydrate and the enhancement of production of trichloroethanol, the active drug of chloral hydrate, by ethanol. The two should not be used together.

LABORATORY INTERFERENCE

Chloral hydrate may interfere with urine glucose tests, such as Clinitest, giving false-positive results. Glucose enzymatic tests are not affected. Chloral hydrate also interferes with fluorometric tests of urine catecholamines and some assays of urine 17-hydroxycorticosteroids. Chloral hydrate may also cause false-positive results of the phentolamine test.

DOSAGE AND ADMINISTRATION

Chloral hydrate comes as capsules, syrup, or rectal suppositories. Capsules come in 250-mg and 500-mg strengths. Syrup comes in concentrations of 500 mg per 5 mL. Oral solution should be kept sealed and away from light to prevent deterioration. Oral solution may be irritating to the stomach and should be mixed in 4 to 8 ounces of water or juice. Suppositories come in strengths of 325 mg, 500 mg, and 650 mg.

Use in Insomnia Although insomnia is a common complaint in psychiatric practice, it is often symptomatic of underlying mood, anxiety, psychotic, or substance abuse disorders. If the primary psychiatric syndrome is targeted by other treatment, then adjunctive treatment with chloral hydrate may be appropriate. However, insomnia is often better treated with benzodiazepines or zolpidem because of their lower potential for toxicity. Some clinicians prefer to use chloral hydrate to treat insomnia in geriatric patients although this is controversial and research findings are mixed. If chloral hydrate is used it should be given 15 to 30 minutes before bedtime at doses of 500 or 1000 mg; some patients may require up to 2 grams. The dose for geriatric patients is 500 mg.

Sedation for Diagnostic Tests in Children For EEG sedation, 25 mg per kg of body weight is suggested for oral or rectal use. For other procedures the manufacturer-recommended dose is 50 mg per kg body weight, by oral capsule or rectal suppository, with a maximum dose of 1 gram. For many children the 50-mg per kg dose may be inadequate, and doses up to 100 mg per kg of body weight (up to 3 grams) are required. Because an insufficient dose may lead to agitation and inability to complete a procedure, underdosing is a clinical problem and it is suggested that children over age 5 not be given chloral hydrate for procedure sedation.

SUGGESTED CROSS-REFERENCES

Barbiturates are discussed in Section 31.8, and benzodiazepines are discussed in Section 31.9. Substance-related disorders are presented in Chapter 11, and sleep disorders are presented in Chapter 21.

31.15 CHOLINESTERASE INHIBITORS

STEVEN C. SAMUELS, M.D., AND KENNETH L. DAVIS, M.D.

Alzheimer's disease is a progressive neurodegenerative disease that gradually destroys brain function. Symptoms of the disease include cognitive deterioration involving memory, language, praxis, higher executive functioning and behavioral changes. In the United States, 4 million patients are afflicted with the disease, with direct and indirect costs for the disease approaching 100 billion dollars annually. The disease is age related with the prevalence of 3.0 percent at age 65, approaching 50 percent by age 85 years and leveling off at 40 percent by age 95. As the population ages, increased numbers of people will develop Alzheimer's disease. Cautious optimism stems from the recent availability of cholinesterase inhibitors that may slow down the progression of this terrible disease, but much more research is required before the disease can be arrested or reversed or those at risk for the disease can be reliably identified and prevented from developing it.

Several lines of evidence suggest that cholinergic function has a substantial role in Alzheimer's disease. Cholinergic transmission is involved in learning and memory. Anticholinergic agents cause memory and attention deficits in animals and humans. Destruction of the basal forebrain in animals or cholinergic circuitry in humans results in cognitive deficits. In clinical trials, cholinergic agents have restored cognitive function and decreased decline in Alzheimer's disease patients. The correlation between cholinergic abnormalities and the degree of cognitive impairment in Alzheimer's disease is a consistent finding in a number of studies. The significance of the cholinergic changes in Alzheimer's disease was eloquently described in a comprehensive examination of neuropathological and neurochemical changes in brains of those afflicted. The strongest correlations between clinical measures of dementia severity and neurochemical changes involved choline acetyltransferase, the enzyme necessary for the formation of acetylcholine.

The cholinergic hypothesis in Alzheimer's disease led to research and development of a number of potential therapeutic agents. These agents are in various stages of preclinical and clinical development in animals and humans. The agents currently approved by the Food and Drug Administration (FDA) for Alzheimer's disease are predominantly cholinesterase inhibitors. Attempts to alter cholinergic transmission have included increasing presynaptic precursors to acetylcholine, stimulating muscarinic receptors with selective muscarinic agonists and decreasing the enzymatic degradation of acetylcholine by blocking acetylcholinesterase or butylcholinesterase with cholinesterase inhibitors.

Lecithin and choline, the precursors to acetylcholine, have been extensively studied and shown not to be beneficial in Alzheimer's disease. Muscarinic agonists have demonstrated benefit in preclinical studies, and some compounds are now in clinical trials. Although tonic stimulation may be relevant in arousal and attention, continuous stimulation of receptors by cholinergic agonists may result in receptor downregulation because the physiological stimulation is not pulsatile. This downregulation may limit the effectiveness of the muscarinic agonists. Advancing age and Alzheimer's disease progression are associated with a decrease in number and function of cholinergic neurons, possibly explaining the failure of precursors affect the disease. Moreover, this decline in cholinergic neuron number and function may also decrease the effectiveness of the muscarinic agonists and the cholinesterase inhibitors.

TACRINE

Tacrine (Cognex), the first FDA-approved cholinesterase inhibitor for the treatment of dementia of the Alzheimer's type, is a centrally acting, noncompetitive, reversible inhibitor of acetylcholinesterase and butyrylcholinesterase. Originally synthesized in 1945, tacrine was not recognized as a cholinesterase inhibitor until 1953. Tacrine was initially used to attenuate morphine withdrawal in patients with cancer and pain syndromes. Tacrine is effective in slowing the apparent progression of dementia in a subgroup of patients with Alzheimer's disease who can tolerate the medication for sufficient duration. Tacrine's use in Alzheimer's disease is limited by four-times-a-day dosing, gastrointestinal adverse effects, the potential for hepatic toxicity, and the need for frequent serum monitoring.

Chemistry The molecular structure of tacrine (9-amino-1,2,3,4-tetrahydroacridine) is shown in Figure 31.15-1. Tacrine is metabolized to a number of hydroxylated products, including 1-OH-tacrine (which itself was being developed for the treatment of dementia of the Alzheimer's type) as velnacrine.

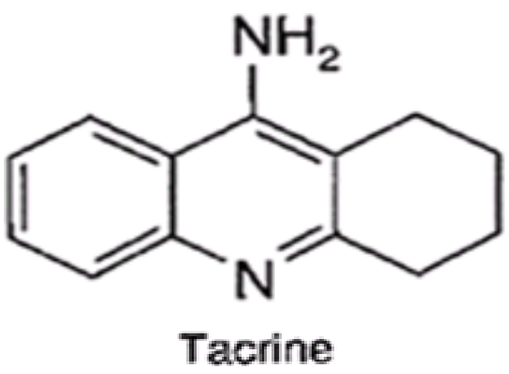

FIGURE 31.15-1 Molecular structure of tacrine.

Pharmacological Actions

Pharmacokinetics Tacrine is well absorbed from the gastrointestinal tract; however, intake with food reduces its bioavailability by 30 to 40 percent. Peak plasma concentration is reached 1 to 2 hours after oral dosing. Steady-state tacrine concentrations are reached after dosage initiation or change in 24 to 36 hours. The steady-state volume of distribution is about 300 L. The elimination half-life of tacrine is 2 to 3 hours. Tacrine is hepatically metabolized by the cytochrome P450 (CYP) is 0 enzymes 1A2 (CYP 1A) and CYP 2D6 and undergoes hydroxylation and conjugation. A small percentage of the drug is excreted in the urine, and dose adjustments are not necessary in patients with renal impairment.

Pharmacodynamics Tacrine's mechanism of action in Alzheimer's disease appears related to acetylcholinesterase inhibition resulting in increased acetylcholine availability. The relation between plasma concentration and oral dosing is nonlinear. Plasma concentrations of tacrine in women are double those of men, possibly related to decreased CYP 1A2 activity in women. Cigarette smokers have up to one-third lower serum tacrine levels than nonsmokers, probably related to induction of CYP 1A2 in smokers. Age and tacrine clearance are not directly related.

Design and Interpretation of Clinical Drug Studies Clinical trials using tacrine for Alzheimer's disease have variable methodological strength. Early studies demonstrating remarkable promise of tacrine for dementia were not well controlled. Additional studies in the 1980s had mixed results and continued methodological problems including inadequate dosing strength and duration of treatment. These concerns limited generalizations that could be made about effectiveness. Improved methodology in one 12-week study and 30-week study were pivotal in the ultimate FDA approval of tacrine.

Tacrine and Functional Brain Studies Brain single photon emission computed tomography (SPECT) and xenon (Xe)-inhalation have been used to examine brain function in Alzheimer's disease patients who received tacrine. These studies revealed correlations between clinical response to tacrine and functional imaging

changes. Tacrine may improve technetium-99 (^{99m}Tc)-labeled ethylene dicysteinate retention abnormalities (a measure of cerebral blood flow) in patients with mild-to-moderate dementia of the Alzheimer's type. The results were dose dependent; patients who received 75 mg of tacrine a day demonstrated improvement, while those receiving 25 mg of tacrine a day did not show functional change in brain SPECT. In an open-label 14-month trial of tacrine with maximum dosage of 125 mg a day, Xe-inhalation methodology was used to measure regional cerebral blood flow (rCBF) in probable Alzheimer's disease patients before and after tacrine treatment. Patients who responded favorably to tacrine showed improvement or stabilization in rCBF compared with those who did not receive tacrine. The results support a dosage-dependent response to tacrine. The possibility of using functional measures as predictors of clinical response to pharmaceuticals is intriguing, and further research is required in this area.

Pharmacoeconomic Considerations Tacrine has been estimated to generate potential savings up to 17 percent of the current costs of Alzheimer's disease, or a total 3.6 billion dollars annually. These calculations were based upon an improvement of 1 point on the Mini-Mental State Examination (MMSE) by patients tolerating 80 to 160 mg a day and a 2 point increase in patients who tolerated 160 mg a day. Patients with 1 to 2 points of improvement on the MMSE are estimated to have 9.5 to 12.1 months of reduced community and institutional costs. Industry-sponsored studies examining the effects of various agents on the direct and indirect costs of Alzheimer's disease are ongoing, and justification for choosing one pharmacotherapeutic agent over another may become closely tied to a drug's pharmacoeconomic profile.

Quality of Life In addition to pharmacoeconomic considerations, tacrine's effects on quality-of-life measures have been examined. The effect of tacrine on mortality and placement into a long-term care facility was examined in about 90 percent of the 663 patients from the 30-week clinical trial. Patients were followed for 2 years or until they died or were placed in a nursing home. Patients receiving more than 80 mg of tacrine daily were less likely to die or be placed in a nursing home than patients on a lower tacrine dose (odds ratio > 2.7). The absence of a control group and the retrospective nature of the study limit generalizations, but the dose-response nature of the findings is intriguing.

Effects on Specific Organs and Systems Tacrine dosages of 80 to 160 mg a day appear necessary for clinical response. At least 12 weeks of dose titration are required to achieve a dosage of 120 mg a day. More time is often required because the patient has gastrointestinal side effects or elevated hepatic transaminases. Transaminase elevations exceeding five times the upper limit of normal should result in tacrine discontinuation. Even with transaminase elevations, patients may still be rechallenged with tacrine after the transaminase levels normalize. In the clinical trials, no deaths associated with hepatitis in these patients were reported. A significant number of patients may tolerate rechallenge with tacrine, often at higher dosages than those that initially led to temporary discontinuation of the drug. Tacrine may have vagotonic effects on the heart rate and should be used with caution in patients with supraventricular cardiac arrhythmias. Gastrointestinal effects secondary to the parasympathetic effects of tacrine necessitate caution in patients at risk for peptic ulcer disease.

Therapeutic Indications Tacrine is indicated for the treatment of mild-to-moderate Alzheimer's disease.

Precautions and Adverse Reactions The clinical trials described above reported frequent adverse effects from tacrine. Hepatic abnormalities, although most often asymptomatic, require frequent monitoring of alanine transaminase (ALT) in serum. Dyspepsia, nausea, vomiting, diarrhea, anorexia, and abdominal pain are the most common adverse gastrointestinal effects. Adverse effects occurring in at least 2 percent of patients in clinical trials are reported in Table 31.15-1. Although many of the adverse effects occurred at similar rates in the tacrine and placebo groups, withdrawal from clinical trials occurred at a much higher rate in the tacrine group.

Adverse Event	Tacrine (%) (N = 634)	Placebo (%) (N = 342)

Table 31.15-1 Adverse Events Associated With Tacrine and Placebo Based Upon Clinical Trial Data

Hepatic Monitoring and Rechallenge Current recommendations for patients on tacrine treatment who tolerate the drug without significant elevations in hepatic transaminase concentrations are serum ALT monitoring every other week for 16 weeks, then monthly for 2 months, then once every 3 months. Patients may continue according to the titration schedule with up to twice the upper limit of normal ALT; weekly transaminase monitoring is necessary in patients with two to three times the upper limit of normal. Patients with ALT values three to five times the upper limit of normal should reduce the tacrine dosage by 40 mg a day and begin weekly transaminase monitoring. The dosing titration may resume with every-other-week transaminase monitoring when the ALT concentrations normalize. Patients with ALT concentrations exceeding 5 times the upper limit of normal should stop taking tacrine and be carefully monitored for signs and symptoms of hepatitis. If there is evidence of clinical jaundice, total bilirubin above 3 mg/dl, or clinical signs and symptoms of hypersensitivity such as rash or fever, patients should permanently stop taking tacrine and not be rechallenged. In one study that led to modification of the prescribing guidelines for tacrine, almost 88 percent of patients tolerated tacrine rechallenge, and 72 percent of the patients tolerated higher tacrine dosages than the initial dosage that resulted in discontinuation.

Weekly transaminase monitoring is required for all patients rechallenged with tacrine. After ALT values return to normal, patients may resume taking tacrine 10 mg four times a day. The titration schedule resumes after 6 weeks if the patient tolerates the drug and transaminase levels are acceptable (less than 3 times the upper limit of normal). Patients with initial elevations in ALT up to 10 times the upper limit of normal may be rechallenged after transaminase values normalize, although there is limited clinical experience with rechallenging these patients. Hypersensitivity reactions to tacrine resulting in eosinophilia or granulomatous hepatitis have been reported, and rechallenge of these patients is not recommended.

Drug Interactions Patients on theophylline (Theo-Dur) who also take tacrine show a doubling of theophylline concentration, as both drugs are metabolized by CYP 1A2. Cimetidine (Tagamet) is also metabolized by the same isoenzyme as tacrine, and coadministration of these agents requires judicious monitoring, as both drug concentrations increase. Tacrine prolongs the effect of succinylcholine by inhibiting butylcholinesterase, the enzyme responsible for succinylcholine degradation. There have been no reported drug interactions with digoxin (Lanoxin), warfarin (Coumadin), or diazepam (Valium).

Laboratory Interferences Tacrine does not interfere with urinalysis, spectroscopy, or other laboratory tests. Elevation of transaminases is associated with tacrine use.

Dosage and Administration Tacrine is available in 10-mg, 20-mg, 30-mg, and 40-mg capsules. After a thorough physical examination and review of transaminase levels, tacrine administration should be started at 10-mg four times a day for 6 weeks. The dosage may then be increased by 10 mg four times a day every 6 weeks until the target dosage of 40 mg four times a day is reached. Titration should proceed unless transaminases are elevated or there is other evidence of intolerance. If transaminase elevations occur, tacrine dosage is maintained at the current level or reduced. Patients who discontinue tacrine for 4 weeks must resume taking it at initial dosages of 10 mg four times a day, with attendant transaminase serum monitoring. Patients with gastrointestinal intolerance of tacrine may benefit from coadministration of tacrine with meals, although the drug's bioavailability may decrease by 30 to 40 percent.

DONEPEZIL

In December 1996, donepezil (Aricept) became the second cholinesterase inhibitor FDA-approved for treating dementia of the Alzheimer's type. This compound has once-daily dosing, lacks significant hepatotoxicity, and does not require serum monitoring. Prolonged dosage titration of the drug is not required. Donepezil was in development for close to four decades; in vitro selectivity of donepezil for acetylcholinesterase compared to butylcholinesterase was studied first in 1961.

Chemistry Donepezil, known chemically as (±) -2,3-dihydro-5,6-dimethoxy-2-1 [[1-(phenylmethyl)-4-piperidinyl]methyl]-1 *H*-inden-1-one hydrochloride, is a

piperidine-based acetylcholinesterase inhibitor. The empirical formula is $C_{24}H_{29}NO_3HCl$, and the molecular weight is 415.96. The molecular structure is shown in Figure 31.15-2.

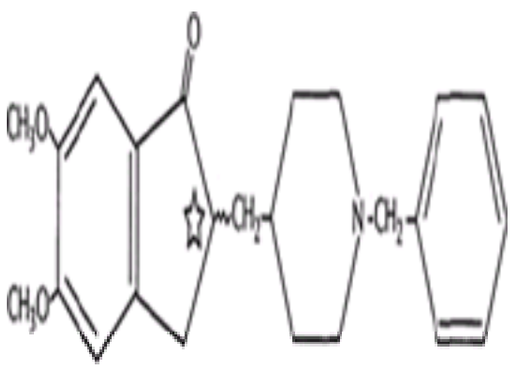

FIGURE 31.15-2 Molecular structure of donepezil.

Pharmacological Actions

Pharmacokinetics Donepezil is well absorbed in the gastrointestinal tract, and has an oral availability of 100 percent. Administration time and intake with food does not influence absorption. Peak plasma concentration is reached 3 to 4 hours after oral dosing. The steady-state volume of distribution is 12 L/kg. Donepezil is 96 percent bound to human plasma proteins, predominantly albumin (75 percent) and a_1 acid glycoprotein (21 percent). Multiple-dose administration leads to steady state in 15 days with a four- to sevenfold increase in donepezil concentration. The elimination half-life of donepezil is 70 hours. Donepezil is excreted in the urine and hepatically metabolized by CYP 3D4 and CYP 2D6 and undergoes glucuronidation. There are four major metabolites, two of which are active, and a number of minor metabolites. The package labeling reports that patients with hepatic disease (stable alcoholic cirrhosis) had 20 percent less hepatic clearance of donepezil than healthy controls. Patients with renal disease did not differ from healthy subjects in their clearance of donepezil.

Pharmacodynamics The drug reversibly and noncompetitively inhibits hydrolysis of acetylcholine by acetylcholinesterase in the brain, which results in increased availability of acetylcholine in the synaptic cleft. The inhibitor dissociation constant for donepezil is one or two orders of magnitude lower than that for tacrine, indicating a stronger inhibitory effect by donepezil on acetylcholinesterase. The selective inhibition of donepezil is 1250 times greater for acetylcholinesterase than for butylcholinesterase. The plasma concentration is linearly correlated with daily oral dose in the range of 1 to 10 mg.

Design and Interpretation of Clinical Drug Studies In a double-blind placebo-controlled study, probable Alzheimer's disease patients were treated with donepezil in dosages of 1 mg, 3 mg, and 5 mg a day or placebo for 12 weeks. The donepezil-treated patients demonstrated dosage-related improvements in the cognitive subscale of the Alzheimer's Disease Assessment Scale (ADAS-cog) and the MMSE. The 5-mg donepezil group demonstrated statistically significant improvement in the ADAS-cog compared with the placebo group. Donepezil was not associated with hepatic toxicity and was well tolerated in this study.

In another 12-week double-blind placebo-controlled study with a 3-week placebo washout period, patients received either placebo or 5 mg or 10 mg a day of donepezil. Patients randomized to 10 mg a day received this dosage after 1 week at 5 mg a day. At 12 weeks, the means in ADAS-cog scores in the donepezil-treated groups and placebo group differed significantly. The differences between the 5-mg and 10-mg groups were not statistically significant. After 3 weeks of placebo washout, the donepezil-treated groups demonstrated loss of treatment effect. The difference in ADAS cog scores between donepezil-treated patients and the placebo group was about 3 units at 12 weeks. Studies have reported an expected change of 9 points on the ADAS cog in untreated probable Alzheimer's disease patients. At 12 weeks, patients receiving donepezil also demonstrated statistically significant improvement compared with the placebo group in Clinician's Interview-Based Impression of Change Plus Caregiver (CIBIC-plus) scores, a clinician-based assessment of change after interview with the patient and caregiver.

A 30-week study also used the ADAS-cog and CIBIC-plus Assessment as outcome measures. After 24 weeks of active double-blind placebo-controlled treatment, patients had 6 weeks of single-blind placebo-controlled washout. Patients were randomized to receive donepezil at 5 mg a day, 10 mg a day (after 1 week at 5 mg a day), or placebo. After 24 weeks, ADAS-cog scores were higher in donepezil-treated patients than in those in the placebo group, although there was no statistically significant difference between the 5- and 10-mg groups. CIBIC plus scores at 24 weeks also statistically favored the donepezil-treated groups. There was no difference between the groups receiving 5 and 10 mg a day. After the 6-week placebo washout, the placebo groups and donepezil-treated groups were indistinguishable in ADAS-cog scores, suggesting that donepezil treatment did not change the underlying disease. There have been no direct comparisons of tacrine and donepezil. However, the change in the ADAS-cog scores for donepezil at its best has not been as large as the change in ADAS-cog scores for tacrine at its best.

Effects on Specific Organs and Systems Donepezil does not appear to cause hepatic injury. The drug may have vagotonic effects on the heart rate and should be used cautiously in patients with supraventricular cardiac arrhythmias including sick sinus syndrome. Gastrointestinal effects are secondary to the parasympathetic effects of donepezil. Gastric acid secretion may increase with donepezil. Patients with or at risk of peptic ulcer disease and patients taking nonsteroidal anti-inflammatory drugs (NSAIDs) should be carefully monitored for evidence of gastrointestinal bleeding while receiving donepezil. Nausea, diarrhea, and vomiting may occur more commonly with the 10 mg than the 5 mg a day dosage.

Therapeutic Indications Donepezil is indicated for the treatment of mild-to-moderate dementia of the Alzheimer's type. Other forms of dementia may have some cholinergic depletion but are not currently indicated conditions for prescribing donepezil.

Precautions and Adverse Reactions Table 13.15-2 includes all adverse events reported in clinical trials of donepezil that occurred at a rate of at least 2 percent and at greater frequency than in placebo-treated patients. The most common adverse effects associated with donepezil use were diarrhea, nausea, insomnia, vomiting, muscle cramps, fatigue, and anorexia. These events were frequently mild and transient, resolving during continued treatment with donepezil. Adverse events occurred more frequently in women and the elderly. The most common adverse effects associated with donepezil that led to discontinuation of clinical trials were nausea, diarrhea, and vomiting. Patients who were titrated up to 10 mg a day after 1 week had a higher discontinuation rate than those taking 5 mg a day. An open-label study of the placebo-treated groups revealed that the adverse event rates were lower in the patients titrated up to 10 mg over 6 weeks than in patients titrated to 10 mg a day in 1 week. The rates of adverse effects in the slower-titration group were similar to those in the group receiving 5 mg a day of donepezil.

Adverse Event	Placebo (N = 333)	Donepezil (N = 747)

Table 31.15-2 Adverse Events Reported in Clinical Trials Comparing Donepezil With Placebo

Drug Interactions The package insert for donepezil reports that the drug is highly protein bound. In vitro displacement studies with donepezil did not demonstrate

displacement of other tightly protein-bound drugs (furosemide [Lasix]), warfarin, digoxin). However, no in vivo drug displacement studies have been performed. Such studies in animals, with rapid infusion of drugs through the intravenous route as might occur under some clinical circumstances, would be revealing. The implications of tight protein binding for donepezil will remain unclear until in vivo studies are performed and potential drug interactions evaluated, especially since the average patient with Alzheimer's disease is taking multiple medications. The company reports that donepezil binding to albumin was not affected by furosemide, warfarin, or digoxin. The effect of donepezil on malnourished or cachectic patients has not been examined. Although there have been no formal studies examining drug interactions, the company reports that donepezil has no significant pharmacokinetic effects on warfarin, theophylline, cimetidine, and digoxin. Donepezil may increase succinylcholine effects on muscle relaxation. Agents that inhibit CYP 2D6 or CYP 3A4 may inhibit donepezil metabolism. Inducers of CYP 2D6 and CYP 3A4 may increase the elimination rate of donepezil. Cholinesterase inhibitors may also interfere with the effects of anticholinergic agents. This concern may be more academic than practical, as anticholinergic agents should generally be avoided in patients with Alzheimer's disease.

Laboratory Interferences There is no current evidence that donepezil interferes with urinalysis, spectrometry, or other laboratory tests.

Dosage and Administration Donepezil is supplied as a round tablet containing either 5 or 10 mg of donezepil hydrochloride. The 5-mg tablets are white, and the 10-mg tablets are yellow. The recommended starting dose is 5 mg daily. The medication is usually administered in the evening so the peak plasma concentration occurs when the patient is sleeping, minimizing adverse effects. The clinical trials demonstrated a dose trend favoring 10 mg over 5 mg a day, although the results were not statistically significant. Based on the clinical trials, it is a matter of prescriber and patient collaboration whether to increase from 5 to 10 mg a day. Open trials with 10 mg titration occurring at 6 weeks demonstrated no significant difference in adverse effects in the 5-mg and 10-mg groups. These authors recommend that patients be given a trial at 10 mg a day after 4 to 6 weeks if they are tolerating the 5 mg a day dosage. The half-life of donepezil is reported to be 70 hours on the basis of studies with younger patients. No half-life studies have been performed with elderly patients. Pharmacokinetic and pharmacodynamic changes in elderly persons may lead to an increased half-life, and it may be preferable to use dosages of 5 mg a day.

INVESTIGATIONAL DRUGS

Physostigmine Physostigmine's molecular structure is shown in Figure 31.15-3. Physostigmine (Antilirium, Eserine), a short-acting reversible cholinesterase inhibitor, has been extensively studied in Alzheimer's disease. Physostigmine improves recognition memory and enhances long-term memory processing. The response is dose dependent with a significant amount of individual variability, requiring a dose-finding phase of treatment to determine a patient's best dosage. Physostigmine is available in parenteral and oral preparations. Studies of oral and parenteral physostigmine in Alzheimer's disease patients have demonstrated variable responses. The drug's effectiveness in dementia appears related to cholinergic inhibition in serum and cerebrospinal fluid (CSF), and drug concentrations in serum and CSF fluctuate significantly with either parenteral or oral administration. Physostigmine is also associated with peripheral cholinergic side effects that often lead to discontinuation of the drug. More recently, a longer-acting oral preparation, physostigmine salicylate, has demonstrated some benefit in Alzheimer's disease patients in phase III clinical trials.

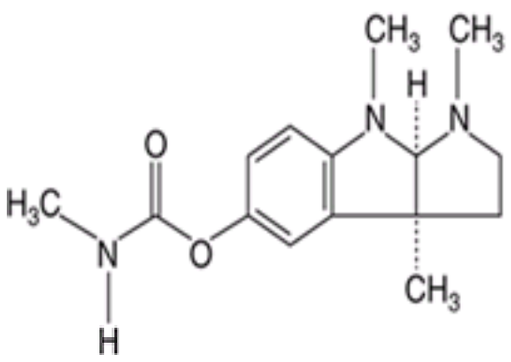

FIGURE 31.15-3 Molecular structure of physostigmine.

Eptastigmine Eptastigmine's molecular structure is shown in Figure 31.15-4. Eptastigmine, or heptylphysostigmine, is another longer-acting preparation of physostigmine. One 13-week controlled clinical trial of eptastagmine included 103 patients with probable Alzheimer's disease. The first 4 weeks were randomized, double-blind placebo-controlled, followed by 1 week of washout and an 8-week open-label phase. Subjects had MMSE scores between 10 and 26. Uniform dosing resulted in nausea and vomiting in some patients, and the methodology was changed to dosing the drug by weight. Outcome ratings included both physician and caregiver global ratings, independent activities-of-daily-living measure, and tests of logical memory, semantic word fluency, and executive functioning. One hundred three patients entered the double-blind phase (81 eptastigmine, 22 placebo). After 4 weeks, 94 remained in the study (74 eptastigmine, 20 placebo). Cholinergic adverse effects, uncooperation, protocol violation, and clinical worsening were all cited as reasons for dropout. At completion of the double-blind phase, the physician global measure and independent activities-of-daily-living measure favored the eptastigmine group. The tests of memory, word fluency, and higher executive functioning demonstrated no between-group differences. Dosage response followed an inverted U shape. Agranulocytosis has been reported with high doses of this drug and may limit its use. More clinical trial data are required with this agent.

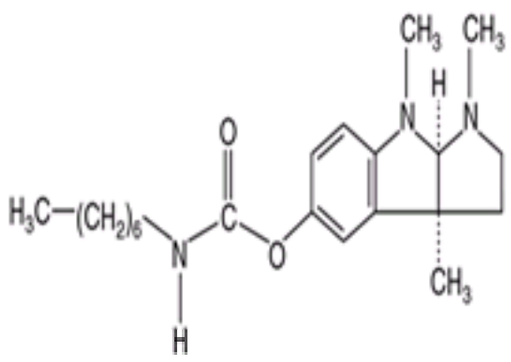

FIGURE 31.15-4 Molecular structure of eptastigmine.

Rivastigmine Rivastigmine's molecular structure is shown in Figure 31.15-5.

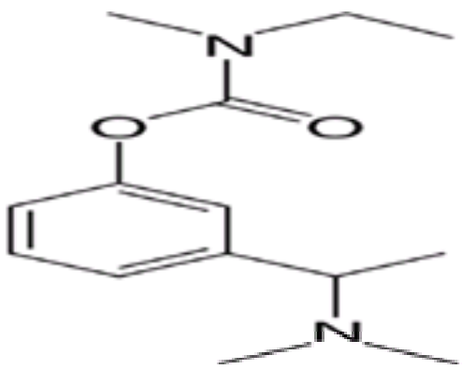

FIGURE 31.15-5 Molecular structure of rivastigmine.

Rivastigmine is a pseudoirreversible carbamate acetylcholinesterase inhibitor that is selective for the hippocampus and cortex. The drug is not metabolized by the liver, and no hepatic toxicity has been reported. It is metabolized by cholinesterase and is not protein bound. Rivastigmine was demonstrated to improve acquisition and retention memory in animals with selective basal forebrain lesions. Phase III clinical trials have been completed, and significant benefits have been reported in the ADAS, CIBIC Assessment and activities-of-daily-living measures. Concern about the possibility of increased deaths in the high-dosage group receiving rivastigmine compared with placebo led to inquiry of the Executive Director of Novartis. He responded that 62 patients died in the clinical trials with rivastigmine (including deaths occurring in patients treated up to 5 years prior to June 30, 1997). No statistical significant difference in the incidence of mortality was seen in placebo-controlled studies in phase I (rivastigmine, 0.8 percent, placebo, 0.5 percent) or phase III (rivastigmine –0.3 percent; placebo –0.1 percent). In phase 3 trials, no difference was found in mortality rates (Kaplan-Meier survival analysis) for patients treated long term with rivastigmine, which was assessed by comparing mortality in patients who were randomized to rivastigmine (13.0 deaths per 1000 patient-years) and treated long term with rivastigmine, with patients randomized to placebo for the first six months and treated long term with rivastigmine (13.5 deaths per 1000 patient-years). Nested case-control analyses were conducted to explore a dosage-response relationship for mortality, based on last prescribed dosage of rivastigmine and post hoc assignment of patients to nonoverlapping dosage ranges of 1 to <4, 4 to 6, >6 to 9, and >9 to 12 mg a day. Analyses comparing the highest to the lowest dose categories yielded a rate ratio of 0.8, indicating the absence of increased risk of mortality at higher dosages of rivastigmine. The causes of death in the rivastigmine clinical trials were numerous and similar to those reported in the literature for an Alzheimer's disease population.

Galanthamine Galanthamine's molecular structure is shown in Figure 31.15-6. It is a tertiary amine of the phenthrene group that competitively inhibits acetylcholinesterase but not butyrylcholinesterase. The compound is plant derived, naturally occurring, and an allosteric agonist at nicotinic sites without producing desensitization, as well as a cholinesterase inhibitor. This ability to enhance the sensitivity of the acetylcholine receptor is possessed only by galanthamine and physostigmine. The mechanism of action is analogous to that of benzodiazepines at the g-aminobutyric acid (GABA) A site. Consequently, the drug has an in vivo cholinomimetic activity that is even stronger than its acetylcholinesterase inhibitory properties alone would predict. Galanthamine's properties are interesting because in animals the combination of agonist and cholinesterase inhibitor may have an additive effect with fewer adverse events. Placebo-controlled clinical trials have demonstrated benefit in ADAS, and activities-of-daily-living measures. The usual effective dosage of galanthamine is 20 to 40 mg in divided doses. The drug has been approved in Austria, and multicenter clinical trials are under way in Europe and the United States.

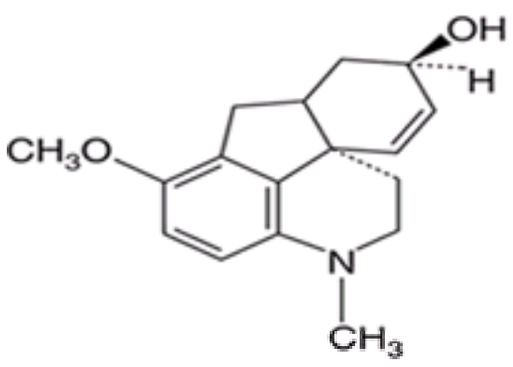

FIGURE 31.15-6 Molecular structure of galanthamine.

Metrifonate Metrifonate's molecular structure is shown in Figure 31.15-7. It is an irreversible cholinesterase inhibitor that is currently used to combat schistosomes. Metrifonate preferentially inhibits butyrylcholinesterase over acetylcholinesterase. Metrifonate is the prodrug of dichlorvos, the long-acting irreversible organic cholinesterase inhibitor. Although metrifonate has a short half-life, it achieves long-acting cholinesterase inhibition. Animal and human studies support metrifonate's memory-enhancing effects. Double-blind placebo controlled studies with Alzheimer's disease patients have demonstrated benefits for metrifonate-treated patients in 12- and 26-week trials. The benefits have been in cognitive measures (Alzheimer's Disease Assessment Scale-cog), behavioral measures (Neuropsychiatric Inventory), and global function (Clinician's Interview-Based Impression of Change-plus). The Food and Drug Administration is reviewing metrifonate, but there are no imminent plans for release of this medication because of safety concerns after some patients demonstrated prolonged muscle weakness after receiving the drug.

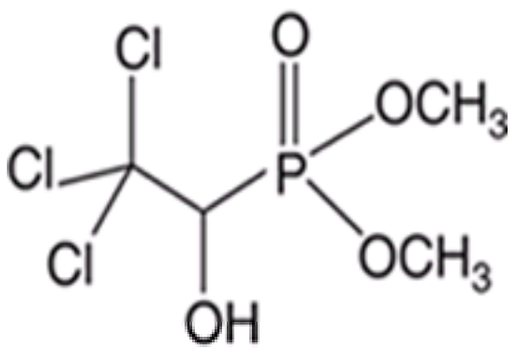

FIGURE 31.15-7 Molecular structure of metrifonate.

FUTURE DIRECTIONS

The concept of a polypharmaceutical approach to Alzheimer's disease has a theoretical rationale, as multiple domains appear to be involved in its pathogenesis. Future therapeutic approaches for Alzheimer's disease may be similar to hypertensive or neoplastic treatment, in which combination therapy is commonplace. Combination treatment with cholinesterase inhibitors and other agents has not been prospectively evaluated in Alzheimer's disease. A retrospective analysis to assess the effects of estrogen replacement therapy on tacrine response was performed using data from the 30-week tacrine study. Women receiving estrogen replacement therapy and tacrine had better measures of cognition and overall function than those not taking estrogen. Although these results are intriguing, prospective studies using cholinesterase inhibitors in combination with other treatments are required prior to recommending combination treatment as a standard of care.

SUGGESTED CROSS-REFERENCES

The neural sciences are discussed in Chapter 1 and dementia in Chapter 10 and Section 51.3e.

31.16 CLONIDINE

NORMAN SUSSMAN, M.D.

INTRODUCTION AND HISTORY

Clonidine (Catapres) is a presynaptic a_2-adrenergic receptor agonist that is approved for use as an antihypertensive agent. Stimulation of a_2-adrenergic receptors reduces the firing rate of noradrenergic neurons and reduces plasma concentrations of norepinephrine. Because of the widespread actions of the noradrenergic system, clonidine has also been adopted for use as a psychopharmacological agent. The most important clinical applications in psychiatry are as therapy for attention-deficit/hyperactivity disorder, opioid-withdrawal, Tourette's disorder, and posttraumatic stress disorder. It is also used as a pharmacological probe to assess central a_2-receptor sensitivity in psychiatric disorders.

Clonidine is clearly a useful drug. The improved symptomatic control provided by clonidine may enable the patient to function more effectively and to benefit from other treatment modalities. Nevertheless, its role as a treatment for selected mental disorders is generally limited to instances when other interventions have failed to ameliorate symptoms adequately. Although many reports exist of clonidine being used for a range of disorders, there are few double-blind controlled studies to support its efficacy for these uses. Clonidine also has significant limitations and risks. The frequent development of tolerance tends to limit its long-term effectiveness, making it more useful as short-term therapy. There is also uncertainty about cardiovascular risks with its use in children. Guanfacine (Tenex), another a_2-adrenergic receptor agonist, appears to offer some advantages over clonidine. It is less sedating than clonidine and has a longer half-life. There is, however, less clinical experience with guanfacine, and fewer controlled studies involve its use in psychiatric disorders than use of clonidine.

CHEMISTRY

Clonidine is an imidazoline compound whose molecular structure is shown in Figure 31.16-1.

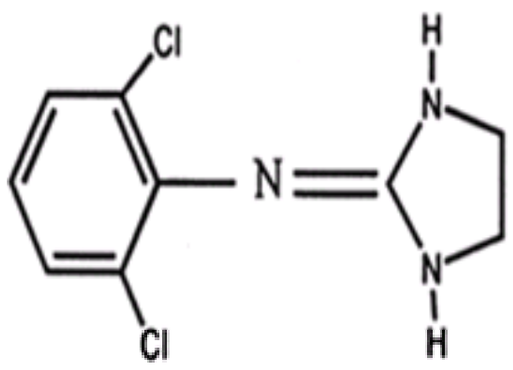

FIGURE 31.16-1 Molecular structure of clonidine.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption Clonidine is well absorbed from the gastrointestinal tract and reaches peak plasma levels 1 to 3 hours after oral administration. It acts rapidly, decreasing blood pressure within 30 to 60 minutes after an oral dose.

Bioavailability The bioavailability of clonidine in healthy adults averages about 75 percent and may approach 100 percent in some patients.

Distribution Clonidine is lipophilic. It rapidly penetrates the brain, its primary site of action. It is also extensively distributed, which shortens its effective half-life.

Elimination In adults, about 50 percent of the drug is metabolized in the liver. Between 40 and 60 percent of the drug is excreted unchanged in the urine. The plasma half-life of the parent compound is 12 to 16 hours. There are no active metabolites. In persons with severely impaired renal function, the half-life increases up to 40 hours. The rate of clonidine metabolism is highest in young children (under age 6). In prepuberty it is still twice the adult rate, which is reached in midadolescence. The clinical significance of this rapid metabolism is the shortening of clonidine's behavioral activity and an increased risk of interdose withdrawal symptoms. In some cases in children it may need to be given four times a day. Both children and adults demonstrate considerable individual variation in the elimination half-life of clonidine.

Pharmacodynamics

Mechanism of Action Short-term administration of clonidine stimulates presynaptic a_2-autoreceptors. This effect is believed to account for the sedative and behavioral effects of the drug. Clonidine has additional central nervous system (CNS) activity that accounts for its overall clinical effects. It is a postsynaptic a_1-adrenergic receptor antagonist and it interacts with nonadrenergic binding sites termed imidazoline receptors. Clonidine has a high affinity for the I1 imidazoline receptor subtype. Clonidine stimulates locus coeruleus neurons through imidazoline receptors. It has been postulated that the interaction with imidazoline receptors contributes to clonidine's hypotensive effects. Both a_2-receptors and imidazoline receptors have also been found to be dysregulated in depression. Both receptors are also involved in mediating the therapeutic effects of some antidepressant drugs.

Administration of clonidine induces secretion of growth hormone through activation of a_2-receptors in the hypothalamus. The growth hormone response is extensively used as a probe to evaluate central noradrenergic function in both psychiatric and neurological disorders. It is presumed to represent an indirect measure of disturbed central adrenergic receptor function and a possible biologic marker of these disorders. Blunted growth hormone response to clonidine has been reported in some studies of patients who are depressed or have panic disorder. This finding among patients with major depressive disorder is presumed to reflect decreased responsiveness of postsynaptic a_2-receptors. Clonidine also fails to increase growth hormone concentration in rat strains that may represent a genetic model of depression. Long-term treatment with antidepressants restores clonidine's effect on growth hormone secretion in these animals. Untreated depressed patients show a

higher affinity of platelet a $_2$-receptors for clonidine than do healthy subjects. Studies also suggest that imidazoline receptors are dysregulated in depression. Chronic treatment with antidepressants normalizes platelet I1 binding sites.

Clonidine has also been used to measure stress response. Clonidine produces greater vasoconstriction and growth hormone release in males. This is of interest because it is consistent with observations that males exhibit more pronounced activation of the sympathoadrenal system after exposure to physiological stressors.

Nocturnal urinary growth hormone concentrations after a clonidine test is used to screen children with short stature for growth hormone deficiency.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Clonidine reduces peripheral sympathetic tone, lowers diastolic and systolic blood pressure, and causes bradycardia. Activation of central a $_2$-receptors results in a sleep-like state in animal studies. Clonidine causes sedation and sleep in humans. It increases slow-wave sleep, reduces rapid eye movement (REM) sleep time and percentage, and increases REM latency. The effects of clonidine on the gastrointestinal tract are minimal. It produces some reduction in basal gastric acid secretion. Clonidine has little effect on renal function.

THERAPEUTIC INDICATIONS

Clonidine is useful in a broad range of conditions seen in psychiatric and neurological practices. As a rule, clonidine is most beneficial in conditions that are associated with a hyperadrenergic state, such as treatment of opioid withdrawal and acute posttraumatic stress disorder. Tic disorders and attention-deficit/disorder represent other common uses in psychiatry.

Opioid Withdrawal Clonidine reduces the manifestations of adrenergic hyperactivity that accompany abrupt opioid withdrawal, including withdrawal from methadone. Signs and symptoms of opioid withdrawal include hypertension, tachycardia, dilated pupils, sweating, lacrimation, and rhinorrhea. The effectiveness of clonidine in treating opiate withdrawal is presumed to derive from its blockade of noradrenergic neurons of the locus coeruleus. Clonidine is best used in an inpatient setting, in part because side effects can be more readily managed. Hypotension can be particularly problematical and requires close monitoring.

Several oral clonidine protocols for opioid withdrawal are used (Table 31.16-1). The doses used to treat withdrawal symptoms are usually higher than those used to treat hypertension. Patients should be started on clonidine before discontinuation is begun, usually at a dosage of 0.1 to 0.2 mg four times a day. After stabilization for 2 to 3 days, the clonidine is tapered over 5 to 10 days. Clonidine can be used alone or combined with naltrexone for opioid detoxification. Other protocols use the transdermal clonidine patch (Table 31.16-1). Before being given the patch, patients should receive a test dose of oral or sublingual clonidine.

Clonidine 0.1–0.2 mg p.o. 4 times a day; hold for systolic blood pressure <90 mm Hg or bradycardia; stabilize for 2–3 days, then taper over 5–10 days

OR

Clonidine 0.1–0.2 mg p.o. q4–6h as needed for withdrawal signs or symptoms; stabilize for 2–3 days, then taper over 5–10 days

OR

Test dose with clonidine 0.1–0.2 mg p.o. or sublingually (for patients weighing over 200 lbs); check blood pressure after 1 h. If diastolic BP >70 mm Hg and no symptoms of hypotension, begin treatment as follows:

Weight (lb)	Number of clonidine patches
<110	2–3 TTS-1 patches
110–160	1 TTS-2 and 2 TTS-1 patches
160–200	2 TTS-2 patches
>200	2–3 TTS-2 patches

OR

Test dose of oral clonidine 0.1 mg; check BP after 1 h (if systolic blood pressure >90, do not give patch)

Place 2 TTS-2 clonidine patches (or 3 patches if patient weighs >150 lb) on hairless area of upper body; then

For first 24 h after patch application, give oral clonidine 0.2 mg q6h; then

For next 24 h, give oral clonidine 0.1 mg q6h

Change patches weekly

After 2 weeks of 2 patches, switch to 1 TTS-2 patch (or 2 TTS-2 patches if patient weighs >150 lb)

After 1 week of 1 patch, discontinue patches

Table 31.16-1 Oral Clonidine Protocols for Opioid Detoxification

Clonidine can reduce neonatal opioid abstinence at doses of 3 to 4 µg/kg. In contrast to acute withdrawal, the use of clonidine as an adjunct to gradual opioid withdrawal has not been established. It may have limited value in alleviating abstinence symptoms during the transitional period between opioid cessation and naltrexone.

Alcohol Withdrawal Some studies suggest that clonidine may reduce the severity of acute alcohol withdrawal. Symptoms of anxiety, diarrhea, headache, lightheadedness, and fatigue of the alcohol withdrawal syndrome may be decreased. However, both clinical experience and research data are limited. Most reported patients were in mild withdrawal. Its effects on reducing delirium and seizures are not known. Thus, clonidine may be useful as adjunctive therapy, mainly with benzodiazepines, but it is not recommended as monotherapy. A recent survey of inpatient alcohol treatment programs in the United States found that of all inpatients treated for alcohol withdrawal, 7 percent received clonidine. About 60 percent of these patients, by comparison, were prescribed benzodiazepines. Clonidine may have some limited value in the management of benzodiazepine withdrawal.

Acute Nicotine Withdrawal Clonidine is a possible alternative to nicotine replacement for smoking cessation. Anxiety, irritability, and craving associated with nicotine withdrawal have been reported to be decreased by clonidine. The transdermal patch is associated with fewer adverse effects and greater compliance.

Tourette's Disorder Although the results of clonidine in treating Tourette's disorder are mixed, some clinicians use the drug as a first-line agent for the treatment of Tourette's disorder because it does not have the serious side effects associated with the standard agents, haloperidol (Haldol) and pimozide (Orap). These include tardive dyskinesia and neuroleptic malignant syndrome. A double-blind placebo-controlled study has found clonidine alone to be of some value. Clonidine can decrease tic severity and frequency, impulsivity, and hyperactivity. The starting child dosage is 0.05 mg a day; it can be raised to 0.3 mg a day in divided doses. Three months are needed before the beneficial effects of clonidine can be seen in Tourette's disorder. Clonidine discontinuation may be associated with rebound agitation and tics.

Autistic Disorder Clonidine reduces irritability, impulsivity, and hyperactivity in children with autistic disorder, and a modest effect has been reported in aggressive children and hyperactive and impulsive children with autistic disorder. A modest effect has been reported when clonidine was used in conjunction with other medications in an adult with autism and intermittent aggressive behavior. Many patients developed tolerance to the therapeutic effects of clonidine after several months of treatment.

Attention-Deficit Disorders and Tic Disorder Children who are hyperactive, highly aroused, defiant, and labile have been reported to show improvement in mood, activity level, cooperation, and frustration tolerance. Sleep disturbances are also common in attention-deficit/hyperactivity disorder whether or not psychostimulants are used. Most children treated with clonidine for attention-deficit/hyperactivity disorder–associated sleep disturbances show significant improvement in the quality of their sleep. When used alone, clonidine is not effective in the treatment of inattention. Clonidine is typically used in combination with stimulants when there is nonresponse, partial response, or negative response to stimulants. It is also used when side effects limit optimal doses of a stimulant.

A typical total daily oral dosage is 0.3 mg as tolerated in divided doses, two to four times a day. One suggested approach is to start with a daily dosage of 0.05 mg and increase the dosage on a three-times-a-day or four-times-a-day basis until a response is obtained. Another strategy is to start with 0.025 mg four times a day. Most patients respond to dosages below 5 mg daily. Transdermal clonidine is a useful alternative when compliance is an obstacle to treatment.

The combination of clonidine with sympathomimetics has not been studied for safety and efficacy, but clinical experience suggests that use of these combinations benefits children with attention-deficit hyperactivity disorder who are unresponsive to other treatments. A potential benefit of combining clonidine with stimulants is improvement of sleep difficulties caused by the activating compounds late in the day. In published reports of dosing for this purpose, doses ranged from 50 to 800 µg.

Instances of sudden death in children taking both clonidine and methylphenidate (Ritalin) have been reported and extensively discussed in the scientific literature. The mechanism causing these deaths has not been identified. Evidence that these deaths were related to this combination of drugs is still viewed as tenuous.

Nevertheless, vital signs should be monitored whenever clonidine is used, because of its hypotensive effects. Electrocardiography is also reasonable, when clonidine is used alone or in combination with other drugs if abnormalities are found during the physical examination or if there is evidence or a history of preexisting heart disease. Alternatives to the clonidine-methylphenidate combination may also be considered. Dextroamphetamine can be substituted for methylphenidate, and guanfacine can be substituted for clonidine.

Posttraumatic Stress Disorder Hyperarousal is a main feature of posttraumatic stress disorder. The effectiveness of clonidine in this disorder is best established during short-term treatment. Clonidine alleviates exaggerated startle response and insomnia, nightmares, and other manifestations of hyperarousal in patients with posttraumatic stress disorder. It is used in both adults and children, and has been studied in children as young as age 3. When used in children, it also improves aggressiveness and other behavioral disturbances. Most children can be given an initial oral dose of 0.05 mg in the morning and, if this is well tolerated an additional 0.05 mg in the evening. Once the patient is stabilized, the daily dosage and the timing of each dose needs to be individualized. The usual total daily dosage is less than 2 mg.

Cognition Clonidine is reported to enhance cognition in young adult volunteers and patients with schizophrenia and Korsakoff's syndrome, possibly through enhancement of CNS noradrenergic responsiveness. Cognitive tasks associated with prefrontal cortex functions show the most improvement.

Mood Disorders Clonidine has a limited role in treating mania. Although open-label studies suggest that clonidine may be useful, controlled trials have failed to confirm these results and have been associated with a high dropout rate because of adverse effects, mainly rash and hypotension. When reported, the observed benefits have been short-lived. In animal models, abrupt withdrawal resulted in behaviors believed to be predictive of clinical depression in humans.

Anxiety Disorders Other potential indications for clonidine include the anxiety disorders. Panic disorder is postulated to involve central noradrenergic dysregulation. The a_2-adrenergic receptor antagonist yohimbine provokes apprehension and panic attacks, while clonidine antagonizes these anxiogenic effects, if only briefly. Clonidine partially attenuates lactate-induced panic attacks.

While better than placebo in some studies of panic disorder patients, clonidine has been shown to be less effective than standard antipanic agents. Limited evidence indicates that clonidine may produce short-term improvement of symptoms in obsessive-compulsive disorder, posttraumatic stress disorder, and generalized anxiety disorder.

Schizophrenia Clinical studies of clonidine monotherapy have produced conflicting results. One study, involving a small number of patients, found haloperidol combined with clonidine to have greater efficacy than haloperidol alone in the treatment of schizophrenia.

Anesthesia and Analgesia Intravenous clonidine is used as a preanesthetic medication. It has anesthetic properties—potentiating morphine-induced antinociception—and is used in association with local anesthetics in epidural anesthesia. Clonidine also provides a sedative effect.

Other Disorders Isolated reports describe successful use of clonidine in treating mental and neurological disorders including premenstrual syndrome, restless leg syndrome, tardive dyskinesia, and smoking cessation. Clonidine has been used for the treatment of aggressiveness in children.

Clonidine can reduce the excessive salivation associated with clozapine treatment. In these patients, use of the transdermal patch is recommended, since it provides clonidine at the time when hypersalivation is most prominent, during naps and nighttime sleep. Transdermal clonidine has been noted to be effective in the prophylaxis of episodic cluster headaches.

PRECAUTIONS AND ADVERSE REACTIONS

Hypotension and sedation are the two side effects that most often limit the use of clonidine, regardless of the condition being treated. No matter what the indication for clonidine use, it should be withheld if a patient becomes hypotensive (blood pressure less than 90/60).

Clonidine can worsen arrhythmias, so electrocardiogram (ECG) abnormalities or bradycardia should prompt a cardiac consultation before clonidine is administered. Sedation is especially problematical, since tolerance to this side effect does not typically occur, which limits dosage increases when tolerance to the therapeutic effects of the drug occurs. Sedation may also lead to paradoxical dyscontrol of aggression and impulsivity. Other common adverse effects associated with clonidine are dry mouth and eyes, dizziness, nausea, and constipation. Some patients experience sexual dysfunction. Uncommon CNS adverse effects include insomnia, anxiety, and depression; rare CNS adverse effects include vivid dreams, nightmares, and hallucinations. Clonidine may interfere with motor recovery after ischemic lesions.

Fluid retention may occur and can be treated with diuretics.

Patients who overdose on clonidine can present with coma and constricted pupils, symptoms that are also seen in an opioid overdose. Other symptoms of overdose are decreased blood pressure, pulse, and respiratory rates and irritability, lethargy, and seizures.

Clonidine should be used with caution for patients with heart disease, renal disease, Raynaud's syndrome, or a history of depression. Clonidine should be avoided during pregnancy and by nursing mothers because of its cardiovascular effects. There is no evidence that clonidine is associated with teratogenicity in animal studies. Elderly persons are more sensitive to the drug than are younger adults, and children and adults are susceptible to the same side effects. Although rare, instances of clonidine abuse occur.

Localized skin irritation may develop with use of the transdermal patch. Moving the patch from one site to another can minimize irritation. Some patients who developed localized contact sensitization to the patch developed a generalized rash when they were switched to oral clonidine.

WITHDRAWAL

Discontinuation of clonidine, especially if it is abrupt and follows long-term use, can result in a severe withdrawal syndrome characterized by apprehension, restlessness, abdominal pain, sweating, tremor, palpitations, and headache. There may be a rapid and severe rise in blood pressure. Withdrawal symptoms typically occur about 20 hours after cessation of use. Clonidine use must always be tapered when it is discontinued. Because of its short half-life, some patients experience withdrawal symptoms between doses.

DRUG INTERACTIONS

Coadministration of clonidine and tricyclic drugs can inhibit the hypotensive effects of clonidine. Trazodone (Desepyl) has the potential to produce hypotension and sedation when combined with clonidine. Any antihypertensive agent or drug that causes hypotension as a side effect may amplify blood pressure drops if coadministered with clonidine. Clonidine may also enhance the CNS depressive effects of barbiturates, alcohol, and other sedative-hypnotic agents. Concomitant use of b-adrenergic receptor antagonists can increase the severity of rebound phenomena, including hypertension, when clonidine use is discontinued. Yohimbine, an a_2-adrenergic receptor antagonist, blocks the pharmacological effects of clonidine. The reported sudden deaths of children taking concurrent methylphenidate and clonidine remains unexplained. They may represent isolated instances of children with preexisting cardiovascular abnormalities who either experienced adverse events unrelated to medication or had reactions to the clonidine alone.

LABORATORY INTERFERENCES

Clonidine is not known to interfere with any commonly used clinical laboratory tests.

DOSAGE AND ADMINISTRATION

Clonidine is available in 0.1-, 0.2-, and 0.3-mg tablets. The usual starting dosage, 0.1 mg orally twice a day, can be raised by 0.1 mg a day to an appropriate level.

Therapeutic dosages for hypertension commonly range between 0.2 and 1.2 mg a day. The maximum recommended daily dosage is 1.2 mg. When tolerance to the hypotensive effects of clonidine develops, the dosage should be increased or a diuretic be added. There is a dose-response curve.

The transdermal patch delivers 0.1, 0.2, or 0.3 mg every 24 hours and is applied every 7 days. Transdermal clonidine is sometimes useful to improve compliance. It also reduces fluctuations in clonidine plasma concentrations. The recommended starting dose for all adults is the lowest dose. The initial patch contains a dosage of 0.1 mg a day for both children and adults. The maximum dosage, which is determined by both clinical response and tolerability, is about 4 mg a day. The maintenance dosage for a child is 4.5 µg/kg daily, and for an adult is 8 µg/kg daily. The patch is effective for only 5 days in children—as opposed to 7 days in adults—because of more rapid hepatic metabolism.

SUGGESTED CROSS-REFERENCES

Alcohol-related disorders are discussed in Section 11.2, nicotine-related disorders in Section 11.4, and opioid-related disorders in Section 11.9. The biochemical aspects of mood disorders are covered in Section 14.3. Attention-deficit disorders are discussed in Chapter 39, and tic disorders in Chapter 42.

31.17 DOPAMINE RECEPTOR ANTAGONIST (TYPICAL ANTIPSYCHOTICS)

STEPHEN R. MARDER, M.D., AND DANIEL P. VAN KAMMEN, M.D., IH.D.

Before 1990 the traditional antipsychotic drugs were the only specific agents available in the United States for the treatment of psychosis. These agents are highly effective for nearly all disorders that result in psychotic thought processes. However, these drugs have important limitations: they can cause acute and chronic neurological symptoms that significantly limit their effectiveness; they are ineffective or only partially effective for a substantial proportion of psychotic patients; and they are relatively ineffective for some of the most important signs and symptoms of the most common psychotic illness, schizophrenia. A new generation of antipsychotic agents that includes clozapine (Clozaril), risperidone (Risperdal), sertindole (Serlect), olanzapine (Zyprexa), and other drugs may be less severely limited in all three of these areas. These agents have in common similar or greater activity at serotonin (5-hydroxytryptamine [5-HT]-type 2A) (5-HT $_{2A}$) receptors than at dopamine type 2 (D_2) receptors. In contrast, the therapeutic response to the traditional antipsychotics is thought to be associated with their antagonism at D $_2$ receptors. For this reason, the two groups of drugs can be designated dopamine receptor antagonists and serotonin-dopamine antagonists (SDAs). (The term *dopamine receptor antagonist* is a relatively new designation for these agents and is not widely accepted at the time of this publication.) Other terms, which are used interchangeably, are *traditional, conventional*, and *typical antipsychotic*. Since the SDAs have only recently become available, the relative indications for these two groups of agents are not firmly established. However, it remains likely that the use of dopamine receptor antagonist will decrease as the use of SDAs increases.

Despite their limitations, dopamine receptor antagonists have been important in the management of psychosis. The modern era of psychopharmacology began with the discovery of chlorpromazine (Thorazine), the first effective antipsychotic, in the early 1950s. The annual increase in state and county mental hospital beds in the United States that had occurred since the beginning of the twentieth century reversed shortly after the arrival of antipsychotics, because psychotic patients with schizophrenia and other illnesses could be discharged from hospitals after they received drug treatment. Moreover, patients with stabilized illnesses became candidates for psychosocial treatments and rehabilitation. Evidence also suggests that treatment with antipsychotics can improve the long-term course of schizophrenia.

The dopamine receptor antagonists are antipsychotic rather than antischizophrenic. That is, they are effective for treating psychosis, regardless of its cause. As a result, antipsychotics are standard treatments for many patients with secondary psychotic disorders, bipolar disorders, major depressive disorder with psychotic features, and schizoaffective disorder.

Although the introduction of the SDAs will reduce the proportion of patients receiving dopamine receptor antagonists, these agents will continue to be important for the treatment of psychosis. Under a number of conditions these agents will continue to be preferred for antipsychotic treatment. For example, currently, none of the SDAs is available as a long-acting agent or a short-acting intramuscular drug. Also, patients who respond well to dopamine receptor antagonists without discernable adverse effects may do as well on the less costly older drugs. Others may find that adverse effects of SDAs such as ejaculatory disturbances in men and weight gain are of greater concern than the extrapyramidal adverse effects associated with dopamine receptor antagonists. For these reasons psychiatric clinicians must remain familiar with this group of agents.

HISTORY

The first antipsychotic drugs were the phenothiazines. Drugs from this class were originally used as antihelminthics in veterinary medicine and as urinary antiseptics in humans. In 1950 Paul Charpentier at the Rhône-Poulenc Laboratories in Paris synthesized chlorpromazine, a mild antihistaminic that appeared notable as a sedating agent. Henri Laborit, a surgeon interested in drugs that would decrease preoperative anxiety and prevent postsurgical shock, convinced the Rhône-Poulenc laboratories of the importance of identifying compounds that would relax patients and make surgical shock less likely. Chlorpromazine appeared to fulfill these criteria, and also appeared qualitatively different from other sedating drugs. Patients appeared indifferent toward the environment and more tranquil. These properties led Laborit to attempt to convince psychiatrists, including Jean Delay and Pierre Deniker, to administer chlorpromazine to patients with mania and schizophrenia. In 1952 they reported that chlorpromazine was effective in treating mania and schizophrenia. Within a year, the atmosphere in Paris psychiatric hospitals had improved substantially. The discovery of chlorpromazine's effectiveness for psychosis marked the beginning of modern psychopharmacology by showing that drugs could have specific effects on the symptoms of mental disorders that went beyond sedation. Moreover, the availability of drugs with direct effects on mental disorders became a powerful tool for laboratory studies with animals; that is, understanding how drugs affect the brain could provide information on the illnesses that were affected.

The use of chlorpromazine was reported by Heinz Lehman from Montreal in 1954, and it rapidly captured the interest of U.S. psychiatrists. In 1955 Henry Brill, the assistant state mental health commissioner in New York, initiated the general use of chlorpromazine and reserpine in state hospitals in that state. Although reserpine was also an effective antipsychotic, its adverse effects led clinicians to prefer chlorpromazine, and as a result, it is rarely used for treating psychosis.

In 1953 reports surfaced indicating that chlorpromazine caused parkinsonian symptoms. Although some individuals warned that these symptoms were evidence of neural toxicity, others suggested that the dosage should be increased until patients experienced a mild form of parkinsonism. Later that year, clinicians noted that chlorpromazine could also elicit forms of persistent dyskinesia, a syndrome later called *tardive dyskinesia*.

The introduction of chlorpromazine was followed by the introduction of other phenothiazines including perphenazine (Trilafon) and fluphenazine (Prolixin). In 1958 the first effective butyrophenone, haloperidol (Haldol), was introduced by Paul Janssen from Belgium. The first thioxanthene antipsychotics were introduced the same year by P.V. Peterson and his coworkers.

Although many other dopamine receptor antagonists were introduced in subsequent years, they were all similar in effectiveness and differed only in their adverse-effect profiles. The first long-acting antipsychotic, fluphenazine enanthate was introduced in the early 1960s. Although this and subsequent long-acting agents were similar to other antipsychotics in effectiveness and adverse effects, they provided a way to administer an antipsychotic without requiring patients to take daily oral medication.

CHEMISTRY

The dopamine receptor antagonists have been referred to by a number of names including neuroleptics, antipsychotics, and major tranquilizers. The designation *neuroleptic* was suggested because of the tendency of these agents to have neurological adverse effects and thus to appear to “seize the neuron.” This term is based on the observation that neurological adverse effects are inevitably associated with the antipsychotic activity of these agents. However, the effectiveness of drugs such as clozapine suggests that neurological adverse effects are not necessary to treat psychosis; thus, referring to an adverse effect of these agents rather than the primary clinical effect may be misleading. The term *major tranquilizer* referred to the strange quietness or blandness (or ataraxia) that had been associated with these agents. However, the suggestion that these agents function by their tranquilizing effects is also misleading. These agents, as a group, can be most economically called *antipsychotic drugs*, thus referring to their target symptoms. Differentiating two classes of antipsychotics, the dopamine receptor antagonists and the SDAs, appears to be meaningful since it suggests a mechanism that underlies important clinical differences between these two groups of agents.

The dopamine receptor antagonists may be subclassified according to either their chemical structure or their clinical effects. In the section that follows these agents

will be classified according to their chemical structure. Another system for subclassifying this group uses the antipsychotic potency of these agents (Table 31.17-1). According to this system, agents are classified as low-, mid-, and high-potency agents. This method is probably more useful to clinicians because it provides information about the amount of drug required for a clinical effect and the likelihood of important adverse effects.

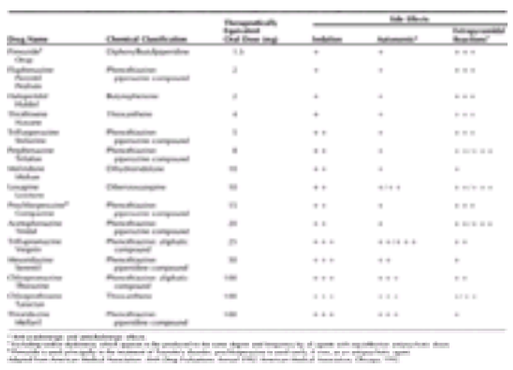

Table 31.17-1 Dopamine Receptor Antagonists: Potency and Adverse Effects

Phenothiazines All phenothiazines have the same three-ring structure with different side chains joined at the nitrogen atom of the middle ring (Fig. 31.17-1). Their activity can be affected by substitutions at positions 2 or 10. The phenothiazines are usually divided into three classes on the basis of substitutions at position 10. These substitutions have important effects on the pharmacological characteristics of the phenothiazine. Substituting an aliphatic side chain results in a drug with relatively low antipsychotic potency such as chlorpromazine. These agents also tend to be sedating and to cause anticholinergic and hypotensive effects at their effective dosages. Chlorpromazine has a chlorine atom at position 2. Eliminating the chlorine atom yields promazine, a weak antipsychotic. Substituting a piperidine ring at position 10 leads to an effective group of antipsychotics that includes thioridazine (Mellaril) and mesoridazine (Serentil). These drugs and the aliphatic phenothiazines have similar potencies and adverse-effect profiles. Fluphenazine and trifluoperazine (Vesprin) are representative antipsychotics with a piperazine group substituted at the 10 position. Piperazine phenothiazines have fewer anticholinergic and autonomic effects but greater affinity for D_2 sites, and as a result they produce more extrapyramidal adverse effects. A number of piperazine phenothiazines have been esterified at a free hydroxyl group with ethanoic or decanoic acid to produce injectable, long-acting antipsychotics.

Figure 31.17-1 Molecular structure of dopamine receptor antagonists and reserpine.

Thioxanthenes The thioxanthenes share a similar three-ring structure with the phenothiazines but with a carbon atom substituted for nitrogen at position 10. Chlorprothixene is an effective low-potency aliphatic thioxanthene agent with antipsychotic potency and an adverse-effect profile similar to those of its phenothiazine counterpart, chlorpromazine. Thiothixene (Navane), clopenthixol (not marketed in the United States), and flupenthixol (not marketed in the United States) are thioxanthenes with a piperazine substitution. Again, their clinical characteristics resemble those of their phenothiazine counterparts. As a result of their double bond at position 10, these agents have geometric isomers; the *cis* isomers demonstrate greater antipsychotic activity.

Butyrophenones Butyrophenones are characterized by a substituted phenyl ring attached to a carbonyl group that is linked by a 3-carbon chain to a tertiary amino group. Most of the clinically useful butyrophenones have a piperidine ring attached to the tertiary amino group. Haloperidol is the representative drug for this class. It and other butyrophenones tend to be potent D_2 antagonists with minimal anticholinergic and autonomic effects. Haloperidol, a substituted piperidine, is the most commonly used drug from this class. Other important butyrophenones include droperidol (Inapsine), a short-acting, sedating compound commonly used to control agitation, and spiperone, an agent with a very high affinity for D_2 receptors, commonly used to label receptors in animal studies and in positron emission tomography (PET) scanning.

Dibenzoxazepines Dibenzoxazepine antipsychotic drugs have a three-ring structure with a seven-member center ring. Loxapine (Loxitane) is the only drug from this group that is available in the United States. Clozapine, a dibenzodiazepine, serotonin-dopamine antagonist, differs from loxapine in having a nitrogen instead of an oxygen atom in the middle ring, as well as differences in the side chains.

Dihydroindoles The dihydroindoles are structurally related to serotonin, melatonin, and indole hallucinogens such as dimethyltryptamine. The only dihydroindole available in the United States is molindone (Moban).

Diphenylbutylpiperidines The diphenylbutylpiperidines are similar in structure to the butyrophenones. Pimozide (Orap), the only diphenylbutylpiperidine available in the United States, is derived from the butyrophenone benperidol. Penfluridol and fluspirilene are antipsychotics from this group that are available outside of the United States.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics The antipsychotic drugs come from a number of chemical classes, each with somewhat different pharmacokinetic properties (Table 31.17-2 and Table 31.17-3), which can have important effects on the clinical use of the drugs. The phenothiazines and the thioxanthenes share structural similarities and have a number of shared metabolic pathways. The same is true for the butyrophenones and the diphenylbutylpiperidines. This overview focuses on chlorpromazine and haloperidol as representative compounds. Since the pharmacokinetics of the long-acting agents differ substantially from those of the short-acting agents, they are discussed separately.

Drug	Bioavailability (%)	Protein Binding (%)	Vd (L/kg)	$t_{1/2}$ (h)	Active Metabolites	Plasma Concentration 12 Hours Postdose (ng/mL)
Chlorpromazine	≤10–15	90–95	7–20	8–15	7-Hydroxy, others	100–300
Thioridazine	25–35	99	–	5–10	Mesoridazine, sulforidazine	200–800
Perphenazine	~25	90–95	10–15	8–12	None known	0.5–5.0
Fluphenazine	20–50	90–95	–	14–24	7-Hydroxy*	0.2–2.0
Thiothixene	~30	90–95	–	34	None known	1.0–5.0
Haloperidol	45–70	92	10–15	12–36	Reduced haloperidol	2.0–10.0
Fluspirilene	45–60	90–93	12–24	22–36	None known	1.0–10.0

Table 31.17-2 Comparison of the Pharmacokinetics of Different Antipsychotics

Age
Elderly patients demonstrate greater variability in drug clearance
The "super-elderly" (those greater than 80 years of age) demonstrate the most consistent reduction in clearance rates
Genetics
Polymorphism at CYP 2D6 and CYP 2C19
Wide intrapatient variability at CYP 3A
Ethnic differences in metabolism
Substance abuse behaviors
Cigarette smokers demonstrate increased metabolic capacity, CYP 1A2
Ethanol abusers can demonstrate increased or diminished metabolic capacity dependent on the extent of their drinking behavior and their hepatic and nutritional status
Medical conditions
Decreased hepatic blood flow can reduce clearance, e.g., congestive heart failure
Hepatic disease such as cirrhosis and hepatitis can decrease clearance
Enzyme inducers
Carbamazepine, phenytoin, ethanol/etoh, barbiturates
Clearance inhibitors
Examples include: serotonin selective reuptake inhibitors, tricyclic antidepressants, cimetidine, beta-blockers, isoniazid, methylphenidate, erythromycin, triazolobenzodiazepines, chloramphenicol, ciprofloxacin, ketoconazole, and many others
Changes in binding proteins
Stress (acute phase reactants increase such as α_1 acid glycoprotein increase)
Hypoalbuminemia can occur with malnutrition or hepatic failure
Changes in protein binding occur due to hepatic or renal failure

Table 31.17-3 Variables That Influence the Pharmacokinetics of Antipsychotics

Plasma concentrations of short-acting drugs rise rather rapidly during the so-called absorption phase and then decline during the distribution, metabolic, and elimination phases. Each of these three latter phases is influenced by different factors related to the chemical structure of the agent.

Absorption In general, the dopamine receptor antagonists are well absorbed when they are administered orally or parenterally. As with most drugs, oral administration results in less-predictable absorption than parenteral administration. Liquid concentrates are absorbed slightly more rapidly than pills. Plasma concentrations of the drugs usually peak 1 to 4 hours after ingestion and 30 to 60 minutes after intramuscular administration. In general, intramuscular preparations reach their peak concentrations faster than oral drugs and thus have an earlier onset of action. For example, intramuscular administration of most antipsychotics results in peak plasma concentrations in about 30 minutes, with clinical effects apparent within 15 to 30 minutes. Most orally administered dopamine receptor antagonists result in peak plasma concentrations 1 to 4 hours after administration. A number of factors can interfere with gastrointestinal absorption of these drugs, including antacids, coffee, smoking, and food.

Drug concentrations usually reach steady state in about 3 to 5 times their half-lives. Thus, steady-state levels for chloropromazine, haloperidol, and most other dopamine receptor antagonists are reached in about 3 to 5 days, since their half-lives are about 24 hours. The bioavailability (i.e., the amount of drug reaching the systemic circulation) increases substantially—as much as 10-fold—when dopamine receptor antagonists are administered parenterally. This difference may reflect incomplete absorption of the drug in the gastrointestinal tract and extensive metabolism of oral drugs during the first pass through liver and gut.

Distribution The initial decline in the plasma concentration of an antipsychotic (or any drug) results primarily from drug distribution into various bodily compartments. Since antipsychotics are highly lipophilic, they tend to accumulate in tissues such as fat, lungs, and brain. Brain concentrations of antipsychotics tend to be substantially higher than those in plasma. Since plasma and brain concentrations are in equilibrium, measuring plasma levels concentrations suffices for estimating concentrations in brain.

Most dopamine receptor antagonists are highly protein bound. For example, more than 90 percent of drugs such as fluphenazine and haloperidol is bound to plasma protein. The remaining unbound portion is the drug available to pass through the blood-brain barrier. In theory, conditions that alter the amount of plasma protein (e.g., malnutrition) alter the amount of bioavailable antipsychotic drug.

Metabolism and Elimination The metabolism of antipsychotic drugs is largely hepatic and occurs through conjugation with glucuronic acid, hydroxylation, oxidation, demethylation, and sulfoxide formation. The metabolism of the phenothiazines and thioxanthenes is particularly complex. For example, chlorpromazine has more than 100 different potential metabolites, with some metabolites having significant amounts of pharmacological activity. For thioridazine, a substantial amount of the drug's activity is from metabolites that may be more active than thioridazine itself. One metabolite, mesoridazine, is also marketed as an antipsychotic. On the other hand, haloperidol has only one major metabolite, reduced haloperidol, which has substantially less antidopaminergic activity than the parent compound. However, reduced haloperidol is converted back to the parent compound and thus may contribute to antipsychotic activity.

Most dopamine receptor antagonists are metabolized by the cytochrome P450 (CYP) 2D6 and CYP 3A isoenzymes. Since these same isoenzymes also metabolize a number of drugs that are commonly used in combination with antipsychotics, a number of important drug-drug interactions are possible.

Patients demonstrate substantial differences in the extent to which they metabolize these compounds, which explains, in part, the marked differences among patients in the oral dosages required. This, along with differences in absorption, may also explain the 20-fold variation in plasma concentrations found among patients treated with the same dosage of an antipsychotic.

The systemic clearance of dopamine receptor antagonists is high because of a high hepatic extraction ratio. As a result, only negligible amounts of the unchanged drug are excreted by the kidneys. Phenothiazines, thioxanthines, and their metabolites are excreted in the urine and the feces.

Pharmacokinetics of Long-Acting Antipsychotics The pharmacokinetics of long-acting injectable antipsychotics differ markedly from those of short-acting oral and injectable drugs. Long-acting fluphenazine and haloperidol are administered as esters dissolved in sesame oil. The oil is injected into a muscle, and the drug gradually diffuses from the oily vehicle into the surrounding tissues. The rate-limiting step appears to be the rate of diffusion; once the drug enters the tissue, it is rapidly hydrolyzed and the parent compound is released. Long-acting compounds, on the other hand, are absorbed continually during the interval between injections. Moreover, patients who have received multiple injections absorbed the drug from multiple injection sites simultaneously. As a result, it takes long-acting compounds much longer to reach steady state, and they are eliminated much more slowly. For example, the decanoate forms of haloperidol and fluphenazine require about 3 months to reach steady state, and substantial plasma concentrations can be detected months after therapy has been discontinued.

Elderly Patients Elderly patients require lower-than-usual dosages of dopamine receptor antagonists for a number of reasons, including decreased renal clearance, decreased cardiac output, decreased liver size, and decreased P450 activity. In addition, elderly patients may be more sensitive to the parkinsonian adverse effects of the drugs.

Pharmacodynamics The pharmacodynamics of an antipsychotic describe its activity at important sites of action, particularly at its brain receptors. Neuroscience research has recently provided important information about the effects of dopamine receptor antagonists at a number of different receptor sites, how these effects influence groups of neurons, and how activity at receptors is translated into intracellular events.

Mechanism of Action of Dopamine Receptor Antagonists

Dopamine Hypothesis The dopamine hypothesis states that antipsychotics reduce psychotic symptoms by decreasing dopamine activity. It was originally proposed by Arvid Carlsson from Sweden and other basic scientists, based on the observation that haloperidol and chlorpromazine increased the concentration of dopamine metabolites in dopamine-rich areas of the mouse brain and had inconsistent effects on other neurotransmitters. They interpreted these findings as indicating that these two agents were acting as dopamine antagonists and that self-regulating systems were compensating by increasing dopamine production. Other investigators noted that dopamine receptor antagonists inhibited amphetamine-induced activation and stereotypical behaviors of rodents. This effect has been found to be a reasonably reliable predictor of antipsychotic activity in humans. Moreover, the dose-response relation in animals provides information about the likely clinical dosage range for patients. These behaviors are thought to be mediated by dopamine and have been used to screen for compounds that are likely to have clinical efficacy as antipsychotics. Other evidence supporting a role of dopamine in psychosis comes from the observation that all drugs—at least to date—capable of reducing psychosis are also dopamine receptor antagonists. Moreover, agents associated with increased dopamine activity such as amphetamines, methylphenidate (Ritalin), or cocaine tend to increase dopamine neurotransmission or are themselves dopamine agonists.

A role for dopamine in the activity of antipsychotics was given strong support by the work of Solomon Snyder from Johns Hopkins University and Philip Seeman from the University of Toronto in the mid 1970s. Using similar receptor binding methods, both found that the antipsychotic potency of a number of drugs was highly correlated with the drug's affinity for D_2 receptors. Recent studies using highly selective D_2-receptor ligands and PET indicate that dopamine receptor antagonists are effective when approximately 80 percent of D_2 receptors in the brain are occupied (Table 31.17-4). Higher occupancy rates may be associated with more adverse effects without greater effectiveness. In contrast clozapine is effective when only 40 to 60 percent of D_2 receptors are occupied. Although why clozapine is effective at lower levels of D_2 occupancy is unclear, it has been suggested that activity at other receptors, particularly 5-HT_{2A} receptors, may contribute to clozapine's clinical activity (Fig. 31.17-2).

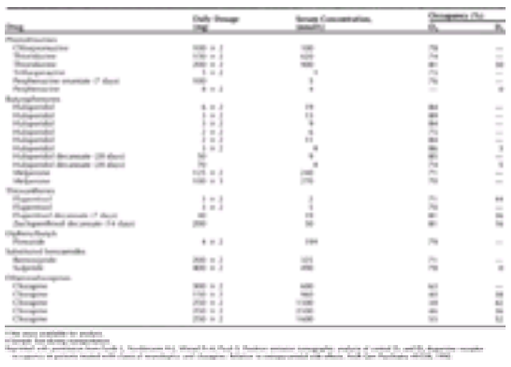

Table 31.17-4 Dopamine Receptor Occupancy of Antipsychotics in Recent Studies

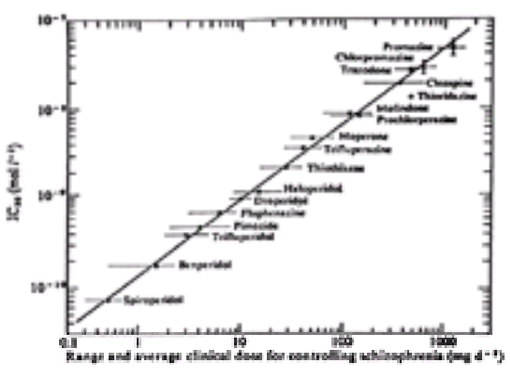

Figure 31.17-2. Blockade of dopamine release. (Reprinted with permission from Seeman P, Lee T: Antipsychotic drugs: Direct correlation between clinical potency and presynaptic action on dopamine neurons. Science *188:*1217, 1975.)

Other studies using PET scanning have found no difference in D_2 receptor occupancy in the striatum between individuals who respond to an antipsychotic and those who do not. This finding suggests that processes beyond the dopamine receptor affect response or that dopamine blockade in the striatum does not mediate behavior change.

Effects of Dopamine Receptor Antagonists on the Dopamine System Dopamine neurons with cell bodies in the ventral tegmental area (the A_{10} cell group in rat brain) project via the mesolimbocortical dopamine system to the nucleus accumbens, amygdala, and the neocortex. Dopamine cells in the substantia nigra (the A_9 cell group) project to the caudate putamen via the nigrostriatal system. It has been proposed that activity in the mesolimbocortical system explains the antipsychotic activity of drugs whereas neurological adverse effects such as extrapyramidal effects and tardive dyskinesia result from activity in the nigrostriatal system. Thus drugs with preferential activity at mesolimbocortical sites would exhibit clinical effectiveness with fewer neurological adverse effects.

Recent advances in molecular biology have permitted cloning of a number of dopamine receptor subtypes. The discovery of these subtypes has raised the question of their possible role in the treatment of psychosis. Dopamine receptors can be classified into two groups, D_1-like (D_1 and D_5) and D_2-like receptors (D_2, D_3, D_4). Moreover, each of these receptor subtypes may have variants, which can potentially explain heterogeneity in drug responses. The antipsychotic potency of dopamine receptor antagonists is highly correlated with their affinity for D_2 receptors. This relationship has not been established with other dopamine receptor subtypes. Nevertheless, certain characteristics of receptor subtypes suggest that they may contribute to clinical responses. For example, a role for D_4 receptors has been suggested by clozapine's high affinity for this subtype. Also, the distribution of D_1 receptors in cortical areas and the localization of D_3 receptors in limbic areas suggest that these subtypes may be clinically important for antipsychotic effects.

Recent studies of the dopamine system in animals and man have suggested important interactions between the subcortical and prefrontal dopamine systems that may affect responses to dopamine receptor antagonists. Lesions in the prefrontal cortex of rats increase dopamine activity in the striatum, suggesting important functional linkages. Similarly, increases in dopamine activity in the prefrontal cortex are associated with decreases in striatal activity. A number of investigators have proposed that negative symptoms of schizophrenia are associated with decreased dopamine receptor antagonist prefrontal activity, while positive symptoms are generated by subcortical increases in dopamine receptor antagonist activity. In this model, an effective antipsychotic would increase dopamine receptor antagonist activity in prefrontal areas and decrease activity in subcortical areas.

Other clinical evidence for a role of dopamine in the antipsychotic effects of dopamine receptor antagonists comes from studies of homovanillic acid, a metabolite of dopamine. In these investigations, changes in plasma concentrations of homovanillic acid in patients taking antipsychotics are assumed to reflect changes in dopamine activity in the brain. These studies indicate that plasma homovanillic acid concentration rises soon after patients begin treatment with an antipsychotic and then falls below the pretreatment concentration in patients who improve. Moreover, a number of studies indicate that patients with a high concentration of homovanillic acid in plasma prior to drug treatment are more likely to improve than those with low concentrations. These findings suggest that improvement on an antipsychotic agent is associated with an overall reduction in dopamine activity. Since subcortical areas contribute most to dopamine activity in the brain, this finding may not reflect cortical dopamine activity.

Studies that monitor the intracellular firing rates of dopamine neurons have also improved understanding of the effects of antipsychotics. L.A. Chiodo and Benjamin S.

Bunney reported that administration of haloperidol to rats results in a short-term increase in the firing of midbrain dopamine neurons followed by a prolonged decrease in firing, referred to as “depolarization inactivation.” It has been proposed that the antipsychotic effects of these drugs is associated with the decreased firing. Taken together with the studies of plasma homovanillic acid concentration, these findings suggest that an antipsychotic response requires the blockade of D_2 receptors followed by a decreased dopamine activity.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Design The dopamine receptor antagonists were the first specific compounds for treating a major mental illness. Their effectiveness challenged the views of some clinicians who believed that psychosis was a psychological reaction related to early experiences and that only psychological treatment could have antipsychotic effects. This skepticism helped inspire the development of controlled clinical drug trials aimed at demonstrating the effectiveness of antipsychotics. Early studies, such as those developed by the Veterans Administration and the National Institute of Mental Health (NIMH) were influential in establishing objective research methods. From those trials a number of principles emerged that have guided the study of antipsychotics and other drugs in psychiatry and medicine.

One principle is that to be considered effective, an antipsychotic or any other drug should yield a better outcome than a placebo. That principle controls for nonspecific improvement that occurs because of such factors as (1) spontaneous fluctuations in symptoms; (2) the rate of spontaneous improvement for the illness; (3) the expectation of improvement, which is related to starting treatment with a new drug; (4) the subject's protection from environmental stresses that may occur with hospitalization; and (5) other environmental factors such as the hospital milieu and psychological treatments that can lead to improvement.

Two other principles that reduce sources of bias are random assignment to a treatment group and double-blind methods. Random assignment ensures that differences in outcome between groups (usually between those receiving a drug and those receiving a placebo or between two different active-treatment groups) is not attributable to patients with different expected outcomes or drug responses being assigned to one group. (For example assigning more severely ill patients or those predicted to improve spontaneously to a particular group.) Double-blind methods were developed to ensure that bias by patients or by those who evaluate the outcome does not influence the study. (For example, a person who performs a clinical rating might rate patients receiving a drug as more improved than those receiving a placebo.) Double-blind methods also protect against bias in the way treatment is administered. (For example, a treating clinician might give more attention to a patient who is receiving a certain drug.)

A number of modifications in trial methods have been developed since the first studies of dopamine receptor antagonists, although the principles of random assignment and blindness remain important. For example, treating acutely ill patients with schizophrenia with dopamine receptor antagonists has become a standard of care and has led some to question the use of placebos. Alternative methods for demonstrating the efficacy of a compound include showing that it is as effective as an antipsychotic agent with proved efficacy or showing that a dosage thought to be subtherapeutic is less effective than a higher dosage. Since blindness is often difficult to preserve when a drug has known adverse effects, active placebos with side effects but without central nervous system (CNS) effects have been used.

Interpretation

Acute Psychosis Numerous double-blind studies have demonstrated that dopamine receptor antagonists are more effective than placebos for relieving symptoms of psychosis. The most compelling studies were carried out in the 1960s by the NIMH and have been replicated by many research groups since then. These studies also demonstrated that antipsychotics are effective for every subtype and subgroup of patients with schizophrenia. In 1995 the Schizophrenia Patient Outcomes Research Team (PORT) updated prior reviews and concluded that dopamine receptor antagonists are clearly effective in reducing positive symptoms during acute psychotic episodes. Donald Klein and John Davis reviewed studies that compared more than one antipsychotic and found that with the exception of mepazine and promazine, all of these agents were equally effective.

Controlled clinical trials have demonstrated that antipsychotic medications are effective in diminishing most symptoms of schizophrenia. Thus, symptoms such as hallucinations and paranoid ideation are improved by these agents whereas anxiety and depression are relatively unaffected. The extent to which patients improve on these agents varies considerably. Dopamine receptor antagonists can lead to complete remission of psychotic symptoms. Studies from the NIMH indicate that 60 percent of drug-treated patients achieve a complete remission or experience only mild symptoms; the remaining 40 percent continue to experience psychotic symptoms. Approximately 8 percent of patients do not improve with drug treatment. The 1995 PORT found that dopamine receptor antagonists can induce remission of positive symptoms in about 70 percent of patients.

The so-called positive or psychotic symptoms—which include hallucinations and delusions—are more responsive to dopamine receptor antagonists than are negative symptoms such as blunted affect, emotional withdrawal, and lack of social or vocational interest or disorganized symptoms such as impaired attention and disorganized thought processes. Although the latter two groups of symptoms are less responsive than psychotic symptoms, double-blind studies indicate that they do improve to some degree. However, the responses are complex. Extrapyramidal effects can cause negative symptoms or worsen them. Patients with parkinsonism may demonstrate fewer expressive gestures and diminished interest in their environment. Anticholinergic antiparkinson medications may impair memory in patients who require these drugs to treat parkinsonism and other extrapyramidal adverse effects.

All forms and types of schizophrenia improve with dopamine receptor antagonists. Moreover, no evidence suggests that any particular subtype of schizophrenia responds better to a particular type of antipsychotic. Although it was proposed that low-potency, sedating dopamine receptor antagonists were more effective for agitated patients and high-potency, nonsedating drugs were more effective for more-withdrawn patients, this was never substantiated in controlled trials. As a group, female patients tend to respond better and to require lower dosages than male patients. Unfortunately, the only indicator that can be used to predict patient response to an antipsychotic is the patient's prior responses.

Maintenance Therapy A number of studies have compared the ability of dopamine receptor antagonists and placebos to prevent relapse in patients who have been stabilized following a psychotic episode. These studies provide strong support for continued dopamine receptor antagonist treatment after patients have recovered from a psychotic episode. A review of 24 double-blind studies of maintenance antipsychotic therapy found that in all studies many more patients relapsed on placebo compared to those who received an antipsychotic drug. A meta-analysis that included most of these studies reported that approximately 72 percent of patients relapsed in a year when given a placebo compared with only 23 percent of those given a conventional antipsychotic. A more recent review cited 66 studies in which antipsychotic use was discontinued. The mean relapse rate was 53 percent for patients withdrawn from medication and 16 percent for patients maintained on antipsychotic treatment.

A number of recent investigations have focused on the usefulness of continuing medication for patients who have recovered from a first episode of schizophrenia. Again, maintenance medication bestowed a substantial advantage, although relapse rates were lower for first-episode patients than for multiepisode patients. Other studies indicate that patients who have been well and stable on antipsychotic therapy for years have a high likelihood of relapse when their medications are discontinued.

Studies by Donald Johnson suggest other advantages for maintenance antipsychotics in schizophrenia. He found that patients who relapsed when they were receiving dopamine receptor antagonists had episodes that were less severe than those in patients who had discontinued taking their drugs. Drug-maintained patients were less likely to have episodes with self-destructive behaviors, violence, and antisocial acts than patients who were not receiving medication. Patients who were not receiving medication were also more likely to require involuntary hospitalization. Patients who discontinued their medications ended up, on average, receiving more total medication because the dosage needed to treat acute relapses is much higher than the dosages usually prescribed for preventing relapse.

A number of statistics also indicate the limitations of pharmacotherapy for chronic schizophrenia. Because medication compliance is a serious problem for patients with schizophrenia, up to 50 percent of patients fail to comply with recommended treatments. Even when patients respond to treatment, 10 percent are permanently disabled. In addition, more than 80 percent of patients are not fully employed and require public support. In large cities, individuals with schizophrenia comprise 14 to 50 percent of the homeless. The rate of completed suicide is about 10 percent, and the mortality rate is increased because of greater accident proneness.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Effects on Motor Systems Animals given high doses of a dopamine receptor antagonist develop a syndrome with immobility, increased muscle tone, and abnormal postures called catalepsy. In addition, these agents decrease spontaneous motor activity in rodents. These motor effects in animals and humans are caused by dopamine receptor blockade in the striatum and inactivation of dopamine neurons in the substantia nigra.

In humans, all of the traditional antipsychotic medications produce extrapyramidal adverse effects including parkinsonism (i.e., stiffness, tremor, and shuffling gait), dystonia (i.e., abrupt onset, sometimes bizarre muscular spasms affecting mainly the musculature of the head and neck), and akathisia (i.e., objective and subjective restlessness). In addition, prolonged treatment with dopamine receptor antagonists can lead to the development of late-appearing abnormal movements called tardive dyskinesia.

Neuroendocrine Effects Antipsychotic drugs influence the secretion of hormones in the pituitary and elsewhere, mainly because of their blockade of dopamine receptors. Dopamine—either through the blockade of receptors in the hypothalamus or in the pituitary itself—affects the secretion of a number of hormones, particularly prolactin. Prolactin secretion is tonically inhibited by dopamine. As a result, dopamine receptor antagonists increase serum prolactin concentration in the usual clinical dose range, and this ability is correlated with their antipsychotic potency. Increased prolactin secretion sometimes produces gynecomastia and galactorrhea. Dopamine receptor antagonists also suppress luteinizing hormone (LH) and follicle-stimulating hormone concentrations. These changes can lead to amenorrhea and inhibition of orgasms in women. Evidence also indicates that dopamine receptor antagonists can inhibit the release of growth hormone (GH).

THERAPEUTIC INDICATIONS

Indications for dopamine receptor antagonists are shown on Table 31.17-5.

Acute psychotic episodes in schizophrenia and schizoaffective disorder
Maintenance treatment in schizophrenia and schizoaffective disorders
Mania
Depression with psychotic symptoms
Delusional disorder
Borderline personality disorder
Substance-induced psychotic disorder
Delirium and dementia
Mental disorders due to a medical condition
Childhood schizophrenia
Pervasive developmental disorder
Tourette's disorder
Huntington's disease

Table 31.17-5 Indications for Dopamine Receptor Antagonists

Acute Psychotic Episodes in Schizophrenia and Schizoaffective Disorder Schizophrenia is usually characterized by periods of relapse and remission. Acute psychotic episodes are periods during which patients demonstrate the emergence or worsening of positive or disorganized symptoms of schizophrenia such as hallucinations, delusions, and disorganized thoughts.

Maintenance Treatment in Schizophrenia and Schizoaffective Disorders Dopamine receptor antagonists are effective in decreasing the risk of psychotic relapse in patients who have recovered from a psychotic episode. An international consensus conference on guidelines for relapse prevention recommended that patients who had multiple prior psychotic episodes continue maintenance therapy for at least 2 to 5 years and often indefinitely. One to 2 years of maintenance treatment was recommended for patients following a first episode of psychosis.

Mania Dopamine receptor antagonists are effective in reducing excitement and psychotic symptoms in mania. These agents tend to have a more rapid onset of action than antimanic drugs including lithium (Eskalith), valproic acid (Depakene), and carbamazepine (Tegretol). This observation has led to the widespread practice of using combined treatment with antipsychotic and antimanic drugs during the first days of treatment of severe excited states, before the antimanic compound has its onset of action. When the antimanic compound has become effective, the dosage of antipsychotic can usually be reduced or use of the drug can be discontinued. Although only limited evidence supports the use of antipsychotics for long-term management of bipolar disorder, it is common clinical practice to manage some patients with severe illness with maintenance antipsychotics combined with antimanic agents. Some studies indicate that patients with mood disorders are more apt to develop tardive dyskinesia than patients with schizophrenia, suggesting the importance of using these drugs for as short a time as possible and only when clearly indicated.

Depression With Psychotic Symptoms Patients with major depressive disorder may develop psychotic symptoms such as hallucinations or delusions. These patients tend to exhibit faster improvement when an antipsychotic is added to an antidepressant agent. Although most studies have focused on perphenazine, fluphenazine, and haloperidol, no evidence suggests that any dopamine receptor antagonist is more effective than any other for this indication. The added benefits of dopamine receptor antagonists are most apparent for patients tormented by severe delusions. When the psychotic symptoms have remitted, antipsychotic use should be discontinued.

Delusional Disorder Delusional disorder is characterized by nonbizarre delusions, that is delusions within the realm of possibility for the patient. Moreover, patients with this disorder seldom hallucinate, and their behavior is seldom bizarre. Patients with delusional disorder often improve substantially when they are treated with a dopamine receptor antagonist.

Borderline Personality Disorder Borderline personality disorder is characterized by a pervasive pattern of instability that affects mood, interpersonal relationships, and self-image. Some patients with severe forms of this disorder may experience transient psychotic states, particularly when they are under stress. These states may be characterized by suspiciousness, ideas of reference, impulsiveness, and aggressiveness.

Low dosages of thiothixene and haloperidol have been found effective in some of these patients, and no evidence indicates that other dopamine receptor antagonists are less effective. Unfortunately, most trials have been relatively brief, and it is unclear how medications affect the overall course of this disorder or how they interact with the psychotherapeutic management these patients usually require.

Substance-Induced Psychotic Disorder A number of drugs including amphetamines, cocaine, alcohol, and phencyclidine can cause psychotic symptoms while the patient is intoxicated or during drug withdrawal. These symptoms are usually time limited and remit within hours or days, depending upon the concentration of the drug ingested and the rate of elimination of the agent. Although dopamine receptor antagonists may reduce psychotic symptoms, most of these episodes do not require treatment with antipsychotics unless the symptoms cause dangerous behaviors or unusual suffering. Benzodiazepines may help calm the patient until psychotic symptoms remit. Some authors recommend prescribing benzodiazepines rather than dopamine receptor antagonists for phencyclidine intoxication. In some circumstances it may be helpful to follow the patient's untreated course, to differentiate drug-induced syndromes from schizophrenia or bipolar I disorder.

Dopamine receptor antagonists are also useful for patients with hallucinations or delusions that occur with alcoholism, particularly chronic alcoholic hallucinosis. They should be prescribed carefully since these drugs may increase the likelihood of seizures that occur during alcohol withdrawal. As a result, benzodiazepines are more appropriate than antipsychotics for uncomplicated alcohol withdrawal.

Delirium and Dementia Low dosages of high-potency dopamine receptor antagonists can be useful in the treatment of the psychotic symptoms and agitation associated with delirium that may be due to organic conditions. Interactions with the anticholinergic properties of low-potency drugs may exacerbate or prolong toxic deliriums caused by anticholinergic agents.

Dopamine receptor antagonists can be useful for reducing agitation and psychotic symptoms related to dementia, Wernicke's encephalopathy, and Korsakoff's syndrome. A number of careful double-blind studies have found these drugs superior to placebo for treating agitated elderly patients. A review by Philip Janicak found that 66 percent of geriatric patients with organic psychosis improved when given an antipsychotic (versus 35 percent of those given a placebo). Low dosages of high-potency dopamine receptor antagonists are usually preferable for elderly patients with dementia. Low-potency medications can cause orthostatic hypotension and falling episodes. In addition, the anticholinergic effects of low-potency drugs can worsen cognitive and memory impairments. The treatment of elderly patients is complicated since many receive multiple medications and are vulnerable to drug-drug interactions. Nevertheless, the adverse effects of these drugs should be

weighed against the dangers of agitation in elderly patients.

Mental Disorders Due to a Medical Condition Dopamine receptor antagonists are effective for a broad range of medical conditions that result in psychosis. This category includes endocrinopathies and psychoses associated with temporal lobe epilepsy. Dopamine receptor antagonists are also helpful for patients with psychotic symptoms that result from steroid use.

Early-Onset Schizophrenia Schizophrenia infrequently has its onset during childhood. Children with schizophrenia may have symptoms similar to those in adults with schizophrenia. Although clinical experience indicates that children improve with antipsychotics, few controlled trials are available to demonstrate this effect. Children must be treated with the lowest effective dosage of an antipsychotic, since these drugs may impair learning.

Pervasive Developmental Disorders Patients with pervasive developmental disorders (e.g., autistic disorder) may display periods of hyperactivity, screaming, and agitation with combativeness. Although few controlled studies exist for this disorder, patients tend to improve with high-potency agents. Since these agents may impair learning, there is concern that they are overprescribed in some settings.

Impulse-Control Disorders Prescribing dopamine receptor antagonists for individuals with extremely poor impulse control and a propensity for violent behavior is a long-standing, but controversial, practice. This practice is not supported by controlled clinical trials and may be appropriate only when other measures such as the use of carbamazepine, lithium, or b-adrenergic receptor antagonist (beta-blockers) has failed.

Tourette's Disorder Tourette's disorder is a neurobehavioral disorder associated with motor and vocal tics. Motor tics may involve a single muscle group or several, thus appearing as purposeful movements. Similarly, vocal tics may involve an inarticulate sound or actual words. Often the words are socially inappropriate or even obscene. Milder tics may not require pharmacotherapy. However, when the tics are disabling, an antipsychotic medication can reduce the severity of both motor and vocal tics. Although haloperidol and pimozide are the most commonly used agents, no evidence indicates that other agents are less effective.

Huntington's Disease Genetically transmitted, Huntington's disease follows an autosomal dominant type of heritability with 100 percent penetrance. The median age of onset is 35 to 40 years, but childhood onset and much later onsets also occur. The most common mental symptom is depression, which may progress to a psychotic delusional state, sometimes followed by manic or hypomanic episodes. Individuals may exhibit symptoms that closely resemble schizophrenia with delusions and hallucinations.

Antipsychotics are useful during the early stages of the illness to reduce chorea. They are also effective in managing irritability, paranoia, hallucinations, violent tendencies, and bizarre behaviors. High-potency agents are usually preferred, but all agents appear to be effective. Clinicians should be aware of acute extrapyramidal symptoms, particularly in the rigid forms of the disorder.

Other Indications Antipsychotics are also effective for treating ballismus, an illness characterized by abnormal activity of the axial and proximal musculature. Because of their antiemetic effects, dopamine receptor antagonists are sometimes prescribed for severe emesis associated with chemotherapy. Patients with intractable hiccups are sometimes helped by dopamine receptor antagonists. Metoclopramide (Reglan), a dopamine receptor antagonist, is commonly prescribed for patients with gastroesophageal reflux and delayed gastric emptying.

PRECAUTIONS AND ADVERSE REACTIONS

Neurological Adverse Effects The most serious adverse effects of dopamine receptor antagonists are neurological and largely confined to the extrapyramidal motor system (Table 31.17-6). These extrapyramidal effects are, in turn, separated into acute effects that occur in the first days or weeks of treatment and chronic effects that occur after patients have received medications for months or years.

Acute extrapyramidal syndromes
Akathisia
Acute dystonia
Parkinsonism
Neuroleptic malignant syndrome
Chronic extrapyramidal syndromes
Tardive dyskinesia
Perioral tremor

Table 31.17-6 Neurological Adverse Effects of Dopamine Receptor Antagonists

Acute Extrapyramidal Syndromes All of the dopamine receptor antagonists are associated with extrapyramidal adverse effects. These effects—particularly parkinsonism—are attributed to decreased dopamine activity in the basal ganglia, which suggests that they are inescapable, since blockade of D_2 receptors is associated with the antipsychotic effect of these agents. This relation also explains why the potency of dopamine receptor antagonists for causing extrapyramidal adverse effects is related to their affinity for D_2 receptors in the basal ganglia. Acute extrapyramidal effects, which include dystonia, akathisia, and drug-induced parkinsonism, have their onset relatively soon after the initiation of antipsychotic drug treatment and remit soon after drug use is discontinued. In contrast, tardive extrapyramidal syndromes occur after months of treatment and commonly persist after medication use is discontinued.

AKATHISIA Akathisia comes from the Greek word *akathizin*, which means inability to sit still. It is the most common acute extrapyramidal adverse effect and often the most distressing. A recent study found that 41 percent of patients treated with an antipsychotic had mild akathisia, and an additional 21 percent had moderate-to-severe akathisia. The most common clinical manifestations consist of shifting the weight from foot to foot, walking in place, inability to keep the legs still, feelings of inner restlessness, and shifting of body positions in a chair. Patients with akathisia may describe a compelling urge to walk or initiate movement. In mild cases, patients may experience a subjective feeling of restlessness but not show increased motor activity. Akathisia may appear in the second or third day of antipsychotic treatment but more frequently has its onset after 5 days.

Differentiating akathisia from behaviors related to the psychotic illness may be difficult. Feelings of restlessness may result in irritability or anxiety. Psychotic patients with akathisia may also appear more hostile or belligerent. This could lead clinicians to conclude incorrectly that the patient requires an increase in medication, which in turn could worsen the extrapyramidal effect. Akathisia is also thought to be a correlate of poor antipsychotic drug response.

ACUTE DYSTONIA Acute dystonias consist of intermittent and sustained spasms of the muscles of the trunk, head, and neck, leading to involuntary movements. They can be experienced as the most frightening adverse effect of dopamine receptor antagonists, particularly when patients experience the sudden onset of what may appear to be a form of paralysis.

Ten percent of drug-induced dystonias occur during the first hours of drug treatment, and 90 percent occur within the first 3 days. Common types of dystonia include opisthotonos, a rigid contraction of the back muscles with arching; retrocollis and torticollis of the neck; oculogyric crisis, a spasm in which an eye or both eyes are turned upward; macroglossia and tongue protrusion, which can lead to choking; and laryngeal dystonias. Rarely, dystonias of laryngeal or pharyngeal muscles can lead to sudden death.

Younger patients, particularly young males, are more likely to develop dystonias. They are more common when patients are treated with large doses of high-potency dopamine receptor antagonists. Dystonias almost always respond rapidly to antiparkinson medications and can usually be prevented by either pretreatment with antiparkinson medications or by limiting the antipsychotic dosage prescribed. Dystonic reactions occur in about 40 percent of patients treated with high-potency drugs

without prophylactic antiparkinsonian medications.

PARKINSONISM Patients taking dopamine receptor antagonists may experience all of the common motor symptoms of idiopathic parkinsonism including rigidity, bradykinesia, shuffling gait, and tremor. These adverse effects commonly occur during the first 5 to 30 days of treatment and may persist until the dosage is lowered or use of the drug is discontinued. Examination usually reveals a positive glabella tap. This motor disturbance affects about 30 percent of patients treated long-term with dopamine receptor antagonists. The first evidence of drug-induced parkinsonism may be a diminished arm swing or decreased facial expressiveness.

Risk factors for drug-induced parkinsonism include increasing age, dose, a history of parkinsonism, and underlying basal ganglia damage (e.g., vascular insult).

In its milder forms, neuroleptic-induced parkinsonism may appear as a decrease in spontaneous gestures, a masked facial expression, apathy, unspontaneous speech, and difficulty in initiating usual activities—so-called akinesia. These symptoms may be difficult to distinguish from the negative or deficit symptoms of schizophrenia. Patients with akinesia may also appear to be depressed. The tendency of akinetic patients not to cross their legs can be helpful in diagnosing this adverse effect.

MANAGEMENT OF ACUTE EXTRAPYRAMIDAL SYNDROMES Anticholinergic agents are the most effective treatment for extrapyramidal adverse effects. The acute dystonias are alleviated by intramuscular or intravenous diphenhydramine (Benadryl) (50 mg, 25 mg in children), intramuscular or intravenous benztropine (Cogentin), or other anticholinergics within minutes after the drug enters the bloodstream. Oral anticholinergic agents are usually prescribed for parkinsonism and often for akathisia. Reducing the dosage of the antipsychotic is often effective, but patients commonly experience extrapyramidal adverse effects at the minimum dosage needed to manage psychosis. Amantadine (Symmetrel), an antiviral agent that affects dopamine release, also effectively reduces most extrapyramidal adverse effects. Direct dopamine agonists (e.g., bromocriptine [Parlodel]) and indirect dopamine agonists (e.g., levadopa [Larodopa]) are not preferred, as they may aggravate psychotic symptoms.

Anticholinergics are frequently, but not always, effective for treating akathisia. b-Adrenergic receptor antagonists, particularly propranolol (Inderal; 10 to 80 mg a day), have been found effective for treating akathisia and are preferred by many clinicians. b-Adrenergic receptor antagonists may be effective because akathisia is a disturbance in the normal balance between dopamine and norepinephrine.

Anticholinergic antiparkinson medications should be prescribed with caution in combination with low-potency dopamine receptor antagonists and some antidepressants because the combined anticholinergic activity may lead to a number of adverse effects including hyperthermia and delirium. Sustained tachycardia may also occur. Further caution is warranted in the use of these agents in individuals with glaucoma, ileus, urinary retention, or prostatic hypertrophy. Because many over-the-counter cold remedies, sedatives, and sleep aids contain anticholinergic agents and antihistamines, patients should be warned about the interaction between these agents and anticholinergic antiparkinson drugs.

Some controversy surrounds the appropriateness of prescribing antiparkinson medications prophylactically when treatment with dopamine receptor antagonists is initiated. Reports indicate that 30 to 50 percent of patients receiving long-term treatment do not need anticholinergics. In 1990 the World Health Organization (WHO) published a consensus statement on the use of anticholinergics in patients receiving long-term antipsychotic treatment. The statement argued against the prophylactic use of these agents because of some of their adverse effects (e.g., possible worsening of tardive dyskinesia, risk of anticholinergic toxicity, impaired memory, and possible pharmacokinetic interactions with the primary treatment agent). The consensus group concluded that anticholinergics are overprescribed, that they should be given only as needed, and that adverse effects should first be treated by lowering the antipsychotic dosage or by using other agents. However, reports indicate that anticholinergics may be helpful in managing forms of extrapyramidal adverse effects that the clinician may not recognize as adverse side effects (i.e., milder forms of akathisia may appear as anxiety or irritability and milder forms of akinesia may appear as negative symptoms such as decreased motivation and a lack of affect). In these individuals, long-term anticholinergics may be useful for optimal pharmacotherapy.

Prophylactic antiparkinson medications may be helpful in other circumstances. Because of the discomfort and anxiety associated with acute dystonias, prophylaxis is prudent when there is a substantial risk of this effect, for example when young patients are treated with high-potency dopamine receptor antagonists. Some patients may interpret a dystonia as evidence that they are allergic to a particular drug, which may lead to drug refusal. Prudent practice may include using prophylactic antiparkinson drugs in high-risk patients but gradually lowering their dosage, with regular evaluations for obvious and subtle manifestations of extrapyramidal adverse effects.

SDAs are an important alternative for patients with extrapyramidal adverse effects. Patients with extrapyramidal effects that cannot be adequately controlled with dosage reduction or an adjunctive medication will probably improve if they are given a newer drug.

NEUROLEPTIC MALIGNANT SYNDROME Neuroleptic malignant syndrome is an uncommon but potentially fatal complication of dopamine receptor antagonists. Its main clinical features include (1) hyperthermia; (2) severe muscular rigidity; (3) autonomic instability including hyperthermia, tachycardia, increased blood pressure, tachypnea, and diaphoresis; and (4) changing levels of consciousness. It usually presents as muscular rigidity and progresses to elevated temperature, fluctuating consciousness, and unstable vital signs. These symptoms are often associated with increased creatine phosphokinase (CPK) and aldolase activity. Less common are increased liver transaminase activity, leukocytosis, myoglobinemia and myoglobinuria. Acute renal failure may also occur. Mortality in well-developed cases has been reported to range from 20 to 30 percent and may be higher when depot forms are used. Recent improvements in the early recognition of neuroleptic malignant syndrome have substantially improved the mortality rate.

The neuroleptic malignant syndrome is more common when high-potency dopamine receptor antagonists are prescribed at high dosages and when dosage is escalated rapidly. The syndrome is twice as common in males as in females and is more likely to occur in younger patients. Clinicians should be concerned about any patient who displays severe muscular rigidity and a rising body temperature, since early diagnosis and treatment can be life saving.

Management of Neuroleptic Malignant Syndrome When neuroleptic malignant syndrome is diagnosed or suspected, antipsychotic use should be discontinued and supportive and symptomatic treatment should begin. This may include treating extrapyramidal adverse effects with antiparkinson medications, correcting fluid and electrolyte imbalances, treating fever, and managing cardiovascular symptoms such as hypertension or hypotension. Recent studies indicate that dantrolene (Dantrium) may be effective for treating severe neuroleptic malignant syndrome. Treatment begins with intravenous administration of 0.8 to 2.5 mg/kg every 6 hours, with a maximum of 10 mg/kg daily. When the symptoms subside and the patient can swallow, dantrolene is administered orally in dosages of 100 to 200 mg daily. Bromocriptine can then be added at dosages of 20 to 30 mg daily in four divided doses. Amantadine may be helpful if the other agents do not suffice. The course of treatment is commonly 5 to 10 days unless a long-acting injectable agent has been used.

Although neuroleptic malignant syndrome is considered by some to be an extreme extrapyramidal adverse effect, its cause and biological risk factors are unknown. Most patients require antipsychotic medications after they recover from neuroleptic malignant syndrome, and usually either the same dopamine receptor antagonist or a different one can be used. Low-potency drugs may be preferable for patients who have previously had neuroleptic malignant syndrome. However, even clozapine can cause the syndrome. At this time there are no data to indicate if clozapine or other SDAs are associated with a lower risk of neuroleptic malignant syndrome than traditional antipsychotics.

Chronic Extrapyramidal Syndromes

TARDIVE DYSKINESIA Tardive dyskinesia is a movement disorder that may occur following long-term treatment with antipsychotic medications. Patients with tardive dyskinesia may have any or all of a number of abnormal movements, which frequently consist of mouth and tongue movements, such as lip smacking, sucking and puckering as well as facial grimacing. Other movements may include irregular movements of the limbs, particularly choreoathetoid-like movements of the fingers and toes and slow, writhing movements of the trunk. Younger patients tend to develop slower athetoid movements of the trunk, extremities, and neck. Although seriously disabling, dyskinesia is uncommon, in a small proportion it may affect walking, breathing, eating, and talking.

The differential diagnosis of tardive dyskinesia includes a number of disorders of the basal ganglia (including Huntington's disease, Wilson's disease, and Sydenham's chorea), hyperthyroidism, hypoparathyroidism, tardive Tourette's disorder, and dyskinesias related to other drugs, such as levodopa and amphetamines. Abnormal movements were also described in patients with schizophrenia before the introduction of antipsychotic medications.

Although antipsychotic medications frequently suppress the movements of tardive dyskinesia, increasing the medication dosage is only appropriate when the movements are severe and incapacitating. When patients have their dosages of antipsychotic medication either decreased or discontinued, abnormal movements

may worsen temporarily or appear for the first time and then diminish. Abnormal movements that occur in this context have been referred to as *withdrawal emergent dyskinesias*. Antiparkinson medications often worsen the movements of tardive dyskinesia. However, when patients suffer from combined tardive dyskinesia and acute extrapyramidal adverse effects, antiparkinson medication is often unavoidable.

Although the biological mechanism underlying tardive dyskinesia is still controversial, a number of investigators have hypothesized that the disorder is related to increased sensitivity of dopamine receptors in the basal ganglia. This is supported by the observation that drugs that block dopamine such as antipsychotic medications suppress tardive dyskinesia, whereas dopamine agonists worsen the disorder. These observations are consistent with findings from preclinical laboratories indicating that blocking dopamine receptors can result in their upward regulation.

At least 10 to 20 percent of patients treated with dopamine receptor ntagonists for more than a year develop tardive dyskinesia. In long-term institutionalized patients the prevalence is between 15 and 20 percent. Recent prospective studies indicate that approximately 4 to 5 percent of patients who are undergoing antipsychotic drug treatment will develop tardive dyskinesia each year, and certain populations are at a greater risk than others. Increasing age increases risk, with elderly women being particularly vulnerable. A recent prospective study by Margaret Woerner and coworkers found that cumulative rates of tardive dyskinesia in an elderly cohort were 25 percent, 34 percent and 53 percent after 1, 2, and 3 years of treatment with an antipsychotic. Moreover, tardive dyskinesia in elderly adults is less likely to remit when use of dopamine receptor antagonists is discontinued. Patients with affective disorders may also be at greater risk for tardive dyskinesia when they are treated with dopamine receptor antagonists. Other possible risk factors for tardive dyskinesia are the dosage of antipsychotic medications and the duration of treatment with these drugs.

Early observations of the course of tardive dyskinesia suggested that the disorder was inevitably progressive and irreversible. In other words, patients who developed even mild dyskinesias were likely to progress toward severe tardive dyskinesia. More-recent evidence indicates otherwise. When dopamine receptor antagonist therapy is discontinued, a substantial proportion of tardive dyskinesia patients enjoy a remission, particularly those with tardive dyskinesia of rather recent onset. Sometimes this remission will take several months to occur.

Tardive dyskinesia does not appear to be a progressive disorder for most patients. The disorder seems to develop rather rapidly and then stabilize and often improve. A number of studies followed the course of tardive dyskinesia in patients who continued to take drugs for several years and found that the severity of tardive dyskinesia improves in most patients, even if treatment with dopamine receptor antagonists continues. Moreover, this improvement can be clinically meaningful in some patients. Individuals who are most likely to remit are those with a recent onset and those with an onset prior to age 40. This remission may take months or longer to occur.

Perioral Tremor This is an uncommon side effect of dopamine receptor antagonists that appears after months or years of drug treatment. The peculiar tremors of the mouth have led to this disorder being called “rabbit syndrome.”

Management of Tardive Dyskinesia The authors recommend that all patients with schizophrenia who receive dopamine receptor antagonists for more than 6 months have regular, systematic evaluations for tardive dyskinesia. Although instruments such as the Abnormal Involuntary Movement Scale (AIMS) were originally developed as research tools, they also provide a structured system for evaluating and recording abnormal movements. Thus, performing an AIMS test once every 3 to 6 months is a reasonable way to monitor patients.

Once tardive dyskinesia is diagnosed, the clinician should evaluate the need for continued antipsychotic treatment. This decision requires considering the dangers of both the psychotic illness and the tardive dyskinesia. Whenever possible this decision should be made in collaboration with both patient and family, and the results of this discussion should be documented in the patient's medical record. For most patients with chronic schizophrenia, the best decision will probably involve continuing the antipsychotic. If this is the case, some evidence suggests that using the lowest effective dosage may minimize the risk of tardive dyskinesia.

Patients with severe tardive dyskinesia may also be candidates for a trial of clozapine. Most clinical reports indicate that clozapine can suppress tardive dyskinesia. In addition, substantial data indicate that clozapine is less likely to cause the disorder than other antipsychotic medications and therefore is promising for the long-term management of patients who have developed tardive dyskinesia. This potential advantage of clozapine should be considered tentative, since data on the incidence of tardive dyskinesia in patients on clozapine are inadequate. In addition, studies using animal models indicate that clozapine use does not evoke the increased sensitivity of striatal D_2 receptors that is associated with typical neuroleptics and has been theorized to result in tardive dyskinesia. At this time data are inadequate to indicate whether newer SDAs are effective in suppressing tardive dyskinesia.

The American Psychiatric Association task force on tardive dyskinesia recommends a number of steps for the prevention and management of the disorder, including (1) establishing objective evidence that antipsychotic medications are effective; (2) using the minimum effective dosage for long-term treatment; (3) exercising caution with children, elderly adults, and patients with mood disorders; (4) examining patients on a regular basis for evidence of dyskinesia and noting the results of the examination in the medical record; (5) if tardive dyskinesia is diagnosed, considering alternatives to antipsychotics, obtaining informed consent, and considering dosage reduction; and (6) if the dyskinesia worsens, considering discontinuation of the antipsychotic, use of a different drug, or a trial of clozapine.

Cardiovascular Effects

Cardiac Adverse Effects Animal studies have shown that antipsychotic agents may decrease cardiac contractility, disrupt enzyme activity in cardiac cells, decrease tissue concentrations and increase circulating concentrations of catecholamines, and prolong atrial and ventricular conduction time and refractory periods. Low-potency agents—particularly chlorpromazine and thioridazine—can induce electrocardiographic (ECG) abnormalities such as prolongation of the QT and PR intervals, blunting of the T waves, and depression of the ST segment. Malignant arrhythmias (including torsade de pointes) have been associated with thioridazine. Clinicians should consider obtaining an ECG before and during treatment with thioridazine when patients have preexisting cardiac pathology or prolonged QT intervals. Patients with a history of cardiac disease are probably most safely managed with a high-potency antipsychotic such as haloperidol.

Orthostatic (Postural) Hypotension Low-potency dopamine receptor antagonists (e.g., chlorpromazine and thioridazine) may cause orthostatic hypotension, particularly when these agents are first administered. This adverse effect can be dangerous when it results in fainting or falls. Both elderly patients and individuals with impaired balance should be monitored carefully for orthostatic changes. Since tolerance may develop gradually, patients should initially be treated with a relatively low dosage of these agents (e.g., 25 mg orally twice daily) and the dosage should be titrated upward over several days until a target dosage is reached. When appropriate, patients should be warned of this adverse effect and told to sit or stand up slowly, to sit with their feet outside the bed when arising, to wait for as long as a minute, and to sit or lie down if they feel faint. Some patients—particularly elderly adults—may have persisting orthostatic hypotension and thus may benefit from a change to high-potency antipsychotic treatment.

Orthostatic hypotension is more likely when low-potency agents are administered intramuscularly. Thus, clinicians should consider measuring the patient's blood pressure (both lying and standing) before and 1 to 2 hours after the first dose and before subsequent doses during the first days of treatment.

If hypotension does occur, even with higher-potency agents, it can usually be managed by having patients lie down and instructing them to arise slowly. Some patients may benefit from stockings, volume expansion, or pressor agents. The use of epinephrine paradoxically worsens antipsychotic-induced hypotension through b-adrenergic stimulation and is thus contraindicated. Pure a-adrenergic agents such as metaraminol (Aramine) and norepinephrine (Levophed) are the drugs of choice for this condition.

Sudden Unexplained Death In spite of reports associating dopamine receptor antagonists with sudden unexplained death, no evidence indicates that the incidence of such deaths changed in psychiatric patients after introduction of antipsychotic therapy. Similarly, the incidence of sudden unexplained death does not differ in patients on high-potency drugs and those on low-potency drugs. An American Psychiatric Association task force report concluded:

> [Al]though a relationship between the use of antipsychotic drugs and sudden death has not been firmly established, it has also not been disproved. From a neurocardiologic perspective, these drugs have the potential for both increasing and decreasing the risk of sudden death. Ultimate outcome is probably determined by a multitude of interacting factors, and the role played by the drug in a given individual is difficult, if not impossible to determine.

Reports of sudden death in patients treated with antipsychotics could be explained by cardiac arrhythmias or other causes. For example, seizures, asphyxiation, heat stroke, malignant hyperthermia, and neuroleptic malignant syndrome could result in relatively sudden death. Individuals who may be more vulnerable to sudden death

include elderly adults, physically debilitated individuals, and agitated patients (particularly those who are physically restrained).

Gastrointestinal Tract The most common gastrointestinal adverse effects of dopamine receptor antagonists are related to their peripheral anticholinergic effects. These include dry mouth, constipation, occasional diarrhea, and urinary retention. Nausea and vomiting are less common. Anticholinergic effects are most prevalent with low-potency dopamine receptor antagonists such as chlorpromazine or thioridazine and are uncommon with high-potency drugs. These effects can be exacerbated when other anticholinergic drugs such as tricyclic drugs are combined with a low-potency antipsychotic.

Patients who experience a severely dry mouth should be advised to rinse their mouth frequently and to chew sugarless gum or candy. Sugar-containing candies may lead to fungal infections in the mouth and increase the risk of dental caries. Constipation can be managed with stool softeners or laxatives. Clinicians should manage severe constipation carefully, since it can progress to paralytic ileus.

Liver Dopamine receptor antagonists may cause transient abnormalities in liver function test results. These are seldom of serious medical concern. Obstructive or cholestatic jaundice, a serious condition that was commonly associated with chlorpromazine treatment in the past, is currently uncommon.

Blood Dopamine receptor antagonist therapy may be associated with temporary and transient depression of leukopoiesis. Mild leukopenia may occur for prolonged periods, although more commonly, the leukocyte count eventually returns to normal. Agranulocytosis is rare with dopamine receptor antagonists, occurring in fewer than 1 in 10,000 cases. Thrombocytopenia and pancytopenia may also occur.

Kidney and Urinary Function Chlorpromazine has weak diuretic effects. The anticholinergic effects of low-potency drugs may lead to urinary retention.

Skin and Eye Effects Cutaneous reactions seen during the first weeks of antipsychotic drug treatment include urticarial, maculopapular, petechial, and edematous reactions. These reactions usually improve when drug use is discontinued and sometimes clear even when drug use continues. Patients receiving low-potency dopamine receptor antagonists (particularly chlorpromazine) may develop photosensitivity reactions consisting of severe sunburn or rash. Patients should be instructed to avoid direct sunlight or use sunscreens.

Low-potency dopamine receptor antagonists, especially chlorpromazine, are associated with an uncommon discoloration of the skin. Skin areas that are exposed to sunlight, particularly the face and neck develop blue-gray, metallic discoloration. This skin reaction is usually associated with long-term treatment with high drug dosages. Changing to treatment with a high-potency drug usually leads to gradual improvement.

Patients receiving long-term treatment with chlorpromazine may develop granular deposits in the anterior lens and posterior cornea. These deposits—visualized on slit lamp examination—seldom affect the patient's vision. Changing to another drug usually yields gradual improvement in the condition.

High dosages of thioridazine—above 1000 mg daily—can cause retinal pigmentation, which can lead to serious visual impairment or blindness. Moreover, this condition may not remit when thioridazine therapy is discontinued. As a result, thioridazine should not be prescribed at dosages above 800 mg daily.

Endocrine Effects Dopamine receptor antagonists increase circulating prolactin concentrations. In women, increased prolactin concentration can lead to breast enlargement, galactorrhea, and irregular menses including anovulatory cycles and infertility, menses with abnormal luteal phases, or frank amenorrhea and hypoestrogenemia. Increased prolactin concentration associated with dopamine receptor antagonists may also suppress testosterone in men. Prolactin concentration elevation results directly from D_2 blockade in the tuberoinfundibular dopamine pathway and the pituitary. Since prolactin concentration is under tonic inhibitory control by dopamine, blockade of dopamine receptors increases prolactin concentration. Some patients—but not all—develop tolerance to the effects of these drugs on prolactin concentration after several weeks. Dosage reduction may relieve symptoms related to increased prolactin concentration.

Effects on Sexual Function Dopamine receptor antagonists can have important effects on sexual functioning in both men and women. In men use of these agents can decrease libido and cause ejaculatory and erectile disturbances. Erectile dysfunction reportedly occurs in 23 to 54 percent of males receiving an antipsychotic and can be an important cause of medication noncompliance in men. Retrograde ejaculation has been reported with some dopamine receptor antagonists, particularly thioridazine. In addition, these agents can affect ejaculatory latency and the quantity of ejaculate. Since sexual functioning is affected by dopamine, serotonergic, and adrenergic systems it is unclear how sexual dysfunction resulting from dopamine receptor antagonists is mediated. Dosage reduction may be helpful in some individuals.

Women who receive dopamine receptor antagonists may experience decreased libido, anorgasmia, and decreased lubrication. Although a number of adjunctive medications have been reported, there is little evidence that any are effective. As with men, reducing the dosage of the antipsychotic may be helpful.

Pregnancy Although dopamine receptor antagonists cross the placenta, little evidence suggests any association between prenatal exposure to an antipsychotic and increased incidence of congenital malformations. A recent meta-analysis by Lori Altshuler and colleagues found that the baseline incidence of congenital anomalies is 2.0 percent and the incidence with antipsychotics is 2.4 percent. This suggests that these agents add a small additional risk to the fetus. This meta-analysis found no evidence that high-potency drugs increase the risk to the fetus.

Prenatal exposure of rats to dopamine receptor antagonists may lead to a decreased number of brain dopamine receptors. Other animal studies indicate that prenatal haloperidol exposure may raise cholesterol concentrations in offspring. It is unclear if these animal findings indicate risks in humans.

In developing a treatment for pregnant patients with schizophrenia, the relatively low risk of congenital abnormalities associated with antipsychotics should be weighed against the dangers of psychotic episodes. Clinicians may attempt to discontinue these medications during the first trimester if this is feasible and should consider carefully whether the risks of taking these drugs during the remainder of the pregnancy are justified by the likely benefits. If patients have a history of relapse when treatment with dopamine receptor antagonists is discontinued, the drugs are relatively safe. If dopamine receptor antagonists are prescribed, high-potency compounds are probably safer.

Lactation Dopamine receptor antagonists are secreted in low concentrations with lactation, suggesting that patients should be advised against breast-feeding during antipsychotic treatment.

Seizure Threshold Dopamine receptor antagonists use tends to lower the seizure threshold. Thus they are associated with an increased risk of seizures. This risk is usually clinically important in individuals with a prior history of seizures. Low-potency drugs have a greater tendency to lower the seizure threshold. Therefore, high-potency dopamine receptor antagonists may be preferable for seizure-prone individuals.

Temperature Regulation Effects Some patients become poikilothermic (i.e., they become hypothermic in the winter and overheat in the summer) when taking chlorpromazine or other low-potency agents. Special precautions should be taken for these patients during exposure to temperature extremes.

Overdosage Overdosages with dopamine receptor antagonists are usually characterized by exaggeration of their usual adverse effects. Thus, high-potency drugs are associated with severe extrapyramidal reactions, including dystonias and severe rigidity, as well as hypotension and sedation. Lower-potency drugs are more likely to be associated with central nervous system (CNS) depression, sedation, anticholinergic effects, and hypotension. The clinical picture may also include agitation, restlessness, convulsions, fever, autonomic reactions such as dry mouth and ileus, ECG changes, and cardiac arrhythmias. In severe overdoses with dopamine receptor antagonists the pupils are mydriatic, deep tendon reflexes decrease and areflexia may occur, tachycardia and hypotension are present, and the electroencephalogram (EEG) shows diffuse slowing and low voltage. This picture may progress to delirium and coma, with respiratory depression and hypotension.

The management of dopamine receptor antagonist overdose is symptomatic and supportive, since overdoses with these agents are seldom lethal. However, the outcome may be unfavorable when these agents are combined with others, particularly CNS depressants such as alcohol, barbiturates, and benzodiazepines. If the overdose is recent, gastric lavage is helpful. If the patient can swallow, activated charcoal is indicated. Emetics should not be administered because their effects may be attenuated by the antipsychotic and because they are associated with a risk of aspiration pneumonia. Aspiration may be a serious risk if the patient develops a dystonic reaction of the head or neck. Forced diuresis and hemodialysis are not effective because dopamine receptor antagonists are highly protein bound and lipophilic.

When hypotension occurs, standard measures for managing circulatory shock should be implemented. The hypotension may occur when b-adrenergic receptors are unopposed during a-receptor blockade. Therefore, the clinician should consider norepinephrine or dopamine. Epinephrine is contraindicated.

Because of their quinidine-like effects, overdoses with thioridazine and mesoridazine may lead to heart block and ventricular fibrillation. Since these agents may have long half-lives, patients recovering from substantial overdoses may require cardiac monitoring for several days.

Tolerance, Dependence, and Withdrawal Symptoms Some tolerance develops to the sedative, anticholinergic, hypotensive, and some other effects of dopamine receptor antagonists. Tolerance does not develop to the antipsychotic effects. Some patients experience a decrease in extrapyramidal adverse effects, suggesting tolerance to the motor effects of these agents.

Dopamine receptor antagonists are not addicting. As a result, most patients can be withdrawn from use of these agents without difficulty. Rapid withdrawal of low-potency dopamine receptor antagonists can evoke symptoms related to their anticholinergic effects, commonly manifestations of “cholinergic rebound” including nausea, vomiting, and diarrhea. Other reported withdrawal symptoms include headache, sweating, restlessness, and insomnia. These symptoms tend to occur within 2 to 3 days of drug withdrawal and may last as long as 2 weeks. Most patients who stop taking high-potency dopamine receptor antagonists do not show withdrawal symptoms. These observations suggest that withdrawal from low-potency agents should occur gradually over one to 2 weeks or longer.

DRUG INTERACTIONS

Clinicians should be aware of several types of interactions. Drugs may interact with the metabolism of dopamine receptor antagonists; age and gender may affect metabolic pathways; medical conditions may affect protein-binding, absorption, and fecal or renal clearance. Individuals who are dehydrated or malnourished or who have impaired liver and kidney function are at risk for altered sensitivity and metabolism.

Metabolism Dopamine receptor antagonists may have clinically important interactions with drugs that are metabolized by the same cytochrome P450 enzymes. For the conventional antipsychotics, particularly haloperidol, perphenazine, and thioridazine, this involves cytochrome P450 (CYP) isoenzyme 2D6 (CYP 2D6). Since some selective serotonin reuptake inhibitor (SSRIs)—particularly fluoxetine (Prozac) and paroxetine (Paxil)—are potent inhibitors of this enzyme, plasma concentration of the dopamine receptor antagonist is likely to increase when an SSRI is added, which may increase or worsen extrapyramidal adverse effects. Other drugs that are substrates for CYP 2D6—including tricyclic and tetracyclic drugs, b-adrenergic receptor antagonists, and cimetidine (Tagamet)—may also increase antipsychotic plasma concentrations.

Other drugs—particularly phenytoin (Dilantin), carbamazapine, and barbiturates—can reduce antipsychotic plasma concentrations by increasing the metabolism of the dopamine receptor antagonist. Reports indicate that carbamazapine can reduce the plasma concentration of haloperidol by 50 percent. Phenobarbital increases urinary excretion and thus decreases the plasma concentration of chlorpromazine.

Other common interactions should concern clinicians. Antacids, activated charcoal, cimetidine, cholestyramine (Questran), kaolin, and pectin can decrease the absorption of antipsychotics from the gut. Increased absorption may occur with drugs that decrease gastrointestinal motility such as digoxin (Lanoxin) and steroids.

Coffee and tea may precipitate dopamine receptor antagonists in vitro, but the clinical significance of this is unclear. Trifluoperazine and chlorpromazine have been reported to precipitate with lithium citrate.

Antipsychotic drugs antagonize the effects of dopamine agonists or levodopa when these drugs are used to treat parkinsonism. Chlorpromazine, haloperidol, and thiothixene can block the antihypertensive effects of guanethidine (Ismelin). Dopamine receptor antagonists may also enhance the effects of CNS depressants such as analgesics, anxiolytics, and hypnotics.

Dopamine receptor antagonists may enhance the effects of oral hypoglycemics. Phenothiazines enhance the effects of oral anticoagulants, although haloperidol may decrease these effects. Cigarette smoking may lower dopamine receptor antagonist blood concentrations by enzyme induction.

Adverse Effect Interactions Opioids, captopril (Capoten), trazodone (Desyrel), tricyclic and tetracyclic drugs, hydralazine (Apresoline), and minoxidil (Loniten) may increase hypotension. Combination of a low-potency dopamine receptor antagonist and another sedating drug may lead to excessive sedation. Combining low-potency dopamine receptor antagonist with other anticholinergic compounds can lead to peripheral anticholinergic symptoms such as dry mouth and urinary retention and central effects such as cognitive deficits and delirium (atropine psychosis). Patients should be warned about the use of over-the-counter medications that contain anticholinergics.

Amoxapine (Asendin), fluoxetine, chloroquine (Aralen), and lithium may increase extrapyramidal symptoms. Hydroxyzine (Vistaril) potentiates thioridazine and mesoridazine toxicity. Diuretics and corticosteroids enhance cardiotoxic adverse effects through hypokalemia, and quinidine enhances the quinidine-like effects of these agents.

LABORATORY INTERFERENCES

Chlorpromazine and perphenazine may give false-positive or false-negative results on pregnancy tests. These drugs may also give inaccurate reports of bilirubin (with reagent test strips) and urobilinogen (with Ehrlich's reagent test). Phenothiazines may produce false-positive results in tests for phenylketonuria. Phenothiazines may also interfere with 17-ketosteroid assays (with the Haltorff-Koch modification of the Zimmermann reaction) and 17-OH corticosteroid assays (with the modified Glenn-Nelson technique).

DOSAGE AND ADMINISTRATION

Dopamine receptor antagonists are available in a wide range of formulations and dose sizes (Table 31.17-7).

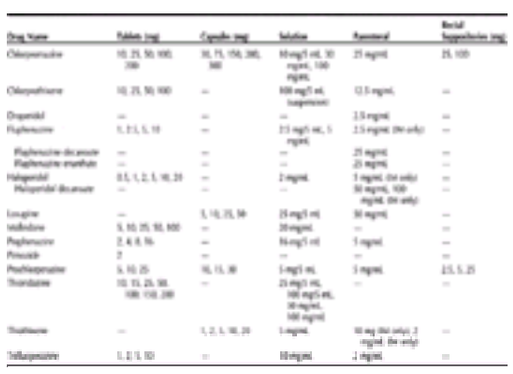

Table 31.17-7 Dopamine Receptor Antagonist Preparations

Treatment of Acute Psychosis

Initiation of Treatment Treatment with a dopamine receptor antagonist is usually initiated soon after a diagnosis is made. Whenever possible patients should receive a psychiatric evaluation including a history, a physical examination, and a laboratory evaluation that includes complete blood count (CBC); blood electrolytes and glucose determinations; liver, renal and thyroid function tests; and other appropriate evaluations (including ECG, pregnancy tests, and screens for alcohol and drugs).

The results of this evaluation can be useful in confirming the diagnosis and establishing pretreatment baselines. Usually it is not necessary to delay treatment while awaiting the results from these tests. Moreover, since there are few contraindications to dopamine receptor antagonists, these evaluations can be postponed when patients refuse an evaluation or when treatment is urgent.

Choice of Agent No evidence indicates that any dopamine receptor antagonist is more effective than any other. The choice among these agents is based on prior responses (both objective improvement and the patient's subjective response to the drug), available routes of administration and dosage forms, adverse-effect profiles, and cost.

The introduction of the SDAs (clozapine, risperidone, olanzapine, and sertindole at this time) has complicated the decision-making process because these agents have certain advantages over the dopamine receptor antagonists. The most important is that SDAs cause substantially less severe extrapyramidal adverse effects. Patients who experience these effects at dosages of conventional antipsychotics needed to treat their psychosis will probably not experience them with an effective dosage of an SDA. Clozapine is effective for patients who remain symptomatic when taking a dopamine receptor antagonist. Some evidence indicates that other SDAs are also effective for this treatment-refractory population. Substantial evidence indicates that SDAs are more effective than dopamine receptor antagonists for the treatment of negative symptoms. An additional advantage of some SDAs (including clozapine, olanzapine, and sertindole) is that they are less likely to increase prolactin concentration. As a result, these agents may be helpful for women who experience galactorrhea and irregular menses with dopamine receptor antagonist. All of these advantages of SDAs indicate that the dopamine receptor antagonists are likely to play a declining role in the treatment of psychosis. For example, a recent schizophrenia treatment algorithm from Texas recommends that patients receive trials with three newer antipsychotics, risperidone, olanzapine, and quetiapine (Seroquel) before being treated with a dopamine receptor antagonist. Treatment algorithms from the American Psychiatric Association and the Department of Veterans Affairs, on the other hand, recommend dopamine receptor antagonists as first-line antipsychotics, along with newer drugs. Populations that may continue to receive dopamine receptor antagonists include patients who require treatment with a long-acting depot drug and those who experience minimal adverse effects. Dopamine receptor antagonists are less expensive than SDAs; thus, certain payers for medical care may only permit changing to an SDA under certain circumstances.

High-potency dopamine receptor antagonists such as haloperidol and fluphenazine are more commonly prescribed than low-potency compounds. High-potency drugs are more strongly antidopaminergic and thus more likely to cause extrapyramidal adverse effects than the low-potency medications such as chlorpromazine or thioridazine. However, the extrapyramidal effects may be easier to manage than the sedation and orthostatic hypotension associated with low-potency medications. High-potency medications can be administered intramuscularly more readily because they seldom cause problems with blood pressure. In addition, because of sedation, orthostatic hypotension, and lethargy, the dosage of low-potency dopamine receptor antagonists should be gradually titrated upward; patients on high-potency medications can usually be treated with a therapeutic dosage within a day or two. Midpotency drugs such as loxapine and molindone are options for patients who have difficulty tolerating the adverse effects of high- or low-potency drugs.

Route of Administration Dopamine receptor antagonists can be administered orally or in short- or long-acting injectable forms (Table 31.17-7). Under most conditions, the oral forms of these agents are preferred by patients. Once patients are stabilized on a dosage, most patients can be managed with a single daily dose. Short-acting injectable forms are administered intramuscularly to calm agitated patients or for patients who refuse oral medication. The clinical effects of an intramuscular dose may appear as soon as 15 minutes after the injection. Since the dopamine receptor antagonists are most effective when patients have been in a steady state for several days or even weeks, patients should be given the drugs by the oral route as soon as possible.

Dopamine receptor antagonists can also be administered in long-acting injectable form. In the United States, only two antipsychotics, haloperidol and fluphenazine, are available in long-acting formulations. Long-acting antipsychotics are usually prescribed for maintenance treatment of stabilized patients. These drugs are usually poor choices for the treatment of acute psychosis because of their pharmacokinetics. Since it takes months to reach steady state or to eliminate drugs that are administered in this manner, the clinician cannot titrate dosage against clinical effectiveness. Moreover, if patients develop adverse effects from a depot drug, a period of time will separate the reduction of drug dosage and decreased the plasma concentration and adverse effects. Long-acting depot drugs are much better suited to long-term maintenance, after the effectiveness and sensitivity to adverse effects have been established during short-term treatment.

Dosage Patients demonstrate marked differences in the dosage of a dopamine receptor antagonist that is optimal (Table 31.17-8). For example, some patients find it difficult to tolerate the adverse effects from 1 mg of haloperidol whereas others tolerate 100 mg without suffering any adverse effects. Finding the best dosage for a dopamine receptor antagonist is both important and difficult. The importance stems from the tendency of these drugs to cause adverse effects at their effective doses. Often the clinician must weigh the therapeutic advantages of a particular dosage against discomforting or disabling adverse effects. Determining the best dosage is difficult because often one cannot titrate dosage against clinical response because there is a delay—often of several weeks—between a dosage change and the clinical response. Thus the most reasonable practice may be to administer a dosage that is likely to be effective and then wait an adequate amount of time (usually 4 to 6 weeks) to determine if the patient is responding.

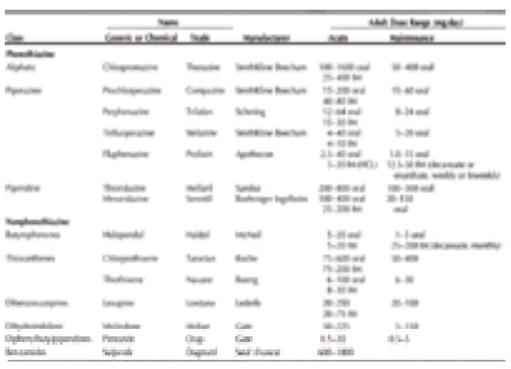

Table 31.17-8 Dopamine Receptor Antagnoists

Dosage comparison studies provide guidance to clinicians who are making decisions regarding the dosages of dopamine receptor antagonists for most patients with schizophrenia or schizoaffective disorder. Dosages below 300 mg a day of chlorpromazine (or 5 mg of fluphenazine or haloperidol) are likely to be too low for many psychotic patients. At the same time dosages above 1000 mg a day of chlorpromazine (or 20 mg of haloperidol or fluphenazine) are seldom necessary and may lead to substantial adverse effects. Most patients respond to daily dosages between 5 and 20 mg of fluphenazine or haloperidol or equivalent amounts of another dopamine receptor antagonist. Children and elderly patients should be given much lower dosages.

Some patients can tolerate very high dosages of dopamine receptor antagonists, particularly high-potency drugs. This observation led some clinicians to raise the prescribed dosages in hope that more is better, which resulted in a substantial increase in the average dose of antipsychotic prescribed in the United States during the 1970s and 1980s. However, dosage comparison studies failed to support the routine use of higher doses; when groups of patients were given daily dosages above 2000 mg of chlorpromazine or 40 mg of haloperidol, the rate of improvement and the amount of improvement was no greater than for those given more-moderate doses. Moreover, these higher dosages were associated with greater extrapyramidal adverse effects. Clinicians are sometimes impressed by individuals who require these higher dosages, suggesting that a small group of patients may benefit from high dosages.

As-Needed Medication Prescribing medication as needed is recommended only for the initial phases of treatment. Although dopamine receptor antagonists can result in nearly immediate calming of agitated individuals, this response appears to differ from the true antipsychotic effect of these medications, which has a delayed onset. Treating excitement and agitation with the addition of benzodiazepines such as lorazepam (Ativan) has the advantage of calming patients without causing extrapyramidal adverse effects.

Blood Concentrations and Clinical Activity Finding the best dosage of an antipsychotic for an individual patient often requires weeks or months of treatment. The clinician usually selects a drug dosage that is effective for most patients with the same illness or a dosage that was effective for the patient at an earlier time. Once the dosage is selected and administered, the clinician must wait days or weeks until it is clear whether it is effective, toxic, or ineffective. If clinicians could select a

drug dosage on the basis of a patient's plasma or blood concentration it would decrease the amount of time it takes to arrive at an appropriate dosage.

Early studies showed that plasma concentrations in patients who received the same dosage of a drug varied widely, which suggested that studying individual differences in plasma concentrations would provide information that could be useful to clinicians. However, early studies were limited to drugs such as chlorpromazine with a complex metabolism, so that some of the antipsychotic activity could result from metabolites rather than the parent drug. This and other problems (including flawed research methods) may explain why early studies failed to find a reliable relation.

A number of more recent studies have focused on other dopamine receptor antagonists and have shown more promising results. Haloperidol has received the most attention for the study of the relation between plasma concentration and clinical response. Haloperidol has a single important metabolite, reduced haloperidol, which does not have significant antipsychotic activity. Thus, the plasma concentration of haloperidol may accurately represent the effective amount of the drug. At least five research groups, but not all, have reported a relation between haloperidol concentration and clinical response. Table 31.17-9 gives reported plasma concentration ranges for four commonly prescribed dopamine receptor antagonists. Although all of these ranges are supported by one or more high-quality studies, the strongest evidence is for haloperidol.

Drug	Therapeutic Plasma Concentration (ng/mL)
Chlorpromazine	30–100*
Fluphenazine	0.2–2.0†
Haloperidol	2–15*
Perphenazine	0.8–2.4†

* Consider dosage reduction in patients with plasma concentration above upper limit.
† Range of concentration in which good response without debilitating adverse effects has been found; no evidence that reduction of plasma concentration above the upper limit improves the antipsychotic effect.
Adapted from Van Putten T, Marder SR, Wirshing WC, Aravagiri M, Chaber N: Neuroleptic plasma levels. Schizophr Bull 17:197, 1991.

Table 31.17-9 Reported Therapeutic Plasma Concentration Ranges for Antipsychotic Drugs

At this time, empirical studies do not support routine measurement of plasma concentration. However, the data suggest certain circumstances in which antipsychotic plasma concentrations can be helpful to clinicians. A concentration measurement may be helpful in the patient who is receiving an apparently adequate dosage but not responding. A low concentration may suggest that the patient is not complying or that poor absorption or extensive drug metabolism is interfering. In other cases, the clinician may find it difficult to interpret anxiety or agitation and may consider whether psychotic agitation could come from an inadequate dosage or akathisia result from an excessive dosage. A high or low plasma concentration could provide valuable information in these circumstances.

Plasma concentrations should be determined only after steady state has been reached, preferably during the late phase of the plasma concentration curve. This usually means after 5 days on a stable oral dosage and 10 to 12 hours after the last dose.

Adjunctive Medications Antipsychotic medications are often supplemented by other psychotropic medications to manage comorbid conditions that frequently occur with schizophrenia. Substantial evidence indicates that antidepressants are effective for treating depression in patients with schizophrenia and schizoaffective disorder that remains after psychosis is adequately treated. Mood-stabilizing drugs including lithium, carbamazepine, and valproate are effective for patients with unstable moods. Benzodiazepines are often effective for treating anxiety as well as agitation and excitement.

Maintenance Treatment

Duration of Treatment During the maintenance phase of treatment the treatment goals include preventing psychotic relapse and improving the patient's level of functioning and quality of life. Although dopamine receptor antagonists are effective in delaying or preventing relapse, they are also associated with short- and long-term adverse effects. The analysis of costs and benefits usually favors continuing to treat patients with schizophrenia or schizoaffective illness with an antipsychotic. Patients who have recovered from a single psychotic episode have a substantial risk of relapse if medication is discontinued. As a result, an international consensus conference recommended that first-episode patients receive 1 to 2 years of maintenance antipsychotic therapy. The same group recommended that patients who have had multiple episodes should continue to receive an antipsychotic for at least 2 to 5 years. Patients with a history of violent, aggressive behavior or serious suicide attempts should receive antipsychotics indefinitely. If a decision is made to discontinue medications, the dosage should be reduced gradually and the patient should be carefully observed.

Long-Acting Injectable Antipsychotics Substantial evidence indicates that long-acting injectable antipsychotics have advantages for patients during the maintenance stage of treatment, partly because these agents help solve the problem of poor medication compliance in schizophrenia. Clinicians can administer drugs without depending upon patients taking pills. In addition, because depot drugs bypass variations in drug absorption and first-pass hepatic and gut metabolism, drug concentrations may be more consistent. A number of studies have compared the relative effectiveness of long-acting and oral drugs for preventing relapse in stabilized patients. Studies that closely resemble treatment in the community have found that patients are better protected by depot medications. A number of more carefully controlled studies have compared the risk of psychotic relapse in patients randomly assigned to receive either oral or depot medication. The only comparison that lasted more than 1 year found an advantage for depot drugs. A meta-analysis of the studies comparing oral and depot agents found a significantly lower relapse rate in patients who received depot treatment ($P < .0002$).

Treatment Strategies During Maintenance Concerns about the adverse effects of antipsychotics and the risk for tardive dyskinesia have led to a number of proposed strategies for safely managing patients on the lowest possible dosage of a dopamine receptor antagonist. A number of studies have found that patients can be safely managed with substantially lower dosages of a long-acting depot antipsychotic than are commonly prescribed. These studies found that most patients did well when their dosages were 80 percent lower than those usually prescribed for short-term treatment. Patients treated with lower dosages had a small increase in the risk of relapse that was balanced in some studies by reductions in adverse effects, improved compliance, and suggestions of improved community adjustment.

Other studies have focused on a strategy named *targeted* or *intermittent therapy* in which antipsychotic dosage is gradually reduced to zero. Patients are monitored carefully for early, or prodromal, signs of relapse. Antipsychotic treatment is resumed when these signs appear. A number of studies, including a recent NIMH collaborative study, found that this strategy is associated with high relapse rates, indicating that it is probably not advisable for most patients. Another study found that early intervention was helpful for patients who were already receiving a low dose of a depot dopamine receptor antagonist. When these individuals demonstrate prodromal signs of relapse, their depot medication is supplemented with oral medication.

Management of Psychosis and Disruptive Behavior in Elderly Patients with Dementia Psychomotor agitation and aggressive behaviors are relatively common in patients with Alzheimer's Disease and other dementing illnesses. Dopamine receptor antagonists and SDAs are commonly prescribed for these conditions and have been found to be moderately effective when compared with placebos. Although thioridazine was frequently prescribed for agitated elderly patients in nursing homes, its adverse effects on blood pressure and memory have led many clinicians to prescribe high-potency agents, particularly haloperidol. A recent report from the New York State Psychitaric Institute found that treating agitated Alzheimer's Disease patients with 2 to 3 mg of haloperidol daily was more effective than .5 to .75 mg daily or placebo. The authors recommended starting these patients on 1 mg daily and gradually increasing the dosage as tolerated.

SUGGESTED CROSS-REFERENCES

Serotonin-dopamine antagonists are discussed in Section 31.26, and other biological therapies are discussed in other sections of Chapter 31. Psychiatric rating scales are discussed in Section 7.8. Cognitive disorders are discussed in Chapter 10, substance-related disorders in Chapter 11, schizophrenia in Chapter 12, other psychotic disorders in Chapter 13, and mood disorders in Chapter 14. Schizophrenia and delusional disorders in the elderly are discussed in Section 51.3f, and the use of antipsychotics in the elderly is discussed in Section 51.4e. Medication-induced movement disorders are covered in Section 31.4.

31.18 LITHIUM

JAMES W. JEFFERSON, M.D., AND JOHN H. GREIST, M.D.

HISTORY

A report appeared in 1800 describing the discovery of two new minerals, petalite and spodumene, on an island near Stockholm, Sweden. When the former was analyzed, a small percent remained unidentified until 1817 when Johan Arfwedson discovered a new alkali that was named lithion by Jons Jacob Berzelius, his laboratory chief. The next year, Humphrey Davy was the first to isolate lithium metal.

In 1843 Alexander Ure introduced lithium into medicine when he showed in vitro that a uric acid bladder stone lost weight in a lithium carbonate solution. By the early 1860s Sir Alfred Garrod had discovered that gouty uric acid deposits in finger joints were also soluble in vitro in a lithium solution. In the second half of the nineteenth century the notion of uric acid imbalances as the cause of disease expanded far beyond bladder stones and gout to include many ills. A. Trousseau in France and Alexander Haig in England incorporated mania and depression into the uric acid diathesis. In 1886, Karl Lange, a Dane, reported that a mixture containing lithium carbonate was effective in the prophylactic treatment of depression, and in 1894 his brother, Fritz Lange, described the effectiveness of lithium carbonate for treating acute depression. In the United States, William A. Hammond (a former Surgeon General of the Army) wrote in 1871: “Latterly I have used the bromide of lithium in cases of acute mania, and have more reason to be satisfied with it than any other medicine calculated to diminish the amount of blood in the cerebral vessels, and to calm any nervous excitement that may be present.” For mania, Hammond preferred lithium bromide to other bromide preparations and suggested rather generous amounts: “The doses should be large—as high as 60 grains or even more—and should be repeated every two or three hours till sleep be produced, or at least till half a dozen doses be taken.” Since this represents a more than generous amount of both lithium and bromide, Hammond's patients may well have been toxic rather than tranquilized.

From the late 1880s through the early 1900s, lithium was embraced by the general public in the form of mineral spring waters. Taking the waters was reputed to cure just about everything, as evidenced by an advertisement for Bear Lithia Water: “Cures kidney and bladder troubles, uric acid, gout, and rheumatism, phosphoric deposits, inflammation of the bladder, dropsical affections, brick-dust deposits, and all forms of dyspepsia. . .” (Fig. 31.18-1). A testimonial to Buffalo Lithia Water stated: “The water from spring No. 1 is the most powerful restorative of the broken-down enfeebled human system that I have known.” In Wisconsin lithia spring water was used to brew Lithia Beer, a regional favorite for decades. As late as 1920 the White Rock Mineral Spring Company was bottling 120,000 bottles of lithia water daily. Nonetheless, the lithia water bubble had burst many years earlier. In 1896 the U.S. Bureau of Chemistry found that nearly all lithia waters on the United States market contained at most only spectroscopic traces of lithium, and in the early 1900s the Supreme Court of the District of Columbia concluded: “For a person to obtain a therapeutic dose of lithium by drinking Buffalo Lithia Water he would have to drink from one hundred and fifty thousand to two hundred and twenty-five thousand gallons of water per day.” It was difficult not to conclude that the only condition that lithia water cured was thirst.

FIGURE 31.18-1 Advertisement for Bear Lithia Water.

Nevertheless, lithium remained in the public eye. Lithium tablets became available, and by 1907 the *Merck Index* listed 43 medicinal preparations containing lithium. With the tablets came an awareness of the toxic potential of lithium—generalized weakness and tremor in patients was reported in 1898 and diarrhea, vomiting, and death were described in animals in 1903. These early lessons were apparently forgotten, for when lithium reemerged into popularity in 1948 in the form of a 25 percent solution of lithium chloride for use as a salt substitute in patients on low-sodium diets, the dangers were not appreciated. By 1949, however, reports of severe lithium intoxication and death resulted in the removal of lithium products from the market and delayed the acceptance of lithium by American psychiatry for many years.

At almost the same time that lithium was poisoning cardiac patients in the United States, the Australian psychiatrist, John F.J. Cade was observing its antimanic effect in psychiatric patients. To explore the hypothesis that mania might be “a state of intoxication by a normal product of the body circulating in excess, whilst melancholia is the corresponding deprative condition,” Cade injected urine from patients into guinea pigs. He noted that lithium urate modified the toxicity of urea in a favorable direction which, he stated, “argues for a strong protective function for the lithium ion against the convulsant mode of death produced by toxic doses of urea.” Based on the use of lithium salts in the nineteenth century and particularly because “single and repeated doses of lithium citrate and lithium carbonate in the doses contemplated produced no discernible ill effects on the investigator himself,” Cade concluded that there were “no ethical contraindications to using them in mania.” In 1949 he described strikingly favorable results in 10 patients with mania including the first who had been hospitalized for 5 years in a state of manic excitement—”He had enjoyed preeminent nuisance value in a back ward all those years and bid fair to remain there for the rest of his life.” Instead, the illness went into full remission, the patient was discharged and returned to work. The story does not end here, however, for euthymia led to noncompliance which in turn reignited the mania with resultant hospitalization. Lithium was reinstituted successfully, but eventually (22 months after first taking lithium) he died from“[-T]oxaemia due to lithium salts therapeutically administered.” Cade's success with lithium led him to investigations of other ions such as rubidium, cesium, lanthanum, neodymium, and strontium, but the remarkable effects of lithium were never duplicated.

Later, the clinical observations of Cade were substantiated in more rigorous clinical trials conducted by Mogens Schou and others who firmly established the effectiveness of lithium for mania and for the prophylactic treatment of manic-depressive disorder. Lithium use in the United States increased gradually in the late 1960s, but not until 1970 did the Food and Drug Administration (FDA) approve its labeling for the treatment of mania. The only other approved indication was in 1974 for maintenance therapy in patients with a history of mania.

In 1975 the Lithium Information Center was established at the University of Wisconsin in Madison to collect, catagorize, and disseminate information on lithium and its roles in medicine. The Center, now at the Madison Institute of Medicine in Madison, Wisconsin, contains an ever-increasing database of over 28,400 articles.

CHEMISTRY

Lithium follows hydrogen and helium on the periodic table, making it the third simplest element (atomic number 3, atomic weight 6.94) and the first solid element. It is a member of the group IA alkaline metals together with sodium, potassium, rubidium, cesium, and francium. Among them, lithium has the smallest atomic radius and the highest melting point, boiling point, and ionic charge density. In nature lithium exists as two quadrupolar isotopes, Li^{6} (7.42 percent) and Li^{7} (92.58 percent). Most of the lithium used in the United States is obtained from spodumene ore in North Carolina with lesser amounts from brines in Nevada. Its applications extend far beyond psychiatry, including the manufacture of aluminum, ceramics, and synthetic rubber; uses in batteries, greases, air conditioning, industrial drying, welding, brazing, and as a carbon dioxide absorbent; and as a vehicle for delivering chlorine to swimming pools (lithium hypochlorite). Trace amounts of lithium are present in food and water and hence in all living tissue. Whether lithium is essential to normal human growth and development has not been established, and there is no evidence of a lithium deficiency state in humans. Experimentally produced lithium deficiency in goats and rats led to reduced fertility, retarded development, and reduced longevity.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics Lithium is rapidly and completely absorbed, with serum concentrations peaking in 1 to 1½ hours with standard preparations and in 4 to 4½ hours with the slow and controlled-release forms. Unlike most psychiatric drugs, lithium has no clinically important protein-binding properties and no metabolites. It is excreted almost entirely by the kidneys, although small amounts are also lost in sweat and feces. A substantial amount of filtered lithium is reabsorbed (primarily in the proximal tubules), so that renal lithium clearance is about one-fifth of creatinine clearance. The elimination half-life of lithium is about 18 to 24 hours, although it is considerably longer in the elderly because of the age-related decrease in glomerular filtration rate (GFR). Consequently, elderly patients tend to need lower than usual doses to reach a given serum concentration and require longer than usual to reach steady-state. Duration of treatment may also affect half-life as evidenced by a small study that found it to be 1.3 days in those just starting treatment but 2.4 days in those treated for over a year. Obesity may alter lithium kinetics based on the observation that clearance was almost 50 percent higher in obese subjects than in normal-weight volunteers. Lithium is distributed widely throughout the body, although the rate and extent of entry into tissues varies. For example, thyroid and renal concentrations exceed serum level, whereas red blood cell, spinal fluid, and brain concentrations do not. Lithium enters and leaves the central nervous system (CNS) slowly, which may explain why acute overdoses with relatively high blood levels are sometimes well tolerated and why clinical manifestations of chronic intoxications often persist long after blood levels have decreased.

Pharmacodynamics “Because the key is so small, it fits into many locks.” Thus did Mogens Schou describe the difficulty defining the mechanism of action of lithium. There is no evidence for lithium deficiency being the cause of bipolar disorders. Indeed, the amount of lithium required for a clinical effect dwarfs the naturally occurring levels in the body by a factor of about 100. A monovalent cation, lithium has chemical similarities to sodium and potassium as well as to the divalent cations, calcium and magnesium. Consequently, ion substitution has been evoked to explain its clinical effects with considerable attention focused on ion pumps and channels, particularly sodium-lithium counterexchange. Sodium, potassium-adenosine triphosphatase (Na, K-ATPase) has been implicated in the cause and treatment of bipolar disorder. Altered levels of Na, K-ATPase activity have been found in subjects with manic and depressed bipolar disorder compared to euthymic subjects with bipolar disorders in some but not all studies. Since neuronal transmembrane potential differences are maintained by the Na, K-ATPase pump (also known as the sodium pump), perturbations of this system are felt to lead to neurotransmitter aberrations that translate into the clinical manifestations of bipolar disorders. Lithium crosses cell membranes by various mechanisms including the sodium pump, the sodium leak canal, a lithium-bicarbonate exchange, and the sodium-lithium counterexchange system. By substituting for sodium in these transmembranal ion exchanges, lithium is believed to exert its therapeutic effect. Although this theory has been examined and refined since the late 1970s, it continues to be challenged by experimental inconsistencies.

No neurotransmitter has been shown to be unaffected by lithium. As a result, serotonin, norepinephrine, dopamine, acetylcholine, g-aminobutyric acid (GABA), and a variety of neuropeptides have been implicated both singularly and in combination to explain lithium's diverse effects.

Other theories involve effects on neuroendocrine systems, kindling and behavioral sensitization, biological rhythms, viruses, and a variety of signal transduction pathways. Both the adenylate cyclase and phosphoinosotide second-messenger systems are altered profoundly by lithium in a variety of ways, including effects on guanine nucleotide-binding proteins (G proteins) and protein kinase C. The complexity of the situation was summarized by Husseini Manji and Robert Lenox:

> Chronic lithium exerts significant transcriptional and posttranscriptional effects, and that those actions of lithium may be mediated via protein kinase C (PKC)-induced alterations in nuclear transcription regulatory factors responsible for modulating the expression of proteins involved in the long-term neural plasticity and cellular response.

The observation that lithium inhibited inositol monophosphatase, reduced brain inositol levels, and inhibited inositol 1,4,5-trisphosphate (IP_3) accumulation in rat and mouse cerebral cortex led to the inositol depletion hypothesis of its mechanism of action. Further studies, however, using guinea pig, rabbit, and monkey cerebral cortex found that lithium actually increased IP_3 concentrations (the same was seen in rat and mouse if supplemental inositol was provided). Subsequently it was shown that the accumulation of IP_3 was promoted by lithium-induced glutamate release activating the *N*-methyl-D-aspartate (NMDA) receptor. If glutamate release was inhibited by carbetapentane or if the ionotropic NMDA receptor was blocked by selective antagonists, lithium failed to stimulate IP_3 accumulation. Interestingly, in the same model valproate also stimulated glutamate release and increased IP_3 concentrations, although the mechanism appeared to be different from that of lithium. At concentrations that were maximally effective when used alone, the combination of the two drugs had additive effects on glutamate release (an observation that may explain the clinically observed benefits of combining these drugs in treatment-resistant patients.)

G proteins have also been targeted as sites of lithium activity. Studies of long-term lithium administration have found altered G protein function (such as stabilization of subunit dissociation) suggesting that transmembranal signal transduction is affected. Because G proteins are involved in conveying information from numerous neurotransmitters, neuromodulators, and hormones to intracellular effectors, lithium's effects at this level can cascade widely and deeply within cells.

In addition to lithium altering G-protein function, it has also been shown that lithium decreases concentrations of some of the PKC isozymes and of myrisoylated alanine-rich C kinase substrate (MARCKS), a protein involved in neurotransmission; similar effects were also seen with valproate. Furthermore, therapeutically equivalent concentrations of lithium in cultured rat neurons increased transcriptional factor binding to both activated protein-1 (AP-1) and adenosine monophosphate cAMP-responsive element (CRE). It should be obvious that signal transduction pathways provide numerous interrelated targets for lithium's actions. Which of these, if any, would explain its mechanism of action in bipolar disorder remains to be determined.

In keeping with the “one key fits many locks” observation, lithium has also been shown to inhibit glycogen synthase kinase-3 (GSK-3), a protein kinase involved neuronal in cytoskeletal development. Among its many activities, GSK-3 regulates the phosphorylation of tau, the microtubule-associated proteins involved in the paired helical filaments of Alzheimer's disease. It has been speculated that lithium may even play a role in the treatment of Alzheimer's disease.

The bipolarity virus theory arose from the observation that lithium is an effective treatment for two episodic illnesses; namely, genital herpes simplex and bipolar disorder. Its inhibitory effect on herpes simplex viral replication is well established, but whether it also inhibits an unidentified virus that causes bipolar disorders is a matter of speculation. Investigators have yet to explain how this simple ion with its ubiquitous neurobiological effects manages to resolve mania and depressions and provide long-term mood stabilization.

Design and Interpretation of Clinical Drug Studies The history of lithium encompasses most of the history of clinical drug trials in psychiatry. The research that established its antimanic activity to the satisfaction of the FDA was meager compared to today's large, double-blind, placebo-controlled parallel design, multi-center trials. Although the response rate consistently favored lithium over placebo, the studies were small, short-term, and of crossover design. Nonetheless, the recent large (*N* = 179) multicenter, randomized, double-blind, parallel design, 3-week comparison of lithium, divalproex (Depakote), and placebo for the treatment of acute mania found lithium to be twice as effective as placebo (49 percent versus 25 percent) and the equal of divalproex (49 percent versus 48 percent). Since the study design excluded patients previously treated with divalproex or valproic acid but included numerous patients in whom lithium had been previously ineffective or not well tolerated, to conclude that the two drugs have equal efficacy for the treatment of mania may be premature.

In the 1960s open studies by experienced clinicians comparing episode frequency before and during lithium treatment did much to establish the long-term effectiveness of the drug. Citing lack of scientific rigor in the design of these studies, critics cast doubt on the conclusion and stimulated a plethora of double-blind, placebo-controlled studies (both prospective and discontinuation) that convincingly established the long-term prophylactic efficacy of lithium in bipolar disorder. Currently in the United States divalproex appears to be evolving over a similar course with an initial ground swell of clinical enthusiasm now being subjected to the

rigors of more scientific scrutiny.

THERAPEUTIC INDICATIONS

Bipolar Disorders

Mania Lithium is accepted universally as an antimanic drug with effectiveness greater than placebo. Its onset of action is relatively slow, with clinical improvement usually occurring over the first 1 to 3 weeks of treatment. Although one small open study suggested that oral lithium loading might produce improvement in a few days, this approach has yet to be substantiated. Instead, the concomitant use of a benzodiazepine and an antipsychotic drug is often necessary during the initial phase of treatment. Since disturbed sleep may ignite or fuel a manic episode, early treatment of insomnia with a sedative such as clonazepam (Klonopin) or lorazepam (Ativan) may be useful.

Not all patients with acute mania respond equally well to lithium. The response rate of 78 percent in the initial research trials contrasts with findings of less success when dealing with patients with mixed or dysphoric mania, rapid cycling, comorbid substance abuse, or organicity. For mania patients unresponsive to lithium or intolerant of it, alternative treatments include valproate, carbamazepine (Tegretol), antipsychotics drugs, electroconvulsive therapy (ECT), and a variety of less well established pharmacological agents. Whether another mood-stabilizer would be preferable to lithium as the initial treatment of mania, or at least for some subtypes of mania, has not been established in well-designed studies. The effectiveness of lithium maintenance therapy is far better established than for any other drug, which may weigh in favor of using lithium to treat the initial manic episode.

Depression Lithium is not approved by the FDA as an antidepressant medication, nonetheless, research supports its effectiveness, at least for depression in bipolar disorders. In placebo-controlled studies 79 percent of depressed bipolar disorder patients and 36 percent of major depressive disorder patients had a partial or complete response to lithium. Four of five double-blind comparisons found lithium just as effective as tricyclic drugs (the data did not distinguish between bipolar and unipolar depression). Using a conventional antidepressant as the sole treatment for bipolar disorder depression appears to increase the risk of drug-induced mania and rapid cycling, a risk established most clearly with tricyclic drugs. Consequently, initial treatment with lithium alone is often preferred for bipolar depression, although for more severe depressions, some clinicians prefer to combine lithium with an antidepressant drug. Therapeutic blood concentrations have not been well established for the antidepressant effect of lithium, but appear to be in the same general range as for mania. If an antidepressant is combined with lithium to treat depression, the antidepressant should be withdrawn gradually soon after remission to minimize the risk of antidepressant-induced mania or rapid cycling. In practice, however, patients often seem to require and tolerate the long-term use of both lithium and an antidepressant. The role of carbamazepine and valproate as monotherapies for bipolar depression has not been adequately studied.

If breakthrough depression occurs during lithium maintenance, lithium-induced hypothyroidism, noncompliance, and substance abuse must be considered as possible causes. Often, however, no apparent cause can be found and it must be assumed that the pressure of the illness overcame the protective effect of lithium. With that in mind, increasing the serum lithium level to 1 or 1.2 mEq/L may be all that is necessary to terminate the episode. Even if the patient's thyroid function is normal, supplementation with thyroid hormone in the form of 25 µg a day of liothyronine (Cytomel) may be beneficial. Milder episodes of depression may resolve spontaneously or with brief psychotherapy. For moderate to severe depression, it may be necessary to add an antidepressant drug. Although tricyclic medications have been studied most extensively and are more effective than placebo, evidence is growing to support the preferential use of bupropion (Wellbutrin) or a selective serotonin reuptake inhibitor (SSRI) in part because antidepressant-associated mania may be less frequent, milder, less dysphoric, and easier to manage. In a comparative study the monoamine oxidase inhibitor tranylcypromine (Parnate) was more effective and better tolerated than imipramine (Tofranil) in bipolar depressed outpatients who were not receiving a mood stabilizer. The role of other antidepressants such as venlafaxine (Effexor), nefazodone (Serzone), and mirtazapine (Remeron) remains to be established. Augmenting lithium with either valproate or carbamazepine may have a beneficial antidepressant effect without increasing the risk of antidepressant-induced mania or rapid cycling.

ECT is an effective treatment for bipolar depression, although it tends to be used only after medications have failed. Concern has been expressed that the presence of lithium during ECT increases the risk and severity of cognitive dysfunction, but whether this is true remains controversial.

Maintenance Therapy Long-term treatment with lithium is an effective way to reduce the frequency, severity, and duration of manic and depressive episodes in patients with bipolar disorder. In 10 double-blind studies the relapse rate when patients were receiving lithium was 34 percent versus 81 percent on placebo. Lithium was somewhat more effective against mania than against depression. Treatment response to lithium monotherapy is usually less than complete and supplemental pharmacotherapies are often necessary either intermittently or continuously. Nonetheless, there is growing evidence for a major benefit from long-term lithium therapy: namely, reduced mortality. In general, bipolar disorder carries with it an increased risk of premature death, particularly but not entirely from suicide. Studies comparing mortality rates in lithium-treated patients to the general population, to patients following discontinuation of lithium, and to patients treated with alternative prophylactic medications all support the mortality-lowering and suicide-reducing effect of lithium.

Work by Paul Grof and others to predict a favorable response to lithium maintenance found that the diagnosis of a mood disorder, an episodic course with euthymic intervals, and the absence of rapid cycling were the main predictors. The following factors have been associated with a less than ideal response to lithium maintenance: mixed or dysphoric mania, rapid cycling (four or more episodes per year), many prior episodes, poor interepisode functioning, an episode pattern of depression-mania-euthymia, comorbid substance abuse, and comorbid personality disorder. Of great interest and as yet unresolved by properly designed studies is whether alternatives to lithium such as valproate and carbamazepine will yield better results under similar circumstances.

Just exactly when to begin long-term lithium treatment is not fully resolved, although most recommendations suggest earlier rather than later—possibly after only one episode of mania and certainly after two. There is growing concern that episodes beget episodes (perhaps a form of kindling or behavioral sensitization), and that each episode increases the likelihood of the next and may shorten the interval to the next, hence the recent trend toward earlier initiation of maintenance therapy. Obviously, many individual factors must be taken into consideration, including the abruptness, severity, and frequency of episodes; the presence of risk factors; and attitudes toward medication. Early initiation of maintenance therapy may benefit many patients at the expense of some patients being treated unnecessarily.

> A patient had two manic episodes in two years, one resolving spontaneously and one with ECT, followed by 18 euthymic years without any treatment before the next episode occurred. Had she been treated with lithium after the second manic episode, the subsequent 18 years would have been considered a testimonial to the therapeutic effectiveness of lithium.

The maximum benefits of lithium maintenance may not be immediate; with continued treatment relapses sometimes become less severe and less frequent. Some patients appear to develop a tolerance to lithium after several years of successful use; this tolerance can sometimes be overcome by the addition of carbamazepine or valproate. Similarly, patients who are only partial responders to lithium maintenance may benefit from the addition of one of these drugs. Just as breakthrough depression may respond to a temporary increase in serum lithium concentration so may breakthrough mania. At such times, however, supplementing lithium with an antipsychotic drug or a benzodiazepine may be necessary.

Maintenance lithium concentrations are usually lower than those used for the treatment of acute mania. Package inserts for lithium products refer to 0.6 to 1.2 mEq/L as desirable for long-term control; in general, higher serum lithium concentrations within this range are more likely to be effective but they cause more adverse effects and noncompliance.

Long-term treatment does not cure bipolar disorders. Following discontinuation of successful lithium therapy, the risk of recurrence increases substantially. For example, a review of discontinuation studies of patients with bipolar I disorder found the monthly risk of recurrence to be 28 times higher after lithium was stopped. In addition, rapid discontinuation of lithium appears to be associated with a rebound phenomenon characterized by increased risk of early recurrence of manic and depressive episodes. Gradual withdrawal of lithium seems to delay but not prevent recurrent mania and it may both delay and reduce the risk of recurrent depression.

Another phenomenon of concern has been termed lithium discontinuation-induced refractoriness. Some patients, approaching 15 percent, who had responded well to lithium prophylaxis may not respond again when lithium is reintroduced after a failed discontinuation trial. A decision to discontinue successful lithium maintenance should not be taken lightly, but rather must be weighed carefully against the continued risk of adverse effects and toxicity.

Major Depressive Disorder Although major depressive episodes may respond to lithium alone, traditional antidepressant medications are considerably more effective and are the preferred treatment. The major value of lithium in patients with major depressive disorder is as an augmenting agent when antidepressants alone have been ineffective. On average, 50 to 60 percent of patients respond when lithium carbonate, usually 300 mg three times daily (less in the elderly), is added to a

wide variety of antidepressant drugs. Occasionally, a dramatic response is noted in 24 to 48 hours but improvement is more likely to occur gradually over several weeks. Favorable responses have been described in both psychotic and nonpsychotic depression. While alternative explanations may apply in some situations (spontaneous remission, the longer duration of antidepressant treatment, or an independent effect of lithium), research support for a true augmenting interaction is quite persuasive. Experts disagree, however, as to when lithium augmentation should be introduced during the course of dealing with treatment resistance.

Mogens Schou states: “Doubt about the efficacy of prophylactic lithium treatment in unipolar illness seems almost exclusively a U.S. phenomenon.” Indeed, most studies have found lithium to be more effective than placebo and as effective as antidepressant drugs for the long-term management of major depressive disorder. Lithium has not, however, demonstrated clear advantages over conventional antidepressant drugs, and since long-term treatment is most likely to involve the drug that ended the acute episode (an antidepressant), lithium maintenance for major depressive disorder is likely to be reserved for treatment failures.

Schizoaffective Disorder and Schizophrenia In general, the less affective and the more schizophrenic an illness is, the less likely it is to respond to lithium. The same cannot be said of an episode because the acute manifestations of mania and schizophrenia may be indistinguishable. Although not approved by the FDA for schizoaffective disorder and not specifically studied for the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) version of this disorder, lithium is generally accepted to be of value for treating this condition, especially in combination with antipsychotic drugs.

Antipsychotic drugs remain the treatment of choice for schizophrenia, although patient response is often less than ideal. The addition of lithium to an antipsychotic agent is one of several reasonable treatment strategies for antipsychotic-resistant schizophrenia, although the availability of serotonin–dopamine antagonists (atypical antipsychotics), such as clozapine (Clozaril), risperidone (Risperdal), olanzapine (Zyprexa), and others, make this less necessary. Improvement of schizophrenia with lithium augmentation of an antipsychotic medication does not depend on the presence of symptoms of a mood disorder.

Aggression Lithium appears to have anti-aggressive effects independent of its mood-stabilizing action. Several controlled studies have found reduced aggression in subjects recruited from prison populations. Behavioral dyscontrol and self-mutilation in mentally retarded patients have also been successfully treated with lithium. However, lithium has not been used extensively to treat aggression associated with head trauma or epilepsy, and the results have been mixed. No work has been done to evaluate the effect of lithium in those patients defined by DSM-IV as having intermittent explosive disorder. Aggressive outbursts are also treated with medications such as anticonvulsants, b-adrenergic receptor antagonists, benzodiazepines, buspirone (BuSpar), antipsychotic drugs, and trazodone (Desyrel). The relative ranking of lithium among those other drugs must be determined on an individual basis.

Alcohol Use Disorders Lithium's potential for treating alcohol dependence and abuse is based in part on the close association between mood disorders and alcohol use disorders and in part on animal research that found reduced alcohol intake in rodents receiving lithium. Efforts to establish lithium as a useful treatment for alcoholism have been largely unsuccessful. A large (*N* = 457), multicenter, double-blind, placebo-controlled 1-year study found that lithium did not alter the course of alcoholism in depressed or nondepressed alcoholics. Although not all research reports have been that discouraging, lithium is unlikely to play a major role in the treatment of alcoholism. Some patients may be exceptions, but clinicians have found no way to identify them prospectively.

Other Indications The philosophy that “lithium is good for what ails you” led to the treatment of a wide variety of psychiatric (Table 31.18-1) and nonpsychiatric medical conditions (Table 31.18-2) with the drug. In general, reports in these areas involve small numbers of patients in studies often lacking in scientific rigor. In such situations both positive and negative outcomes may be inconclusive and even misleading. For example, two double-blind, placebo-controlled trials found lithium ineffective in obsessive-compulsive disorder. Only 16 patients were involved, however, and the treatment duration of 2 weeks was insufficient to evaluate the drug adequately. Two recent well-designed, placebo-controlled studies did find lithium to be ineffective in augmenting conventional drugs for obsessive-compulsive disorder in treatment-resistant patients.

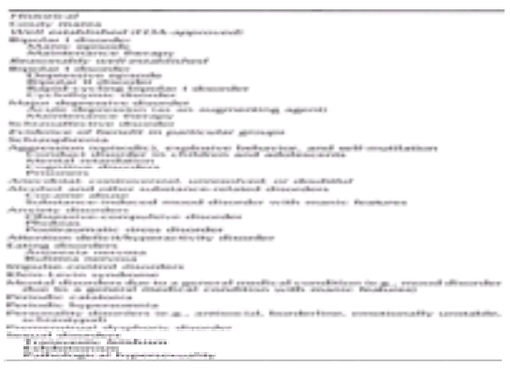

Table 31.18-1 Psychiatric Uses of Lithium

Table 31.18-2 Nonpsychiatric Uses of Lithium*

Efforts to establish lithium as a useful treatment for personality disorders have been largely unsuccessful. When favorable outcomes do occur, it is likely that a comorbid mood disorder has responded followed by indirect improvement in “personality.” In days of the first edition of DSM (DSM-I), lithium was used successfully to treat inpatients with emotionally unstable character disorder. The findings were never replicated or extended to outpatients, and the disorder failed to appear in subsequent editions of DSM. Today, the substantial mood component of borderline personality disorder suggests a role for lithium in its treatment, but controlled trials have not been conducted.

There has been considerable interest in lithium's potential for treating a wide variety of nonpsychiatric medical conditions (Table 31.18-2). The granulocyte-stimulating effect of the drug has been used to increase white blood cell count in conditions such as Felty's syndrome, idiopathic neutropenia, chemotherapy-induced granulocytopenia, and immunosuppressant drug-induced leukopenias. Lithium's antithyroid effects have been utilized investigationally to treat hyperthyroidism. Neurologists have found lithium useful as a treatment for chronic and episodic cluster headaches. The observation that lithium inhibits replication of deoxyribonucleic acid (DNA) viruses such as human herpesvirus 1 and 2 led to successful double-blind, placebo-controlled trials of both topical and oral preparations to treat herpes genitalis. Seborrheic dermatitis has also been shown in controlled studies to respond to a lithium-containing ointment that is marketed outside the United States. The therapeutic promise of lithium extends beyond medicine as evidenced by its fungicidal effects on powdery mildew, a serious affliction of cucumbers.

PRECAUTIONS

Children and Adolescents At least 20 to 30 percent of patients with bipolar I disorder have their first episode before the age of 20 years. This percentage may be even higher if age of onset is dated from first appearance of symptoms rather than from first well-defined episode or first hospitalization. Although adolescent onset is

common, prepubertal onset is far less so, but its prevalence may be underestimated because of atypical presentations and reluctance to make the diagnosis in children.

In general, diagnostic criteria for bipolar disorder in the young are the same as in adults; however, atypical presentations and comorbidity, especially with attention-deficit/hyperactivity disorder, may make recognition more difficult. Lack of a well-established longitudinal history further complicates diagnosis and may contribute to miscategorizing first-episode psychotic mania as schizophrenia.

Another diagnostic dilemma is whether a first episode depression will follow a bipolar or unipolar course. The following factors may be predictive of a bipolar outcome and influence early treatment with lithium or another mood stabilizer: (1) rapid onset with psychosis and psychomotor retardation, (2) family history of bipolar disorder, and (3) antidepressant-induced hypomania.

Despite a substantial literature on the use of lithium to treat children and adolescents with conditions such as bipolar disorder, aggression, and behavioral problems associated with mental retardation and developmental disorders, there remains a paucity of well-controlled studies. The range of serum lithium concentrations in adolescents is similar to that in adults and the likelihood of responding appears the same. The adverse effect profile of lithium is also the same across age groups, although in view of adolescent concern about body image, adverse events such as acne and weight gain may be poorly tolerated. Also, nontoxic cognitive dulling induced by therapeutic amounts of lithium may impact negatively on academic performance.

When and if to begin long-term lithium therapy is an even more difficult decision when treating young patients than when treating adults. Because of concern about possible long-term adverse effects, some experts think that children and young adolescents should not be treated for longer than 6 months. At the same time, they acknowledge that untreated bipolar disorders can have devastating effects on development.

Elderly Patients In the absence of organicity and substance abuse, most evidence suggests that advanced age alone does not compromise responsiveness to lithium. However, the use of lithium in the elderly is complicated by factors that include associated medical illnesses and medications, special diets, age-related reduction in GFR, and increased sensitivity to adverse effects.

Whether the elderly as a group respond to lower serum concentrations of lithium than do their younger counterparts is not known. Increased sensitivity to adverse effects and toxicity confine many elderly patients to relatively low doses and blood concentrations, which may prevent them from benefiting from the drug. However, this is not always the case:

> After ten hospitalizations for mania and depression beginning at age 20, a 53-year-old woman was stabilized on 1500 mg a day of lithium carbonate and remained on this regimen for the next 15 years with serum concentrations ranging between 0.6 and 0.75 mEq/L. It was only at age 68 that an increase in serum concentration led to a dose reduction to 1200 mg daily. The patient continues to take this dose at age 74 and remains in remission and is free of adverse effects.

In general, the elderly should be started on lower-than-usual dosages, with dosage changes occurring less frequently than in younger patients. The elimination half-life of lithium increases with age, and the time required to reach steady state is much longer in the elderly. If lithium is stopped, serum levels fall more slowly and the resolution of adverse effects and toxicity may be prolonged.

> A 60-year-old man was treated with 900 mg a day of lithium carbonate. The dosage was continued unchanged for 10 years, despite laboratory evidence of gradually increasing serum lithium and creatinine concentrations. Even as the clinical symptoms of toxicity were being reported, a thiazide diuretic was added to treat hypertension. Three weeks later, the patient was hospitalized with a serum lithium concentration of 4.2 mEq/L and marked neurological impairment that never fully resolved.

With appropriate monitoring, lithium use in the elderly can be both safe and effective. Direct comparisons with other mood stabilizers in this age population are lacking.

Pregnant Patients Lithium is in FDA pregnancy category D, which includes drugs for which there is evidence of human fetal risk, but whose potential benefits may outweigh the risk in some pregnant women. The International Register of Lithium Babies reported an 11 percent incidence of major malformations in babies exposed to lithium during the first trimester, with a disproportionate representation of cardiovascular malformations, especially Ebstein's anomaly of the tricuspid valve. These data may exaggerate risk because of the greater likelihood of reporting abnormal outcomes, failing to control for other medications and medical conditions, and failing to control for the effect of the illness itself on outcome. Recent studies have not confirmed such a high incidence of malformations and the link with cardiovascular anomalies. Also, extensive investigations in a variety of animal species have not found lithium to be a cardiac teratogen. Consequently, the teratogenic risk of lithium appears to be lower than was once believed, and exposure per se is not considered grounds for a therapeutic abortion. Nonetheless, the teratogenic risk of lithium still appears to be greater than that found in the general population (4 to 12 percent versus 2 to 3 percent). Fetal echocardiography is advised to screen for cardiovascular malformations in women exposed to lithium during the first trimester of pregnancy.

Physiological changes accompanying pregnancy alter maternal lithium metabolism. The GFR increases 30 to 50 percent over baseline and plasma volume increases by 50 percent. The filtered sodium load increases markedly (5000 to 10,000 mEq daily), as does the renal tubular reabsorption of sodium, resulting in a cumulative sodium retention of close to 1000 mEq. Complications of pregnancy, such as hypertension and edema and their treatments may further complicate lithium therapy. Following delivery, the altered renal physiology of pregnancy returns rapidly to normal. These factors and their variability among individual patients dictate that lithium use during pregnancy be closely supervised. Fetal and maternal blood concentrations are similar, so women should receive only minimum effective dosages. To reduce the risk of toxicity in the newborn, clinicians should markedly reduce or possibly temporarily discontinue the drug shortly before delivery. In view of evidence that abrupt or rapid discontinuation of lithium is associated with a high risk of relapse (which may be increased further postpartum), dosage reduction rather than discontinuation may be more appropriate as delivery approaches. Full prophylactic concentrations should be reestablished following delivery because this is a time of great vulnerability to recurrence. Because lithium appears in breast milk and in the blood of breast-fed babies, the American Academy of Pediatrics Committee on Drugs feels that lithium is contraindicated during breastfeeding. On the other hand, the merits of breastfeeding are considerable, and in some situations the benefits may outweigh the risks.

Medically Ill Patients The patient with a bipolar disorder and coexisting medical illnesses presents a particularly difficult therapeutic challenge. Untreated manic or depressive disorder can adversely affect a medical illness (e.g., mania and congestive heart failure) and lithium may be more difficult or impossible to use in the presence of a medical illness (e.g., severe renal disease). Also, because medically ill patients are receiving other medications, the risk of adverse drug interactions is increased. Consequently, treatment of such patients requires close collaboration between psychiatric and nonpsychiatric physicians.

Rapid-Cycling Patients Rapid cycling has been defined as four or more mood disorder episodes per year. Up to 20 percent of bipolar disorder patients are rapid cyclers and the majority of them are women. Risk factors associated with rapid cycling include a depression-hypomania course, antidepressant drug therapy, thyroid abnormalities, and neurological disease. Ultra-rapid cyclers have 24 to 48 cycles, and the concept of ultra-ultra rapid cycling has been introduced to describe patients with frequent mood shifts within a 24-hour period.

Overall, rapid-cycling patients are less responsive to lithium than are those who cycle more slowly, although both full and partial responses are common. Prior treatment with antidepressant drugs may predict a poorer response to lithium. Also, because antidepressant drugs may induce rapid cycling, merely discontinuing the antidepressant agent may be sufficient to slow the cycling pattern. Correcting thyroid abnormalities is an important aspect of treating rapid cycling. Preliminary research suggests that hypermetabolic doses of thyroid hormone may be useful in dealing with treatment-resistant rapid cycling. Valproate or carbamazepine alone or in combination with lithium are the most viable alternatives to lithium alone. Approaches that are less well established include calcium-channel inhibitors (particularly nimodipine [Nimotop] for ultrarapid cycling), choline, clozapine, olanzepine (Zyprexa) risperidone, newer anticonvulsants such as gabapentin (Neurontin) and lamotrigine (Lamictal), and ECT.

ADVERSE REACTIONS

Adverse effects are to be expected during lithium therapy. Fewer than 20 percent of patients have no adverse effects, but only about 30 percent have more than minor complaints. The incidence of severe adverse effects may be underestimated, however, because patients who do not tolerate therapy may not be available for

comment. Recognizing and minimizing adverse effects can do much to enhance compliance with lithium treatment (Table 31.18-3).

Neurological
Benign, nontoxic: dysphoria, lack of spontaneity, slowed reaction time, memory difficulties
Tremor: postural, occasional extrapyramidal
Toxic: coarse tremor, dysarthria, ataxia, neuromuscular irritability, seizures, coma, death
Miscellaneous: peripheral neuropathy, benign intracranial hypertension, myasthenia gravis–like syndrome, altered creativity, lowered seizure threshold
Endocrine
Thyroid: goiter, hypothyroidism, exophthalmos, hyperthyroidism (rare)
Parathyroid: hyperparathyroidism, adenoma
Cardiovascular
Benign T-wave changes, sinus node dysfunction
Renal
Concentrating defect, morphological changes, polyuria (nephrogenic diabetes insipidus), reduced GFR, nephrotic syndrome, renal tubular acidosis
Dermatological
Acne, hair loss, psoriasis, rash
Gastrointestinal
Appetite loss, nausea, vomiting, diarrhea
Miscellaneous
Altered carbohydrate metabolism, weight gain, fluid retention

Table 31.18-3 Adverse Effects of Lithium

Neurological Reactions Patients often complain of dysphoria, lack of spontaneity, slow reaction times, intellectual inefficiency, and spotty impairment of memory. Although these complaints may be subtle, they are a common cause of poor compliance. The following must also be considered as possible causes of these complaints: breakthrough depression, lithium-induced hypothyroidism or hypercalcemia, other illnesses, and other drugs. Single daily dosing at bedtime or a dosage reduction may be helpful, although switching to another mood stabilizer may be necessary.

> After 19 years of successful lithium maintenance, a 37-year-old woman was switched to carbamazepine because of polyuria and proteinuria. Only in retrospect did she and her physician become aware of the cognitive dulling and impaired concentration that had been present during her many years on lithium.

Tremor The most common tremor associated with lithium use is a benign postural tremor with a frequency of 8 to 12 Hz in the hands (which is similar to the tremor seen with valproate). Because the tremor worsens during activities requiring fine motor control, it can be socially embarrassing and occupationally troublesome. A nontoxic tremor often improves spontaneously, but if it does not, benefit may be obtained from dose reduction, use of a slow-release lithium preparation, elimination of dietary caffeine, discontinuation of other medications, and treatment of associated anxiety. Medications useful in treating lithium tremor include primidone (Mysoline) and b-adrenergic receptor antagonists such as propranolol (Inderal). With long-term lithium therapy, a tremor with parkinsonian characteristics may occur occasionally. A severe tremor at any time during the course of lithium therapy may be an indication of lithium intoxication.

Other Nontoxic Effects Lithium use has been associated rarely with peripheral neuropathy, downbeat nystagmus, benign intracranial hypertension (pseudotumor cerebri), a myasthenia gravis-like syndrome, and lowering of the seizure threshold. Creativity has been variously enhanced, impaired, and unaltered by lithium therapy.

Lithium Intoxication Lithium intoxication is primarily a neurotoxicity that can lead to death or permanent neurological damage (often cerebellar). Cardiovascular, gastrointestinal, and renal manifestations may also be present. Factors associated with toxicity include excessive intake (accidental or deliberate), reduced excretion (kidney disease, low-sodium diet, drug interaction), reduced volume of distribution (dehydration), and individual sensitivity (the elderly and the organically impaired).

> A woman with lithium-induced nephrogenic diabetes insipidus was hospitalized for treatment of a manic episode. Antipsychotic drug-induced sedation impaired her ability to replace fluids, and she quickly became lithium toxic and hypernatremic. Permanent cerebellar damage was the result.

There is no magic serum lithium concentration below which intoxication never occurs and above which it is inevitable. Severe toxicity has been described in patients whose serum concentrations were within the so-called therapeutic range of 0.5 to 1.5 mEq/L. Other patients have tolerated high concentrations after deliberate overdoses without noticeable clinical consequences. In general, however, the higher the concentration and the longer the exposure, the more serious the intoxication. Early clinical manifestations include dysarthria, ataxia, and coarse tremor. Ominous findings include impaired consciousness, neuromuscular irritability (fasciculations, myoclonus), seizures, and coma. Some cases of lithium intoxication have resembled Creutzfeldt-Jakob disease or neuroleptic malignant syndrome.

Treatment is directed at the removal of lithium from the body. In mild cases, nothing more may be necessary than discontinuation of intake. After an overdose, gastric lavage is indicated and may have to be repeated. Although activated charcoal is not helpful following an acute overdose with lithium, preliminary reports using polystyrene sulfonate (Kayexalate), a cation exchange resin, or whole bowel irrigation with polyethylene glycol solution (GoLYTELY) have been promising. In the presence of normal renal function, mild to moderate toxicity often responds to correcting dehydration and maintaining proper fluid and electrolyte balance. Whether forced diuresis provides additional benefit is open to debate. Hemodialysis is the treatment of choice for severe intoxication. Lithium is removed effectively by dialysis because it is water soluble, unbound to plasma protein, without metabolites, and of simple structure (an element). Redistribution of lithium from tissues to blood after dialysis usually results in a rebound increase in its blood level; this may necessitate further dialysis. Because of the drug's tissue-toxic effects and its gradual removal from the CNS, clinical improvement may lag many days behind the lowering of serum concentration.

Thyroid Reactions Transient mild abnormalities in thyroid function testing are common early in the course of lithium treatment, but are usually of little or no clinical consequence. Some patients, however, develop goiter or clinical hypothyroidism sometime during the course of treatment. Women and those with pre-existing thyroid dysfunction are more than usually susceptible. Among lithium's many effects on thyroid function, it impedes the release of hormone from the gland. The goiter that has been described in about 5 percent of patients taking lithium is rarely of cosmetic or obstructive importance; however, a recent ultrasound study suggested that thyroid gland enlargement is considerably more common than 5 percent.

Clinical hypothyroidism occurs in at least 4 percent of patients taking lithium. Once diagnosed, it can be treated with supplemental levothyroxine (Synthroid) at a dosage that returns the thyroid-stimulating hormone (TSH) concentration to normal. Chemical hypothyroidism (abnormal thyroid function tests without clinical manifestations) as determined by elevated serum TSH concentrations is considerably more common than clinical hypothyroidism. Substantial elevations of TSH are likely to progress to clinical hypothyroidism and thus should be treated with exogenous thyroid hormone. Minor elevations, on the other hand, especially early in the course of lithium therapy are likely to normalize without treatment.

Both exophthalmos and hyperthyroidism have been described during lithium therapy. One small study found long-term lithium use to be associated with thyrotoxicosis at a rate three times higher than that found in the general population. Monitoring of thyroid function (usually measurement of serum TSH concentration with or without triiodethyronine [T_3] and thyroxine [T4] concentrations) is an integral part of lithium therapy. Whether it is done routinely (every 6 or 12 months) or only when clinical suspicions are aroused is a matter of preference.

Cardiovascular Reactions Benign, reversible T-wave changes on the electrocardiogram (ECG) are common during lithium therapy and are of no clinical consequence. Varying degrees of heart block have been reported during lithium intoxication and occasionally during the therapeutic use of lithium. Electrophysiological studies show that lithium can impair sinus node function, and sinus dysrhythmias, sometimes associated with syncopal episodes, have been reported in a few patients. Lithium does not have clinically important effects on blood pressure.

Although the drug is not contraindicated in the presence of cardiovascular disease, it should be used with caution. A pacemaker may be necessary if lithium is used in the presence of clinically significant sinus node disease. Low-salt diets, certain diuretics, angiotensin-converting enzyme inhibitors, fluid-electrolyte imbalances, and impaired renal function all predispose to lithium toxicity.

Renal Reactions The great kidney debate over the nephrotoxicity of lithium is likely to resist full resolution, despite voluminous writings on the subject. In the majority of patients lithium impairs renal concentrating ability, which in itself is of no clinical importance. The concentrating defect is not always reversible after lithium

discontinuation, suggesting that both functional and structural changes have occurred in the distal tubules and collecting ducts.

Polyuria is the most clinically troublesome renal effect of lithium. Figures vary considerably, but a 24-hour urine volume of more than 3 liters (1 to 2 L is normal) has been reported in as many as 35 percent of patients taking lithium. Lithium increases urine volume primarily by inhibiting the effect of antidiuretic hormone on the kidneys, although additional renal and CNS mechanisms have been identified. When severe, polyuria can be socially and occupationally compromising; a cause of insomnia, weight gain (through consumption of high-calorie beverages), poor nutrition, and noncompliance; and potentially dangerous if dehydration occurs. Treatment considerations include (1) adequate fluid replacement, (2) using the lowest effective dosage, (3) and counteractive medications such as thiazides or potassium sparing diuretics, or indomethacin (Indocin). Amiloride (Midamor) or an amiloride-hydrochlorothiazide combination (Moduretic) is preferred to minimize the risk of hypokalemia. Whether single-daily dosing is beneficial remains controversial, as do treatments such as inositol, potassium supplementation, and desmopressin (DDAVP).

Lithium can also alter kidney morphology. The most common finding is a nonspecific interstitial fibrosis, although a lithium-distinctive tubular lesion has also been described. In the absence of lithium intoxication, the morphological changes attributed to lithium tend to be mild, especially when compared with appropriately selected controls.

Most studies of GFR find few or no reductions that could be attributed to lithium. Although reassuring, these observations do not exclude the possibility that a small number of patients are susceptible to lithium-induced reductions in GFR. Clinicians have described patients whose creatinine clearance has crept downward over the years to an extent that exceeds that expected from age alone. A study of 142 patients on lithium for a minimum of 15 years found reduced glomerular filtration rates in 21 percent and increased serum creatinine in 12 percent (after correcting for age).

A 55-year-old man, successfully stabilized on lithium for 22 years, experienced a gradual increase in serum creatinine to 2.4 mg/dL (range of normal 0.6 to 1.3). A thorough evaluation by a nephrologist produced no another explanation, and lithium was felt to be the most likely cause.

There have been occasional well-documented reports of lithium-related nephrotic syndrome and of incomplete distal renal tubular acidosis.

Regular monitoring of renal function is a necessary part of long-term lithium therapy. For most patients, the periodic measurement of serum creatinine, a urinalysis, and a clinical estimate of urine volume will suffice. If appropriate, a 24-hour urine volume, protein, and creatinine clearance will provide more comprehensive information. Because there are many causes of impaired kidney function, consultation with a nephrologist is appropriate if abnormalities are found.

Other Reactions Weight gain is a common adverse effect of lithium and may be due to the drug's complex effects on carbohydrate metabolism. Other possible causes include lithium-induced hypothyroidism and increased caloric intake from thirst-quenching beverages.

Gastrointestinal adverse effects—including nausea, appetite loss, and loose stools—are common but usually mild. Severe gastrointestinal symptoms may portend impending lithium intoxication.

The most common hematological effect of lithium is a benign, reversible, and usually mild granulocytosis induced by stimulation of granulocyte production. An increase in platelet count is noted occasionally, but there are no clinically important effects on red blood cell count.

Dermatological adverse effects include the first occurrence or worsening of acne and psoriasis, scattered reports of rashes of various types, and hair loss that is only occasionally related to lithium-induced hypothyroidism.

Alterations in calcium metabolism and parathyroid function have also been described. Lithium decreases the renal excretion of calcium, with an associated increase in serum calcium concentration, which usually does not exceed normal. Over time, parathyroid hyperplasia or a parathyroid adenoma may occur with elevated parathyroid hormone concentrations and hypercalcemia.

Sexual dysfunction, including erectile disorder, has been attributed to lithium, but documented cases are quite uncommon.

There is an inverse relation between dietary sodium intake and serum lithium concentration. Low-sodium diets result in increased serum lithium concentrations and may cause lithium intoxication unless the dosage of lithium is reduced. Diets that severely restrict fluid intake place patients at risk for dehydration and subsequent lithium intoxication.

DRUG INTERACTIONS

Antipsychotics Lithium and antipsychotic drugs have been used together safely and effectively for years; however, concern has been expressed that the combination may cause an encephalopathy in certain persons. Although the interaction has been most frequently reported with haloperidol (Haldol), a number of other antipsychotic drugs have also been implicated. A clear cause-and-effect relationship has not been established; nonetheless, caution is advised, and the simultaneous use of high dosages of the two drugs should be avoided.

Anticonvulsants In treatment-resistant cases, lithium is often combined with carbamazepine, clonazepam, or valproate and to a lesser extent with gabapentin and lamotrigine. Neurotoxic interactions have been described, but are usually avoidable with careful clinical management. When two drugs are used together, shared adverse effects may be more pronounced; for example, tremor and weight gain from lithium and valproate. In addition, lithium offers some protection against carbamazepine-induced granulocytopenia although whether it does the same for the rare agranulocytosis and aplastic anemia is unknown.

Antidepressants In general, lithium and antidepressant combinations are safe and effective, although there have been occasional reports of a serotonin-like syndrome when lithium was combined with potent serotonin reuptake inhibitors. Serum lithium concentrations are not altered in any substantial way by antidepressant drugs.

Anti-inflammatory Drugs Most nonsteroidal anti-inflammatory drugs reduce renal lithium clearance and increase the serum lithium concentration in a way that is clinically important and potentially dangerous. Among the drugs that cause this interaction are indomethacin (Indocin), phenylbutazone, diclofenac (Voltaren), ketoprofen (Orudis), oxyphenbutazone, ibuprofen (Motrin, Advil, Nuprin), piroxicam (Feldene), and naproxen (Naprosyn). Aspirin and sulindac (Clinoril) appear to be exceptions. Risk factors include high doses of the anti-inflammatory drug, increased age, and renal impairment. Because many of these drugs are now available without prescription, it is especially important that patients be aware of the possibility of an interaction.

Diuretics Thiazide diuretics decrease renal lithium clearance and increase the serum lithium concentration. Lithium toxicity has been known to occur. If a thiazide is prescribed, lithium dosage reduction is often necessary. If a thiazide is discontinued, lithium dosage may need to be increased to avoid subtherapeutic levels. Although less well established, potassium-sparing diuretics may also cause lithium retention. On the other hand, loop diuretics such as furosemide (Lasix) do not reduce and may actually increase renal lithium clearance. Osmotic and xanthine diuretics (caffeine, theophylline [Theo-dur], and aminophylline) also increase lithium clearance. Because diuretics are often given to patients who are medically ill with unstable fluid electrolyte status, interactions with lithium may not be predictable, and close monitoring is advised.

Angiotensin Converting Enzyme (ACE) Inhibitors ACE inhibitors are used extensively to treat cardiovascular disease. A growing number of case reports suggest that these drugs may cause lithium retention and toxicity in some patients. In contrast, losartan (Cozaar), an angiotensin II receptor (type AT_1) antagonist, does not appear to have this effect.

Other Drug Interactions Adverse interactions with varying degrees of substantiation have been reported between lithium and a number of other drugs (Table 31.18-4). These interactions may involve increases or decreases in serum lithium concentrations or neurotoxic symptoms in the presence of unchanged serum levels. Questions about potential interactions should be addressed by consulting a handbook on drug interactions, a regional drug information center, or the special lithium information center.

Table 31.18-4 Drug Interactions with Lithium

LABORATORY INTERFERENCES

Lithium does not appear to interfere in any clinically important way with other laboratory tests. A distinction must be made, however, between interfering with laboratory tests and causing alterations in laboratory tests. Lithium does cause alterations in a number of areas, including white blood cell count (increase), thyroid function (decrease), and serum calcium (increase). Those changes are induced by lithium rather than by an artifactual interference with the tests themselves.

Laboratory Monitoring Lithium has been measured in virtually every ody fluid, but only blood (serum or plasma) is used in clinical practice. Despite considerable research, red blood cell, saliva, and tear lithium measurements and ratios such as red blood cell to plasma have failed to gain widespread acceptance. Methods used to measure serum lithium include flame photometry, atomic absorption spectrophotometry, and ion-selective electrode analysis. Any of these methods in competent hands yields results that are acceptable for both therapeutic and toxic clinical situations. More recently, a colorimetric assay has been developed. The analyzers used in clinical laboratories are usually not capable of measuring the low levels of naturally occurring lithium in the blood, but more sensitive measures such as flameless atomic absorption spectroscopy and mass spectrometry are available for that purpose. Promising research has been conducted using Li^{7} magnetic resonance spectroscopy to measure lithium concentrations in human brain.

The periodic measurement of serum lithium concentration is an essential aspect of patient care, but it should always be combined with sound clinical judgment. A laboratory report listing the therapeutic range as 0.5 to 1.5 mEq/L may lull a clinician into disregarding early signs of lithium intoxication in patients whose levels are less than 1.5 mEq/L. Clinical toxicity, especially in the elderly, has been well documented as occurring within this so-called therapeutic range.

The 1996 United States package inserts for lithium products list effective serum concentration for mania between 1.0 and 1.5 mEq/L (usually achieved with 1800 mg of lithium carbonate daily) and for long-term maintenance between 0.6 and 1.2 mEq/L (usually achieved with 900 to 1200 mg of lithium carbonate daily). The dose-blood level relationship may vary considerably from patient to patient. The likelihood of achieving a response at levels above 1.5 mEq/L is usually outweighed greatly by the increased risk of toxicity, although occasionally a patient may both require and tolerate a higher-than-usual blood concentration.

What constitutes the lower end of the therapeutic range remains a matter of debate. A prospective 3-year study found that patients maintained at between 0.4 and 0.6 mEq/L (mean 0.54) were 2.6 times more likely to relapse than those maintained at between 0.8 and 1.0 mEq/L (mean 0.83). However, the higher blood concentrations produced more adverse effects and were less well tolerated. A recent reanalysis of these data concluded that lower maintenance levels per se were not responsible for the higher relapse rate, but rather that the risk of relapse was increased only in patients who were abruptly randomized from higher pre-study lithium levels to the lower level group. An international group of experts concluded recently that a good prophylactic effect can usually be obtained within the range of 0.4 to 0.8 mEq/L; unfortunately, trial and error is the only way to establish the minimum effective level for a given patient.

Essential to interpreting serum lithium levels is knowing the sampling interval (the time between the last dose and the drawing of blood), the dose form, and the dosage schedule. Blood concentrations obtained an hour or so after a dose are considerably higher than those obtained after a long sampling interval. The 12-hour interval that has been adopted as standard has been defined as follows: (1) the blood should be drawn in the morning, 12 hours (±30 minutes) after the last dose; (2) a multiple-dose regimen should be used; and (3) a steady-state condition should exist (skipped or extra doses within 4 or 5 days should be avoided). Although the effectiveness of lithium does not depend on the daily dosing schedule (every other day dosing, however, has been shown to be less effective than daily dosing), 12-hour serum concentrations will be higher with single as opposed to multiple daily dosing. This difference may range between 10 and 30 percent and cannot be easily predicted. Consequently, treatment is usually initiated with at least twice-daily dosing, although switching later to single-daily dosing may have the advantage of improved compliance and fewer adverse effects.

Even when these guidelines are followed, the serum level may fluctuate from measurement to measurement, reflecting factors such as dietary sodium intake, mood state, activity level, body position, and improper sample collection (use of a lithium-heparin anticoagulant will increase the concentration by more than 1 mEq/L).

Dosage Prediction In an effort to make lithium as therapeutically efficient as possible, investigators have developed several approaches to predicting the daily dosage required to produce the desired serum concentration. Dosage prediction techniques include giving a single dose of lithium carbonate and using the serum concentration after a given interval (usually 24 hours) to predict the maintenance dose; measuring renal lithium clearance; and the use of mathematical models. Thus far, prediction techniques have not been widely accepted and most clinicians continue to adjust the dosage based on the patient's clinical condition and previous blood concentrations. Nonetheless, “loading” a drug to produce a more rapid onset of action has become more appealing because of economic pressures to minimize length of hospital stay. Although one study found that a 30 mg/kg loading dose of slow-release lithium carbonate was well tolerated and achieved a therapeutic concentration in blood in 12 hours, it remains to be determined whether lithium loading can reduce time to remission or duration of hospitalization.

DOSAGE AND ADMINISTRATION

The extent of medical evaluation necessary before starting lithium is determined by individual patient characteristics such as age, associated illnesses, and the presence of other drugs; consequently, a thorough medical history is essential. The history determines the need for and the extent of physical and laboratory evaluations. All patients, however, should have renal and thyroid function tested before beginning treatment.

In the United States lithium preparations include immediate-release (Eskalith, Lithonate, Lithotabs), slow-release (Lithobid), and controlled-release (Eskalith CR) forms of lithium carbonate and a lithium citrate syrup. There are no parenteral forms. Both 300 mg of the carbonate and 5 ml of the citrate contain about 8 mEq (mmol) of lithium (Table 31.18-5). In view of the increasing prominence of valproate divalproex (Depakote) for the treatment of manic episode, the existence of a lithium valproate compound in Russia is of interest. Elsewhere in the world lithium acetate, glutamate, gluconate, orotate, and sulphate preparations have been available or are currently available. Clinicians should be aware that *lithium* and *lithium carbonate* are not interchangeable (300 mg of lithium is equivalent to 1597 mg of lithium carbonate).

Lithium carbonate capsules	150, 300, 600 mg
Lithium carbonate tablets	300 mg
Lithium carbonate controlled-release tablets	450 mg
Lithium carbonate slow-release tablets	300 mg
Lithium citrate syrup	8 mEq/5 mL

Table 31.18-5 Lithium Preparations Available in the United States

Starting Dosage Lithium therapy is initiated in divided doses. Once a patient is stabilized, single daily dosing is sometimes convenient. In the presence of normal kidney function, a total daily dose of 1200 to 1800 mg of lithium carbonate generally produces an antimanic serum concentration of 0.8 to 1.2 mEq/L. Maintenance levels of 0.6 to 1 mEq/L can usually be attained with 900 to 1200 mg daily. In general, a conservatively low dose is started, perhaps 300 mg twice or three times daily, a serum concentration is obtained after steady-state is reached (in 4 or 5 days), and the dose is adjusted accordingly. Patients vary widely in the dose required to reach a desired blood concentration although the elderly usually require lesser amounts. Consequently, these figures must be considered guidelines rather than absolutes.

Maintenance Dosage During maintenance therapy, patients must be evaluated clinically, lithium levels determined periodically, and appropriate laboratory tests performed at regular intervals. Monthly visits are common early in treatment if the clinical course is uncomplicated. Patients who have been stable for extended periods may be seen at intervals of 3, 4, or even 6 months. Patient education, including written materials and support programs, such as those by the National Depressive and Manic Depressive Association (NDMDA, 730 N. Franklin Street, Chicago, IL 60610), plays an important role in ensuring safe, effective, and compliant long-term treatment.

Discontinuation Lithium is discontinued if it is ineffective or not tolerated. Patients may stop the drug for other reasons, such as a perceived or real loss in creativity, feeling cured, or a dislike for feeling controlled by a medicine. After a period of stability with maintenance therapy, a trial off lithium may be considered, although the risk of recurrence is considerable (especially if there have been several prior episodes), and there have been reports of failure to respond to lithium when treatment is reinstituted. Discontinuation should be gradual over many weeks, because more abrupt discontinuation appears to be associated with a higher likelihood of early recurrence of mania or depression. Teaching patients and significant others to recognize early signs of recurrence is an important part of the discontinuation process.

SUGGESTED CROSS-REFERENCES

Intraneuronal signaling pathways are discussed in Section 1.8; mood disorders are discussed in Chapter 14. Chapter 31 presents biological therapies, particularly calcium channel inhibitors, carbamazepine, valproate, and antidepressant medications. Child psychiatry is discussed in Chapter 32 and Section 51.3d discusses mood disorders in the elderly. Schizophrenia is presented in Chapter 12 and other psychotic disorders are discussed in Chapter 13.

CHAPTER 31. BIOLOGICAL THERAPIES

31.19 MIRTAZAPINE

JAMES L. CLAGHORN, M.D.

Mirtazapine (Remeron) is the first among a new class of antidepressants described as noradrenergic and specific serotonergic antidepressants. Mirtazapine was first marketed in the Netherlands in 1994; it has since been marketed worldwide for the treatment of depression. Mirtazapine was introduced in the United States in 1996 for the treatment of depression.

CHEMISTRY

Mirtazapine (1,2,3,4,50,14b-hexahydro-2-methylpyrazino [2,1-a]pyrido[2,3-c][2]benzazepine) is a novel antidepressant. It belongs to the chemical class of compounds known as the piperazinoazepines and is not related to any known class of psychotropic drugs. It has the empirical formula $C_{17}H_{19}N_3$, and its molecular weight is 265.36 mol. Mirtazapine is marketed as a racemic mixture (50/50) of the (+) and (–) enantiomers, both of which possess pharmacological activity essential for the overall antidepressant effects of the racimate (Fig. 31.19-1).

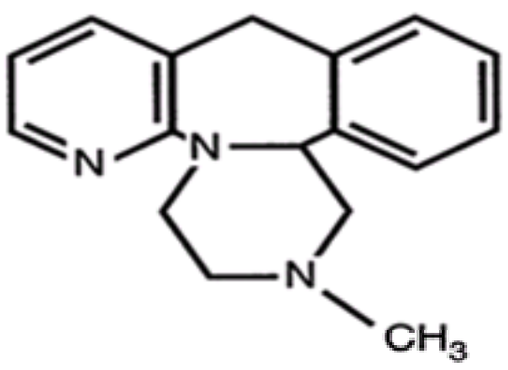

FIGURE 31.19-1 Molecular structure of mirtazapine.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption Mirtazapine is well absorbed from the gastrointestinal tract after single or multiple oral doses and reaches peak plasma concentrations within 2 hours. Both the rate and extent of absorption of mirtazapine are minimally affected by the presence of food in the stomach, so patients may take mirtazapine without regard to meals. The absolute bioavailability of mirtazapine after single and multiple oral dosing is approximately 50 percent.

Distribution Human plasma protein binding is aspecific and reversible, and mirtazapine is approximately 85 percent protein bound at therapeutic dosages.

Metabolism Orally administered mirtazapine is extensively metabolized by the liver via demethylation, hydroxylation and N-oxidation, followed by conjugation with glucuronic acid. In vitro data from human liver microsome studies indicate that mirtazapine is metabolized by multiple cytochrome P450 (CYP) isoenzymes, namely CYP 2D6, CYP 3A4, and possibly CYP 1A2 to produce the 8-hydroxy, *N*-desmethyl, and *N*-oxide metabolites. Demethyl-mirtazapine is the only metabolite that demonstrates pharmacological activity. However, it is five to ten times less active than the parent compound, and it has been estimated that the contribution of the total pharmacodynamic profile of mirtazapine is 3 to 6 percent. Mirtazapine does not appear to have any inducing or inhibiting effects on the cytochrome P450 system, and its disposition appears to be independent of polymorphic CYP 2D6 activity. It appears unlikely that mirtazapine would inhibit the metabolism of drugs metabolized by CYP 1A2, CYP 2D6, or CYP 3A4. Potent inhibitors of CYP 2D6 would not affect the metabolism of the major enantiomer of mirtazapine, though its effect on the minor enantiomer cannot be predicted.

Elimination Mirtazapine follows linear pharmacokinetics within a dose range between 15 and 75 mg and has a mean elimination half-life of 20 to 40 hours after oral administration. Steady-state plasma concentrations of mirtazapine are attained within 5 days, with about 50 percent accumulation. It is eliminated primarily in the urine (80 percent), with small amounts in the feces (15 percent), up to 4 percent of the orally administered drug can be eliminated unchanged in the urine. Elderly persons and patients with liver or renal disease may require cautious dose increases.

Pharmacodynamics

Mechanism of Action As with all antidepressants, the exact mechanism of action of mirtazapine is unknown. Its pharmacological effects can best be described as enhancing noradrenergic activity and having specific serotonergic activity. Preclinical studies demonstrated that mirtazapine does not inhibit norepinephrine reuptake but preferentially antagonizes central presynaptic a_2-adrenergic autoreceptors or heteroreceptors, which respectively control norepinephrine and serotonin release. Mirtazapine blocks presynaptic a_2-adrenergic autoreceptors, leading to an increase in the release of norepinephrine. Mirtazapine's affinity in vitro for central presynaptic a_2-autoreceptors is approximately 30 times higher than that for central and peripheral a_1-adrenoreceptors. The low affinity of mirtazapine for central a_1-adrenoreceptors located on serotonin cell bodies allows for unopposed stimulation of a_1-receptors by released norepinephrine; this increases the firing rate of serotonergic neurons. Mirtazapine also blocks a_2-adrenergic heteroreceptors located on serotonin terminals, thus enhancing serotonin release; therefore the net effect of mirtazapine is an increase in both noradrenergic and serotonergic neurotransmission.

The a_2-adrenergic autoreceptors and heteroreceptors and serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT_2) blocking effects predominate in the (+)-enantiomer; a_2-heteroreceptor blockade and 5-HT_3-blocking effects predominate in the (–)-enantiomer.

The stimulation or blockade of several postsynaptic serotonin receptor subtypes is responsible for both clinical and adverse effects. Stimulation of 5-HT receptors is thought to mediate the therapeutic effects of antidepressants, whereas stimulation of 5-HT_2 and 5-HT_3 receptors is thought to be involved with both clinical and adverse effects. Mirtazapine has a low affinity for 5-HT_{1A} and 5-HT_{1B} subtypes, thus allowing unopposed stimulation of postsynaptic 5-HT_{1A} receptors. In addition, the drug is a potent antagonist of 5-HT_2 and 5-HT_3 receptors, which may account for low incidences of serotonin-related adverse effects such as anxiety, insomnia, nausea, and sexual dysfunction reported during the use of mirtazapine. Blockade of these receptors has also been associated with deep-sleep–promoting and

anxiolytic activity. Mirtazapine reduces rapid eye movement (REM) sleep, increases REM sleep latency, and improves deep sleep.

Mirtazapine has little affinity for dopamine type 1 (D_1) and D_2 receptors and has only moderate affinity for muscarinic and cholinergic receptors, which may explain the low incidence of anticholinergic and dopaminergic adverse effects. Mirtazapine is a potent antagonist of histamine type 1 (H_1) receptors, which may explain its somnolence-inducing effects. Although mirtazapine can cause daytime somnolence, this effect is thought to be partially offset by its action on the noradrenergic system at usual therapeutic dosages.

Blood Concentrations and Relation to Action The available data demonstrate that mirtazapine has linear pharmacokinetics within a dose range of 15 to 75 mg. As with other new antidepressants, there are currently no data to support routine blood concentration measurements as predictors of clinical response.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

In published reports of clinical trials, mirtazapine has been compared with placebo, amitriptyline (Elavil), fluoxetine (Prozac), trazodone (Desyrel), doxepin (Adapin, Sinequan), and clomipramine (Anafranil) in the treatment of depression (Table 31.19-1). Both inpatients and outpatients who met the criteria for major depression in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) participated in these studies. The 17-item Hamilton Rating Scale for Depression (HAM-D) total score was used to assess baseline severity of depression. Patients ranging from 18 to 65 years of age and over with HAM-D scores of 18 or above (moderate to severe depression) participated in the studies.

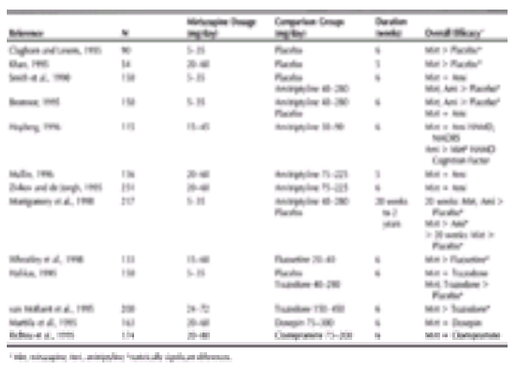

Table 31.19-1 Selected Studies of Mirtazapine in the Treatment of Depression

Antidepressant efficacy was measured using the 17-item HAM-D, Montgomery-Aåsberg Depression Rating Scale (MADRS), Beck Depression Inventory, and Zung's Self-Rating Depression Scale (SDS). The Brief Psychiatric Rating Scale (BPRS), the Clinical Global Impression (CGI) Scale, the Visual Analogue Mood Rating (VAMR) Scale, Quality of Life Enjoyment and Satisfaction Questionnaire (QLESQ), and the Global Assessment Scale (GAS) were used to assess general psychopathology, clinical impression, and global functioning. Efficacy analyses were performed on an intent-to-treat basis, thus including all patients who had received at least one dose of study medication and had at least one postbaseline efficacy assessment: efficacy analysis was based on changes from baseline in rating scales scores during treatment. In addition to weekly observed-case analysis, a last-observation-carried-forward analysis was performed until week 6. A positive response to treatment was defined as a 50 percent or more reduction in the 17-item HAM-D score from baseline.

Most clinical studies allowed dosages to be tailored to individual patient needs and to be titrated on the basis of patient response, which reflects most clinical practice. Dosages ranged from 5 to 60 mg a day in placebo-controlled studies and 5 to 80 mg a day in the active-controlled studies.

Mirtazapine's use in treating a subset of patients with sleep disturbances, anxiety, and cognitive impairment was evaluated using the HAM-D Sleep Disturbance factor IV (sum of items 4, 5, and 6), HAM-D anxiety/somatization factor (sum of items 10, 11, 12, 13, 15, and 17), the HAM-D anxiety/agitation factor (sum of items 9, 10, and 11) and HAM-D Cognitive Disturbance factor III.

Major Depressive Disorder

Comparisons of Mirtazapine and Placebo Ninety outpatients between the ages of 18 and 65 years with moderate-to-severe depression were randomized to either mirtazapine (5 to 35 mg a day) or placebo in a 6-week, double-blind trial. Mirtazapine was significantly superior to placebo (*P* £ .05) for patients with moderate-to-severe depression in weeks 1 to 4 and at endpoint for the following efficacy parameters: 17-item HAM-D, MADRS, and CGI.

Statistically significant (*P* £ .05) between-treatment differences were observed that favored mirtazapine at weeks 1 to 5 and at endpoint in the reduction of the anxiety/somatization factor, at weeks 2 to 3 and at endpoint for the retardation factor, weeks 2 to 4 and endpoint for the cognitive disturbance factor, and weeks 1 to 4 and endpoint for the sleep disturbance factor. The dropout rates were 40 percent for mirtazapine-treated patients and 58 percent for placebo-treated patients. The percentage of dropouts for drug-related adverse effects or lack of efficacy was 27 percent for mirtazapine-treated patients and 40 percent for placebo-treated patients. Significantly more placebo-treated patients (40 percent) than mirtazapine-treated patients (18 percent) discontinued treatment because of a lack of efficacy. Mirtazapine was well tolerated, with somnolence and increased appetite the only adverse effects significantly different from those with placebo.

The efficacy of mirtazapine (20 to 60 mg a day) was compared with that of placebo in a 5-week, randomized, double-blind, placebo-controlled study in 54 inpatients and outpatients with a diagnosis of major depressive disorder. Mirtazapine-treated patients had statistically significant and clinically relevant differences at weeks 4, 5, and at endpoint compared with placebo-treated patients on the 17-item HAM-D and MADRS scales. At the end of the study 56 percent of mirtazapine-treated patients and 36 percent of placebo-treated patients responded to therapy. A similar percentage of patients withdrew from the study, and there was no statistically significant difference between mirtazapine-treated and placebo-treated patients in reported/adverse clinical effects.

In addition to the results of these placebo-controlled trials, a meta-analysis was performed on efficacy data from three U.S. and two European placebo-controlled studies. A total of 495 patients (mirtazapine, 249; placebo, 246) were available for evaluation. The results of the meta-analysis confirmed the efficacy findings of the individual clinical trials: mirtazapine-treated patients showed a significantly greater reduction from baseline in the mean group 17-item HAMD scores than placebo-treated patients. The difference was seen as early as week 1 of treatment and continued throughout the treatment period. Mirtazapine-treated patients also demonstrated significantly greater improvements in MADRS scores at all weekly assessments and at endpoint. At endpoint approximately 51 percent of mirtazapine-treated patients responded to treatment (versus 33 percent of placebo-treated patients) as assessed by HAM-D criterion (*P* £ .05). Also, an analysis of dropout due to lack of efficacy indicated that mirtazapine-treated patients (13.7 percent) were less likely to drop out because of lack of efficiency (*P* £ .05) than placebo-treated patients (21.8 percent).

Comparison of Mirtazapine and Amitriptyline The efficacy of mirtazapine was compared with that of amitriptyline in several placebo-controlled studies. In one 6-week, double-blind study 150 outpatients were randomized to receive mirtazapine (5 to 35 mg a day), amitriptyline (40 to 280 mg a day), or placebo. Both active treatment groups showed statistically significant improvement at weeks 1, 2, 4, and endpoint in HAM-D scores compared with placebo. These findings were further supported by results on the MADRS, SDS, and CGI Scale. Somnolence, constipation, and weight gain were the only three adverse effects reported by more mirtazapine-treated patients than placebo-treated patients, although they were not substantially different from that reported in the amitriptyline group. However, significantly more amitriptyline-treated patients reported decreased visual accommodation, dry mouth, headache, dyspepsia, constipation, tachycardia, hypertension, hypotension, discoordination, dizziness, and tremor than mirtazapine-treated or placebo-treated patients. In this study mirtazapine was more effective than placebo and as effective as amitriptyline in treating depression, with a significantly better tolerability profile than amitriptyline.

Another trial compared the efficacy of mirtazapine (5 to 35 mg a day) with amitriptyline (40 to 280 mg a day) in a 6-week, double-blind placebo-controlled study in 150 outpatients. Statistically significant HAM-D score reductions (*P* £ .05) were seen in the mirtazapine-treated and amitriptyline-treated patient groups from week 1 through endpoint, compared with placebo-treated patients. Mirtazapine-treated patients demonstrated statistically significant (*P* £ .05) reductions at weeks 1 to 6 and endpoint for the HAM-D item 1 (depressed mood) compared with placebo-treated patients. Amitriptyline-treated patients demonstrated statistically significant (*P* £ .05)

reductions at weeks 2, 3, and 4 on the same item, compared with patients treated with placebo. Both active-treatment groups showed significantly greater improvements than placebo-treatment groups on the MADRS, SDS, and CGI Scales. This was further evidenced by the percentage of patients (responders) who had at least a 50 percent reduction in HAM-D total score from baseline to endpoint. Significant differences were noted in responder rates after 6 weeks of treatment: 70 percent of the patients receiving mirtazapine responded, compared with 58 percent of amitriptyline-treated patients, and 33 percent of placebo-treated patients. Mirtazapine was well tolerated, with dry mouth and somnolence occurring more frequently than in placebo-treated patients. Treatment with amitriptyline was associated with significantly higher rates of somnolence, dry mouth, constipation, and dyspepsia than treatment with mirtazapine and placebo.

Some 251 inpatients with major depressive disorder were treated with either mirtazapine (20 to 60 mg a day) or amitriptyline (75 to 225 mg a day) in a 6-week, randomized, double-blind, multicenter study. Most patients in both treatment groups were severely depressed as determined by a group mean 17-item HAM-D score of 28 for mirtazapine-treated patients and 27.6 for amitriptyline-treated patients. Both treatment groups demonstrated equal improvement at all scheduled assessments and at the end of the trial (72 percent response rate). Similar improvements were noted on BPRS and GAS measurements. There were no statistically significant differences between the treatment groups on any scale used. Both treatments were generally well tolerated; however, dry mouth and sweating were reported significantly more frequently after 42 days of treatment with amitriptyline than with mirtazapine (*P* £ .05).

A total of 217 patients who participated in a short-term, double-blind comparison of mirtazapine (5 to 35 mg a day), amitriptyline (40 to 280 mg a day), and placebo were enrolled in a long-term extension for up to 2 years. Efficacy and safety analyses were performed on the first 20 weeks of data. Significantly (*P* < .05) fewer mirtazapine-treated patients relapsed than placebo-treated patients, and mirtazapine-treated patients had a significantly longer time to relapse as well. Similar results were found comparing amitriptyline-treated patients with placebo-treated patients. Mirtazapine also held an advantage in preventing relapses, compared with amitriptyline (*P* < .05). Similar results were found in the prophylactic phase of treatment after 20 weeks. Amitriptyline was better than placebo; however, there was no difference in the number of patients with a sustained response. Mirtazapine was well tolerated, with fewer mirtazapine-treated patients reporting adverse effects than amitriptyline-treated patients.

A meta-analysis was performed on the efficacy and safety data from four randomized, double-blind, 6-week, single-center studies comparing mirtazapine (5 to 35 mg a day) with amitriptyline (40 to 280 mg a day) and placebo in 580 outpatients with DSM-III diagnoses of major depression. Both active treatments were equally effective and significantly (*P* £ .05) more effective than placebo at weekly assessments, as assessed by reductions from baseline on the 17-item HDRS, MADRS, CGI scores, HDRS item 1 (depressed mood), and HDRS factors (anxiety/somatization, sleep disturbance, and melancholia). Both treatment groups demonstrated statistically significant (*P* £ .05) greater improvement and significantly greater percentages of responders and remitters than placebo. Mirtazapine was better tolerated than amitriptyline. Amitriptyline-treated patients reported significantly more dry mouth, dyspepsia, blurred vision, constipation, tremor, vertigo, and tachycardia than mirtazapine-treated patients and placebo-treated patients.

In another study, 115 elderly patients with moderate-to-severe depression were randomized to receive either mirtazapine (15 to 45 mg a day) or amitriptyline (30 to 90 mg a day) in a double-blind, flexible-dose, 6-week study. Both treatments were equally effective, as assessed by the 21-item HRSD and MADRS scales at weeks 2, 4, 6, and endpoint, with no statistically significant differences between the treatment groups at any assessment time or endpoint. Minor, but statistically significant (*P* £ .05), changes favoring amitriptyline were noted at endpoint on GCI-Global Improvement Scale, at all assessments on the HRSD cognitive factor, and at 6 weeks for the HRSD retardation factor. However, an equally high percentage of mirtazapine- (74 percent) and amitriptyline-treated patients (81 percent) responded to therapy according to CGI criteria. Both drugs were well tolerated, and there were no statistically significant differences in reports of adverse reactions.

A meta-analysis was performed on pooled data from randomized, double-blind comparisons of mirtazapine and amitriptyline; 732 patients were available for efficacy analysis. The two treatments were found equally effective at all weekly assessments and at endpoint, as assessed by reductions from baseline in total HAM-D and HAM-D item 1 scores. A similar percentage of mirtazapine-treated patients (70 percent) and amitriptyline-treated patients (73 percent) responded to treatment. Analysis of patients with moderate-to-severe depression indicated that reductions from baseline were statistically significantly larger (*P* £ .001) for mirtazapine-treated patients than for placebo-treated controls and equivalent to those of amitriptyline-treated patients. Also, the percentage of mirtazapine-treated patients (9 percent) who dropped out because of a lack of efficacy was comparable to that of amitriptyline-treated patients (6.6 percent).

Another meta-analysis was performed on pooled data from 405 severely depressed patients from randomized, double-blind, amitriptyline-controlled trials. The treatments were equally effective at all weekly assessments and at endpoint, as assessed by reductions from baseline in total HAM-D and HAM-D item 1 scores. Mirtazapine and amitriptyline were equally effective in treating depressed mood and symptoms more commonly associated with depression, such as anxiety, sleep, and vegetative disturbances.

Comparison of Mirtazapine and Fluoxetine The efficacy of mirtazapine (15 to 60 mg a day) was compared with that of fluoxetine (20 to 40 mg a day) in 133 depressed (mean HAM-D_{17}: 26.0, mirtazapine and 26.1, fluoxetine) inpatients and outpatients in a multicenter, 6-week study. Patients from both treatment groups responded to therapy, although the decrease from baseline on the HAM-D was larger in the mirtazapine group than the fluoxetine group throughout the treatment period. The mirtazapine-treated patients had statistically significant (*P* £ .05) improvement at days 21 and 28 compared with the fluoxetine group. At the assessments from day 21 forward the absolute difference favored mirtazapine over fluoxetine by between 3.7 and 4.2 points on the HAM-D scale, which is comparable to the difference observed in a comparison of antidepressant therapy and placebo. These findings were supported by the results of the CGI Scale. Patients from both treatment groups became calmer and more alert, energetic, relaxed, and tranquil, as assessed by the VAMR Scale. A statistically significant difference favored mirtazapine at day 7 for the Calm/Excited, Lethargic/Energetic, and Agitated/Tranquil items. Both treatment groups demonstrated an improvement in quality of life, as determined by the QLESQ Scale. Both treatments were well tolerated. More fluoxetine-treated patients complained of headache (17.9 percent) and nausea (10.4 percent), while more mirtazapine-treated patients complained of dry mouth (18.2 percent) and blurred vision (7.6 percent).

Comparisons of Mirtazapine and Other Antidepressants The efficacy of mirtazapine was also assessed in comparative trials with trazodone, doxepin, and clomipramine. In one study, mirtazapine (5 to 35 mg a day) was compared with trazodone (40 to 280 mg a day) and placebo in 150 outpatients 55 years of age or older in a 6-week, randomized, double-blind trazodone- and placebo-controlled trial. Statistically significant differences between both active compounds and placebo were noted at weeks 2, 3, and 4 on the MADRS. Mirtazapine (but not trazodone) showed a significant (*P* £ .05) improvement compared with placebo, as assessed by reductions from baseline in the 21-item HAM-D total score at weeks 2, 3, 4, and 6. Mirtazapine and trazodone were associated with a significantly higher frequency of somnolence and dry mouth than placebo; treatment with trazodone resulted in significantly higher frequencies of dizziness and blurred vision than treatment with placebo.

Two hundred inpatients with moderate-to-severe depression were randomized to receive either mirtazapine (24 to 72 mg a day) or trazodone (150 to 450 mg a day) in a 6-week, double-blind trial. Mirtazapine was clinically more efficacious on day 42 as assessed by changes in HAM-D, BPRS, GAS, and Beck Depression Inventory scores and percentage of responders (*P* £ .05). Mirtazapine was well tolerated. A greater percentage of trazodone-treated patients experienced somnolence and postural hypotension, although the differences were not statistically significant. Mirtazapine demonstrated significant clinical advantages over trazodone in terms of clinical efficacy and tolerability.

Mirtazapine (20 to 60 mg a day) was compared with doxepin (75–300 mg a day) in a 6-week, randomized, double-blind clinical trial. The drugs demonstrated equal efficacy in 163 hospitalized patients or outpatients with depression. Approximately 65 percent of mirtazapine-treated patients and 62 percent of doxepin-treated patients responded to treatment at endpoint; doxepin-treated patients complained more frequently of dry mouth and movement disorders.

Another study compared mirtazapine (20–80 mg a day) with clomipramine (50–200 mg a day) in a multicenter, double-blind, 6-week trial. A total 174 hospitalized, endogenously depressed patients were randomized to receive either mirtazapine or clomipramine. At the end of the study, 80 percent of mirtazapine-treated patients and 86 percent of clomipramine-treated patients responded to therapy, as assessed by the HAM-D criterion. Depressive symptoms assessed by the MADRS, BPRS, and GAS also improved significantly in both treatment groups. Dry mouth, constipation, tremor, vertigo or dizziness, faintness on rising, and nausea were reported more frequently by clomipramine-treated patients. Mirtazapine appears to be as effective as clomipramine in the treatment of depression and is better tolerated.

Major Depressive Disorder With Sleep Disturbances The effect of mirtazapine on sleep disturbances in depressed patients has been examined using HAM-D factor IV (sum of items 4, 5, and 6) in placebo-controlled clinical trials. One placebo-controlled study also showed a significant improvement (*P* £ .05) in sleep disturbances in mirtazapine-treated patients beginning in the first week of treatment, compared with placebo-treated patients. Similarly, the second study showed significantly greater improvement in sleep disturbances (*P* £ .05) in the mirtazapine and amitriptyline groups, compared with placebo. The third study showed significant (*P* £ .05) improvement in sleep disturbances from the second week onward in the mirtazapine and trazodone treatment groups compared with the placebo group. The results of two meta-analyses confirm the efficacy findings of the individual clinical trials. A meta-analysis of 364 mirtazapine-treated patients and 368 amitriptyline-treated patients showed that mirtazapine (5 to 60 mg a day) was significantly better than placebo (*P* £ .05) and comparable to amitriptyline (75 to 280 mg a day) for improving sleep disturbances during treatment and at the endpoint analysis. Another meta-analysis of three U.S. and two European placebo-controlled

studies evaluated the efficacy of mirtazapine for improving sleep disturbances in a total of 249 mirtazapine-treated and 246 placebo-treated patients. Significant (*P* £ .05) improvement favoring mirtazapine was shown for the overall population as well as for a subgroup of depressed patients with prominent sleep disturbances at baseline.

Major Depressive Disorder With Anxiety Mirtazapine's potential value in treating patients with major depressive disorder with anxiety features has also been studied. Mirtazapine-treated patients experienced significantly greater improvements from baseline in somatic anxiety, psychic anxiety, and agitation than placebo-treated patients. In one study, the mirtazapine and amitriptyline groups had significantly (*P* £ .05) greater improvement in the HAM-D Anxiety factor scores. Similar results were noted in another study in which the reductions in the mean HAM-D Anxiety factor scores were significantly greater (*P* £ .05) in the mirtazapine and trazodone groups than in the placebo group. A meta-analysis of 364 mirtazapine-treated (5 to 60 mg a day) and 368 amitriptyline-treated (75 to 280 mg a day) patients demonstrated that mirtazapine was significantly better than placebo and similar to amitriptyline in reducing HAM-D Anxiety factor scores.

A meta-analysis was performed to compare the efficacy data of mirtazapine with that for placebo and amitriptyline in patients with major depressive disorder and either Anxiety/Agitation (sum of HAM-D items 9, 10, 11) or Anxiety/Somatization (mean of HAM-D items 10, 11, 12, 13, 15, 17). Efficacy data from eight randomized, double-blind, placebo-controlled clinical trials were evaluated. A total of 385 patients (132 placebo-treated, 161 mirtazapine-treated and 92 amitriptyline-treated) were available for evaluation. Mirtazapine-treated patients demonstrated a statistically significant (*P* £ .05) reduction in the Anxiety/Agitation factor compared with placebo-treated patients at weeks 1, 2, 4, 6, and endpoint. There was no statistically significant difference between mirtazapine-treated patients and amitriptyline-treated patients at weeks 1, 3, 4, 5, 6, and endpoint. Similar results were found for the Anxiety/Somatization factor. Mirtazapine-treated patients demonstrated statistically significant (*P* £ .03) greater reductions in Anxiety/Somatization throughout weeks 1 through 6 and were comparable to amitriptyline-treated patients during this same time period.

Major Depressive Disorder With Cognitive Disturbances The effect of mirtazapine on cognitive disturbances in patients with major depressive disorder was evaluated using HAM-D factor III in several studies. In one study mirtazapine-treated patients and amitriptyline-treated patients demonstrated significantly greater reductions from baseline than placebo-treated patients. In a placebo-controlled study, mirtazapine-treated patients demonstrated statistically significant between-treatment differences compared with placebo for cognitive disturbances. These differences were seen at weeks 2 through 4 and at endpoint. Lastly, both mirtazapine (20 to 80 mg a day) and clomipramine (50 to 200 mg a day) were evaluated for their effects on cognitive disturbances; both demonstrated similar improvements in the HAM-D cognitive factor.

ANXIETY DISORDERS

Mirtazapine's potential value for other indications has been studied. The efficacy of 15 to 25 mg of mirtazapine a day was evaluated in 40 patients with a primary diagnosis of anxiety states, according to the World Health Organization's ninth revision of the *International Statistical Classification of Diseases* (ICD-9). Anxiety symptoms were evaluated using the Hamilton Anxiety Scale, Zung Anxiety Scale, and the Global Assessment Scale. Mirtazapine-treated patients experienced significantly greater improvements from baseline in overall anxiety symptoms, psychic anxiety, and global functioning than placebo-treated patients. Further studies are required before mirtazapine can be recommended as primary therapy for generalized anxiety disorder.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Central Nervous System Mirtazapine is a potent antagonist of histamine H_1 receptors, which may explain its somnolence-inducing effects. In placebo-controlled studies in the United States, somnolence was reported in 54 percent of mirtazapine-treated patients, 18 percent of placebo-treated patients, and 60 percent of amitriptyline-treated patients. Somnolence resulted in the discontinuation of therapy in 10.4 percent of all mirtazapine-treated patients and 2.2 percent of all placebo-treated patients in the U.S. controlled studies. Somnolence appears to be transient and to wear off within a few days of starting treatment. In one study, sedation generally appeared during the first week of treatment and then decreased in intensity during further dose titrations. In another 6-week study, reported somnolence typically occurred during the first week of therapy, gradually diminished, and disappeared by the end of week 4. In European placebo-controlled studies, the incidence of somnolence was 14.8 percent in mirtazapine-treated patients and 10.3 percent in placebo-treated patients. The lower incidence of somnolence in placebo-controlled European studies might be attributable to higher starting dosages (15 to 20 mg a day) than those in U.S. studies (5 to 10 mg a day). Mirtazapine's somnolence-inducing effects at higher dosages appear to be less pronounced than anticipated in relation to its potent antihistaminergic properties, probably because of the activating effects of increased noradrenergic neurotransmission that occurs within the recommended dose range (15 to 45 mg a day).

Dizziness was reported in 7 percent of mirtazapine-treated patients, 3 percent of placebo-treated patients, and 14 percent of amitriptyline-treated patients in the United States controlled studies.

Cardiovascular System Mirtazapine has little or no effect on heart rate or blood pressure. In one review individual adverse effects were assigned to different symptom cluster categories (sedation, anticholinergic effects, heart rhythm effects, hypotension/vertigo, typical selective serotonin reuptake inhibitor [SSRI]-related effects, and sexual dysfunction). The percentages of patients with at least one symptom from each of the symptom clusters were calculated on a treatment group basis. There were no differences in the incidences of heart rhythm cluster (arrhythmia, palpitations, tachycardia) between mirtazapine-treated patients (7 percent) and placebo-treated patients (10 percent). The incidence of heart rhythm cluster was 16 percent for amitriptyline, which was statistically significantly higher than in either mirtazapine-treated or placebo-treated patients. The incidence of the hypotension-vertigo symptom cluster (dizziness, postural hypotension, faintness, hypotension, orthostatic hypotension, lightheadedness, syncope, postural syncope, vertigo) was 5 percent for both mirtazapine-treated and placebo-treated patients and 11 percent for amitriptyline-treated patients, which was statistically significant versus both.

Gastrointestinal System Increased appetite and weight gain have been reported more frequently with mirtazapine use than with placebo or amitriptyline. Appetite increase was reported in 17 percent of mirtazapine-treated patients, 2 percent of placebo-treated patients, and 6 percent of amitriptyline-treated patients in controlled studies in the United States. A weight gain of 7 percent or more of body weight was reported in 7.5 percent of mirtazapine-treated patients, 0 percent of placebo-treated patients, and 5.9 percent of amitriptyline-treated patients.

Since 5-HT_3 antagonists have been shown to reduce nausea and other gastrointestinal symptoms, the low incidence of nausea and other gastrointestinal symptoms in mirtazapine-treated patients may be attributable to its blockade of postsynaptic 5-HT_3 receptors. There have been three case reports of patients receiving mirtazapine to alleviate SSRI-related nausea. Mirtazapine (15 mg) was added to the SSRI regimen, and the nausea completely resolved. In each instance, the nausea returned upon discontinuation of mirtazapine. Mirtazapine administration was restarted, and the nausea completely resolved once more.

THERAPEUTIC INDICATIONS

Mirtazapine is currently indicated for the treatment of depression. Its efficacy in the treatment of depression was established in 5- or 6-week randomized, double-blind, placebo-controlled clinical trials. The study populations consisted of inpatients and outpatients whose diagnoses corresponded most closely to the category of major depression as defined by the third editional DSM (DSM-III), with a minimum baseline score of 18 or above on the first 17 items of the HAM-D scale.

Mirtazapine's potential value in treating depressed patients with either sleep or anxiety disturbances has also been studied. Mirtazapine appears to be significantly better than placebo and similar to amitriptyline or trazodone in treating sleep and anxiety disturbances and may be of significant benefit for patients with major depression with symptoms of Anxiety/Agitation or Anxiety/Somatization.

PRECAUTIONS AND ADVERSE REACTIONS

Overall, mirtazapine appears to be well tolerated. Approximately 16 percent of mirtazapine-treated patients (*N* = 453) and 7 percent of placebo-treated patients (*N* = 361) discontinued treatment in U.S. 6-week clinical trials because of adverse effects. The most commonly reported adverse effects for mirtazapine-treated patients included somnolence (10.4 percent) and nausea (1.5 percent).

Mirtazapine's favorable adverse-effect profile may be a result of its pharmacological effects. Its ability to selectively block 5-HT_2 and 5-HT_3 receptors may account for a low incidence of such symptoms as anxiety, insomnia, nausea, and sexual dysfunction. Headache was reported at a significantly (*P* £ .05) higher incidence in placebo-treated patients. The typical SSRI symptom cluster (e.g., nausea, vomiting, diarrhea, headache, agitation, and insomnia) was reported significantly (*P* £ .05)

less frequently in mirtazapine-treated patients than in placebo-treated patients.

Blockade of 5-HT_2 receptors may protect against acute akathesia but may result in slowly developing restless leg syndrome similar to that induced by mianserin. There have been two case reports of restless leg syndrome occurring after 5 to 6 weeks of mirtazapine treatment. In each case, the symptoms of restless legs disappeared after discontinuation of mirtazapine therapy. In one case the patient was rechallenged with mirtazapine and again developed restless leg syndrome. Mirtazapine was discontinued and the symptoms disappeared.

Mirtazapine has little affinity for D_1 and D_3 receptors and moderate affinity for muscarinic and cholinergic receptors, which may explain its low incidence of dopaminergic and anticholinergic adverse effects.

Mirtazapine has not been associated with sexual dysfunction in controlled clinical trials. In U.S. clinical trials, impotence was reported infrequently (1 of 100 to 1 of 1000) and abnormal ejaculation was reported rarely (<1 of 1000). Decreased libido was reported at a similar low incidence in mirtazapine- and placebo-treated males (4 percent and 7 percent, respectively) and female patients (4 percent for both) but occurred at a higher rate in males treated with amitriptyline (14 percent). Interpretation of these data is difficult since reports of decreased libido may be associated with either depressive illness or treatment.

Drowsiness, excessive sedation, dry mouth, increased appetite, and weight gain appear to occur more frequently with mirtazapine than with placebo. These complaints were typically mild and transient, did not require dosage adjustments, and may improve with continued use.

Anticholinergic symptoms (dry mouth, constipation, taste perversion, and visual disturbances), cardiovascular symptoms (palpitations and tachycardia), and neurological symptoms (tremor and vertigo) occurred more frequently with amitriptyline than with mirtazapine.

Mirtazapine has little or no effect on heart rate, blood pressure, or body temperature.

Rare adverse reactions such as mania or seizures have been reported in a few mirtazapine-treated patients. Hypomanic or manic switch occurred in 3 of 1299 (0.2 percent) of patients treated with mirtazapine in U.S. studies. In premarketing trials, only one seizure was reported among 2796 patients receiving mirtazapine. No controlled trials have been conducted in patients with a history of seizure, and caution should be exercised when mirtazapine is used in these patients.

In premarketing clinical trials, 2 of 2796 patients receiving mirtazapine developed severe symptomatic neutropenia (agranulocytosis) and a third patient developed severe neutropenia; this hematological disorder was reversible in all three patients. One of the patients who developed severe symptomatic neutropenia had Sjögren's syndrome, an autoimmune disease frequently associated with hematological disorders, including neutropenia. The other patient was concomitantly taking ibuprofen (Motrin) and aspirin, both of which can cause agranulocytosis. There have been five reported cases of severe white blood cell (WBC) disorders in mirtazapine-treated patients worldwide from September 1994 through May 1998. The precise cause of the WBC disorders in these cases is unknown because of the possible association of agranulocytosis in each case with known risk factors.

Data regarding the effects of overdose with mirtazapine are accumulating, demonstrating a benign profile. Mirtazapine appears to be safe in a limited number of overdose cases, which sharply contrasts with tricyclic drug overdose. Six patients took a substantial overdose of mirtazapine in multiples of 10 to 30 times the maximum recommended daily dose. The characteristic symptoms were transient without any clinically relevant changes in vital signs or electrocardiogram (ECG) readings. ECG abnormalities have been observed in 70 to 90 percent of patients overdosing on tricyclic drugs, which differs significantly from mirtazapine. Mirtazapine appears to be safe in overdose of substantial multiples of the recommended daily dose.

Clinically significant but reversible elevations (³3 times the upper limit of normal) in alanine aminotransferase (ALT) were noted in 2 percent (8 of 424) of mirtazapine-treated patients in a pool of short-term U.S. controlled trials, compared with 0.3 percent (1 of 328) of placebo-treated patients and 2 percent (3 of 181) of amitriptyline-treated patients. ALT concentrations returned to normal both in patients who discontinued mirtazapine and in those who continued mirtazapine. The incidence of clinically significant elevations in ALT, aspartate transferase (AST), and g-glutamyltransferase was similar in mirtazapine- and placebo-treatment groups (0.10, 0.12, and 0.072, respectively) in terms of patient exposure years. There have also been reports of elevated nonfasting cholesterol levels and nonfasting triglyceride levels in patients receiving mirtazapine. However, low-density lipoprotein (LDL) and high-density lipoprotein (HDL) ratio data collected at one site in an uncontrolled study of 49 nonfasting patients showed that lipid metabolism did not change significantly from visit to visit, suggesting that the changes from baseline may be related to increased dietary intake associated with increased appetite.

There is currently no experience with mirtazapine in pregnant women. Women who plan to become pregnant or who are pregnant should be informed that the risk to the fetus is unclear and that the drug should only be used if clearly needed. It is not known whether mirtazapine is excreted into human breast milk.

DRUG INTERACTIONS

Formal studies have been performed on pharmacodynamic drug interactions between mirtazapine and other drugs commonly used in patients with depression. A study in healthy volunteers showed that mirtazapine can have additive subjective and objective effects on cognitive and motor performances when given with either alcohol or diazepam (valium). Caution should be used when mirtazapine is combined with other central nervous system–depressant drugs, and patients should be warned about the concomitant use of alcohol.

Mirtazapine has minimal inhibitory effects on CYP 2D6, CYP 1A2, and CYP 3A4 in vitro. The lack of cytochrome P450 inhibition suggests that mirtazapine is not likely to have a clinically significant inhibitory effect on the metabolism of any drugs that are substrates for these cytochrome P450 enzymes. However, further research is needed before any definitive conclusions can be made about the risks associated with coadministration of mirtazapine with other drugs metabolized by the cytochrome P450 subfamilies.

Although there have been no reports of an interaction between mirtazapine and the monamine oxidase inhibitors (MAOIs), it is recommended that mirtazapine not be used in combination with an MAOI or within 14 days of initiating or discontinuing MAOI therapy.

LABORATORY INTERFERENCES

There are currently no data that indicate that mirtazapine interferes with urinalysis, spectrometry, or other laboratory tests.

DOSAGE AND ADMINISTRATION

The average adult starting dosage of mirtazapine is 15 mg a day administered as a single oral dose, preferably at bedtime. Controlled clinical trials have established an effective dosage range of 15 to 45 mg a day. The pharmacokinetics of mirtazapine indicate that once-daily dosing is sufficient and that dose increases can be made at 4- to 5-day intervals. Elderly patients or those with renal or hepatic disease may develop higher serum concentrations than younger patients; no specific dosage reduction appears necessary, but dosage should be increased with caution.

Mirtazapine is available as 15-mg, oval, scored, yellow tablets and 30-mg oval, scored, red-brown tablets.

SUGGESTED CROSS-REFERENCES

The biochemical aspects of mood disorders are reviewed in Section 14.3 and their clinical features are reviewed in Section 14.6. Other pharmacological treatments of depressive disorders appear in Section 14.7.

31.20 MONOAMINE OXIDASE INHIBITORS

SIDNEY H. KENNEDY, M.D., KEVIN F. MCKENNA, M.D., ıH.D. AND GLEN B. BAKER, PH.D.

HISTORY

It is now 40 years since the introduction of monoamine oxidase inhibitor (MAOI) antidepressants. Using leftover hydrazine V-2 rocket fuel from World War II, scientists developed isonicotinic acid 2-isopropylhydrazine (iproniazid) as an antituberculous agent. Following reports of unexpected euphoria among tuberculous patients, investigators evaluated this “psychic energizer” in depressed psychiatric patients, and in 1958 one author wrote: “the best news for psychiatry in 1957 was the discovery that iproniazid protects serotonin from monoamine oxidase. Serotonin, allowed free activity in the brain is perhaps the most energetic releaser of reserve power in the human machine.”

The MAOI honeymoon proved to be relatively brief. Iproniazid was ultimately withdrawn because of its toxic effects on the liver; a fatal hypertensive reaction to its less hepatotoxic nonhydrazine successor, tranylcypromine (Parnate), was attributed to the drug's interaction with tyramine in mature cheese, “the cheese reaction,” and several multicenter trials involving phenelzine (Nardil) failed to demonstrate its clinical efficacy.

Nevertheless, a small but convinced group of psychopharmacologists in both the United States and the United Kingdom continued to evaluate the safety and efficacy of tranylcypromine, phenelzine, and isocarboxazid (Marplan) as the three surviving representatives of what have come to be known as the classic MAOIs. Several developments are responsible for renewed interest in the field of MAOI therapies:

1. Evidence of a preferential clinical response to MAOIs in patients with atypical and anergic bipolar depressions
2. Reduced concerns about food and drug interactions
3. Availability of rapidly acting effective antidotes such as the calcium channel inhibitor nifedipine (Adalat, Procardia) to treat hypertensive reactions
4. Discovery that monoamine oxidase (MAO) has at least two isoenzyme forms (A and B) that metabolize different neurotransmitters; serotonin and norepinephrine are preferred substrates for the A form, dopamine is a substrate for both A and B forms, and phenylethylamine is metabolized by the B-isoenzyme
5. The development of selective A and B inhibitor drugs that can be prescribed without dietary restrictions. As well as selectivity, new members of the MAOI drug class are also reversible inhibitors of MAO, which has important clinical implications. Instead of a further 2-week washout after the discontinuation of phenelzine, tranylcypromine, or isocarboxazid to allow the body to replace irreversibly bound MAO with a new supply of active enzyme, reversible inhibitors such as moclobemide (Manerix) leave no lasting effects on MAO beyond 48 hours.

CHEMISTRY

In 1997, only irreversible MAOIs had Food and Drug Administration (FDA) approval in the United States. In addition to phenelzine and tranylcypromine, selegiline (Eldepryl) had approval for the treatment of Parkinson's disease. Pargyline was approved for treatment of severe hypertension but is no longer manufactured. Although, manufacturing of the antidepressant isocarboxazid was discontinued in 1990 in the United States and 1992 in Canada, it was relaunched in the United States in 1998. Moclobemide, a reversible inhibitor of MAO type A (MAO $_A$) (RIMA) has been available in Europe, Canada, Australia, and elsewhere since the early 1990s but is not available in the United States. Brofaromine, also a RIMA with demonstrated antidepressant efficacy, is not currently under active investigation. However, a new RIMA compound, befloxatone, is undergoing clinical trial evaluation in the United States and Europe.

The MAOIs may be classified according to chemical structure (hydrazine versus nonhydrazine); by affinity for substrate site (reversible versus irreversible) or by degree of selectivity for the A or B isoenzyme (A or B inhibitor) (Table 31.20-1).

Generic Name	Brand Name or Company Code	Presently Marketed in North America	Reversible/Irreversible Selectivity
Iproniazid	Marsilid	No	Irreversible, nonselective
Isocarboxazid, INN	Marplan	Yes, as antitubercular	Irreversible, nonselective
Phenelzine	Nardil	Yes	Irreversible, nonselective
Isocarboxazid	Marplan	Yes*	Irreversible, nonselective
Tranylcypromine	Parnate	Yes	Irreversible, nonselective
Clorgyline	—	No	Irreversible, MAO_A selective
Pargyline	Eutonyl	Recently withdrawn as an antihypertensive	Irreversible, MAO_B selective
Selegiline	Eldepryl, (–)-Deprenyl	Yes	Irreversible, MAO_B selective
Moclobemide	Aurorix, Manerix	Not in U.S. but available in Canada	Reversible, MAO_A selective
Brofaromine	Consonar	No	Reversible, MAO_A selective
Lazabemide	Ro 19-6327	No	Reversible, MAO_B selective
Befloxatone	—	No	Irreversible, MAO_B selective
Milacemide	—	No	Partially reversible, relatively nonselective
Toloxatone	—	No	Reversible, MAO_A selective
Befloxatone	—	No	Reversible, MAO_A selective

* Isocarboxazid was reintroduced for clinical use in the United States in 1998.

Table 31.20-1 Some MAO Inhibitors and Their Actions

Hydrazine Status Both phenelzine and isocarboxazid are hydrazine derivatives, with a nitrogen-nitrogen bond in their side chains. The first generation of hydrazine compounds (iproniazid and isoniazid) was withdrawn because of hepatotoxicity. Tranylcypromine and selegiline represent nonhydrazine arylalkylamines. These compounds are structurally related to amphetamines, and in a single case report of tranylcypromine overdose, detectable levels of amphetamine and its metabolites were found, although this finding has not been replicated. Some have suggested that this may explain why tranylcypromine has a more rapid therapeutic effect than nonhydrazines. However, euphoric effects of amphetamine levels are not detected at therapeutic doses.

Selectivity and Reversibility Pargyline was the first selective MAOI to receive FDA approval. Although it proved selective for the B isoenzyme and did not require dietary restriction of tyramine intake (the gastrointestinal tract contains predominantly MAO $_A$), it was not an effective antidepressant. Selegiline is also a B inhibitor at low doses, but even at therapeutic doses in antidepressant trials, the selectivity is diminished. Despite their selectivity, both pargyline and selegiline represent examples of irreversible selective inhibitors, in contrast to moclobemide with both reversibility and selectivity (Fig. 31.20-1).

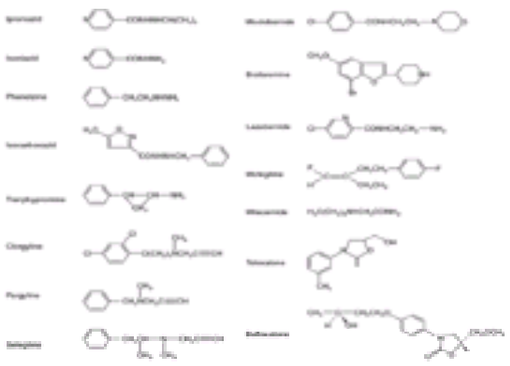

FIGURE 31.20-1 Molecular structures of some MAOI.

PHARMACOLOGICAL ACTIONS

Characteristics of the MAO Enzyme System The MAOs are flavoproteins found on the outer membranes of mitochondria. They catalyze the oxidative deamination of a variety of alkylamines, resulting in the formation of hydrogen peroxide and an aldehyde derivative of the amine (Fig. 31.20-2). The aldehyde is then further reduced or oxidized to the corresponding alcohol or carboxylic acid, respectively.

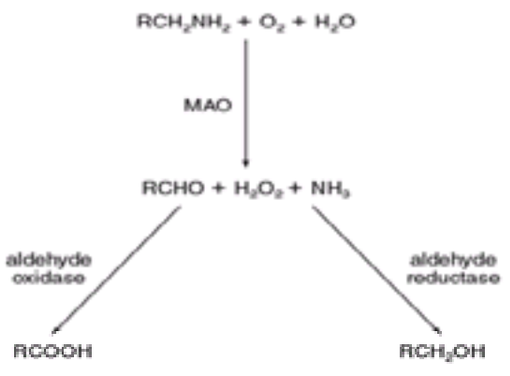

FIGURE 31.20-2 The reaction catalyzed by MAO.

Free cytoplasmic and extraneuronal neurotransmitter amines would be most susceptible to MAO metabolism. The presence of high concentrations of MAO in the blood-gut and blood-brain barriers supports the idea that MAO serves a protective or detoxifying role.

Irreversible inhibitors attach to the flavin–adenine dinucleotide group, decreasing breakdown of the substrate neurotransmitters and denaturing the original MAO, which results in a deficiency of MAO to denature dietary tyramine or amine medications. In contrast, the reversible inhibitors such as moclobemide have a direct inhibitory action on MAO_A and may be competitively displaced by tyramine, substantially reducing the likelihood of food and drug interactions.

The enzyme is expressed widely among eukaryotic organisms and in all mammals studied to date. Many cells express both forms of MAO, in differing proportions, but some tissues contain only one form, which has expedited purification of the enzymes. In human tissue, MAO_A is found in the placenta while MAO_B is found in platelets. As platelets are relatively easy to procure, the vast majority of human research on MAO has examined MAO_B. The human brain expresses both enzymes, but MAO_B predominates (80 to 95 percent), while in the rat brain MAO_A predominates over MAO_B. Immunohistochemical studies using polyclonal or monoclonal antibodies in postmortem human brain have demonstrated that serotoninergic neurons contain predominantly MAO_B, while catecholaminergic neurons contain MAO_A. Both forms of MAO are present in glial and endothelial cells. These findings suggest that the two forms of MAO are independently regulated and perform different functions. The presence of MAO_B in serotonergic neurons is surprising, since serotonin is preferentially deaminated by MAO_A; this finding suggests that MAO_B may function to degrade low levels of dietary and endogenous amines such as phenylethylamine or tyramine, with little effect on serotonin unless concentrations of this amine are elevated. Under normal conditions the classic neurotransmitters metabolized by MAO (norepinephine, dopamine, and serotonin) are preferentially stored in vesicles where they are not exposed to MAO.

Homology between the amino acid sequences of A and B isoforms is 70 percent and they are encoded by separate genes located on the short arm of the X chromosome. During development, the MAO_A form is expressed first, followed by MAO_B, which increases in proportion through life. Complete absence of MAO and its corresponding messenger ribonucleic acid (mRNA) has been described in a family of male cousins with a submicroscopic deletion of Xp21-p11, an area that includes the Norrie disease gene. Norrie disease is a rare X-linked recessive neurological disorder characterized by retinal dysplasia with blindness, mental retardation, and progressive hearing loss. Clinical features in these patients that may be related to complete absence of MAO include somatic growth failure, abnormal sexual maturation, autonomic nervous system dysfunction with hypotension, sleep disturbances with a marked reduction in the amount of rapid eye movement (REM) sleep, flushing, atonic seizures, motoric hyperactivity, and hyperreflexia. Large reductions in the urinary excretion of the norepinephrine metabolites, 3-methoxy-4-hydroxyphenyl glycol (MHPG) and vanillylmandelic acid (VMA), as well as the dopamine metabolite, homovanillic acid (HVA), were observed in these individuals. There was also a marked increase in the urinary excretion of phenylethylamine (PEA), a substrate of MAO-B (Table 31.20-2). The neurochemical changes are dramatic and much more pervasive than those following drug-induced inhibition of MAO.

MAO_A	Mixed	MAO_B
Epinephrine	*m,p*-Tyramine	β-Phenylethylamine
Norepinephrine	Dopamine	Phenylethanolamine
Metanephrine	Octopamine	*o*-Tyramine
Serotonin (5-HT)	Synephrine	Benzylamine
Sumatriptan	Tryptamine	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
	N-methyltryptamine	
	N,N-dimethyltryptamine	

Table 31.20-2 Some Common Substrates of MAO

Numerous attempts have been made to correlate hereditary variations in MAO activity with human disease. Wide interindividual variations in platelet and fibroblast MAO activity, as much as 50-fold, have been described in studies of normal volunteers and those with psychiatric disorders. Low MAO_B activity has been associated with stimulus-seeking and suicidal behavior, alcoholism, and bipolar disorder. MAO_B activity increases with age in animals, elderly healthy humans, and (to a greater extent) patients with neurodegenerative disease. The increased activity of MAO_B with age may reflect the glial cell proliferation that is linked to neuronal loss during

aging, as the concentration of the enzyme is thought to be higher in glial than in neuronal cells.

Platelet MAO Patients with more than 80 percent inhibition of platelet MAO after 2 weeks of treatment were reported to have a better antidepressant response than patients with less than 80 percent inhibition. However, other studies have not demonstrated a significant relation between clinical response and percentage of platelet MAO inhibition with phenelzine, tranylcypromine, or selegiline. Platelet MAO, of course, is exclusively MAO_B and does not necessarily reflect the central effect of the drugs on MAO_A. Also no role exists for platelet MAO inhibition measurement with RIMAs.

Effects of MAOIs on Brain Amine and Acid Levels The inhibition of MAO by drugs such as phenelzine and tranylcypromine results in an often dramatic increase in the concentration of a number of brain amines termed “trace amines,” for example, PEA, *meta*- and *para*-tyramine, and octopamine. In addition, PEA is a metabolite of phenelzine. These trace amines can markedly affect uptake, release, or both of catecholamines and serotonin at nerve endings. They may also act as neuromodulators through direct actions on receptors for the catecholamines, serotonin, or both.

Several groups of researchers have noted that administering phenelzine to rats increases brain concentrations of g-aminobutyric acid (GABA). Long- and short-term studies suggest that this elevation results, at least in part, from an inhibition of the catabolic enzyme GABA-transaminase. Increased brain concentrations of the amino acid alanine and inhibition of alanine transaminase have also been observed. Increasing evidence indicates that GABA is involved in the action of antipanic drugs, and phenelzine is commonly used to treat panic disorder. Although the N^2-acetyl analogue of phenelzine is also an effective MAOI, it neither alters GABA levels nor produces anxiolytic effects in the rat. Phenelzine's inhibition of GABA transaminase and elevation of GABA can be dramatically reduced by pretreating rats with another MAOI. This suggests that a metabolite produced by the action of MAO on phenelzine is ultimately responsible for the increase in brain GABA concentration. In theory this would make phenelzine a preferred antidepressant in the treatment of depressed patients with seizure disorders.

The structures of phenelzine and tranylcypromine are similar to those of PEA and amphetamine, and not surprisingly, they affect the uptake, release, or both of dopamine, norepinephrine, and, to a lesser extent, serotonin. At therapeutically equivalent doses of phenelzine and tranylcypromine in animal studies, concentrations of these drugs in the brain high enough to affect the uptake and release of these neurotransmitters could be attained. Several reports indicate that high doses of tranylcypromine (1.3 to 3.0 mg/kg a day) are effective in treating patients who suffer from refractory depression. Since these doses are well above those reported to inhibit MAO by more than 90 percent, effects of tranylcypromine other than MAO inhibition may contribute to its antidepressant effects at the high dosages. Free tranylcypromine concentration may also contribute to the adverse effects of this drug, including mean orthostatic drop of systolic blood pressure and increased pulse rate. Blood pressure elevations have also been significantly correlated with the dose of tranylcypromine; one group of investigators hypothesized that the initial hypertensive response to tranylcypromine is mediated by norepinephrine and that the orthostatic hypotensive effect is mediated by a direct interaction between tranylcypromine and a-adrenergic receptors. Of the RIMA compounds so far investigated, moclobemide appears to have few effects beyond MAO inhibition. In contrast, brofaromine is also a relatively potent inhibitor of serotonin reuptake, which may contribute to its therapeutic efficacy.

Changes in several presynaptic and postsynaptic receptors may follow the increase in concentrations of the amines, amino acid neurotransmitters, or both caused by the MAOIs. These delayed effects may be associated with the lag between administration of the MAOI and onset of antidepressant effect. Downregulation of b- and a_2 adrenergic, serotonin (5-hydroxytryptame [5-HT]) type 2 ($5\text{-}HT_2$), and tryptamine receptors occurs after long-term administration of phenelzine or tranylcypromine.

Phenelzine has been reported to inhibit tyrosine amino transaminase, aromatic amino acid decarboxylase, and dopamine b-hydroxylase, in addition to inhibiting GABA transaminase and alanine transaminase. Aromatic amino acid decarboxylase, GABA transaminase, and tyrosine amino transferase are pyridoxal-dependent enzymes, and phenelzine may deplete blood pyridoxal-5-phosphate concentrations in humans. In vitro studies of rats suggest that phenelzine increased phenylethanolamine *N*-methyltransferase and catechol *O*-methyltransferase activities above control values. Long-term administration of tranylcypromine is also reported to increase activity of aromatic amino acid decarboxylase. Reports also indicate that both phenelzine and tranylcypromine interact with enzymes involved in drug metabolism. Patients prescribed phenelzine or tranylcypromine may be taking other drugs concomitantly; thus metabolic drug-drug interactions may occur. MAOIs have been reported to inhibit the degradation of such drugs as hexobarbital, ethylmorphine, aminopyrine, meperidine (Demerol), and antipyrine (Auralgan). Recent studies indicate that tranylcypromine is a relatively potent inhibitor of cytochrome P450 (CYP) isoenzyme 2C19 (CYP 2C19).

Another factor that must be considered in the actions of tranylcypromine is the presence of chiral centers. Tranylcypromine is used clinically as the racemate but the (+) enantiomer is more potent than (–)-tranylcypromine in inhibiting MAO, whereas (–)-tranylcypromine is more effective than (+)-tranylcypromine in inhibiting uptake of catecholamines. The two enantiomers also differ in their interaction with $5\text{-}HT_1$ receptors in human postmortem frontal cortex, with (–)-tranylcypromine displaying a higher affinity than the enantiomer. (+) Results to date from studies on laboratory animals and humans indicate marked pharmacokinetic differences between the two enantiomers in brain and plasma.

METABOLISM

Phenelzine Although both phenelzine and tranylcypromine are absorbed rapidly after oral administration and have short elimination half-lives, much is still unknown about the metabolism of these two drugs and the contribution of metabolites to their overall pharmacological profiles, even though both drugs have been commercially available for many years. Numerous studies have been carried out on the relation between acetylator status of patients and response to treatment with phenelzine. These investigations were based on the assumption that phenelzine is acetylated because it is similar in structure to drugs such as isoniazid, which are known to be acetylated. In fact, the existence of *N*-acetyl phenelzine as a metabolite of phenelzine was adequately demonstrated only recently, and current indications are that it is only a minor metabolite. Phenelzine is an unusual drug in that it not only inhibits MAO but is also apparently a substrate for MAO. Studies with radiolabeled phenelzine suggest that phenylacetic acid and *p*-hydroxyphenylacetic acid are metabolites of phenelzine. *p*-Hydroxyphenylacetic acid is also of interest because it is a metabolite of the endogenous amine *p*-tyramine (*p*-hydroxy-b-phenylethylamine). b-PEA is also a known metabolite of phenelzine and evidence now indicates formation of *p*-hydroxyphenelzine from phenelzine. These observations raise the question of the route of formation of *p*-hydroxyphenylacetic acid. Possible routes are as follows: Phenelzine ® phenylacetic acid ® *p*-hydroxyphenylacetic acid; phenelzine ® PEA ® *p*-tyramine or phenylacetic acid or both ® *p*-hydroxyphenylacetic acid and phenelzine ® *p*-hydroxyphenelzine ® *p*-hydroxyphenylacetic acid (with or without *p*-tyramine intermediate). These routes have not been studied thoroughly, nor is there detailed information on the pharmacological activity of metabolites such as *p*-hydroxyphenelzine. Phenylethylidene hydrazine ($PhCH_2CH = N\text{-}NH_2$) or 1-(2-phenylethyl) diazene ($PhCH_2CH_2N = NH$) may be intermediates in going from phenelzine to phenylacetic acids, and hydrazine (H_2NNH_2) itself is a possible endproduct of phenelzine metabolism. Another possible route of metabolism of phenelzine is N-methylation. No information is available about involvement of cytochrome P450 isozymes in the various steps of PHE metabolism.

Tranylcypromine Although several popular textbooks mention that amphetamine is a metabolite of tranylcypromine, the bulk of evidence in the literature indicates that this is not the case. Despite a case report on the presence of amphetamine in the plasma of a patient who had overdosed on tranylcypromine, other studies conducted on humans and rats have not revealed amphetamine in human urine or rat brain after administration of pharmacologically relevant doses of tranylcypromine. The presence of the N-acetyl and ring hydroxylated metabolites of tranylcypromine (Fig. 31.20-3) have been demonstrated in rats and microbes. Little information is available about involvement of specific cytochrome P450 (CYP) isozymes in the metabolism of tranylcypromine, but tranylcypromine itself is a relatively potent inhibitor of CYP 2C19.

Selegiline [(–)-Deprenyl] Selegiline is extensively metabolized to (–)-methamphetamine, (–)-amphetamine and (–)-*N*-desmethyldeprenyl (*N*-propargylamphetamine) (Fig. 31.20-4). Cytochrome P450 isozymes may be involved in these metabolic pathways. The relative contribution of these metabolites to the therapeutic actions and side effects of selegiline remains controversial.

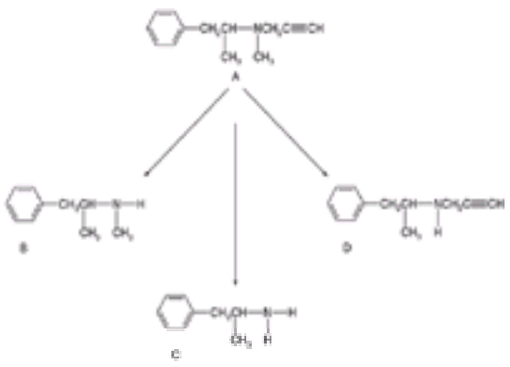

FIGURE 31.20-4 Principal metabolites of deprenyl (selegiline) **A, B**, methamphetamine; **C**, amphetamine; **D**, *N*-desmethylselegiline (*N*-propargylamphetamine).

Moclobemide and Brofaromine The two RIMAs moclobemide and brofaromine demonstrate similar T_{max} values, but brofaromine is more highly protein bound and has a longer elimination half-life than moclobemide. Both are extensively metabolized (Fig. 31.20-5 and Fig. 31.20-6). Little information is available on involvement of cytochrome P450 isozymes in these metabolic routes, although it has been reported that moclobemide is a substrate of CYP 2C19 and an inhibitor of CYP 2C19, CYP 2D6, and CYP 1A2 and that CYP 2D6 contributes to O-demethylation of brofaromine. It is suggested that the moclobemide dosage should be reduced by one-half when it is given in combination with the potent CYP 2D6 inhibitor, cimetidine (Tagamet). It has been suspected for some time, but not yet definitely shown, that an active metabolite may contribute to the MAOI activity of moclobemide.

THERAPEUTIC INDICATIONS

The MAOIs have found an important niche and are often the drugs of choice for atypical depression and depression associated with anxiety, panic, and phobias. However, they may be more useful in treating major depressive disorders than is generally realized, and tranylcypromine in daily doses of 100 mg or more is reportedly effective treatment for previously treatment-resistant depression.

The concept of “atypical depression” has been applied to different subtypes of depression; in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), it refers to a depression characterized by mood reactivity, extreme sensitivity to interpersonal loss or rejection, prominent anergia, and increased appetite, weight, and sleep. Previously, atypical depression was subclassified into anxious (type A) and reversed vegetative (type V) types. The Columbia University definition of atypical depression combined reversed vegetative symptoms with mood reactivity and intense rejection sensitivity. This group has demonstrated a better response to phenelzine than to imipramine (Tofranil) in patients with “Columbia University atypical depression.” Considerable overlap appears to exist between the rejection sensitivity predisposition and Axis II personality disorders, especially borderline personality disorder. Both phenelzine and tranylcypromine have been shown superior to comparative drugs in borderline personality disorder, and a relation between favorable response to tranylcypromine and history of childhood attention-deficit disorder was noted. To date little evidence suggests superior efficacy of RIMA agents such as moclobemide in atypical depression or borderline personality disorder. Preliminary reports suggest that selective serotonin reuptake inhibitors (SSRIs) may be as effective as phenelzine in atypical depression.

A 38-year-old divorced mother of two teenage daughters presented at the Mood Disorders Clinic with a history of failed antidepressant treatment trials. Two years earlier she had become increasingly irritable, exhausted, and tearful following the breakup of her marriage. She could not tolerate fluoxetine (Prozac) or sertraline (Zoloft) and discontinued each of these SSRIs after only a few days because of gastrointestinal symptoms. Although she could tolerate desipramine (Norpramin) up to 300 mg daily, she felt no benefit after 4 months and was reluctant to continue this tricyclic antidepressant medication because of adverse effects (weight gain and sweating in particular). Because of her increasing fatigue, increasing sleep needs, and generally “atypical” profile, she was offered a trial of phenelzine. After 4 weeks, at a dosage of 60 mg daily she reported significant improvement in her energy level, mood, and sleep pattern. Two years later she continues to take phenelzine 45 mg daily with significant adverse effects (occasional insomnia and anorgasmia).

A group at the University of Pittsburgh has emphasized the presence of type V (reversed vegetative) symptoms in what they describe as “anergic bipolar depression.” Although not replicated elsewhere, this group has consistently demonstrated superiority of tranylcypromine over imipramine in bipolar depression. The extent to which findings from the Columbia group are specific to phenelzine and those of the Pittsburgh group are specific to tranylcypromine remains unknown.

Many patients with atypical depression also suffer from panic attacks and anxiety symptoms. Some authors consider phenelzine the treatment of choice for panic disorder. Limited evidence of efficacy exists in other disorders that overlap with the depressive and anxiety disorders, including bulimia nervosa, anorexia nervosa, social phobia, and posttraumatic stress disorder.

MAOIs have also been used in the therapeutic management of various conditions including anginal pain, atypical facial pain, refractory thought disorders, neurodermatitis, treatment-resistant narcoleptic states, migraine, narcolepsy, attention-deficit disorder, and idiopathic orthostatic hypotension.

> A 33-year-old anesthesiology resident developed symptoms of major depression. He had always been a socially anxious and avoidant student with few close friends. He reluctantly tried a series of SSRI, tricyclic, and MAOI antidepressants, on each occasion claiming that adverse effects prevented him from continuing. He reluctantly agreed to try moclobemide because of its apparently favorable side-effect profile. He took moclobemide to a maximum dosage of 600 mg daily for 1 year, successfully completed his residency, and no longer takes antidepressant medication.

Moclobemide and brofaromine are effective therapeutic agents with more favorable side-effect profiles than the classical irreversible inhibitors. Both have been reported to be effective antidepressants, and recent reports indicate that they may also be useful in the treatment of panic disorder and social phobia. Selegiline, an irreversible selective MAO_B inhibitor is not a particularly effective antidepressant at doses at which only MAO_B is inhibited but has shown some efficacy in depressive disorders at higher dosages at which both MAO_B and MAO_A are inhibited. Selegiline has been used extensively, usually in combination with levodopa (Larodopa), for treatment of Parkinson's disease. The reasons for its effectiveness in this disorder are not entirely clear, but suggested mechanisms include reduced metabolism of dopamine reduced oxidative stress, increased expression of aromatic amino acid decarboxylase, and neurotrophic actions (by selegiline, its metabolites, or both). Because of selegiline's reported neuroprotective and neuronal rescue properties, it has been proposed that this drug may also be useful in treatment of other neurodegenerative disorders, such as Alzheimer's disease.

Continuation and maintenance treatments with MAOI and RIMA therapies have been understudied. Three published randomized, placebo-controlled trials exist involving long-term MAOI therapy, all with phenelzine, which proved superior to nortriptyline (Aventyl, Pamelor) in a maintenance trial in elderly depressive patients and superior to placebo and imipramine in adult depressed populations.

PRECAUTIONS AND ADVERSE REACTIONS

The most feared adverse effect of irreversible MAOIs is the tyramine-induced hypertensive crisis. Once it is decided to initiate a trial of an irreversible MAOI, the patient should be instructed to avoid foods with substantial tyramine content (other sympathomimetic amines such as PEA may also be culprits in this regard). Tyramine, a substrate of MAO present in significant concentrations in certain fermented foodstuffs including red wine, tap beer, cheese, yeast extracts, and pickled fish, causes a vasopressor response, an effect dramatically accentuated in patients taking an MAOI. This response is partly due to the MAO-inhibited patient's inability to deaminate tyramine (which is normally broken down by MAO_A in the gut), resulting in displacement of intracellular stores of norepinephrine. When dietary restrictions are followed, the risk of a serious hypertensive problem is curtailed. Although lists of foods that should be avoided by patients taking MAOIs are available, many of these are generally considered too extensive, and recent years have seen a trend to develop more user-friendly MAOI diets. Case reports exist of rare patients who developed idiosyncratic, spontaneous, hypertensive episodes shortly after taking initial doses of tranylcypromine and (more rarely) phenelzine. Reports of minimal blood pressure rises in response to intravenous and oral tyramine administration in patients taking RIMAs (moclobemide and brofaromine) suggest that these drugs are safer and can be used without stringent dietary control. However, it is suggested that they be given after meals, to reduce the likelihood of causing any inhibition of tyramine metabolism. At usual therapeutic doses, the cheese effect should not be a problem with the selective MAO_B inhibitor selegiline, but at higher doses this drug exhibits some inhibition of MAO_A, and dietary restrictions should be followed.

> A 57-year-old male had been successfully treated with tranylcypromine for 10 years after failing to respond to previous antidepressants. At his follow-up appointments he admitted to being somewhat complacent about following a low-tyramine diet, since there appeared to be no hazardous sequelae. A confirmed hypertensive crisis occurred sometime later and was successfully treated with sublingual nifedipine (10 mg). The cause of this reaction was ultimately traced to a change in his beer-drinking habit. For years he had consumed one or two standard domestic beers every week. Just prior to the reaction he sampled a microbrewery bottled draft beer that on subsequent analysis turned out to have a high tyramine content.

Because of its a-adrenergic receptor blocking properties, phentolamine (Regitine) (5 mg intramuscularly or intravenously) has traditionally been the recommended treatment for an MAOI-induced hypertensive crisis. Onset of action is rapid, usually within 5 minutes, and a single dose is generally effective. A diuretic such as furosemide (Lasix) may be given intravenously to avoid fluid retention, and if necessary a b-adrenergic receptor antagonist (beta-blocker) such as propranolol (Inderal) may be given to control tachycardia. If necessary, additional doses of phentolamine can be given over several hours. A recent alternative treatment is sublingual nifedipine (10 mg with a repeat dose after 20 minutes if required). As with phentolamine, the onset of action occurs within 5 minutes.

Although a hypertensive crisis is the most feared reaction with classical MAOIs, paradoxically hypotension is a more common cardiovascular adverse effect, leading to dizziness and fainting after sudden postural changes. In fact this may be a useful clinical sign for determining therapeutic dosage; that is, the dosage may be titrated upward cautiously until some postural hypotension is observed. If postural hypotension becomes a problem in otherwise responsive patients, mineraloglucocorticoids may be given while monitoring serum potassium concentration to avoid hypokalemia. Insomnia can be problematic with MAOIs, ultimately necessitating discontinuation of the drug in a small number of persons; this adverse effect can often be managed by lowering the drug dosage or adding a sedative drug (e.g., a benzodiazepine or trazodone [Desyrel]) to the therapeutic regimen at bedtime. Paradoxically, some patients are sedated on phenelzine and take the medication prior to sleep. The irreversible MAOIs may cause a marked suppression of REM sleep, which is less likely to be experienced with RIMAs. Other common adverse effects of MAOIs include weight gain, peripheral edema, and sexual dysfunction. A peripheral neuropathy resulting from pyridoxine deficiency produced by phenelzine may occur in some patients. In comparison, there is a reduced incidence of sleep disorders, sexual dysfunction, and weight gain with the RIMAs. There are virtually no reports of sexual dysfunction associated with moclobemide.

A discontinuation syndrome consisting of arousal, mood disturbance, and somatic symptoms has been reported with sudden cessation of phenelzine or tranylcypromine administration. As with other classes of antidepressants, it is prudent to taper the dosage of MAOIs and RIMAs over several weeks. With MAOIs (but not with RIMAs) one must avoid administering other antidepressants for at least 10 to 14 days after drug discontinuation to allow a full return to normal MAO activity before starting treatment with a new drug.

DRUG-DRUG INTERACTIONS

The major drug-drug and food-drug interactions (including the so-called “cheese effect”) involving MAOIs are summarized in Table 31.20-3.

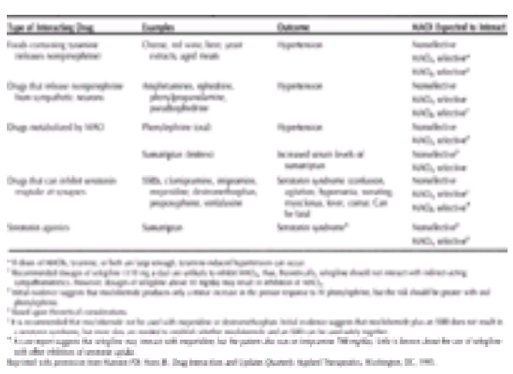

Table 31.20-3 Examples of Interactions of MAOIs with Drugs and Food

Although coadministration of certain MAOIs with tricyclic drugs, SSRIs and psychostimulants such as amphetamines are listed in Table 31.20-4, all three of these combinations have been used successfully in the treatment of refractory depression, but they should only be used with extreme caution. Although MAOIs have been used effectively in combination with amitriptyline (Elavil), imipramine, doxepin (Sinequan), and trazodone (Desyrel), their use with SSRIs or clomipramine (Anafranil) may lead to the potentially fatal serotonin syndrome. Combinations involving tranylcypromine and clomipramine are among the most dangerous and should be avoided. When switching treatment from irreversible MAOIs to tricyclic drugs or SSRIs, a minimum washout of 2 weeks is required to allow complete recovery of MAO activity. Moclobemide and SSRI or tricyclic drug combinations have been reported in the literature to be safe and efficacious, but this work is preliminary and close observation of patients is important. When moclobemide or brofaromine treatment stops, patients completely recover MAO activity in only 24 to 48 hours. When switching from administration of tricyclic antidepressants or SSRI antidepressants to an MAOI, a washout period of 10 to 14 days suffices, except in the case of fluoxetine, which requires a washout period of 5 weeks, primarily because of the long elimination half-life of its active metabolite, norfluoxetine.

Drug	Usual Dose (mg/day)	Usual Maximum Dose (mg/day)	Dosage Form
Isocarboxazid (Marplan)	20–40 mg	60	Oral 10-mg tablets
Phenelzine (Nardil)	30–60	90	Oral 15-mg tablets
Tranylcypromine (Parnate)	20–60	60	Oral 10-mg tablets
Selegiline or (−)deprenyl (Eldepryl)	10	30	Oral 5-mg tablets
Moclobemide (Manerix)	300–600	600	Oral 100- or 150-mg tablets

Table 31.20-4 Typical Dosage Forms and Recommended Dosages for Currently Available MAOIs

Effective lithium (Eskalith) augmentation of MAOIs was first reported in 1972. In countries where it is available, L-tryptophan may also be used in augmentation strategies, but treatment should start at low dosages (250 to 500 mg daily) and be gradually titrated upward to reduce the risk of developing the serotonin syndrome. This syndrome, which results from excessive increases in serotonergic tone, is characterized by tremor at rest, hypertonicity, myoclonus, and autonomic signs. Hallucinations may also result, and a life-threatening hyperthermia may occur.

Phenelzine and tranylcypromine have been reported to inhibit the activity of a number of enzymes involved in drug metabolism. Tranylcypromine has been identified as a relatively potent inhibitor of CYP 2C19, and moclobemide has been reported to be a substrate for CYP 2C19 and to inhibit CYP 2D6, CYP 2C19, and CYP 1A2. Thus the potential for metabolic drug-drug interactions between these MAOIs and coadministered drugs that are substrates for or inhibitors of these isozymes should be considered.

Interactions with prodrugs of amino acids or valproic acid (Depakene), which are converted in the body by MAO_B to amino acids or valproic acid, respectively, may occur. Several such drugs are under investigation as anticonvulsants, and the potential for a serious drug-drug interaction with MAOIs must be considered, as the MAOIs will interfere with metabolism of the prodrug to the active drug of interest.

LABORATORY INTERFERENCES

Interference with laboratory tests is not a major problem with the MAOIs. However, these drugs tend to lower blood glucose values. Acutely elevated blood glucose concentrations, such as that produced during a glucose tolerance test, may decrease the activity of platelet MAO, resulting in a possible synergism with the activity of nonselective or type-B MAOIs.

MAOIs may also be associated with a minimal false elevation in thyroid function test results. Since the nonselective and MAO_A-selective MAOIs cause marked increases in metanephrine and nonmetanephrine, there may be an interference with urinary measurements of these amines when testing for pheochromocytoma.

DOSAGE AND ADMINISTRATION OF MAOIs

Table 31.20-4 summarizes dosage forms and recommended dosages for MAOIs.

RECENT ADVANCES IN MAO AND MAOI RESEARCH

Several novel MAOIs are currently under investigation (Tables 31.20-1 and Fig. 31.20-1) as potential therapeutic agents in depression, anxiety, and neurodegenerative disorders. The involvement of imidazoline receptors (which are intimately associated with MAO) in the etiology of depression and the actions of antidepressant drugs is another recent area of interest. There appears to be an increased density of brain and platelet imidazoline receptors in depressed subjects, and irreversible MAOIs downregulate type 2 imidazole (I_2)-receptors in rat brain. Active research continues on possible components of the endogenous inhibitor of MAO, tribulin. Determination of the structure and function of such components may be useful in developing future MAOIs. For several years, there has been keen interest in the possible effects of cigarette smoking on MAO activity. This interest arose from observations that smoking is very prevalent in people with psychiatric disorders and is associated with a decreased risk of Parkinson's disease. This area of research received increased stimulus from the recent observation that brains of living smokers show 40 percent less MAO_B than brains of nonsmokers or former smokers.

SUGGESTED CROSS-REFERENCES

Section 1.4 provides information on monoamine neurotransmitters. Section 7.7 deals with medical assessments and laboratory testing in psychiatry that might help determine where patients require pharmacological treatment. Chapter 14 provides information on mood disorders. Chapter 15 on anxiety disorders provides information on another condition treated by MAOIs—panic disorder. Section 31.1 gives the general principles of psychopharmacology.

31.21 NALTREXONE

STEPHANIE S. O'MALLEY, PH.D., SUCHITRA KRISHNAN-SARIN, PH.D. AND BRUCE J. ROUNSAVILLE, M.D.

Naltrexone (Revia), an opioid antagonist, was synthesized in 1965 and proved to have a number of advantages over earlier opioid antagonists including cyclazocine, nalorphine, and naloxone (Narcan). Specifically, naltrexone had a relatively long half-life, was orally effective, was not associated with dysphoria, and could be administered once a day. While earlier opioid antagonists, principally naloxone, were used to reduce narcotic overdose, these characteristics of naltrexone made it suitable for use in preventing relapse to opioid use in detoxified opioid addicts. In 1984 naltrexone was approved by the Food and Drug Administration (FDA) for providing blockade of the effects of exogenously administered opioids in detoxified opioid addicts. Over the ensuing years, naltrexone has been tried for the treatment of a wide range of psychiatric disorders, including eating disorders, autistic disorders, self-injurious behavior, nicotine dependence, cocaine dependence, and alcohol dependence. On the basis of extensive preclinical literature that linked endogenous opioids to alcohol drinking behavior and demonstrated that opiate antagonists reduced alcohol self-administration in animals, studies of the efficacy of naltrexone in the treatment of alcohol dependence were undertaken. Naltrexone was approved by the FDA for this use in alcohol dependence in 1994.

Naltrexone is a nonspecific opioid antagonist that binds to all three types of opioid receptors in a dose-dependent manner. It has the highest antagonistic potency at the μ-receptors, which is 5 to 10 times greater than that at d-receptors and 13 to 33 times greater than that at k-receptors. New formulations, including depot versions (Biotek, Woburn), are being developed with the goal of minimizing compliance problems associated with opioid antagonist therapy and are currently in phase-two testing. Recently, opioid antagonists have been developed with affinities for specific opioid receptor types, which have enormous use as selective tools to identify specific receptor types involved in specific pharmacological endpoints. Most of the new specific opioid antagonists are nonpeptides that can easily penetrate the blood-brain barrier and therefore can be administered via peripheral routes. All of these are in the preclinical phase of testing.

CHEMISTRY

Naltrexone, or 17-(cyclopropylmethy)-4,5a-epoxy-3,14-dihydroxymorphinan-6-one hydrochloride, is a competitive opioid antagonist that was developed by substituting an *N*-methyl group on the opioid agonist oxymorphone with a methylcyclopropyl moiety. Naltrexone is available as a white crystalline hydrochloride salt that is soluble in water, with a melting point of 275°C and a pK_a of 8.13 at 37°C. Its molecular formula is $C_{20}H_{23}NO_4 \cdot HCl$ (Fig. 31.21-1).

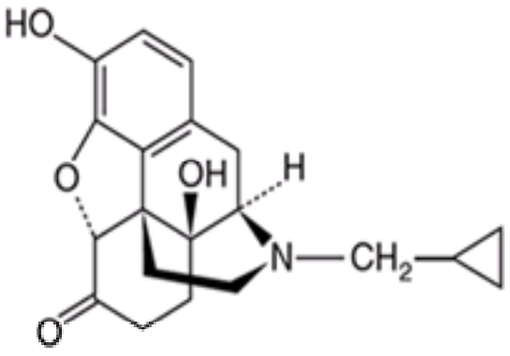

FIGURE 31.21-1 Molecular structure of naltrexone hydrochloride.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics Naltrexone is rapidly and completely absorbed following oral administration of a 100-mg dose, with peak plasma concentrations of 19 to 44 mg/L achieved within 1 hour. Oral bioavailability of naltrexone is 60 percent, with 20 percent of the drug being bound to plasma proteins. A single dose of naltrexone has a volume of distribution of 16.1 L/kg, which decreases to 14.2 L/kg following repeated administration. Naltrexone is almost completely metabolized in the liver. Plasma concentrations of naltrexone exhibit an initial biphasic elimination phase of 3.9 to 10.3 hours' duration, followed by a terminal elimination phase observed 24 hours following administration, with a half-life of 96 hours.

Naltrexone is primarily recovered in plasma, urine, and feces as conjugated naltrexone and conjugated and unconjugated 6b-naltrexol along with minor quantities of 2-hydroxy-3-*O*-methyl-6b-naltrexol and 2-hydroxy-3-*O*-methylnatrexone. Approximately 60 percent of the drug is recovered in the urine in 48 hours following oral administration and in 72 hours following intravenous administration. Naltrexone has a plasma half-life of 10.5 hours regardless of whether it is administered via the oral or intravenous route. Conjugated 6b-naltrexol is a weaker antagonist that has a plasma half-life of 14 to 19 hours and has been proposed to contribute to the longer duration of action of naltrexone. Recent studies indicate that after a 100-mg dose, naltrexone can be detected in plasma for 30 hours, while 6-b-naltrexol can be detected for up to 125 hours.

Pharmacodynamics Naltrexone is a nonspecific opioid antagonist that binds to all three opioid receptor sites (μ, d, k) as a function of dose administered. Naltrexone has minimal opioid agonistic effects, and its relative opiate antagonistic potency is 12 times that of nalorphine and 2.5 times that of naloxone or cyclazocine. The time course of action of oral naltrexone in rodents is about 3 times longer than that of naloxone. No significant species differences in the binding of [^{3}H]naltrexone have been documented. An oral 100-mg dose of naltrexone almost completely antagonized the subjective and objective responses of 25 mg of intravenous heroin. Administration of 50 mg of naltrexone precipitates an abstinence syndrome in morphine-dependent subjects, an effect that decreases with chronic use. This decrease is believed to be due to increases in the number and functional activity of brain opioid receptors with long-term naltrexone administration. Naltrexone increases secretion of gonadotropin-releasing hormone and corticotropin-releasing factor and significantly increases plasma concentrations of b-endorphin, cortisol, lutenizing hormone, and follicle-stimulating hormone.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Design Naltrexone has demonstrated efficacy in blocking the effects of exogenously administered opiates and as an aid in preventing relapse in recently detoxified patients with alcohol dependence. It has been investigated as a key element in several protocols for rapid opioid detoxification and as a treatment for self-injurious and other autistic behavior in patients with mental retardation or autistic disorder. The use of naltrexone as a maintenance treatment for opioid dependence, as treatment for alcohol dependence, and in rapid opioid detoxification is supported by studies using experimental designs. Support for use in mentally retarded and autistic patients is based only on small studies and case reports that have not been confirmed by larger double-blind clinical trials. Open-label and randomized controlled trials with relatively small samples have examined the efficacy of naltrexone in reducing binge eating and obesity.

Interpretation

Alcohol Dependence The efficacy of naltrexone was originally demonstrated in two double-blind placebo-controlled trials of naltrexone in alcohol-dependent patients. In each of these studies, treatment with 50 mg daily was initiated following a minimum of 7 days of abstinence or completion of medical detoxification and was provided with concurrent psychosocial interventions. In a combined analysis of these studies, naltrexone-treated patients were more likely to remain abstinent (54 versus 31 percent), to experience fewer days of drinking (3.1 versus 7.5 percent), and to report lower rates of relapse to heavy drinking (25 versus 52 percent). Furthermore, participants who lapsed (i.e., were nonabstinent) were less likely to experience heavy drinking if they were taking naltrexone rather than placebo (57 versus 77 percent). Reductions in craving were apparent at weeks 3 and 9. Failure to find more consistent differences in craving may be related to the use of single-item analog scales to measure craving.

As naltrexone is used in general practice, less robust effects can be expected in more-heterogeneous samples of patients. While some recent clinical trials have confirmed the overall efficacy of naltrexone, other studies have found that the differences between naltrexone- and placebo-treated patients emerge only when the sample is stratified on the basis of compliance. Thus, strategies to improve compliance are likely to be important. Patients who take their medication in the morning or have an established routine for medication dosing have higher compliance rates.

Current research is examining the potential effectiveness of higher dosages of naltrexone (100 to 150 mg of naltrexone daily) particularly among patients with polysubstance abuse problems. Preclinical research and small human pilot studies suggest that greater suppression of drinking results with concurrent treatment with naltrexone and a serotonin reuptake inhibitor. Larger-scale clinical trials are under way to follow up on these preliminary findings.

Opioid Dependence As an opioid antagonist, naltrexone selectively competes with exogenously ingested opioids for central nervous system (CNS) and non-CNS opioid receptors and blocks their activity. This blockade lasts for up to 72 hours after naltrexone administration and prevents patients from achieving sought-after reinforcement from opioid use. This blockade can have positive psychological consequences including reduced craving related to reduced immediate availability of opioid effects and deconditioning of cue-related craving as patients are exposed to people, places, and things formerly associated with opioid use while protected from opioid effects. The opioid antagonist properties of naltrexone do not appear to be subject to development of tolerance, as potency has been demonstrated after maintenance for 1 year or more. At the dosage used, naltrexone does not have opioid agonist properties, and patients do not obtain a psychoactive reward (high). Neither is it associated with significant withdrawal symptoms if use is discontinued. However, patients may be more sensitive to lower dosages of opioids once naltrexone is discontinued, because of the loss of tolerance to exogenous opioids.

In carefully selected patients who are motivated to take naltrexone, maintenance on naltrexone can be used as an alternative to maintenance treatment with opioid agonists, such as methadone or levomethadyl acetate (ORLAAM). As a nonscheduled medication without psychoactive or addictive properties, naltrexone can be administered as a maintenance treatment in a range of medical settings without any special licensing requirements. Because diversion is not an issue, take-home medications can be provided with no special precautions. However, lack of initial patient acceptance and subsequent medication noncompliance limits the utility of naltrexone for opioid dependence; here the strengths of naltrexone are also its weaknesses. As a drug without psychoactive effects which blocks effects of opioids, naltrexone can be used only after completion of a 7- to 10-day period of complete opioid abstinence or after a rapid-detoxification procedure (see below). Hence, patients must start treatment with a goal of achieving total opioid abstinence and a willingness to undergo detoxification. Unlike patients maintained on opioid agonists, patients on naltrexone achieve no rewarding effects of taking medications and experience no withdrawal effects if doses are missed. Thus, there are no pharmacological barriers to dropping out of treatment. In addition, some patients continue to complain of at least mild adverse effects or opioid withdrawal effects throughout the first several weeks of treatment. Because of these factors, most patients from unselected populations drop out within the first 3 months of treatment. Greater success has been achieved with patients motivated by powerful contingencies, such as opioid-dependent health care professionals for whom opioid abstinence is a condition for regaining medical licensure or incarcerated addicts for whom treatment is a requirement for probation or parole. A treatment plan involving naltrexone dosage monitored by either a medical professional or a significant other also enhances compliance.

Opioid Detoxification Protocols Successful outpatient protocols for rapid detoxification have been developed combining naltrexone with clonidine (Catapres), a selective a_2-adrenergic receptor antagonist initially used as an antihypertensive agent. This combined treatment allows patients to be completely opioid-free from the first day of treatment, to have completed detoxification within 48 to 72 hours, and to be able to begin naltrexone maintenance at that time. For most patients, withdrawal symptoms are moderate to severe on the first day of treatment and drop off sharply thereafter. Because blood pressure may be lowered substantially by clonidine administration, patients must be monitored for up to 8 hours on the initial detoxification day, limiting this procedure to settings in which treatment rooms and adequate nursing staff are available. These protocols are particularly useful in decreasing the need for inpatient treatment and reducing absence from work. Also, as a method of initiating maintenance naltrexone treatment, this mode of detoxification removes the need for an unprotected 7- to 10-day opioid-free period prior to starting naltrexone administration, a time when vulnerability to relapse is high.

A variant method of ultrarapid inpatient detoxification involves naltrexone administered to opioid-dependent patients who are placed under light sedation or general anesthesia (including mechanical ventilation) followed by detoxification using full doses of naltrexone. Subsequently, patients continue to receive naltrexone to prevent relapse. While this method eliminates patients' conscious awareness of withdrawal discomfort, the added risks and expenses of general anesthesia outweigh this benefit. In addition, studies are yet to be conducted comparing relapse rates following this ultrarapid detoxification procedure with the safer clonidine-naltrexone detoxification protocol. As a result, ultrarapid detoxification cannot be recommended at this time.

Nicotine Dependence Several lines of evidence suggest that the opioid system may be involved in nicotine dependence. Nicotine administration is known to stimulate release of endogenous opioids and to attenuate perception of pain via opioid mechanisms. However, the potential clinical utility of naltrexone for smoking cessation remains to be established. Clinical laboratory studies examining the effects of opioid antagonists, including naloxone and naltrexone, on smoking behavior have been inconclusive, with some studies showing reductions in smoking and others finding no effect. Pilot studies suggest that naltrexone in combination with nicotine replacement therapy may have some value in smoking cessation. Given the preliminary stage of this research, naltrexone cannot be recommended for use in smoking cessation.

Self-Injurious Behavior Naltrexone has been proposed as a treatment of self-injurious behavior and of autistic behaviors in patients with mental retardation or autistic disorder. Clinically significant symptom reduction has been reported from numerous open-case studies and trials with small sample sizes. Larger studies using more rigorous experimental designs have failed to replicate these reports. Hence, naltrexone's utility for these symptoms is not established.

Eating Disorders and Obesity Numerous studies in rodents have suggested an association between altered endogenous opioid activity and obesity and other eating disorders. Exogenous and endogenous opioid administration increases food intake, while opioid antagonists block the increase in food intake. The clinical data on the use of opioid antagonists in eating disorders are controversial, and the literature is replete with studies that demonstrate differential effects of these agents based on the type of eating disorder. For example, a laboratory study demonstrated that naloxone reduces the consumption of sweet high-fat foods by both obese and lean binge eaters compared with that by obese and lean nonbingers, suggesting a role of the opioid system in binge eating but not in obesity. Controlled clinical trials in obese individuals have failed to document a significant effect of naltrexone on weight loss. A few small-sample controlled clinical trials have been conducted on bulimia nervosa, with some reporting reductions in binge symptomatology. With regard to anorexia nervosa, naloxone infusion produced a 10-fold increase in weight gain per week, an effect that ended when the naloxone infusion was stopped in patients who were concurrently treated with amitryptyline (Elavil). In a separate study of eight subjects, naltrexone also seemed to have a small nonsignificant beneficial effect on weight gain. These results are preliminary and have not been extended to a larger controlled trial. Therefore, the role for naltrexone and other opioid antagonists in the treatment of eating disorders remains unclear, and larger, more definitive controlled clinical trials are needed.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Respiratory System In opioid-dependent individuals, administration of naltrexone produces a variety of nasal symptoms such as nasal congestion, sneezing, rhinorrhea, sore throat, cough, and shortness of breath. Studies in normal opioid-free individuals have not documented any nasal symptoms. Some subjects have also reported blurred eyes and increased light sensitivity as well as tinnitus.

Heart Naltrexone increases blood pressure in opioid-dependent individuals and can also produce palpitations and tachycardia. Naltrexone also decreases fibrinogen levels in opiate addicts.

Smooth Muscles Naltrexone produced muscle tension, tremors and twitching in opioid-dependent subjects. Individuals who are not dependent on opioids have not

displayed similar changes.

Liver While naltrexone has not been shown to be hepatotoxic when administered in the recommended dose of 50 mg a day, hepatotoxic potential has been documented for a fivefold higher dosage of 300 mg a day in obese subjects and in patients with Alzheimer's disease. At the dosages currently recommended, naltrexone was not associated with increased risk of hepatotoxicity in over 500 alcohol-dependent patients treated for up to 12 weeks. Nonetheless, naltrexone is contraindicated in subjects with acute hepatitis or liver failure. However, mild-to-moderate transaminase elevations associated with alcohol or other substance use are not a contraindication.

Endocrine System Changes in baseline levels of some hypothalamic, pituitary, and gonadal hormones have been reported with naltrexone. Naltrexone significantly increases plasma testosterone luteinizing hormone, adrenocorticotropic hormone (ACTH), and cortisol concentration in opioid-dependent subjects and to reverse heroin-induced decreases in the same. In healthy adults, naltrexone has been shown to increase plasma prolactin, luteinizing hormone, testosterone, ACTH, follicle-stimulating hormone (FSH), and cortisol concentrations.

Gastrointestinal Symptoms Abdominal pain and cramps have been documented following naltrexone administration in both opioid-dependent, alcohol-dependent and nondependent persons. Some persons also report nausea, vomiting, loss of appetite, diarrhea, or constipation.

Carcinogenesis and Mutagenesis Carcinogenicity studies in rats have documented a small increase in mesotheliomas and vascular tumors. No evidence of mutagenicity has been documented.

Pregnancy Naltrexone administered at doses that were 140 times the therapeutic dose in humans decreased the pregnancy rate in rats and had an embryocidal effect in rats and rabbits; 100-mg/kg doses in rats and 60-mg/kg doses in rabbits had similar effects. Preclinical studies showed that naltrexone passes through the placenta to the fetus. There are no adequate or controlled studies of naltrexone in pregnant or nursing women.

Genitourinary Less than 10 percent of subjects report increased frequency of urination, discomfort during urination, increased frequency of erections, or alteration in sexual interest.

Psychiatric Symptoms Non-opioid-dependent individuals have also reported feeling fatigued, tired, and listless following administration of naltrexone. Both opioid-dependent and nondependent individuals report increased irritability, restlessness, mental confusion, and slowing following naltrexone administration. Substance abusers have an increased risk of suicide, and this risk is not reduced by naltrexone.

THERAPEUTIC INDICATIONS

FDA-approved indications for naltrexone include the maintenance treatment for detoxified patients with opioid dependence and relapse prevention in patients with alcohol dependence. Naltrexone has established utility when combined with clonidine as part of outpatient and inpatient detoxification protocols.

PRECAUTIONS AND ADVERSE REACTIONS

As an opioid antagonist, naltrexone can precipitate an acute withdrawal syndrome in persons who are dependent on opioids. As a result, patients should be abstinent from short-acting opioids (e.g., heroin) for at least 5 days and from longer-acting opioids (e.g., methadone [Dolophine]) for 10 days or more as judged by self-report and urine toxicology screening test. If there is a question of occult dependence in an individual with a negative urine toxicology screen for opioids who shows no signs of withdrawal, a naloxone challenge test is recommended in which the patient is observed for signs and symptoms of opioid withdrawal for 20 minutes following a subcutaneous injection of 0.8 mg of naloxone. Otherwise, naltrexone is generally well tolerated, and most patients who have no reaction to a test dose of naloxone report no adverse effects. The profile of reported adverse effects has considerable similarity to the symptoms of opioid withdrawal and includes gastrointestinal distress (nausea, vomiting, diarrhea, abdominal pain), anxiety and restlessness, dysphoria, mild hypertension, headache, and insomnia. These adverse effects are most prominent in the first several days of use and improve rapidly for patients remaining in treatment. However, a substantial minority of those with a diagnosis of opioid dependence (5 to 10 percent) may refuse a second dose, and an additional 10 to 20 percent may discontinue medication in the first month of treatment, often citing continued discomfort reminiscent of opioid withdrawal throughout the first 1 to 3 weeks of treatment. Adverse effects can be minimized by ensuring an adequate interval between cessation of opioid use and initiation of naltrexone therapy and by a graduated initial dosage schedule starting with 12.5 or 25 mg daily for the first several days.

Patients should be advised that taking large quantities of exogenous opioids in an attempt to overcome the blockade provided by naltrexone can be extremely dangerous. Life-threatening opioid intoxication may result, including respiratory arrest or circulatory collapse. In addition, patients should be advised that once naltrexone use is discontinued, they may be more sensitive to the effects of opioids because of loss of tolerance and may be at greater risk for overdose.

Among alcohol-dependent patients, nausea is the most common adverse reaction to naltrexone; it can be mild to severe and typically occurs within 90 minutes of administration. In a large multisite safety study, adverse effects that occurred in more than 2 percent of patients included nausea (10 percent), headache (7 percent), dizziness (4 percent), nervousness (4 percent), fatigue (4 percent), insomnia (3 percent), vomiting (3 percent), anxiety (2 percent), and somnolence (2 percent). The effect of naltrexone on acute alcohol withdrawal has not been investigated, and the studies demonstrating the efficacy of naltrexone in alcohol dependence required a minimum of 7 days of abstinence or medical detoxification from alcohol prior to initiating treatment. The rate of early termination due to adverse events has been substantially higher in studies in which naltrexone was administered to actively drinking alcoholics. As a result, naltrexone should probably be administered only after the risk of alcohol withdrawal has passed (4 to 5 days). Women and younger patients appear to be at somewhat increased risk of adverse effects.

The potential for hepatotoxicity at high doses has been raised as a more serious concern. However, convincing reports of elevated liver function test results have been limited to patients treated for eating disorders with doses of 250 to 300 mg daily, five to six times higher than the recommended maintenance dosage for opioid or alcohol dependence. As a precaution, patients should receive a full battery of liver function tests prior to receiving naltrexone, and naltrexone is contraindicated in patients with liver failure or acute hepatitis. The moderate transaminitis often seen in alcohol and opioid dependence is not a contraindication; however, baseline bilirubin and serum transaminases and periodic monitoring of transaminases are indicated. As a guideline, liver function tests should be repeated monthly for the first 3 months and every 3 to 6 months thereafter, if there is no evidence of rising enzyme levels. If persistent elevations in liver enzymes occur, naltrexone should be discontinued. The possibility of medication noncompliance and continued alcohol or drug use should be ruled out when mild transaminase elevations (threefold or less) occur.

Because naltrexone is metabolized by the liver and excreted through the kidneys, caution should be used in patients with severe liver disease or renal impairment. Patients with compensated and decompensated liver cirrhosis show a 5- to 10-fold increase in naltrexone levels relative to subjects with normal liver function. The increased systemic availability of naltrexone, which is believed to be due to lower rates of conversion of naltrexone to 6-b-naltrexol, appears to be related to the severity of liver disease.

Naltrexone has not been studied in pregnant or nursing women, but an embryocidal effect was demonstrated in the rat and rabbit given doses approximately 140 times the recommended human dose. As a result, naltrexone should be used during pregnancy only when the potential benefit clearly outweighs the potential risks to the fetus. Intensive psychosocial methods to support abstinence should be considered first-line therapy in pregnant women.

DRUG INTERACTIONS

Because naltrexone is an opioid antagonist, it blocks the pain-relieving effects of analgesics. In patients maintained on naltrexone, nonopioid pain medications or approaches should be tried first when possible. Thus, the use of nonsteroidal anti-inflammatory drugs should be considered the first line of pharmacological therapy for pain management. For elective surgery, cessation of naltrexone treatment 72 hours prior to surgery is recommended. Naltrexone does not reverse effects of nerve root blocks or spinal anesthesia and does not antagonize agents used for general anesthesia. If opioid medications are necessary for treatment of severe pain, the blockade can be overridden with a rapidly acting analgesic, but treatment requires close monitoring in a setting equipped and staffed for cardiopulmonary resuscitation, because the resulting respiratory depression may be deep and prolonged. Patients should be given a card stating that they are on naltrexone to alert medical personnel in case of an emergency.

The safety and efficacy of combined use of disulfiram (Antabuse) and naltrexone are unknown. Given that both medications are potentially hepatotoxic, their concomitant use is not routinely recommended at this time. However, some clinicians use the two drugs concomitantly for brief periods with more-frequent monitoring of hepatic function. Although formal drug interaction studies have not been conducted with antidepressant medications, the incidence of adverse events reported by patients receiving naltrexone in addition to antidepressants was similar to that of patients receiving naltrexone alone in a large safety study. Increased lethargy and somnolence have been reported with the combined use of naltrexone and thioridazine (Mellaril).

LABORATORY INTERFERENCES

Thin-layer, gas-liquid, and high-pressure liquid chromatographic methods used for the detection of opioids in the urine are not interfered with by naltrexone. The potential for a false-positive urine result for opioids using less-specific urine screening tests such as enzyme multiplied immunoassay technique (EMIT) may exist, because naltrexone is a derivative of oxymorphone.

DOSAGE AND ADMINISTRATION

Naltrexone is prepared in scored 50-mg capsule-shaped tablets. Blister packages of 28 tablets are available as a means of enhancing compliance. The recommended dosage for adults is 50 mg a day for alcohol or opioid dependence. Lower initial dosages can be considered over the first few days for patients at increased risk of adverse effects with the dosage increased as tolerated. The efficacy of doses ranging from 25 mg to 150 mg daily is being investigated. Morning administration is recommended for improved medication compliance. To supervise the ingestion of naltrexone in the treatment of narcotic addiction, flexible dosing can be used, including 100 mg every other day or 150 mg every third day.

Naltrexone should not be administered until there is no reasonable possibility of opiate use within the past 7 to 10 days or unless the patient has completed a clonidine (Catapres)-naltrexone detoxification, and abstinence has been verified by urine testing for opiates. If there is a question about continued opiate use, opiate-free status should be confirmed by a negative response to an intramuscular naloxone test dose of 0.8 mg. If substantial opioid withdrawal symptoms do emerge, initiation of naltrexone should be delayed at least 1 additional day. Graduated daily dosing beginning with 25 mg on the first day is recommended during the initial 1- to 2-week period prior to initiating the above thrice weekly schedule.

For rapid detoxification from opioids, patients begin the first opioid-free day with clonidine 0.2 mg orally given every 2 hours for a daily total of up to 1.8 mg, and blood pressure is checked every 30 to 60 minutes as needed. Naltrexone (12.5 mg) is administered 1 to 3 hours after the first clonidine dose. To reduce muscle cramps and later insomnia, oxazepam (Serax), 30 to 60 mg is administered orally at the same time as the initial clonidine dose, and 15 to 30 mg is given every 4 to 6 hours as needed, with a maximum daily dose of 180 mg. Patients should remain at the clinic with a bed available for up to 8 hours on this day and be taken home by a reliable escort. On day 2, similar doses of clonidine and oxazepam are provided, but naltrexone (25 mg) is administered at the onset of the day. Relatively asymptomatic patients can return home after 3 to 4 hours. On days 3 to 5, 50 mg of naltrexone is administered, and doses of clonidine and oxazepam are tapered such that these are discontinued by 5 to 10 days after beginning detoxification while naltrexone administration (50 mg daily) is continued.

SUGGESTED CROSS-REFERENCES

Issues related to specific disorders are in the following sections: alcohol-related disorders (Section 11.2), opioid-related disorders (Section 11.9), and eating disorders (Chapter 20). Clonidine is reviewed in Section 31.16.

31.22 NEFAZODONE

STEVEN J. GARLOW, M.D., PH.D., MICHAEL J. OWENS, PH.D. AND CHARLES B. NEMEROFF, M.D., PH.D.

Nefazodone (Serzone) is an antidepressant that was introduced in the United States in 1995. Nefazodone is chemically unrelated to selective serotonin reuptake inhibitors (SSRIs), tricyclic drugs, tetracyclics drugs, or monamine oxidase inhibitors. Nefazodone exerts multiple effects on serotonergic neurons and their receptors, which are believed responsible for its antidepressant action. Nefazodone has a pharmacological profile that overlaps significantly with that of trazodone (Desyrel), with some notable differences. This is not unexpected because nefazodone resulted from a drug development program that sought to improve on the actions of trazodone by maintaining its efficacy in the treatment of depression while minimizing some of its adverse effects. The only current Food and Drug Administration (FDA) indication for the use of nefazodone is in the treatment of major depressive disorder.

Nefazodone is a phenylpiperazine with some structural similarity to trazodone. Like trazodone, nefazodone has diffuse and complex pharmacological actions that include antagonism at the serotonin (5-hydroxytryptamine [5-HT]) type 2A (5-HT $_{2A}$) receptor and inhibition of the serotonin transporter. This combination of actions is hypothesized to account for the antidepressant action displayed by nefazodone. The structural differences between nefazodone and trazodone account for the differences in their respective side-effect profiles. In particular, nefazodone is less sedating than trazodone, and to date no cases of nefazodone-induced priapism have been reported. This particular difference is thought to be due to nefazodone's relatively low affinity for peripheral a $_1$-adrenergic receptors compared with trazodone. While lower than that of trazodone, nefazodone does have some antagonist action at peripheral a $_1$-receptors, and this is thought to mediate the orthostatic hypotension that it can cause.

CHEMISTRY

Nefazodone hydrochloride is a synthetically derived phenylpiperazine antidepressant (Fig. 31.22-1). Its formal chemical designation is 2-[3-[4-(3-chlorophenoxyl)-1-piperazinyl]-propyl]-5-ethyl-2,4-dihydro-4-(2-phenoxyethyl)-3 *H*-1,2,4-triazol-3-one monohydrochloride, with a generic formula of $C_{25}H_{32}ClN_5O_2 \cdot HCl$, and a molecular weight of 506.5.

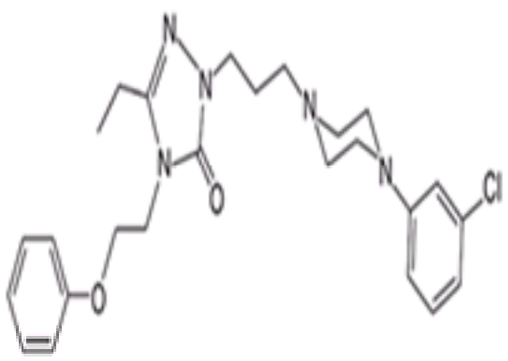

FIGURE 31.22-1 Molecular structure of nefazodone.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption Nefazodone is rapidly and completely absorbed after oral administration. Peak plasma concentrations occur within 1 hour of oral dosing. Ingestion of nefazodone with food slows the rate of absorption from the gastrointestinal tract; whether this has clinically meaningful effects is unclear.

Distribution Nefazodone is widely distributed in the body after oral dosing. The compound is distributed into all tissues and compartments and readily crosses the blood-brain barrier. Nefazodone is extensively (99 percent) but loosely protein bound in serum. It does not displace other protein-bound drugs including chlorpromazine (Thorazine), desipramine (Norpramin, Pertofrane), diazepam (Valium), phenytoin (Dilantin), lidocaine (Xylocaine), prazosin (Minipress), propranolol (Inderal), verapamil (Calan, Isoptin), or warfarin (Coumadin).

Metabolism Nefazodone is extensively metabolized in the liver via n-dealkylation and aliphatic and aromatic hydroxylation. Nefazodone is a substrate for the cytochrome P450 (CYP) 3A4 (CYP 3A4) isoenzyme. Three major pharmacologically active metabolites result from this hepatic biotransformation, hydroxynefazodone, triazoledione, and *m*-chlorophenylpiperazine (m-CPP). Less than 1 percent of an oral dose of nefazodone is excreted unchanged in urine. The half-life of nefazodone after oral administration is 2 to 4 hours. Nefazodone and hydroxynefazodone display nonlinear pharmacokinetics, with serum concentrations exhibiting greater than expected increases with dosage increases. Thus the increases in area under the curve (AUC) and maximum concentration (C_{max}) are on the order of threefold to fourfold in response to doubling of the dosage. Steady-state serum levels are achieved at 4 to 5 days with twice-daily dosing regimens or with changes in previous regimens. In older patients, single oral doses of nefazodone resulted in AUCs and C_{max}s as much as twice as high as in nonelderly patients. With a multiple-dose regimen, serum concentrations in elderly patients were on the order of 10 to 20 percent higher than in nonelderly persons. There was also a sex-based difference in serum concentrations, with females having higher AUCs and C_{max}s than male subjects after a single oral dose; no such differences were noted on a multiple-dose schedule. This concatenation of results suggests that elderly patients (particularly, elderly female patients) should initially receive half the normal dosage of nefazodone. However, the final therapeutic range is the same in elderly and nonelderly patients and in female and male patients. Patients with liver disease (in particular, cirrhosis) exhibited final serum concentrations of nefazodone that were 25 percent higher than those in normal volunteers. Therefore, nefazodone dosage should be adjusted downward for patients with liver disease. Renal disease seems to have no effect on serum concentrations of nefazodone. The CYP 2D6 is responsible for the metabolism of a large number of drugs including tricyclic drugs and SSRIs but not nefazodone. Thus patients with low CYP 2D6 activity, also referred to as “poor metabolizers,” do not require dosage adjustments of nefazodone.

Pharmacodynamics Nefazodone and its metabolites display a diverse and complex pharmacological profile. Nefazodone is a potent antagonist of the 5-HT $_{2A}$ receptor. This has been demonstrated both in vitro and in vivo. This antagonist action is hypothesized to be central to the antidepressant action of nefazodone. The antagonist action at the 5-HT$_{2A}$ receptor is one of the areas of overlap between nefazodone and trazodone. Nefazodone inhibits the serotonin transporter, which likely also contributes to this drug's antidepressant actions. Nefazodone displays moderate antagonism of the serotonin transporter in vitro, but at clinically relevant doses it does antagonize the serotonin transporter in vivo. Nefazodone also displays moderate inhibition of the norepinephrine transporter, which may contribute to its antidepressant action; in contrast it has little affinity for the dopamine transporter. Nefazodone has low-to-moderate antagonist affinity for a $_1$-receptors, much less than trazodone. Presumably this accounts for the differences between the two compounds in the incidence of both orthostatic hypotension and priapism. While both cause

some orthostatic hypotension due to antagonism of the peripheral a_1-receptors, only trazodone has been reported to cause priapism, presumably because of its higher affinity to this receptor. Otherwise, nefazodone appears to have little or no affinity for other receptor types including muscarinic cholinergic, adenosine, dopamine, g-aminobutyric acid (GABA), opioid, glutamate, glycine, and other serotonin receptors.

Hydroxynefazodone displays a pharmacological profile almost identical to that of the parent compound, with similar binding affinities. Hydroxynefazodone is a potent antagonist of the 5-HT_{2A} receptor and an inhibitor of the serotonin transporter. This metabolite has moderate inhibitor affinity for the nonepinephrine transporter. Given the receptor affinities and pharmacokinetics of hydroxynefazodone, it seems reasonable to conclude that this metabolite contributes significantly to the therapeutic efficacy of nefazodone. The trizalodione metabolite has a range of receptor activities similar to those of nefazodone and hydroxynefazodone but has much lower affinity for the various transporters and receptors than the other two compounds. While the hydroxynefazodone metabolite almost certainly participates in the antidepressant action of the agent, it is not clear whether the trizalodione compound does so.

The third pharmacologically active metabolite of nefazodone, m-CPP, results from hepatic transformation of both nefazodone and trazodone. This compound has a number of actions; most notably, it is a weak antagonist of the 5-HT_{2A} receptor but a moderately potent agonist of the 5-HT_{2C} and 5-HT_{1B} receptors. Administration of m-CPP to experimental animals results in behavioral activation and potentiation of anxiogenic stimuli. Administration of m-CPP to human subjects has anxiogenic effects and when given to anxiety-prone subjects can trigger significant symptoms of anxiety and panic. Both antidepressants, nefazodone and trazodone, are reported to cause symptoms of anxiety in some patients at the beginning of treatment, which is probably due to the m-CPP metabolite. m-CPP and trazodone have also been reported to provoke migraine headache in susceptible individuals.

THERAPEUTIC INDICATIONS

Nefazodone became available in the United States in early 1995. Most of the clinical-trials literature about nefazodone supports its action as an antidepressant. Because this agent is newly approved, relatively few studies have been published on its use in other disorders. In contrast, trazodone has been available in the United States since 1981, and a large body of information exists related to its use in a wide range of psychiatric disorders and clinical settings.

Major Depressive Disorder Nefazodone was evaluated as an antidepressant in four phase III clinical trials. These double-blind, placebo- and active treatment (imipramine [Tofranil])-controlled trials evaluated the efficacy of nefazodone in the treatment of outpatients with major depressive disorder. Treatment response was quantified with the 17-item Hamilton Rating Scale for Depression (HAM-D-17) and the Clinical Global Improvement (CGI) scale. Nefazodone showed greater efficacy than placebo and equal efficacy to imipramine in the treatment of depression in three of the four trials. In the fourth trial, neither nefazodone nor imipramine were superior to placebo. Both agents continued to maintain efficacy during long-term (continuation) treatment. The endpoint dosage for patients receiving nefazodone was in the 300 to 500 mg a day range. Patients treated with nefazodone reported fewer adverse effects and had fewer premature treatment terminations than patients treated with imipramine. The principal conclusion drawn from these trials is that nefazodone has efficacy equal to that of imipramine in the treatment of major depressive disorder. Additionally, nefazodone is well tolerated, with fewer reported adverse effects than with imipramine.

Nefazodone has been directly compared with sertraline (Zoloft) and paroxetine (Paxil) in the treatment of major depressive disorder. In the trial comparing nefazodone with sertraline, 166 patients that fulfilled the revised third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) criteria for nonpsychotic major depression were randomized to treatment with either nefazodone (100 to 600 mg a day) or sertraline (50 to 200 mg a day). Patients were treated for 6 weeks with active agent and were assessed with the HAM-D-17, the CGI, and a sexual function questionnaire. The mean daily dosage for each agent at the end of the study was 148 mg for sertraline and 456 mg for nefazodone. Both agents were judged efficacious in the treatment of depression, with no statistically significant difference in their antidepressant action. Treatment with sertraline was reported to have a negative impact on sexual functioning and satisfaction in men and women; patients treated with nefazodone did not report adverse sexual consequences during the trial.

The trial comparing nefazodone with paroxetine was carried out in 20 centers in the United Kingdom and Ireland. In this trial, 206 patients that fulfilled DSM-III-R criteria for moderate-to-severe nonpsychotic depressive disorders were randomized to treatment with either nefazodone or paroxetine. One limitation of this trial is that patients deemed to be at risk for suicide were specifically excluded from the study. The battery of outcome measures was similar to that used in the sertraline comparator study cited above, though sexual functioning was not assessed directly. Both treatment groups had virtually identical outcomes—significant improvement in depressive symptoms. Both agents were concluded to possess similar efficacy in the treatment of major depression. Both treatment groups had virtually identical rates of discontinuation due to adverse events; 15 (14 percent) of the nefazodone-treated patients, and 13 (13 percent) of the paroxetine-treated patients dropped out of the trial. These studies indicate that nefazodone is as effective in the treatment of major depression as the two well-studied SSRIs sertraline and paroxetine. All three agents carried similar rates of adverse events, but nefazodone seems to cause fewer adverse sexual effects than the other agents, especially sertraline.

Nefazodone has also been compared directly with amitriptyline (Elavil) in the treatment of depression. In this trial, 106 inpatients with a diagnosis of major depression were randomized to treatment with nefazodone or amitriptyline in a 6-week, double-blind trial. Treatment response was measured with multiple instruments including the Montgomery-Asberg scale, Hamilton Rating Scale for Depression (HAM-D), CGI, and the Patient Global Assessment scale. Amitriptyline demonstrated significant superiority to nefazodone in the treatment of depression. However, this study differed from those cited above demonstrating that nefazodone had efficacy equal to that of imipramine in terms of the final modal dosage of nefazodone. In this study comparing nefazodone with amitriptyline, the modal dosage of nefazodone was 242 mg a day, while in the studies comparing nefazodone with imipramine, the dosage range of nefazodone was 300 to 500 mg a day. Based on these data, it seems reasonable to conclude that the lack of efficacy reported in this study is merely due to inadequate dosage of nefazodone.

The efficacy of nefazodone as a treatment for various syndromal types of depression was assessed by analyzing the pooled data from four placebo-controlled trials. The efficacy of nefazodone in the treatment of severe depression, melancholic depression, and recurrent depression was determined with this analysis. Patients were defined as having severe depression by the CGI. Patients were defined as having melancholic features or recurrent depression by DSM-III-R criteria. This pooled analysis revealed that nefazodone was effective in the treatment of all three depressive subtypes. The mean endpoint dose of nefazodone for the patients in this analysis was 379 mg a day.

The cost-effectiveness of nefazodone as a treatment for depression has been analyzed in two different studies. Nefazodone was compared with either imipramine, fluoxetine (Prozac) or a step regimen in which patients who failed on imipramine were treated with nefazodone, with a model that represented “ideal” primary care practice. The measures that were compared for the three regimens included total lifetime medical cost, quality-adjusted life years, and cost per quality-adjusted life years gained. The lifetime medical cost of treatment with nefazodone was $16,669, for imipramine $15,348, for the step regimen $16,061, and for fluoxetine, $16,998. Treatment with nefazodone resulted in the largest gain of in quality-adjusted life years 14.64; treatment with imipramine yielded 14.32, the step regimen 14.40, and fluoxetine 14.58. Thus, nefazodone is a cost-effective treatment for depression in comparison to imipramine or fluoxetine. The analysis also reveals that fluoxetine treatment is cost-effective, though slightly more expensive and slightly less effective than nefazodone. In a second analysis, the costs of nefazodone treatment were compared with those of imipramine over the course of a 1-year continuation-phase of a double-blind trial comparing the efficacy of the two agents. The clinical trial was conducted in the United Kingdom. The average cost per successfully treated patient with nefazodone was 254 British pounds; the cost for imipramine was 323 British pounds. Thus, for patients carried through the continuation phase of the protocol (who by definition are those who responded to the particular agent during the initial 8-week phase), the cost of treatment with nefazodone is lower than that of imipramine.

Panic and Other Anxiety Disorders Nefazodone has been evaluated as a treatment of panic and anxiety symptoms both in the setting of panic and anxiety symptoms secondary to or comorbid with a diagnosis of major depressive disorder and as syndromal noncomorbid entities. The results of two randomized, placebo-controlled studies of nefazodone in the treatment of depression were retrospectively analyzed for specific actions on symptoms of anxiety. The patients enrolled in the trials had primary diagnoses of major depressive disorder, and the trials were carried out in both primary care and psychiatric clinic settings. Nefazodone was found effective in treating the anxiety symptoms associated with depression. The active comparator, imipramine, was also effective in treating these symptoms, though not as effective as nefazodone. Retrospective, blinded record review revealed that a subgroup of the patients treated in the psychiatric clinic was suffering from comorbid panic disorder. Patients from this subgroup who received nefazodone had significant improvement in their panic symptoms including relief of panic and phobic anxiety. Patients from the panic-prone subgroup who received imipramine did not differ from those that received placebo. Thus in this particular cohort of patients with comorbid major depressive disorder and panic disorder, nefazodone was superior to both placebo and imipramine, particularly in the relief of panic symptoms.

The results of six randomized, double-blind trials of nefazodone as a treatment for major depressive disorder were subjected to a meta-analysis to assess its efficacy as a treatment for anxiety symptoms associated with depression. The patients fulfilled criteria for major depression and had HAM-D scores of 18 or above. The retrospective analysis was carried out on 817 patients: 345 received placebo, 288 received imipramine, and 184 received nefazodone. Treatment with either imipramine or nefazodone was associated with statistically significant improvement in the Hamilton Rating Scale for Anxiety (HAM-A), the HAM-D anxiety factor,

HAM-D psychic anxiety item, and the HAM-D agitation item. The patients who received nefazodone experienced significant improvement in somatic anxiety (HAM-D, item 11), while those that received imipramine did not differ from those that received placebo. Nefazodone treatment was associated with more-rapid improvement in agitation (HAM-D, item 9) than treatment with either imipramine or placebo. The improvement in this item was discernible after as little as 1 week of nefazodone treatment.

Nefazodone has been evaluated in open-label trials as a treatment for panic disorder, generalized anxiety disorder, and obsessive-compulsive disorder. Fourteen patients who fulfilled DSM-III-R criteria for panic disorder were entered in an 8-week open-label trial of nefazodone. Patients were not excluded for having comorbid diagnoses of major depression, dysthymia, generalized anxiety disorder, or depression not otherwise specified. A flexible dosage regimen was used with a range of 200 to 600 mg a day. Panic attack frequency and severity and the CGI were used to assess outcome, and 10 of 14 patients were rated as much or very much improved after 8 weeks of treatment. The frequency of panic attacks decreased from a mean of 5.4 pretreatment to 2.1 after 8 weeks of treatment. Improvements were reported in panic attack severity, HAM-D, HAM-A, CGI, and the Sheehan Disability Scale after 4 weeks of active treatment. Six of the patients initially enrolled in the study had “pure” panic or only minor depressive symptoms; five improved. Eight of the patients had diagnoses of comorbid major depression; five improved. Five patients had comorbid generalized anxiety disorder; three improved. No patient prematurely terminated treatment because of adverse reactions.

Twenty-one patients who fulfilled DSM-IV criteria for generalized anxiety disorder were enrolled in an open-label trial of nefazodone. The patients were treated for 8 weeks, and outcome measures included the HAM-A and CGI scales. Of the 21 patients initially enrolled, 15 completed the entire 8-week trial. Of these, 12 of 15 were rated very much or much improved, 1 minimally improved, and 2 unchanged; no patients were rated worse. The results of the open-label trials and the post hoc analyses of the original clinical trials data sets indicate that nefazodone may be effective in the treatment of panic, generalized anxiety disorder, and other anxiety disorders. This seems to be true in the setting of panic and anxiety comorbid to major depression and in anxiety disorders occurring independently of depression. These preliminary observations need to be confirmed with double-blind, placebo-controlled trials specifically designed to test nefazodone as a treatment for panic disorder, generalized anxiety disorder, and other anxiety disorders.

There is one small open-label trial of nefazodone in the treatment of obsessive-compulsive disorder. This study was conducted in depressed patients with comorbid obsessive-compulsive disorder. Of the 15 patients who completed the depression trial, 9 had comorbid obsessive-compulsive disorder as defined by DSM-III-R criteria. The patients who completed the 8-week trial showed significant improvement in depressive and anxiety symptoms, regardless of whether they had comorbid obsessive-compulsive disorder. The author reported a trend toward efficacy in reducing obsessional thoughts in patients with obsessive-compulsive disorder, but this did not attain statistical significance. The results of this study do not support the use of nefazodone in the treatment of obsessive-compulsive disorder; whether or not this agent has such efficacy must await the completion of double-blind, placebo-controlled studies.

Premenstrual Syndrome Nefazodone has been evaluated as a treatment for premenstrual syndrome (PMS), premenstrual dysphoric disorder, and depression comorbid with PMS. In this open-label trial, patients with PMS without comorbid depression and patients with PMS with comorbid depression or dysthymia were treated with nefazodone. The patients were treated for 8 weeks with a flexible dosage range from 100 to 600 mg a day with twice-daily dosing. Both groups experienced significant improvement in premenstrual symptoms by the end of the first treated menstrual cycle. The average daily dosage at the end of the first cycle was 245 mg (range, 100 to 400 mg). Of the 54 patients initially enrolled in the study, 47 completed the full 8 weeks of treatment, with a mean daily dosage at the end of 8 weeks of 319 mg. This promising preliminary result serves as an impetus for placebo-controlled, double-blind studies specifically designed to test the efficacy of nefazodone as a treatment for PMS as well as PMS comorbid with depression.

Pain Although there are no references to the clinical utility of nefazodone in the treatment of pain, there are preclinical data that bear on this issue. Given that nefazodone has some structural and neurochemical similarity to trazodone, it might be expected to have similar antinocioceptive properties. Nefazodone demonstrates analgesic properties in certain animal models but not in others. It potentiates morphine-induced analgesia in a number of animal models. Interestingly, nefazodone does not affect the lethal dose (LD_{50}) for morphine, nor does it affect the morphine's action on gastrointestinal motility. This concatenation of observations suggests that nefazodone potentiates the analgesic action of morphine without enhancing its adverse effects. Nefazodone may be a useful adjunct in the treatment of chronic pain. Clearly controlled clinical trials are needed.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

General Nefazodone has been reported to cause relatively few adverse events. Approximately 3500 patients have received nefazodone in controlled clinical trials, including 1300 patients in long-term (1 year or more) continuation treatment. The incidence of adverse effects and the frequency of their occurrence in patients receiving nefazodone can be directly compared with those in patients receiving other antidepressants (tricyclic drugs, SSRIs) and placebo. In comparison to patients receiving placebo, the most frequently reported adverse effects of patients being treated with nefazodone are nausea (21 versus 14 percent), somnolence (19 versus 13 percent), dry mouth (19 versus 13 percent), dizziness (12 versus 6 percent), constipation (11 versus 7 percent), asthenia (11 versus 6 percent), lightheadedness (10 versus 4 percent), and amblyopia or blurred vision (6 versus 3 percent).

P>**Central Nervous System** The adverse events most frequently referable to the nervous system experienced by patients receiving nefazodone are somnolence, dizziness, lightheadedness, asthenia, and amblyopia. While potentially bothersome to individual patients, these side effects are considered benign. Nefazodone does not appear to alter the seizure threshold, and it is not associated with an increase in the incidence of seizures. There are no reports of its use in patients receiving electroconvulsive therapy (ECT).

Nefazodone has interesting effects on sleep architecture. Nefazodone treatment tends to increase the density of rapid eye movement (REM) sleep in both healthy volunteers and depressed patients. In a study of eight healthy volunteers, subjects received 100 mg of nefazodone twice daily for 7 days. Polysomnographs were recorded after 1 and 7 days of treatment. Treatment with nefazodone increased REM sleep time in both the 1-day and 7-day recordings. The largest increase in REM sleep time occurred after 7 days of treatment. Treatment with nefazodone did not alter other parameters of REM sleep (i.e., REM latency or number of REM periods). Treatment with nefazodone was also associated with a decrease in the wake-after-sleep-onset measure and an increase in the percentage of actual time asleep. In a double-blind, placebo-controlled, crossover designed study, 12 healthy volunteers were treated with either trazodone, buspirone (BuSpar), or nefazodone and subjected to multiple sleep studies. Nefazodone treatment increased REM sleep time, while the other two agents suppressed REM sleep. All three agents had minimal impact on the other sleep stages. Nefazodone was reported to have no impact on sleep architecture or REM sleep time in a larger study. In this double-blind, placebo-controlled study, 37 healthy volunteers were randomized to receive either paroxetine (30 mg a day) or nefazodone (400 mg a day) for a total 16 days of treatment. Polysomnographs were recorded after 1 and 16 days of treatment. Treatment with paroxetine reduced total REM sleep and increased REM latency. Paroxetine treatment was also associated with reduced actual sleep time and sleep efficiency. Treatment with nefazodone resulted in no change in REM sleep or any of the measures of sleep continuity. Thus in healthy subjects, nefazodone has little impact on REM sleep and may actually increase the total REM time in comparison to other antidepressant agents, which tend to suppress REM density and increase REM latency.

Nefazodone has been reported to increase REM sleep time in patients with major depressive disorder. In an open-label trial, 10 patients who were suffering from major depression were treated with nefazodone (400 to 600 mg a day) and subjected to polysomnographic study at baseline and during the treatment phase of the trial. All of the patients enrolled in the study were deemed to be nefazodone responders because they all experienced a 50 percent reduction in HAM-D scores from pretreatment baselines. Treatment with nefazodone neither increased REM latency nor suppressed REM sleep. There was a trend toward increased REM sleep during the second REM period and a trend toward decreased REM during the third period. Treatment with nefazodone was associated with improved sleep continuity as measured by decreased wake and movement time and increased stage 2 sleep. Nefazodone clearly improves sleep continuity in patients suffering from major depression, has no effect on REM latency, does not suppress REM sleep, and may even increase total REM time.

The mechanism by which nefazodone increases REM sleep remains obscure. Generally, agents that potentiate cholinergic functioning increase REM sleep, but nefazodone does not have cholinergic agonist properties. One possible explanation is that nefazodone affects the cells of the dorsolateral and pedunculopontine nuclei. These cholinergic cells are intimately involved in generating the pontine-geniculate-occipital waves associated with REM sleep. These cell groups also have a high density of $5\text{-}HT_{2A}$ receptors. Antagonizing the $5\text{-}HT_{2A}$ receptors on these cells may potentiate their cholinergic outflow, resulting in increased REM sleep.

The effect of nefazodone on daytime sleepiness, highway driving, and cognitive functions was determined in healthy adult and elderly volunteers. This was a double-blind, placebo-controlled, crossover designed study in which the subjects received either placebo, imipramine (50 mg twice daily), or nefazodone (100 or 200 mg twice daily). The subjects were tested with an “over-the-road” driving test, a battery of psychomotor tests, and multiple sleep latency tests. The most prominent result of this study was that the subjects treated with imipramine had decreased lateral position control in the driving test after the first dose. This effect disappeared after 7 days of treatment. In comparison, 1 day of nefazodone administration at either dosage had no effect on the driving performance test. Seven days of nefazodone treatment at the 200-mg dosage was associated with slight impairment in the lateral position control in the driving test. Imipramine treatment was

associated with minor impairment in the psychomotor test battery after 1 and 7 days. Nefazodone treatment for 7 days at the higher dosage was associated with minor impairment in cognitive and memory function. Neither agent was noted to increase daytime sleepiness. Two main conclusions seem warranted: (1) neither drug has a deleterious impact upon driving or cognitive performance and (2) although somnolence is a frequently reported side effect of nefazodone, its use is not associated with an actual increase in daytime sleepiness as revealed by the multiple sleep latency test.

The effect of nefazodone on a number of psychomotor and cognitive performance measures was determined in a study of 12 healthy volunteers. In this study, patients were randomized to receive either nefazodone (200 or 400 mg a day), imipramine (150 mg a day), or placebo for 8 days. The subjects were tested on days 1, 7, and 8 of treatment. Nefazodone treatment was associated with a dose-dependent improvement in psychomotor performance and complex memory tasks. In contrast, treatment with imipramine impaired performance of these tasks. Subjects who received either active compound reported subjective changes in alertness and other bodily symptoms. The subjects received a measured dose of alcohol on the eighth day of treatment, followed by the battery of tests. Treatment with nefazodone did not potentiate the sedative-hypnotic effects of alcohol, whereas imipramine tended to enhance the impact of alcohol on psychomotor performance and memory tasks. The lack of impact of nefazodone on the psychomotor and memory tasks is hypothesized to be due to its lack of anticholinergic activity.

Genitourinary System Unlike trazodone, nefazodone has not been reported to cause priapism. The reason for this is not known, but one hypothesis attributes it to the fact that nefazodone has a lower affinity for peripheral a_1-receptors than does trazodone. Trazodone is thought to cause priapism through direct action on a_1-receptors on the vascular tissues in the penis and clitoris. Nefazodone does increase total nighttime tumescence in patients while they are asleep, but this is apparently due to its impact on REM sleep and not due to peripheral adrenergic activity. In a study in which the effects of nefazodone on sleep were compared with those of trazodone and buspirone, nefazodone was noted to increase REM sleep time. Subjects treated with nefazodone exhibited a concomitant increase in nighttime tumescence that correlated directly with REM sleep time. In subjects treated with trazodone, tumescence was increased because of an increase in the time to detumescence. Trazodone-treated subjects had normal initiation of erection with the onset of REM sleep, but the erection persisted past the point of termination of REM sleep because of a failure of detumescence. This increased time to detumescence caused by trazodone is likely due to its direct action on peripheral a_1-receptors.

The incidence of sexual adverse effects of any kind is low for nefazodone in comparison to other agents. In at least one clinical trial in which nefazodone was compared with an SSRI, sertraline, patients who received nefazodone reported significantly better and more satisfying sexual functioning than did those receiving the SSRI. This was a consistent finding, reported by both male and female patients.

Cardiovascular System Treatment with nefazodone is associated with an increased risk for the occurrence of hypotensive episodes. A pooled analysis of the vital sign data generated during the placebo-controlled premarketing studies revealed that 5.1 percent of nefazodone-treated patients experienced a hypotensive episode, compared with 2.5 percent of the placebo-treated patients. Interestingly, there was no difference between nefazodone and placebo-treated patients in the report of syncopal episodes. The incidence of postural hypotension recorded in the premarketing data base was 2.8 percent of nefazodone-treated patients, 10.9 percent of those treated with tricyclic drugs, 1.1 percent of the SSRI treated, and 0.8 percent of placebo-treated patients. Care should be used when prescribing nefazodone to patients with a condition that might be worsened by hypotensive episodes. This includes patients with known cardiovascular and cerebrovascular disease, those at risk for dehydration or hypovolemia, and those taking antihypertensive agents. Treatment with nefazodone during the premarketing trials was not associated with the development of clinically significant electrocardiogram (ECG) abnormalities. The nefazodone-treated patients had a slightly higher incidence of sinus bradycardia than those who received placebo. Sinus bradycardia was defined as a heart rate below 50 beats per minute (bpm) and a drop of 15 bpm from pretreatment baseline. This event occurred in 1.5 percent of the nefazodone-treated patients and only 0.4 percent of those receiving placebo. Because patients with recent myocardial infarction or unstable heart disease were excluded from the premarket clinical trials, it is not possible to assess the risks of nefazodone in this patient population.

Other Systems Nefazodone has no carcinogenic or mutagenic activity in an array of preclinical assay systems. Nefazodone slightly decreased fertility in a rat assay system at doses three times the maximal human dose but had no effect at dosages that approximated the therapeutic range in humans. Nefazodone's teratogenic potential has been evaluated in rabbit and rat systems. Treatment at doses five to six times the maximal human dose resulted in no malformations. In the rat, dosages five times the human dose increased early pup mortality and decreased pup weights. This effect disappeared at a dose 1.3 times the maximal human dose. There are no systematic studies of nefazodone use in pregnant women. This agent is classified in the category C risk group, indicating that it should be used in pregnancy only if its potential benefits outweigh the potential risk to the fetus. It is not known whether nefazodone or its metabolites enter human breast milk.

Studies in both monkeys and humans indicate that nefazodone has no abuse liability.

PRECAUTIONS AND ADVERSE EFFECTS

Overdose The experience with nefazodone in overdose during the premarketing trials was very limited. A total of seven overdose incidents were reported during these trials. There were no fatalities in patients after nefazodone overdose alone or in combination with other agents. The reported dose range of nefazodone ingested in overdose was 1000 to 11,200 mg. Symptoms of nefazodone overdose include nausea, vomiting, sedation, and somnolence. There are no specific treatments for nefazodone overdose. Treatment should be supportive and directed at particular symptoms, specifically at maintaining an adequate airway and cardiovascular function.

Use in Medically Compromised Patients The pharmacokinetics of nefazodone have been evaluated in patients who suffered from hepatic impairment. In one study, the metabolism of nefazodone in patients with biopsy-proven hepatic cirrhosis was compared with that of healthy controls matched by age, sex, and weight. Acute and chronic exposure paradigms were used to determine the effects of hepatic cirrhosis on the immediate and steady-state concentrations of nefazodone and its metabolites. The concentration of nefazodone and hydroxynefazodone after a single oral dose in subjects with cirrhosis was approximately twice that in controls. At steady state, the concentration of nefazodone and hydroxynefazodone in the subjects with cirrhosis was approximately 25 percent greater than that in the controls. The concentration of m-CPP in the subjects with cirrhosis was two- to threefold higher than that in controls, while there was no difference in the concentration of the triazoledione metabolite between the two groups. In a separate study, the kinetics of nefazodone, hydroxynefazodone, and m-CPP were compared in healthy subjects and those with mild and severe hepatic impairment. The results indicated that mild liver disease does not affect the kinetics of nefazodone metabolism, but severe impairment does. The presence of liver disease is clearly not a contraindication to nefazodone use. The starting dose should be lowered as should the steady-state dose in patients with hepatic insufficiency.

The kinetics of nefazodone, hydroxynefazodone, and m-CPP in healthy elderly subjects (over 65 years) were compared with those in healthy younger subjects (18 to 40 years). The study included four separate groups: younger men, younger women, elderly men, and elderly women. The CYP 2D6 activity was determined for all of the subjects, and all of the study participants were classified as extensive metabolizers. The peak plasma concentration of nefazodone and hydroxynefazodone was approximately twofold higher in the elderly subjects than in the younger subjects. The levels of nefazodone and hydroxynefazodone at steady state were approximately 50 percent higher in the elderly women than in the other three groups. The premarketing trials included 488 elderly individuals. These patients did not experience increased numbers or types of adverse events. In particular, the elderly group had the same rate of cardiovascular events as did the nonelderly group. Based on these results, nefazodone appears to be quite safe to use in elderly patients. The manufacturer recommends initiating therapy in elderly persons at half the dose recommended for nonelderly persons. The dosage in elderly persons should be increased into the same range recommended for nonelderly patients, but the usual precautions observed in treating elderly patients (slow dosage escalation) should be observed.

Because patients with previous myocardial infarction or with unstable cardiac disease were excluded from the premarket clinical trials, there is no information available on the use of nefazodone in this population. In a study of patients suffering from renal disease (with creatinine clearances from 7 to 60 mL a minute per 1.73 m^2), renal impairment had no effect on steady-state concentrations of nefazodone. No information is available on the use of nefazodone in patients with other chronic or systemic diseases (neurological, metabolic, oncological). Given the lack of systematic study in these patients populations, caution should be exercised when considering the use of nefazodone or other antidepressant agents in medically ill patients.

Drug-Drug Interactions The identification and characterization of specific isoenzymes of the cytochrome P450 system has greatly improved the ability to predict drug-drug interactions. Knowledge of which drugs are metabolized by specific isoenzymes, coupled to the knowledge of which drugs inhibit specific isoenzymes allows treatment regimens to be tailored to the needs of the individual patient. This knowledge also helps prevent adverse events arising from pharmacokinetic interactions between different therapeutic agents.

Nefazodone, hydroxynefazodone, and *p*-hydroxynefazodone all inhibit the CYP 3A4 in vitro and in vivo. Nefazodone and its metabolites are very weak inhibitors of CYP 2D6 and have no activity on CYP 1A2. Caution must be exercised when using nefazodone in combination with other drugs metabolized by CYP 3A4. Specifically, nefazodone should not be used in combination with terfenadine (Seldane), astemizole (Hismanal), or cisapride (Propulsid), as all three of these agents

are substrates of CYP 3A4. Increased concentrations of these agents are associated with torsade de pointes (QT prolongation and potentially lethal ventricular arrhythmias). The interaction of nefazodone with these three agents has not been directly observed in human subjects, but the interaction between other inhibitors of CYP 3A4 (ketoconazole [Nizarol]; erythromycin) and these agents has been shown to cause this type of ventricular tachyarrhythmia.

The specific in vivo interaction between nefazodone and a number of other drugs has been directly assayed in a series of clinical trials. The interaction between nefazodone and triazolam (Halcion), which is metabolized by CYP 3A4, was assessed in a placebo-controlled, double-blind study in healthy male volunteers. The immediate and long-term administration of triazolam did not affect the pharmacokinetics of nefazodone. Twice-daily administration of nefazodone for 7 days significantly affected the pharmacokinetics of triazolam, resulting in a 60 percent increase in circulating triazolam concentrations, associated with pronounced alterations in measures of psychomotor performance and sedation. Similarly designed studies were used to assess the interaction between nefazodone and alprazolam (Xanax), which is also metabolized by CYP 3A4. Coadministration of the two agents did not affect the pharmacokinetics of nefazodone, hydroxynefazodone, or triazoldione, but the steady-state concentration of m-CPP was increased threefold and the half-life ($t_{1/2}$) of m-CPP was increased twofold; the steady-state concentration of alprazolam was increased twofold. Coadministration of nefazodone and alprazolam resulted in poorer psychomotor performance and increased sedation, compared with alprazolam alone. The interaction between nefazodone and lorazepam was evaluated in similarly designed studies. Lorazepam (Ativan) is metabolized via conjugation, not hydroxylation, and is probably not a substrate of CYP 3A4. Coadministration of lorazepam and nefazodone had no effect on the pharmacokinetics of either agent. Steady-state levels of m-CPP in the coadministration group were slightly decreased. There were no impairments in psychomotor performance, memory, or sedation in the subjects who received nefazodone and lorazepam together. Thus, when nefazodone is coadministered with benzodiazepines that are metabolized via the CYP 3A4 pathway (triazolam, alprazolam), the dosage of the benzodiazepine should be decreased, whereas no dosage adjustment is necessary when benzodiazepines metabolized via direct conjugation (lorazepam) are coadministered with this antidepressant.

The pharmacokinetics and pharmacodynamics of theophylline, which is metabolized via the CYP 1A2 pathway, were not affected by coadministration of nefazodone. Likewise, there were no changes in the pharmacokinetics of nefazodone (Serzone) in the coadministration group. Coadministration of warfarin (which is metabolized via CYP 2C) and nefazodone resulted in a 12 percent decrease in warfarin C_{max}, but no change in prothrombin ratios or bleeding times. Therefore this appears to be a clinically insignificant interaction. The pharmacokinetics of nefazodone were not affected by the coadministration of warfarin. A modest pharmacokinetic interaction was observed between nefazodone and haloperidol (Haldol), which is metabolized by CYP 2D6. In these studies the AUC for a 5-mg oral dose of haloperidol was increased 36 percent in subjects with a steady-state plasma concentration of nefazodone. Coadministration of haloperidol did not affect the pharmacokinetics of nefazodone or its metabolites. It does appear that nefazodone and haloperidol are safe to use in combination, but in this situation consideration should be given to lowering the dose of haloperidol, especially in patients known to be prone to antipsychotic drug–induced adverse effects. There is no apparent pharmacokinetic interaction between nefazodone and the histamine type 2 receptor (H_2) inhibitor cimetidine (Tagamet).

Coadministration of nefazodone and digoxin (Lanoxin) resulted in a 29 percent increase in C_{max} and a 15 percent increase in AUC for digoxin. There was no effect on the pharmacokinetics of nefazodone. These agents are considered safe to use in combination, but downward adjustment in digoxin dosage is recommended as is monitoring of digoxin concentrations in plasma. Coadministration of propranolol and nefazodone resulted in a 29 percent reduction in C_{max} and 14 percent reduction in AUC for propranolol (Inderal). There were no clinically significant effects on vital signs or ECG results. The changes in propranolol pharmacokinetics are considered clinically insignificant; no particular dosage adjustment is recommended for this combination. Coadministration of propranolol did not affect the pharmacokinetics of nefazodone.

The interaction between nefazodone and monamine oxidase inhibitors (MAOIs) has not been systematically studied in experimental animals or human subjects. Significant interactions between MAOIs and both SSRIs and tricyclic drugs have been reported. The serotonin syndrome, characterized by hyperthermia, autonomic instability, rigidity, myoclonus, agitation, delirium, and coma has been reported to occur from the interaction of SSRIs and MAOIs. Additionally, severe hyperthermia and potentially fatal seizures have been reported to occur from the combination of tricyclic drugs and MAOIs. The manufacturer of nefazodone recommends that this agent not be used in combination with MAOIs, that at least 14 days elapse between terminating treatment with an MAOI and initiating treatment with nefazodone, and that at least 1 week elapse between terminating treatment with nefazodone and initiating treatment with an MAOI.

DOSAGE AND ADMINISTRATION

Nefazodone is indicated for the treatment of major depressive disorder. Labeling for nefazodone suggests initiating therapy in healthy adults at a dosage of 100 mg twice a day. These authors recommend 50 mg twice a day as a starting dosage to diminish adverse events. The effective dosage range from all of the premarket trials is 300 to 600 mg a day. The dosage should be titrated upward in increments of 100 mg a day at weekly intervals. Dosages above 600 mg a day are not recommended. As with all antidepressants, several weeks of treatment in the therapeutic dose range may be required to realize a complete response. There are no data to suggest an optimal maintenance dose of nefazodone once a therapeutic response has been realized. Standard practice with other antidepressants suggests that the therapeutic dose should be continued as the maintenance dosage. The premarket data indicate that nefazodone at therapeutic dosages is safe for at least 1 year.

Treatment of elderly patients should also be initiated at 50 mg twice a day. Upward dosage titration should be adjusted to the individual needs of the elderly patient, generally with a slower rate of dosage escalation. The final therapeutic range for treatment of elderly patients may be similar to that in nonelderly patients, but dosage adjustment should be based on clinical assessment of the individual patient. Similar recommendations pertain to treating medically debilitated patients and patients with liver disease.

Nefazodone tablets are supplied in 50-mg, 100-mg, 150-mg, 200-mg, and 250-mg sizes. The 100-mg and 150-mg tablets are scored so that they can be easily broken in half. This allows finer adjustments in the dosing regimen.

31.23 OPIOID AGONISTS

RICHARD S. SCHOTTENFELD, M.D., AND HERBERT D. KLEBER, M.D.

Methadone (Dolophine, Methadose), an orally effective and long-acting agonist at the μ-opioid receptor, was first synthesized at the end of the Second World War as a substitute analgesic for morphine. Methadone has been in use as a detoxification treatment from heroin or other opiate-like (opioid) drugs since the late 1940s and for maintenance treatment of opioid dependence since the mid 1960s. More recently, a second orally effective, synthetic μ-agonist, levomethadyl acetate (ORLAAM) has gained Food and Drug Administration (FDA) approval for the maintenance treatment of opioid dependence. Because of the long half-lives of its active metabolites, levomethadyl acetate (also known as L-a-acetylmethadol [LAAM] can be administered on a three times per week schedule, rather than daily, as is necessary for methadone. A third medication, buprenorphine (Buprenex), a long-acting partial μ-agonist, is currently under investigation for use in opioid detoxification and for the maintenance treatment of opioid dependence. Buprenorphine's profile of pharmacologic effects suggests that there may be a number of advantages to its use, including a decreased risk of overdose or abuse, greater ease of withdrawal, and the possibility of less than daily administration.

HISTORY

Harris Isbell and his colleagues at the Addiction Research Center in Lexington, Kentucky, were the first to establish the safety and efficacy of methadone for detoxification from heroin and other opioids. Substitution of the longer-acting opioid (methadone) for a shorter-acting opioid (e.g., heroin), followed by gradual tapering of methadone, led to fewer symptoms and less severe withdrawal than abrupt discontinuation or gradual tapering of a shorter-acting opioid. Because methadone is orally effective, additional advantages of its use include the ease and safety of its administration and the absence of reinforcement of injection drug use. While newer treatments for opioid withdrawal (e.g., clonidine [Catapres] and clonidine plus naltrexone [Revia]) can decrease the time needed to complete withdrawal and to initiate maintenance treatment with the opioid antagonist, naltrexone, methadone substitution and tapering remains the gold standard against which all other opioid withdrawal treatments continue to be measured.

The use of methadone for the maintenance treatment of opioid dependence was pioneered by Vincent Dole and Marie Nyswander at the Rockefeller Institute in New York City. These researchers established that once-a-day oral dosing with methadone reduced heroin craving associated with opioid withdrawal but did not lead to the fluctuations in mood or physical state associated with maintenance on heroin or other opioids with shorter half-lives. Prolonged daily maintenance at sufficiently high doses led to development of cross-tolerance to other opioids and attenuation or blocking of the euphoric effects of self-administered heroin or other illicit opioids. After the initial clinical trials demonstrated that methadone maintenance led to substantial and sustained reductions in illicit opioid use and criminal activity and dramatic improvement in social and vocational functioning, methadone was approved for the maintenance treatment of opioid dependence in carefully regulated treatment settings.

Despite more than three decades of scientific investigation and clinical use conclusively demonstrating its safety and efficacy, however, methadone maintenance continues to arouse community and political opposition and controversy. As a result, methadone maintenance is not available in many communities, funding for it has been limited, and program philosophy and policies of some funding and regulatory agencies limit the dosage and duration of treatment to less than optimal levels. Concerns about potential misuse of methadone maintenance or diversion of prescribed methadone for illicit use have also contributed to a regulatory approach that has limited access to methadone maintenance and kept this treatment out of traditional medical practice settings and confined to a relatively small number of specialized treatment programs.

While methadone maintenance has proved to be remarkably effective, development and approval of alternatives to methadone have been delayed. Levomethadyl acetate was extensively evaluated in the mid-1970s as an alternative to methadone for maintenance treatment. Despite promising results, its approval by the FDA was delayed until 1993, and it is still not available in many areas. Buprenorphine appears to offer some advantages over methadone for detoxification and maintenance treatment, but buprenorphine has not yet received FDA approval for either of these uses. Advantages and disadvantages and specific indications for use of buprenorphine compared with methadone or levomethadyl acetate have not been fully investigated.

Key Issues Key issues for agonist maintenance treatment of opiate dependence include choice of agent, optimal dose and duration of treatment, and the relevance to treatment outcome of program features such as treatment setting (e.g., traditional maintenance program, primary care clinic, physician office), counseling, and psychiatric, medical, and vocational services. Patients entering treatment often experience a wide range of medical, social, legal, and other drug-related problems, and high rates of psychiatric comorbidity and concurrent alcohol, cocaine, or other substance abuse or dependence also pose special challenges for treatment. The use of maintenance treatment during pregnancy, as well as its role in limiting transmission of human immunodeficiency virus (HIV) and facilitating medical treatment of acquired immune deficiency syndrome (AIDS), tuberculosis, endocarditis, or other severe complications of injection drug use, also merit special attention. Finally, many federal and state regulations govern agonist maintenance treatment programs, and there is considerable interest in revising these regulations to expand treatment access and permit greater program flexibility and tailoring of treatment to individual needs. Restrictions on take-home doses of methadone need to be considered in relation to their impact on treatment and the potential for diversion of methadone for illicit use. Although the success of maintenance treatment for heroin addiction generally depends on the ability to engage patients in a comprehensive rehabilitation program, some patients may not require additional services to benefit fully from agonist maintenance.

CHEMISTRY

The structural formulas of methadone (4,4-diphenyl-6-dimethylamino-heptanone-3hydrochloride), levomethadyl acetate (L-a-6-dimethylamine-4,4-diphenyl-3-heptyl acetate hydrochloride), and buprenorphine (17-(cycloprophylmethyl)-a-(1,1-dimethylethyl)-4,5-epoxy-18,19-dihydro-3-hydroxy-6-methoxy-a-methyl-6,14-etheneomorphinan-7-methanol hydrochloride) are presented in Figure 31.23-1. Methadone and levomethadyl acetate are chemically only remotely related to morphine and other opium alkaloid derivatives, but their pharmacological properties are qualitatively and quantitatively similar to those of morphine. Buprenorphine is a semisynthetic derivative of thebaine, which is one of the naturally occurring phenanthrene alkaloids derived from the poppy plant and contained in opium.

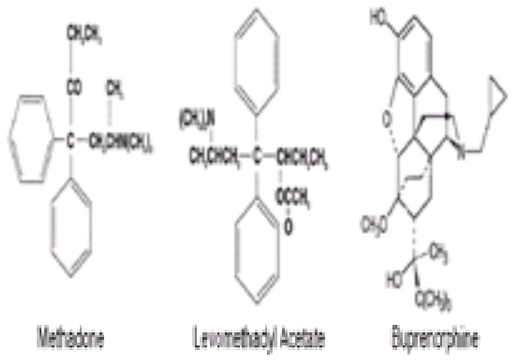

FIGURE 31.23-1 Molecular structures of opioid agonists.

Methadone and levomethadyl acetate act primarily as pure agonists at the μ-receptor. Methadone activity at the μ-receptor results almost entirely from the levorotatory isomer, which is 8 to 50 times more potent at these receptors than dextrorotatory isomer (D-methadone). Its analgesic potency when administered parenterally is approximately equivalent to that of morphine. Oral administration delays the onset of analgesia, reduces peak analgesia, and increases duration of analgesia. Levomethadyl acetate is extensively metabolized to nor-methadyl acetate and dinor-methadyl acetate. Both of these metabolites have longer half-lives and are more potent at the μ receptor than the parent compound. Buprenorphine is a high-affinity partial agonist at the μ-receptor and also acts as a potent k-antagonist. The slow rate of dissociation of buprenorphine from the μ-receptor may account for its prolonged duration of action.

PHARMACOLOGICAL ACTIONS

More than 90 percent of methadone administered orally is rapidly absorbed from the gastrointestinal tract. It is detectable in plasma within 30 minutes, and peak concentrations are reached within 2 to 6 hours. About 90 percent of methadone is reversibly bound to plasma and tissue proteins, including proteins in the brain and liver. Methadone is highly lipid soluble, crosses the blood-brain barrier, and is widely distributed throughout the body. Protein binding as well as the large volume of distribution of methadone result in shortened duration of analgesic activity (about 4 hours) following single-dose administration. Analgesic effects of methadone in nontolerant individuals are associated with methadone plasma concentrations above 30 to 60 ng/mL, whereas much higher concentrations (150 to 300 ng/mL) may be required for chronic pain analgesia. Following repeated administration of large doses of methadone (in patients who have developed tolerance), methadone accumulates in tissues, and reversible protein binding leads to relatively limited fluctuations in methadone levels throughout a 24-hour period. In patients maintained on once-daily administration of methadone (80 to 120 mg), peak concentrations typically range from 400 to 1600 ng/ml, while trough concentrations range from 150 to 1000 ng/ml.

The primary route of elimination of methadone is through biotransformation in the liver to inactive metabolites. Unbound methadone is extracted by the liver and undergoes *N*-demethylation, through the action of cytochrome P450 isoenzyme 3A4 (CYP 3A4), followed by immediate cyclization. Methadone metabolites as well as small amounts of unchanged methadone are excreted in the urine and bile. Acidification of urine increases urinary excretion of methadone and its major metabolites. The elimination half-life of methadone ranges from 24 to 36 hours.

Levomethadyl acetate is also rapidly absorbed from an oral solution, with peak blood concentrations occurring 1.5 to 2 hours after ingestion. Demethylation of levomethadyl acetate to nor-levomethadyl acetate occurs during first-pass liver metabolism; subsequent *N*-demethylation of nor-levomethadyl acetate leads to the formation of dinor-levomethadyl acetate. Nor-levomethadyl acetate is estimated to be 6 to 12 times and dinor-levomethadyl acetate 1.5 to 3 times as potent as at the μ-receptor. Thus, peak opioid effects following oral administration of levomethadyl acetate are delayed until it is metabolized to its more active metabolites, and these metabolites contribute to the efficacy and prolonged duration of activity of levomethadyl acetate. During steady-state administration of levomethadyl acetate (3 mg/kg a week on a three times per week schedule), observed half-lives of methadyl acetate, nor-levomethadyl acetate, and dinor-levomethadyl acetate were approximately 2.6 days, 2 days, and 4 days, respectively. Peak plasma concentrations for levomethadyl acetate and its active metabolites are at least five times higher than trough levels 72 hours after dose administration.

Buprenorphine has a variable bioavailability following sublingual administration but an extremely low bioavailability following oral administration, because of extensive intestinal and first-pass liver metabolism. It is currently available in the United States only in a formulation suitable for injection use, but sublingual liquid and tablet formulations have been investigated for treatment of opioid withdrawal and for maintenance treatment of opioid dependence. A sublingual tablet combining buprenorphine and naloxone (Narcan) is expected to have decreased abuse liability and may thus require less stringent regulations than those governing either methadone or methadyl acetate. Evaluation of the pharmacokinetics and metabolism of buprenorphine has been limited somewhat because of difficulties developing sufficiently sensitive analytic methods to measure the low plasma concentrations associated with its pharmacological effects. Following sublingual administration, there is a two-phase elimination profile, with plasma half-lives estimated at 3 to 5 hours and more than 24 hours. Because buprenorphine dissociates slowly from brain opioid receptors, it appears feasible to administer it during maintenance treatment on an alternate-day or thrice-weekly schedule.

Like other opioids, methadone, levomethadyl acetate, and buprenorphine cross the placental barrier, and long-term administration during pregnancy can result in opioid withdrawal in the neonate. Methadone maintenance during pregnancy, however, appears to be a safer option than continued heroin use by the pregnant addict. The severity of neonatal withdrawal is related to maternal methadone dose and duration of treatment. Use of methadyl acetate during pregnancy is not recommended because its safety has not been extensively studied, and there is a risk of delayed emergence of neonatal withdrawal. There is interest in the use of buprenorphine during pregnancy, because of the possibility that it may lead to less severe neonatal withdrawal, but its safety for use during pregnancy has not been sufficiently evaluated.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Early Studies of Maintenance Treatment Morphine maintenance clinics for the treatment of opioid-dependent patients that opened in many cities in the United States following passage of the Harrison Narcotics Act in 1914 were closed by the U.S. Treasury Department in the 1920s. Approximately 25,000 physicians were indicted for violating the Harrison Narcotic Act; an estimated 20,000 of them paid substantial fines, and 3000 were jailed. Opioid agonist maintenance treatment was not reinstated in the United States until the 1960s. The initial studies of methadone for maintenance treatment were conducted by Dole and Nyswander in collaboration with Mary Jeanne Kreek at Rockefeller Hospital. In six hospitalized narcotic addicts, stable doses of methadone (80 to 120 mg a day) resulted in a gradual cessation of the patients' fluctuations in mood and clinical state and cessation of their obsessive preoccupation with obtaining and administering drugs. Patients did not experience euphoria or sedation following methadone dose administration and appeared to function normally, including successful completion of complex tasks testing vigilance and concentration. With long-term maintenance, these investigators documented the development of tolerance to the euphoric effects of usual street doses of heroin.

Subsequently, 128 carefully selected patients were inducted onto high-dose methadone in the hospital setting and then maintained on methadone in the community following discharge. At 2 years, retention was excellent, with only 13 patients discharged for drug abuse or antisocial behavior. Of the 107 patients remaining in treatment, 71 percent were steadily employed or attending school, and none had relapsed to narcotic use. These findings were extraordinary compared with results of nonmethadone treatment of heroin addicts, whose relapse rates typically exceed 90 percent in the first year after hospital treatment. Similar improvements were reported for heroin addicts maintained on methadone after prison discharge, compared with those placed on waiting lists for methadone.

The initial success of methadone maintenance led to the widespread implementation of methadone maintenance programs nationally, greater variability in treatment outcome, and considerable controversy about both the ethics of substituting one opiate for another and the effectiveness of methadone maintenance programs. By 1993 an estimated 115,000 patients were receiving methadone maintenance treatment at any time in 759 programs in the United States.

Controlled Clinical Trials of Methadone, LAAM, and Buprenorphine Maintenance Three placebo-controlled random assignment clinical trials have established the efficacy of methadone maintenance treatment, and several additional clinical trials have demonstrated that its efficacy is dose dependent. In one study, 100 heroin addicts in Hong Kong were initially stabilized on methadone (60 mg a day), with half the patients undergoing blinded withdrawal from methadone at the rate of 1 mg a day followed by maintenance on placebo for the duration of the 32-week study. Dosage adjustments were allowed for the methadone-treated subjects, and both

groups had equivalent access to counseling and other services. Treatment retention at 32 weeks was 76 percent for the methadone group and 10 percent for the placebo group, and great reductions in illicit heroin use were found for subjects who remained in treatment. A second randomized study, in Sweden, comparing methadone maintenance with outpatient drug-free treatment also found significant benefits of methadone maintenance: at 2 years, 12 of 17 methadone patients were free of illicit drug use and employed or in school, while only 1 of 17 patients allocated to drug-free outpatient treatment was abstinent, 12 were addicted to heroin (including 3 who suffered major medical problems resulting from drug dependence), 2 were in prison, and 2 had died. The most recent placebo-controlled double blind clinical trial, comparing daily placebo and daily maintenance on methadone (20 or 50 mg) in 247 opioid-dependent patients, found significant dosage-dependent effects on both treatment retention and illicit opioid use during the 14-week stable maintenance period. Additional double-blind clinical trials comparing higher (50 to 80 mg) and lower (20 to 40 mg) daily methadone dosages generally also show superiority of the higher dosages with regard to treatment retention and reductions in illicit opioid use. These studies support recommendations that daily methadone doses exceeding 60 mg generally yield better results.

A number of clinical trials of levomethadyl acetate and buprenorphine also demonstrate the dosage-dependent efficacy of these medications for maintenance treatment. In one study, patients randomly assigned to the highest Monday-Wednesday-Friday levomethadyl acetate dosage (100, 100, and 140 mg) had the lowest rates of heroin use during treatment, patients assigned to the lowest dosage (25, 25, and 35 mg) had the highest rates of heroin use, and patients assigned to a mid-range dosage (50, 50, and 75 mg) had intermediate rates of use. Daily buprenorphine dosages of 8 to 16 mg sublingual liquid formulation have been found to reduce heroin use more than lower daily dosages. In meta-analyses of randomized clinical trials comparing methadone and levomethadyl acetate and comparing methadone and buprenorphine, outcomes for methadone-treated patients have generally been somewhat better than for patients treated with either levomethadyl acetate or buprenorphine, suggesting that methadone will continue to be the first-line treatment for most patients except in select situations.

Effectiveness of Methadone Maintenance Programs The results of two nationwide evaluation studies of drug abuse treatment supported by the National Institute on Drug Abuse (NIDA) provide additional evidence for the effectiveness of methadone maintenance treatment. In the Drug Abuse Reporting Project, 1-year retention of methadone maintenance patients entering treatment between 1969 and 1974 exceeded 50 percent, and marked decreases in illicit drug use and criminality as well as increased employment were observed after 3 years for all those entering methadone maintenance. The subsequent Treatment Outcome Prospective Study conducted on patients entering drug treatment programs from 1979 to 1981 found similar benefits of methadone maintenance.

Following the closing of a county methadone program, more than half of the 94 involuntarily discharged clients reverted to heroin abuse within 2 years. Compared with a matched sample from another county clinic, involuntarily discharged patients had nearly double the arrest or incarceration rate. Similar adverse outcomes were noted in methadone-maintained patients who were unable or unwilling to transfer to private, fee-based programs following closure of a publicly supported program in San Diego.

Health status also improves markedly as a result of methadone maintenance. Untreated heroin dependence is associated with substantially increased mortality and morbidity. During methadone maintenance treatment, however, the annual mortality risk averages 25 percent of the risk for untreated opioid-dependent persons, largely as a result of reductions in deaths due to heroin overdose or suicide. Substantial reductions in injection drug use associated with methadone maintenance treatment also lead to reductions in HIV transmission and improvements in immune system function and other health measures. In one study, the prevalence of HIV infection among untreated heroin addicts during an 18-month period was 22 percent, compared to a prevalence of 3.5 percent among methadone maintained patients in the same city.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

The relative safety of long-term methadone maintenance has been established through prospective and retrospective studies. No evidence of methadone toxicity for organ systems has been found during the course of three decades of widespread clinical use. Less information is available regarding the long-term safety of levomethadyl acetate or buprenorphine. Levomethadyl acetate has been found to prolong the QT interval in some patients, so careful monitoring of patients with cardiac conduction deficits is recommended. Although patients entering methadone maintenance programs suffer from high rates of a number of chronic diseases, including (most commonly) HIV infection, hepatitis, tuberculosis, other infectious diseases, and cardiac or renal disorders, methadone maintenance is associated with improved health condition and decreased risk of HIV transmission, largely as a result of reducing injection drug use and facilitating appropriate use of medical services.

THERAPEUTIC INDICATIONS

Methadone is used for the short-term detoxification (30 days), long-term detoxification (180 days), and maintenance of opiate and opioid addicts. Methadone is a schedule II drug; its administration is tightly governed by specific federal laws and regulations.

The highly effective analgesic effects of methadone are used in the management of chronic pain when less potentially addictive agents are inadequate.

Levomethadyl acetate, a control level (schedule) II drug, is used only for maintenance treatment of opioid dependent patients. It is not used for detoxification treatment or for analgesia. Levomethadyl acetate can only be dispensed by approved narcotic treatment programs, and its administration is tightly governed by specific federal and state laws and regulations. Buprenorphine is currently approved only for treatment of moderate to severe pain and is a control level V analgesic. Its use outside of experimental programs for maintenance or detoxification treatment of opioid dependence will require federal approval.

PRECAUTIONS AND ADVERSE EFFECTS

Overdose The acute effects of opioid agonists include miosis, decreased gastrointestinal motility, sedation, hypothermia, bradycardia, hypotension, and respiratory depression. The risk of overdose is greatest during induction onto maintenance treatment, prior to the development of tolerance. During induction, deaths related to methadone overdose have been reported for patients given initial methadone doses of 50 to 60 mg daily. Deaths typically occur 2 to 6 days after initiation of methadone treatment, and evidence of chronic persistent hepatitis is often found on postmortem examination, suggesting that decreased methadone elimination may contribute to overdose. The slow onset of effects of levomethadyl acetate may also increase the risk of opioid overdose during methadyl acetate induction if patients also continue to use illicit drugs, and overdose can also result from too frequent (e.g., daily) dosing. Although buprenorphine may also produce respiratory depression, the risk of overdose appears to be lower with buprenorphine than with either methadone or methadyl acetate. Deaths have been reported in association with overdose on buprenorphine in combination with benzodiazepines.

Adverse Effects Tolerance to most of the pharmacological effects of opioid agonists develops during long-term maintenance, and relatively few adverse effects are reported by patients. The most common adverse effects of methadone include increased sweating, constipation, decreased libido or interference with orgasm, weight gain, and insomnia or sleep irregularities. Menstrual irregularities are reported frequently by women, especially during the initial 6 months on methadone. Occasional adverse effects include peripheral edema, urinary retention, rash, and arthralgia. Adverse effects of methadyl acetate are generally similar to those of methadone and most commonly include anxiety, insomnia, sweating, and constipation.

The effects of long-term methadone maintenance on neuroendocrine and immune system functioning have been the subject of intensive evaluation. Although tolerance develops to many of the endocrine effects of methadone typically found during the first 12 months of treatment (decreased follicle-stimulating hormone [FSH] and luteinizing hormone [LH] levels, abnormalities of cortisol response to stress), several neuroendocrine abnormalities persist. Patients on long-term maintenance may have elevated prolactin concentrations and diminished prolactin response to hypoglycemia and hypothalamically mediated impaired ability to concentrate urine during dehydration. While the results of some in vitro studies suggest that methadone may impair natural killer cell cytotoxicity at high dosages, careful clinical evaluations have not detected methadone-induced impairments of immunological functioning in methadone-maintained patients. Natural killer-cell cytotoxicity activity has been found to be significantly lower in active heroin addicts without HIV infection or other substance abuse than in long-term methadone patients or healthy, non–drug-abusing controls. No differences were noted between methadone patients and healthy controls.

PREGNANCY

Methadone maintenance combined with the provision of adequate psychosocial support and medical services can lead to marked improvements in obstetrical outcome for pregnant heroin addicts. Heroin addiction is associated with increased rates of spontaneous abortion, abruptio placenta, toxemia, eclampsia, infection, premature labor, and septic thrombophlebitis. Improved maternal nutrition and health and increased use of prenatal care among pregnant women treated in

comprehensive methadone programs are associated with improved obstetrical outcomes.

The methadone dosage during pregnancy is a critical issue. Lower methadone dosages can prevent opioid withdrawal in the pregnant woman and reduce the likelihood of opioid withdrawal in the neonate. Higher methadone dosages are associated with higher rates of neonatal withdrawal but may be needed to prevent continued heroin abuse. Especially during the third trimester, methadone metabolism increases so that lower doses may not hold the patient, and it may be necessary to use higher doses or split the daily dose and administer it twice daily. Abnormalities in fetal activity have been noted when methadone is administered in a single daily dose (increased fetal activity prior to dose administration and depressed activity subsequent to methadone administration), and split dosing administered twice daily leads to stabilization of fetal activity. The clinical significance of these fetal movement abnormalities has not been documented.

Because the elimination half-life of methadone is prolonged in the newborn, neonatal withdrawal symptoms may be delayed in onset and last for many weeks. Signs of opioid withdrawal in the neonate include tremor, high-pitched cry, increased muscle tone and activity, poor sleep and eating, mottling, yawning, sweating, and skin excoriation. Withdrawal-related convulsions can be life threatening. Phenobarbital and paregoric can be used to control hyperactivity, prevent convulsions, and relieve gastrointestinal problems. Some studies suggest that there is an increased rate of sudden infant death syndrome among children exposed prenatally to methadone. The decreased effects of buprenorphine on respiratory depression compared with methadone suggest an additional rationale for evaluating buprenorphine maintenance during pregnancy.

DRUG INTERACTIONS

The licit or illicit use of many drugs, including barbiturates, phenytoin (Dilantin), carbamazepine (Tegretol), and rifampin (Rifadin), as well as heavy alcohol use may induce hepatic microsomal enzymes and markedly increase the rate of methadone metabolism. In patients maintained on methadone, enhanced metabolism can lead to opioid withdrawal symptoms and craving, associated with methadone trough concentrations below 100 ng/mL, at previously adequate methadone dosages. The methadone dosage may need to be increased in these patients. For patients maintained on methadyl acetate, however, liver enzyme induction may lead to increased conversion of methadyl acetate to its even more active metabolite, nor-methadyl acetate, and consequently to higher peak activity levels or possibly a shortened duration of action. Acute opioid withdrawal may also be precipitated in methadone- or levomethadyl acetate-maintained patients by ingestion of narcotic antagonists (e.g., naltrexone), partial μ-agonists (e.g., buprenorphine) or analgesics with mixed agonist-antagonist properties, such as pentazocine (Talwin). Methadone- or levomethadyl acetate-maintained patients with illicit use of nonopioid drugs may also experience opioid withdrawal and request a methadone dosage increase, but in the latter situation, appropriate management consists of interventions to decrease illicit drug use rather than necessarily increasing methadone dosage.

Methadone, buprenorphine, and levomethadyl acetate may have important drug interactions with medications that are also metabolized by hepatic cytochrome CYP 3A4. Competitive inhibition of methadone metabolism following acute use of alcohol or administration of cimetidine (Tagamet), erythromycin, ketoconazole (Nizoral), and fluvoxamine (Luvox) may lead to higher plasma concentrations or prolonged duration of effects of methadone. Inhibition of metabolism of methadyl acetate, however, may slow the onset, lower the activity, or increase the duration of action of levomethadyl acetate. Methadone excretion may also be reduced by medications that alkalinize the urine.

Methadone maintenance may also interfere with the metabolism of medications metabolized by cytochrome P450 and lead to elevated plasma concentrations of desipramine (Norpramine, Pertofrane) and fluvoxamine at usual therapeutic dosages. Reductions in dosage of antidepressant medications is warranted if patients are symptomatic, show signs of toxicity, or have markedly elevated plasma concentrations. Recent reports suggest that methadone may also lead to higher zidovudine (Retrovir) concentrations and the possibility of increased zidovidine toxicity at standard dosages. Several new protease inhibitors, including ritonavir (Norvir), indinavir (Crixivan), and saquinavir (Fortovase) are also metabolized by cytochrome P450 and when studied in vitro in human liver microsomes competitively inhibit methadone and buprenorphine demethylation. The clinical implications of interactions between methadone and other antiretroviral agents, including protease inhibitors, have not been extensively evaluated, and there is also a lack of information regarding their potential interactions with either levomethadyl acetate or buprenorphine.

LABORATORY INTERFERENCES

No known laboratory interferences are associated with methadone, levomethadyl acetate, or buprenorphine treatment.

DOSAGE AND ADMINISTRATION

Methadone is supplied in dispersible tablets of 5, 10, and 40 mg; in oral solutions of 5 mg/5 ml, 10 mg/5 ml, and 10 mg/ml; and in a parenteral form of 10 mg/ml.

Levomethadyl acetate is supplied only as an oral solution (10 mg/mL). Buprenorphine is currently supplied only in 1 mL ampules containing 0.3 mg buprenorphine. Sublingual tablet formulations of buprenorphine containing buprenorphine only or buprenorphine combined with naloxone in a 4:1 ratio are in use outside of the United States and are being investigated in the United States for maintenance treatment of opioid dependence.

Variability of Outcome in Clinical Practice Despite clear evidence of the overall effectiveness of methadone maintenance treatment, wide variability in treatment outcome has been observed in different programs. An evaluation of six methadone programs in three cities in the Northeast showed the magnitude of these differences. Current intravenous drug use ranged from 9.8 percent of the patients in one program to 57.1 percent in another program. Methadone dose, program features (philosophy, amount and quality of counseling services, effectiveness of program director, and stability of staff), and patients' characteristics (concomitant psychiatric disorders, polydrug abuse) account for many of these differences.

Methadone Dosage Dole and Nyswander used methadone doses of 80 to 120 mg daily to prevent craving and produce tolerance to usual street doses of opiates so that the effects of illicit opioid use would be blocked or attenuated. Despite compelling evidence that the efficacy of methadone is dosage dependent, with higher daily dosages leading to higher retention and greater reductions in illicit opioid use, many programs prescribe inadequate dosages. In a 1988 survey of methadone programs, the average methadone dosage in two-thirds of the programs was 50 mg a day or less, which is considerably lower than the recommended average dosage exceeding 60 mg a day, and almost 25 percent of methadone maintenance patients were maintained on less than 40 mg of methadone daily. In the study of six methadone clinics, methadone dosage was one of the most important factors associated with illicit opioid use. More than one-third of patients maintained on a methadone dose below 35 mg used heroin at least weekly, while there was no illicit use of opioids among patients maintained at a dosage of 80 mg a day or more. Methadone dosage was not associated with other outcomes, however, including cocaine use or criminal behavior.

In clinical practice, no single methadone dosage will be optimal for all patients, and maintenance dosage should be based on patient response and also possibly guided by assessment of trough methadone concentrations in plasma. Some experts have suggested that an optimal daily methadone dosage will result in trough plasma concentrations above 150 to 200 ng/mL. Methadone plasma concentrations may not correlate directly with the concentration of unbound methadone, thus limiting their clinical utility. On the basis of these considerations, it is clinically appropriate to plan to increase methadone dosage over several weeks to 70 mg a day for all patients. It is important to start at a lower daily dosage (25 to 30 mg) to avoid the possibility of producing a lethal overdose in a nontolerant patient. Patients who experience sedation or other methadone adverse effects as dosage is increased may be maintained at a lower dosage if they remain abstinent from all illicit opiates. Patients who continue opiate use at any given dosage may benefit from an increased methadone dose, and methadone dosage should be increased gradually until patients eliminate or reduce illicit opiate use. The methadone dosage is not likely to affect use of nonopiate illicit drugs.

Program Features Program features, including a program philosophy emphasizing social rehabilitation and long-term maintenance, provision of more and higher quality counseling services, high staff morale and low staff turnover, and presence of an effective program director, are associated with more-favorable treatment outcomes. The magnitude of the effects of program features is illustrated in the results of a large multisite evaluation of methadone and levomethadyl acetate. Despite identical study protocols and medication dosage, rates of early termination among the clinics differed considerably. In two clinics, 30 percent of patients or less terminated treatment prematurely, while 75 percent or more of the patients in seven other clinics left the study before 40 weeks.

A number of controlled clinical trials have demonstrated the importance of psychosocial and behavioral interventions in improving the effectiveness of methadone maintenance. In one study, patients maintained on a fixed methadone dosage were randomly assigned to one of three levels of counseling: minimal (once a month), basic (weekly), or enhanced (weekly plus on-site medical and vocational services). Minimal services were effective for a minority of patients. Outcomes were significantly improved for patients receiving basic or enhanced counseling. Although enhanced services led to the best outcomes, basic services were overall more cost-effective. More recently, another study found that enhanced counseling services were as effective, and more cost-effective, than an intensive day treatment program for newly admitted methadone maintenance patients.

The efficacy of specific counseling approaches and of contingency management has also been evaluated in methadone programs. In one recent study, behavioral counseling based on the community reinforcement approach led to higher rates of abstinence than standard drug counseling. Several studies have shown the benefits of giving patients contingent rewards (e.g., voucher-based incentives with a monetary value or take-home bottle privileges) for maintaining abstinence or complying with treatment plan recommendations. Aversive contingencies for continued illicit drug use, such as methadone dosage reduction or detoxification, are more controversial since they may lead to increased illicit opioid use. Rebound of drug use following discontinuation of contingency management may also be a problem.

Treatment outcome is also associated with program features, including consistent and fair implementation of program policies and rules and the quality of the counseling services. Studies suggest that the most effective counselors are those who (1) establish a supportive relationship with patients, (2) develop and formulate a coherent rehabilitation plan based on discussions with the patient and other staff, (3) follow program rules closely, (4) meet more than once a month with the patient, and (5) provide sensible advice and referral to special resources when needed. The best counselors are those who can anticipate the patient's problems and discuss in advance strategies to prevent or cope with these problems. The success of methadone treatment quite clearly depends on the ability to recruit, train, supervise, and retain effective counselors.

Length of Treatment Virtually all studies of methadone maintenance indicate that longer time in treatment is associated with improved outcome and that involuntary termination of methadone treatment is associated with subsequent high rates of relapse to illicit opiate use. Based on these findings, a consensus recommendation was established by drug abuse researchers and clinicians convened by NIDA that no arbitrary limit should be placed on the duration of methadone treatment and that the decision to terminate treatment should be made jointly by the patient and staff. The findings of the six-site evaluation of methadone treatment programs support these recommendations. Programs emphasizing long-term maintenance and social rehabilitation were found more effective than programs emphasizing short-term treatment. Despite the consensus recommendations, in actual practice, long-term methadone treatment is either discouraged or not available in many programs. In some areas, long-term methadone maintenance is also prohibited by policy makers or not covered by medical insurance. Half of the methadone programs surveyed in 1988 encouraged patients to detoxify in less than 6 months.

ALCOHOL AND OTHER DRUG ABUSE DURING METHADONE MAINTENANCE

Although the pharmacological actions of maintenance on methadone reduce opioid craving, methadone has little direct beneficial effect on other substance use, and abuse of or dependence on alcohol, benzodiazepines, cocaine, marijuana, and other substances often complicates treatment outcome. Although some patients may increase their use of alcohol or other nonopioid substances after entering methadone maintenance programs, methadone maintenance is associated with an overall decrease in rates of nonopioid substance use, especially for patients who cease heroin use.

Alcohol, Benzodiazepine, and Sedative Abuse Alcohol, benzodiazepine, and sedative abuse continues to be a major problem among patients maintained on methadone. Rates of heavy alcohol consumption range from 17 to 30 percent or more of methadone patients, and alcoholism is a leading cause of death among methadone maintenance patients. Some studies suggest that most patients who experience difficulties with alcohol while maintained on methadone had such problems before starting on methadone. High doses of benzodiazepines are often abused by methadone patients to boost their methadone dose or experience a high. Therapeutic approaches to the abuse of alcohol or benzodiazepines in methadone programs include medical withdrawal; behavioral monitoring (daily breathalizer to detect alcohol use, increased frequency of urine monitoring to detect benzodiazepine or sedative use); intensified individual, group, or family counseling; and use of contingency contracting (providing positive incentives such as take-home bottles for abstinence, and aversive consequences such as loss of bottle privileges for continued use). Referral to Alcoholics Anonymous (AA) and supervised disulfiram (Antabuse) administration have also been beneficial in ameliorating alcohol problems. Because many AA programs are inhospitable to methadone patients and discourage them from remaining on the medication, it is important to refer to AA programs that support rather than undermine methadone treatment.

Cocaine Abuse In recent years, cocaine abuse has become a major problem among methadone-maintained patients. Rates of cocaine abuse averaged 58 percent among patients entering the six-site study, and rates among those in treatment range as high as 40 percent or more in many programs. Ethnographic studies suggest that cocaine use has become part of the drug use and social life of patients in some programs, with use not only by the most deviant methadone patients but also by a substantial proportion of patients who are otherwise compliant with program rules.

Cocaine abuse is of particular concern because it negates many of the benefits of methadone maintenance with regard to reducing criminal activity or the spread of HIV infection. Behavioral interventions, including implementing positive or aversive contingencies for abstinence or continued use, have been shown to have short-term beneficial effects. One recent study found that 9 of the 19 patients (47 percent) randomly assigned to voucher-based reinforcement for cocaine-negative urine tests achieved 7 to 12 weeks of sustained abstinence from cocaine during a 12-week study, while only 1 of 18 patients (6 percent) assigned to a noncontingent, yoked voucher-control condition achieved more than 2 weeks of sustained abstinence. Voucher rewards for abstinence had broad beneficial effects in addition to decreasing cocaine use. In another study, use of vouchers with a monetary value to reward participation in planned activities outside of the clinic was more effective than either voucher rewards for abstinence or a no-voucher control in reducing rates of cocaine use. The value and schedule of rewards also affects the efficacy of contingency management. Relapse following cessation of contingency management is often a problem, however, and additional strategies are needed to encourage sustained or long-term abstinence. Although some studies initially suggested that buprenorphine maintenance would be associated with lower rates of cocaine use than methadone maintenance, more-recent double-blind random-assignment studies have not found such a difference. Controlled studies of pharmacological adjuncts, such as desipramine, carbamazepine, mazindol (Sanorex), amantadine (Symmetrel, Symadine), or bromocriptine (Parlodel), have not consistently documented beneficial effects of these agents with patients in methadone programs. Because alcohol is often used along with cocaine and studies suggest that disulfiram pretreatment leads to increased anxiety and dysphoria following cocaine administration, disulfiram is currently being evaluated for the treatment of cocaine dependence in agonist-maintained patients. Two recent double-blind clinical trials found greater reductions in cocaine use among methadone-maintained patients and buprenorphine-maintained patients randomly assigned to disulfiram than in those assigned to placebo.

CONCOMITANT PSYCHIATRIC DISORDERS

High rates of psychiatric disorders, most notably depressive, anxiety, and personality disorders, have been consistently documented in opioid addicts. In one recent study, 47 percent of patients entering a methadone treatment program had at least one lifetime psychiatric diagnosis other than a substance use disorder. While psychiatric comorbidity is associated with poorer treatment outcome overall, professional psychotherapy as an adjunct to traditional counseling and cautious use of psychotropic medications can improve outcome for psychiatrically impaired patients. A recent double-blind study found that depressed methadone-maintained patients randomly assigned to imipramine (Tofranil) had greater improvements in depression and reduced illicit drug use more than patients allocated to placebo.

TERMINATION OF TREATMENT

Whether and when to terminate methadone maintenance treatment remains controversial. The benefits of methadone maintenance are most apparent while patients remain in treatment, and high rates of relapse to illicit drug use with accompanying increases in criminal activity and deteriorating medical, vocational, and social functioning occur after withdrawal from methadone maintenance. After termination of methadone maintenance, 70 to 80 percent of patients return to illicit drug use. The highest rates of relapse occur in patients who have been administratively discharged because of program noncompliance. Even the most successful, socially rehabilitated methadone maintenance patients who have maintained abstinence and voluntarily terminate treatment exhibit relapse rates during the first 3 years ranging from 20 to 50 percent. The fragility of many patients and their need for continued social services and program supports is illustrated by the results of an experimental program of medical maintenance. In this program, patients who had been successfully treated in a methadone maintenance clinic for at least 5 years, as evidenced by stable employment and the absence of criminal activity or use of illegal drugs or excessive alcohol, were offered the opportunity to receive methadone prescriptions from a primary care physician. At follow-up visits from 42 to 111 months, 72 of the first 100 patients remained in medical maintenance; 15 had unfavorable discharges for cocaine use, repeatedly losing medications, or repeatedly missing appointments; 8 had voluntarily withdrawn from methadone or left the program; and 5 had been discharged for medical reasons.

Because relapse is so common following methadone withdrawal, it is unrealistic to set withdrawal from methadone as a goal of treatment for all patients. Patients who decide voluntarily to withdraw from methadone should be offered a choice of withdrawal protocols as well as the opportunity to increase their methadone dosage or return to methadone maintenance if relapse to illicit opioid use seems imminent. Withdrawal protocols may include gradual, blinded tapering of methadone dosage, clonidine, combined clonidine and naltrexone, or buprenorphine substitution and discontinuation. Because protracted abstinence symptoms may be present for up to 1 year following cessation of methadone, it is advisable for patients to remain in treatment following completion of withdrawal and for drug-free patients to have facilitated reentry to a methadone program if relapse seems imminent or has occurred.

REGULATORY AND POLICY ISSUES

The use of opioid agonists for detoxification or maintenance treatment of opioid dependence is tightly regulated by federal, state, and local regulations. Special licenses issued by the Drug Enforcement Agency (DEA) are required for physicians and clinics to prescribe or dispense methadone for detoxification or methadone or levomethadyl acetate for maintenance treatment. Federal rules issued jointly by the FDA and NIDA define standards for admission to maintenance treatment and minimum requirements regarding drug abuse testing during treatment, govern the provision of take-home doses of methadone, and prohibit take-home doses of levomethadyl acetate. State and local regulations and policies often place additional restrictions on the provision of maintenance treatment. While the federal regulations and policies were intended primarily to ensure program quality and prevent improper use or abuse of opioid agonists prescribed for detoxification or maintenance treatment, there has been growing concern that the regulations and policies have prevented needed expansion of maintenance treatment and have inadvertently contributed to stigmatization of patients enrolled in methadone treatment. These issues were addressed in a 1997 National Institutes of Health (NIH) Consensus Statement calling for increased funding, expanded access to and availability of agonist maintenance treatment, and revision of current laws and regulations.

Two policy issues continue to arouse considerable controversy. One concerns take-home doses of methadone or other opioid agonists. Take-home doses are a source of controversy because of the potential for their diversion to street use or accidental ingestion by children or nontolerant individuals. In methadone maintenance programs, take-home bottles are often necessitated by programmatic and fiscal constraints that limit the ability of some clinics to dispense 7 days a week to all patients. When take-home bottles are routinely dispensed to patients, diversion is quite likely. Take-home privileges, however, can be an essential element of the overall rehabilitation program. They provide one of the strongest positive incentives for compliance with the therapeutic goals of treatment and constitute an essential component of contingency contracting in many methadone programs. Additionally, take-home doses allow patients who are engaged in successful rehabilitation efforts to wean themselves from daily contact with the program and from other patients in drug treatment. Monitoring procedures in methadone programs, including routine and random bottle recalls and limitation of take-home bottles to patients who have progressed in treatment and have refrained from illicit drug use, will limit (although not entirely prevent) diversion. The tablet combining buprenorphine and naloxone may also be of sufficiently low abuse or overdose potential to permit its being prescribed routinely for patient self-administration rather than requiring that it be dispensed and ingested under direct observation.

A second area of controversy concerns the need for ancillary services in agonist maintenance programs and the possibility of providing maintenance treatment in primary care clinics or physicians' offices rather than maintenance clinics. Because the costs of full-service methadone programs are in part responsible for the limitation on the number of available methadone treatment slots, no-frills or low-service methadone has been evaluated as a less expensive means of making methadone treatment more widely available. Results of studies evaluating programs that dispense methadone but offer limited or no additional services to new entrants to treatment have been disappointing. Although rates of continued heroin use decrease markedly for patients in these programs, rates of cocaine and other illicit drug use and risk of HIV infection remain high. There is evidence, however, that agonist-maintained patients in more advanced stages of recovery do not necessarily require additional counseling or ancillary services and may be treated successfully in a physician's office. Strategies for providing counseling services along with opioid agonist maintenance medications in primary care settings or physicians offices may also permit expansion of maintenance treatment into these settings while also retaining its effectiveness. Integration of addiction treatment into medical practices may help to expand the availability of services, improve access, and reduce the stigma of addiction treatment.

SUGGESTED CROSS-REFERENCES

Substance-related disorders are discussed in Section 13.10, opioid-related disorders). Noncompliance with treatment is discussed in Section 27.1, adult antisocial behavior and criminality in Section 27.3, and public psychiatry in Section 52.1. Section 31.1 discusses the general principles of psychopharmacology.

31.24 SELECTIVE SEROTONIN-NORADRENALINE REUPTAKE INHIBITORS

LINDA BEAUCLAIR, M.D., DENISA RADOI-ANDRAOUS, M.D., AND GUY CHOUINARD, M.D., M.SC.

The second generation of antidepressant drugs includes the selective serotonin reuptake inhibitors (SSRIs) and bupropion (Wellbutrin), which are safer and better tolerated than and equally effective as the tricyclic drugs and monamine oxidase inhibitors (MAOIs), the first antidepressants. Another class of antidepressant drugs has emerged, the selective serotonin-noradrenaline reuptake inhibitors (SNRIs), which have also been shown to be effective and safe antidepressants. (These drugs have also been called the serotonin-norepinephrine reuptake inhibitors.) Three compounds that inhibit serotonin and noradrenaline reuptake in a selective manner have been studied. These compounds are venlafaxine (Effexor), and milnacipran and duloxetine. A faster onset of antidepressant action in patients with major depressive disorder has been proposed with venlafaxine and, to a lesser extent, with milnacipran, but there are methodological difficulties in measuring the onset of antidepressant action. Because of their lack of affinity for muscarinic, histaminergic, and a $_1$-adrenergic receptors, SNRIs do not cause the unwanted adverse effects common to tricyclic drugs and MAOIs.

CHEMISTRY

Venlafaxine [R/S-1[2-(dimethylamino)-1-(4-methoxyphenyl) ethyl cyclohexanol hydrochloride] and milnacipran [1-phenyl-1-diethyl-aminocarbonyl-2-aminomethyl-cyclopropane (Z) hydrochloride] are tertiary amines. Duloxetine [(+)-*N*-methyl-d-(1-naphthalenyloxy)-2-tiophenepropanamine hydrochloride] is a secondary amine. Their chemical structures are shown in Figure 31.24-1. Unlike milnacipran which shares similarities with the nonselective MAOI tranylcypromine (Parnate), venlafaxine and duloxetine are structurally distinct from tricyclic drugs and MAOIs. Only duloxetine has a structure partially similar to that of fluoxetine (Prozac).

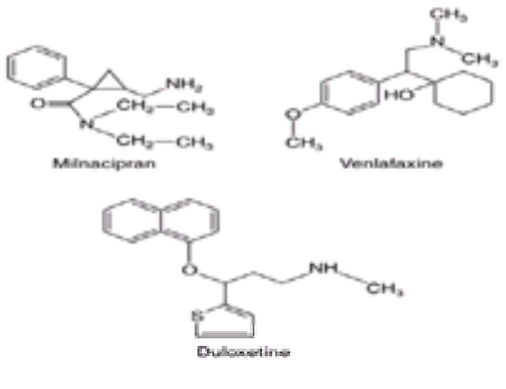

FIGURE 31.24-1 Molecular structure of selective serotonin-noradrenaline reuptake inhibitors.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics Venlafaxine is well absorbed in the gastrointestinal tract, with peak plasma concentrations (t_{max}) occurring at 2 to 2.5 hours for single doses of 25 to 150 mg. The presence of food delays the t_{max} by 20 to 30 minutes but does not affect the peak concentrations or the area under the concentration-time curve of either venlafaxine or its metabolites. Venlafaxine is metabolized by cytochrome P450 (CYP) isoenzyme 2DG (CYP 2D6) to an active metabolite (*O*-desmethylvenlafaxine) and by C4P 3A/4 to an inactive metabolite (*N*-desmethyvenlafaxine). Although venlafaxine is metabolized by these two cytochrome isoenzymes, the presently available data suggest that it does not interact with other drugs metabolized by these hepatic isoenzymes, because venlafaxine does not significantly inhibit or weakly inhibits the activity of isoenzymes CYP 2C9, CYP 2D6, CYP 1A2, or CYP 3A3/4; however, potential drug interactions associated with those isoenzymes do exist. Venlafaxine has an elimination half-life of about 3.5 hours, and that of the active metabolite is in the range of 9 to 11 hours. Venlafaxine and its metabolites are primarily excreted by the kidney. Venlafaxine is poorly dialyzed and is less than 35 percent plasma protein bound. It reaches its steady state within 3 days of multiple-dose therapy and exhibits linear pharmacokinetics.

Milnacipran is well absorbed and is not metabolized by the hepatic cytochrome 450 system. The t_{max} is 1.7 to 2.1 hours. The average plasma elimination half-life ($t_{1/2}$) is 5.8 to 8.1 hours. After a dose, 50 percent of milnacipran is excreted in the urine unchanged and 40 percent as inactive metabolites. Administration of doses of 25 to 200 mg twice daily for 14 days to 10 healthy volunteers resulted in rapid achievement of steady-state concentrations (2 to 3 days).

Duloxetine hydrochloride is acid labile. An enteric-coated formulation has been developed to avoid problems with acid degradation in the stomach. Duloxetine is metabolized by demethylation to a primary amine and a hydroxylated metabolite inducing moderate hepatic induction of both cytochrome P450 $_{1B}$ and P450$_{1A}$. However, hepatic enzyme induction did not alter plasma concentrations of duloxetine and its *N*-desmethyl metabolite. These two metabolites have the same potency in inhibiting the reuptake of serotonin as the parent compound, but the demethylated metabolite is less active in inhibiting the reuptake of noradrenaline than the parent compound. Duloxetine is well absorbed and extensively metabolized, 77 percent of the drug is recovered in urine and 15 percent in feces. The average time to reach maximum plasma concentrations (t_{max}) is about 5 hours, depending on the dose. The average plasma elimination half-life ($t_{1/2}$) is about 13 hours. It is estimated that with daily dosing, a pharmacokinetic steady state would be achieved in 3 to 4 days. Many studies have shown an apparent effect of food on the absorption of duloxetine: a significant delay in the time to maximum concentrations (t_{max}) and a significant increase in the extent of absorption, but there was a consistent t_{max} of 4 to 6 hours in the fasted state.

Pharmacodynamics Venlafaxine, milnacipran, and duloxetine inhibit the reuptake of noradrenaline, serotonin, and (to a lesser extent) dopamine. Venlafaxine and duloxetine are three- to fourfold more potent inhibitors of serotonin than noradrenaline uptake, whereas milnacipran is twice as potent at inhibiting noradrenaline than serotonin. Venlafaxine, milnacipran, and duloxetine lack significant affinity for cholinergic, adrenergic, histaminergic, and opioid receptors. Venlafaxine and milnacipran do not inhibit MAO activity.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Venlafaxine and milnacipran were studied in double-blind, placebo-controlled and active-controlled, parallel-group randomized clinical trials that were designed according to the rules on conducting antidepressant trials. Data from those trials show venlafaxine and milnacipran to be safe and effective antidepressants.

Venlafaxine A 4-week, multicenter, placebo-controlled trial was conducted to evaluate the efficacy and short-term safety of venlafaxine in hospitalized patients (*N* = 93) who met the revised third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) criteria for major depression and melancholia. This study

demonstrated an early benefit from therapy in venlafaxine-treated patients (*N* = 46), related to rapid onset of the antidepressant efficacy of venlafaxine with relatively high daily doses (150 to 375 mg a day) and mean dosages in the range of 350 mg a day. Venlafaxine benefit was statistically significant (*P* £ .01) as reflected in the mean change from baseline for the Montgomery-Asberg Depression Rating Scale (MADRS) total score as early as day 4, and improvement on the Hamilton Depression Rating Scale for (HAM-D) after week 1.

The efficacy and safety of venlafaxine were evaluated in a randomized, double-blind, parallel-group comparison of venlafaxine, imipramine (Tofranil), and placebo in outpatients (*N* = 224) who met the DSM-III-R criteria for major depression for a minimum duration of 1 month. The maximum mean daily doses administered were 182 ± 48 mg of venlafaxine and 176 ± 56 mg of imipramine during the 6-week study. Venlafaxine was found statistically superior to placebo, was well tolerated, and showed a significant advantage over imipramine according to the HAM-D at week 6.

In these two studies, venlafaxine was shown to be effective in both older, severely ill hospitalized patients and younger, moderately to markedly ill outpatients. The results of these two studies suggest the utility of venlafaxine for patients with depression of varying severity.

More recently, a 12-week, double-blind, placebo-controlled study was conducted in 384 outpatients with major depression and major depression associated with anxiety. Fixed total doses of 75, 150, and 200 mg were administered twice daily. This study found that twice-daily doses of 75 to 200 mg a day of venlafaxine produced a dose-related improvement in the primary efficacy parameters and in the onset of significant antidepressant effects, which was noted at weeks 1 to 2 with the highest dosage tested (200 mg a day). The study also found these dosages of venlafaxine safe and effective for the treatment of major depression and depression associated with anxiety.

A multicenter, double-blind, placebo-controlled trial compared the safety and efficacy of venlafaxine and trazodone (Desyrel) in outpatients (*N* = 225) during an initial 6-week treatment study. The mean daily doses after titration were 156 to 160 mg of venlafaxine and 294 to 300 mg of trazodone. The maximum dose for each patient was achieved by day 15. Both active treatments were significantly superior to placebo at week 4 and at final evaluation. Venlafaxine produced more improvement in the cognitive disturbance and retardation factors on the HAM-D, and trazodone was more effective against the sleep disturbance factor. Venlafaxine also produced higher response rates on the Clinical Global Impression (CGI) Scale at the final evaluation, whereas trazodone did not. Some of venlafaxine's advantage over trazodone includes a better side-effect profile and better long-term tolerability.

Venlafaxine was also compared with fluoxetine, an SSRI, in a multicenter inpatient trial. Total scores for both MADRS and HAM-D were lower (*P* > .05) in the venlafaxine group than in the fluoxetine group at weeks 4 and 6. Overall tolerance was similar for both treatments. Venlafaxine was significantly more effective than fluoxetine in a sample of severely depressed patients with melancholia.

In a multicenter double-blind study, the safety and efficacy profile of venlafaxine (37.5 mg twice daily) was compared with that of fluoxetine (20 mg once daily) in outpatients (*N* = 314) with major depression for a maximum of 8 weeks of the study. The dosage of venlafaxine could be increased to 75 mg twice daily. Among patients who increased their dosage at week 2, venlafaxine was superior (*P* < .05) from week 3 onward on the HAM-D.

In a multicenter inpatient study, a full or partial response was achieved after 12 weeks of treatment with venlafaxine (150 to 375 mg a day) in approximately one-third of 70 patients who were refractory to either three different antidepressants from at least two different classes, or electroconvulsive therapy and two different antidepressants.

An open pilot study of 15 patients with primary dysthymia treated with venlafaxine for 12 weeks with a dose range of 75 mg to 225 mg daily showed significant changes of HAM-D from pretreatment to postreatment ($p < 0.001$). These results suggest that venlafaxine could be useful in the treatment of primary dysthymia but further studies are needed to confirm them.

Venlafaxine was also investigated in the treatment of bipolar II disorder in a double-blind six-week study comparing once versus twice daily venlafaxine dosing starting at 37.5 mg daily and increasing up to 225 mg daily. The efficacy and safety of venlafaxine were assessed in 17 bipolar II versus 31 patients with major depression. The efficacy was similar in both groups with no episode of induced mania in both groups. It appeared that a 6-week venlafaxine treatment may be safe and effective in bipolar II major depression. However, further controlled and long-term studies are required to confirm these results.

Two double-blind studies investigated the efficacy of venlafaxine in the treatment of generalized anxiety disorder (GAD), one comparing venlafaxine with placebo and one comparing venlafaxine with placebo and buspirone. These studies suggest that venlafaxine may be a useful treatment of generalized anxiety disorder without concomitant depression.

Some other studies, open and double-blind, suggested that venlafaxine could have potential application in the treatment of obsessive-compulsive disorder, panic disorder, agoraphobia, social phobia and attention deficit disorder.

Milnacipran Milnacipran was studied in double-blind, placebo-controlled and active controlled, parallel-group randomized clinical trials. These studies suggest that milnacipran is a safe and effective antidepressant with faster onset of action, better tolerability than tricyclic drugs, and better efficacy than SSRIs. In these studies, all patients (*N* = 2462) met the DSM-III-R criteria for major depressive disorder. At the optimal dosage (50 mg twice daily), milnacipran was more efficacious than placebo on all outcome measures. Data from these studies that compared three dosages of milnacipran (25, 50, and 100 mg twice daily) with placebo in 112 patients with moderate-to-severe depression showed that after 8 weeks, milnacipran (50 mg twice daily) was superior to placebo as demonstrated by a 50 percent reduction in total HAM-D. Milnacipran (200 mg a day) reduced the MADRS total score more than placebo but did not produce significant changes in the HAM-D score or in the proportion of CGI responders. Milnacipran (25 mg twice daily) was less effective than the other two dosages and its effects did not differ from those of placebo.

Seven randomized, double-blind trials with a comparable design compared the efficacy of milnacipran with that of amitriptyline (Elavil), imipramine (Tofranil), and clomipramine (Anafranil) in patients with major depression. Milnacipran was better tolerated than, and as effective as, the tricyclic drugs in patients with major depression. In a double-blind study comparing the efficacy and safety of milnacipran and imipramine in elderly patients with major depressive episode both drugs were equally efficacious, but milnacipran had a lower incidence of adverse effects and did not impair cognitive functioning.

Comparisons between milnacipran and SSRIs are limited in number. The results of these studies suggest that the tolerability and efficacy of milnacipran are comparable to those of the SSRIs fluoxetine and fluvoxamine (Luvox).

Duloxetine Duloxetine was studied in a 6-week open-label uncontrolled multicenter design at a dosage of 20 mg daily in 79 inpatients and outpatients. Clinical response (defined as a 50 percent reduction in HAM-D total) occurred in 78.2 percent of patients, whereas remission (defined as an HAM-D total of 6 or less) occurred in 60.3 percent of patients. Duloxetine was found to be safe and well tolerated in this patient population.

Another open-label study using three different doses of duloxetine (10–30 mg a day) was designed to evaluate the safety and efficacy of duloxetine in patients with major depression and depressive state. After 6 weeks of administration, the final global improvement rate improved moderately in 52.2 percent of patients. The HAM-D total changed from 24.8 to 9.4, and the response rate (defined as a 50 percent reduction in HAM-D total) was 70.8 percent. Remission rate (defined as a HAM-D total below 7) was 33.3 percent.

In a single-center, double-blind, placebo-controlled study in outpatients who met the DSM-III-R criteria for major depression, patients were randomized to treatment with either duloxetine (20 mg a day) or placebo. The mean change in both the HAM-D and MADRS totals was numerically greater in the duloxetine-treated group than in the placebo-treated group, but these differences were not statistically significant. Statistically significantly more duloxetine-treated patients achieved remission (HAM-D below 7) than placebo-treated patients.

A multicenter, double-blind, placebo-controlled 10-week study in outpatients who met the DSM-III-R criteria for major depression found no significant differences between duloxetine-treated and placebo-treated patients, even though duloxetine-treated patients presented significant improvement in CGI-Severity and CGI-Improvement (*P* = .001 and .002, respectively). Duloxetine-treated patients experienced a significant increase in blood pressure compared with the placebo group, but the magnitude of change was not considered clinically significant. In general, duloxetine was safe and well tolerated.

In a double-blind noncontrolled study using imipramine as comparator, conducted to find the appropriate dosage of duloxetine for patients with major depression, patients were given duloxetine (10 to 30 mg a day) or imipramine (50 to 150 mg a day) for 6 weeks. Response rate (defined as a 50 percent reduction in HAM-D total)

was 44 percent for duloxetine and 40 percent for imipramine, remission rate was 29 percent for duloxetine and 25 percent for imipramine. Adverse effects were reported in 49 percent of patients on duloxetine and 64 percent of those on imipramine (*P* = .08).

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

All the clinical trials done to assess the safety and efficacy of venlafaxine, milnacipran, and duloxetine excluded any serious concomitant systemic illness. Those studies showed, however, that these antidepressants appear safe and well tolerated. However, venlafaxine has been associated with sustained hypertension, especially at dosages above 225 mg a day. It is unknown whether unstable, elevated blood pressure or presenting cardiovascular disease are serious risk factors, since these studies were done on healthy subjects. Further studies are necessary to assess this effect on blood pressure. In a small number of patients, modest sustained elevations in diastolic blood pressure were observed during duloxetine treatment.

THERAPEUTIC INDICATIONS

Sufficient data have shown that venlafaxine and milnacipran are efficacious in relieving symptoms of major depressive disorder, and some clinical data suggest their usefulness in patients with severe depression and in elderly patients who are not responding to SSRIs. According to current data, duloxetine appears to be efficacious in the treatment of major depression. However, as the effectiveness of milnacipran and duloxetine in long-term use has not yet been demonstrated, their use for extended periods should be periodically reevaluated. In long term treatment, venlafaxine reduced the frequency of relapses in comparison with placebo treatment. In 1999 venlafaxine was also approved by the Food and Drug Administration (FDA) for generalized anxiety disorder.

PRECAUTIONS AND ADVERSE REACTIONS

Published studies and unpublished data (from pharmaceutical companies) suggest that venlafaxine, milnacipran, and duloxetine are safe and well tolerated. However, caution is necessary, since the number of patients who have taken these drugs is limited. Also, during these studies, persons with any serious diseases or concomitant medications were excluded.

The adverse reactions most commonly observed (occuring in at least 5 percent of patients) with venlafaxine but not seen at an equivalent incidence among placebo-treated patients (i.e., incidence for venlafaxine at least twice for that of placebo) are asthenia, sweating, nausea, constipation, anorexia, vomiting, somnolence, dry mouth, dizziness, nervousness, anxiety, tremor, blurred vision, abnormal ejaculation or orgasm, and impotence in men. Data from placebo-controlled studies suggest dose dependency for several adverse effects. There is a significant association between higher drug dosage and greater incidence of chills, hypertension, anorexia, nausea, agitation, dizziness, somnolence, tremor, yawning, sweating, and abnormal ejaculation.

Treatment with venlafaxine is associated with sustained hypertension, especially in patients treated with more than 300 mg a day. Sustained hypertension is defined as treatment-emergent supine diastolic blood pressure of 90 mm Hg or above and 10 mm Hg or more above baseline for three consecutive visits. During the clinical trials, most of the blood pressure increases were in the range of 10 to 15 mm Hg for supine diastolic blood pressure. About 3 percent of venlafaxine-treated patients experienced an increase in blood pressure, but less than 1 percent of the venlafaxine-treated group (*N* = 19) discontinued treatment because of hypertension. The incidence of sustained hypertension is dose related: less than 100 mg a day, 3 percent of patients 100 to 200 mg a day, 5 percent; 200 to 300 mg a day, 7 percent; and above 300 mg a day, 13 percent. Either dosage reduction or discontinuation should be considered for patients with sustained hypertension.

A venlafaxine withdrawal syndrome was described by A.K. Louie and colleagues in two patients carrying the diagnosis of major depression and one patient with dysthymia, receiving venlafaxine. The third author and Abdullah Dallal also described three patients who suffered venlafaxine withdrawal reactions involving mainly gastrointestinal and central nervous system symptoms. Because of the severity of venlafaxine withdrawal reactions, it is recommended that the drug be gradually tapered over 2 to 4 weeks and over a longer period when required. Angelink and colleagues also reported a venlafaxine withdrawal syndrome after abrupt discontinuation in two elderly patients treated with 300 mg a day for 4 to 6 weeks.

A possible explanation for the discontinuation symptoms seen with venlafaxine is that it reflects a combined functional deficiency of serotonin and norepinephrine at central norepinephrine and serotonin receptors. In the presence of venlafaxine, the uptake of released serotonin and norepinephrine is continuously blocked, resulting in exposure of the receptors to increased concentrations of serotonin and norepinephrine. This in turn could lead to desensitization or downregulation of these receptors. When venlafaxine is withdrawn, the concentrations of serotonin and norepinephrine fall, providing insufficient functional agonist stimulus for the downregulated receptors.

The events most frequently causing withdrawal of milnacipran have been dysuria, palpitations, hypotension, tachycardia, gastrointestinal events (e.g., constipation, nausea, vomiting), dry mouth, headache, tremor, sweating, dizziness, and nervousness. Dysuria was reported in patients receiving milnacipran and occurred more frequently with this drug than with tricyclic drugs. Precautions and dosage reduction are recommended in elderly patients or in those with renal impairment but not in those with hepatic dysfunction. C_{max}, area under the concentration-time curve, and $t_{1/2}$ values were increased in patients with renal diseases because of significant reductions in apparent total and renal clearance of drug. Changes in total clearance paralleled those in renal clearance, and both parameters were correlated with the decreased glomerular function.

The most common adverse events with duloxetine are insomnia, nausea, headache, diarrhea, dry mouth, somnolence, weakness or fatigue, heartburn, and a flulike syndrome with rhinitis and pharyngitis. A small number of patients have shown sustained elevations in diastolic blood pressure.

The effect of venlafaxine, milnacipran, and duloxetine in pregnancy, or during breast-feeding, is not documented. Therefore, their use is not recommended in those situations until more data are available.

In overdose, according to present data, venlafaxine and milnacipran appear safe. No death was reported, and all patients recovered without sequelae.

Venlafaxine, milnacipran, and duloxetine should not be used in combination with MAOIs or within 2 weeks of terminating treatment with MAOIs. Treatment with MAOIs should be not be started until 2 weeks after discontinuation of these antidepressants.

DRUG INTERACTIONS

Presently available data indicate no drug interaction between venlafaxine and lithium (Eskalith), diazepam (Valium), or alcohol. However, cimetidine (Tagamet) increases the pharmacological activity of venlafaxine and its metabolite. Therefore, caution is advised with the use of cimetidine and venlafaxine in patients with preexisting hypertension, in elderly patients, and in patients with hepatic or renal dysfunction. The same precautions as with cimetidine apply to patients treated with erythromycin and derivatives (e.g., clarithromycin [Biaxin]).

Venlafaxine is a relatively weak inhibitor of CYP 2D6; however, the potential exists for drug interaction between venlafaxine and drugs that inhibit CYP 2D6 metabolism. The general recommendation is to start on one-half to one-quarter of the usual dose when switching from fluoxetine to venlafaxine and after that to titrate the dose of venlafaxine upward as tolerated over a few weeks as the norfluoxetine levels gradually decrease. The reason for titrating the venlafaxine dose when switching from fluoxetine to venlafaxine is that fluoxetine inhibits both CYP 2D6 and CYP 3A3/4 and how venlafaxine and its major metabolite, *O*-desmethylvenlafaxine, are metabolized in the liver by these enzymes may reduce the clearance of both the parent drug and its active metabolite, leading to a higher concentration of venlafaxine in blood.

O-Desmethylvenlafaxine is metabolized by CYP 3A3/4, and its hepatic clearance can be reduced by coadministration of drugs that inhibit this enzyme (ketoconazole and related antifungal agents; fluoxetine, fluvoxamine, nefazodone) or increased by drugs that induce this enzyme (e.g., anticonvulsants such as carbamazepine [Tegretol]). Hence it is preferable to adjust the dosage when using venlafaxine and these other drugs in combination or for a while after discontinuation of fluoxetine, because of its long half-life. Therefore dosage reduction is necessary in older patients and patients with hepatic impairment.

Because milnacipran is not metabolized by the hepatic cytochrome P450 system, it is less likely to interact with drugs that are metabolized by this system. In volunteers, coadministration of lithium or lorazepam (Ativan) did not change the pharmacokinetics of any drug. However, carbamazepine decreased the concentration

of milnacipran in plasma and methotrimeprazine (Levoprome) increased it. The potential for drug-drug interaction is unknown for duloxetine.

LABORATORY INTERFERENCES

The studies of venlafaxine and milnacipran reported no interferences with any specific laboratory tests. A few patients taking duloxetine have developed modest elevations in liver enzymes for which duloxetine treatment has been stopped, even though the drug may not have caused the elevations. No permanent liver injury has been seen.

DOSAGE AND ADMINISTRATION

Venlafaxine is available in 37.5-mg and 75-mg tablets. The usual recommended starting dosage is 75 mg a day, divided in two or three doses, to be taken with food. If there is no clinical improvement after 4 weeks, the dose can be increased by a maximum of 75 mg a day at an interval of no less than 4 days. For moderately depressed outpatients, there is no evidence of usefulness of dosages above 225 mg a day. However, more severely depressed patients responded to higher dosages, between 350 and 375 mg a day. The maximum dose is 375 mg a day. It is recommended that the total daily dose be decreased by 50 percent for patients with hepatic or renal impairment. Elderly patients who are healthy require no dose modification. However, since elderly patients may show greater sensitivity to medication, they should be followed with caution. Because there are no data available, the dosage of venlafaxine is unknown in children.

Milnacipran is most commonly administered at a dosage of 50 or 100 to 150 mg twice daily for the treatment of major depressive disorder. Improvement usually occurs within 2 weeks of treatment initiation, but some patients respond sooner. On the basis of clinical trials, the optimal daily dosage of milnacipran seems to be 100 mg in two divided doses. At a dosage of 50 mg twice daily, patients with melancholia were particularly responsive. Limited data suggest that milnacipran could prevent relapse at a dosage of 50 to 200 mg twice daily. Caution and dose reduction are required in elderly patients or those with renal impairment but not in those with hepatic dysfunction.

The dosage of duloxetine is not yet determined. It appears that 20 mg a day would have an antidepressant effect. Further clinical trials are needed to assess the optimum dosage and whether this new drug requires dose titration or not.

31.25 SELECTIVE SEROTONIN REUPTAKE INHIBITORS

31.25A INTRDUCTION AND OVERVIEW

JEFFREY E. KELSEY, M.D., FH.D., AND CHARLES B. NEMEROFF, M.D., FH.D.

The first of the selective serotonin reuptake inhibitors (SSRIs) (also called serotonin-specific reuptake inhibitors), fluoxetine (Prozac) was introduced in the United States in 1988. Since that time, sertraline (Zoloft) and paroxetine (Paxil) were approved for the treatment of depression and subsequently for panic disorder and obsessive-compulsive disorder. In 1998 citalopram (Celexa), a very selective SSRI, was introduced in the United States. Fluvoxamine (Luvox) is approved in the United States for the treatment of obsessive-compulsive disorder and in other countries for depression. The availability of these agents as well as other newer-generation antidepressants such as venlafaxine (Effexor) nefazodone (Serzone), and mirtazepine (Remeron) has markedly changed the treatment of depression and certain anxiety disorders. Currently, fluoxetine is the second most widely prescribed medication in the United States. Members of this class are characterized by a generally more acceptable adverse effect burden than both tricyclic drugs and monoamine oxidase inhibitors (MAOIs) and a much higher safety margin. None of the SSRIs act as fast as sodium channel inhibitors and thus they do not display the cardiac toxicity seen in tricyclic drug overdose. In addition, SSRIs are not active at a-adrenergic receptors, obviating the orthostatic hypotension associated with the use of older antidepressants including tricyclic drugs, MAOIs, and trazodone (Desyrel).

Since the introduction of fluoxetine, SSRIs have been used successfully to treat an expanding variety of psychiatric disorders. The widespread use of the SSRIs has also provoked a public debate about the widespread use of psychotropic medications in general and antidepressants in particular.

The therapeutic activity of the SSRIs is believed to result from their ability to inhibit the reuptake of serotonin into presynaptic serotonergic nerve terminals, though SSRIs do exert effects on other neurotransmitter systems as well. Studies comparing one SSRI with another have failed to demonstrate any difference in efficacy in the treatment of major depression. One must be cautious in extrapolating the lack of differences in group populations to individual patients. It has been shown repeatedly that a sizable percentage of depressed patients who fail an adequate trial of one SSRI responds to a second SSRI, likely because SSRIs do differ from one another. Each SSRI is structurally unique, and differences exist in the selectivity of reuptake inhibition, medication interactions, and pharmacokinetics of drugs in this class. For example, at clinically effective dosages paroxetine likely inhibits not only serotonin reuptake but norepinephrine reuptake as well. Similarly, sertraline likely blocks both serotonin reuptake and dopamine reuptake. Reuptake potencies of the SSRIs based on in vitro assays for serotonin, norepinephrine, and dopamine are shown in Table 31.25a-1.

	K_i (nM)			
Drug	Serotonin	Norepinephrine	5-HT:NE*	Dopamine
Citalopram	1.3	4,000	3078	28,000
Fluoxetine	6	1,100	183	>10,000
Fluvoxamine	25	500	20	4,200
Paroxetine	1	350	350	2,000
Sertraline	7	1,400	200	230

* Ratio of serotonin to norepinephrine. Not all values are from the same study, so the relative ratios of selectivity (5-HT:NE) are the representative values.

Table 31.25a-1 Relative Selectivity of Serotonin, Norepinephrine or Dopamine Reuptake Inhibition in an In Vitro Assay

PHARMACOKINETICS

The SSRIs as a class exhibit a wide range of serum half-lives ranging from hours to days. Table 31.25a-2 summarizes the pharmacokinetic characteristics of this class of agents. SSRIs as a class demonstrate high protein binding. The significance of this in terms of potential drug-drug interactions remains relatively unexplored. The compartment associated with the biological activity of a drug is the free drug plasma concentration. For fluoxetine, paroxetine and sertraline this represents less than 6 percent of the total drug present in serum, based on in vitro calculations. However the free drug can also be metabolized. The question remains whether or not clinically significant displacement of protein binding occurs with these compounds and drugs of other therapeutic classes such as warfarin (Coumadin). Both albumin and a_1-acid-glycoprotein are involved, though the relative proportions are often not well characterized. Extrapolation of this to clinical practice suggests that other therapeutic compounds with high protein binding and low therapeutic indexes should be monitored when they are coprescribed with SSRIs.

Drug	Time to Peak Plasma Concentration	Half-Life	Half-Life Metabolite	Time to Steady State (days)	Plasma-Protein Binding (%)
Fluoxetine	6-8 h	4-6 days	4-16 days	28-35	95
Fluvoxamine	3-8 h	15 h	–	3-7	80
Paroxetine	5-6 h	21 h	–	5-10	95
Sertraline	4.5-8.5 h	26 h	62-104 h	3-7	95
Citalopram	4	35 h	35 h	7	80

Table 31.25a-2 Pharmacokinetic Profiles of the SSRIs

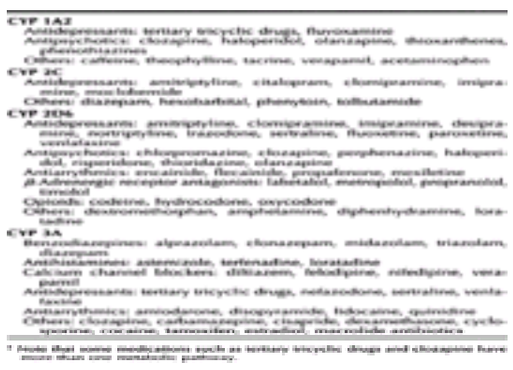
DRUG INTERACTIONS

Drug-drug interactions among SSRIs and other therapeutic drugs have received increasing scrutiny in the past few years; however, firm recommendations for clinical practice remain less than ideal. The two major classes of drug-drug interactions involving SSRIs are protein binding and enzyme inhibition through the cytochrome P450 (CYP) isoenzyme system. Indications that a drug-drug interaction is occurring, either by protein-binding displacement or inhibition of metabolism include increased adverse effects at a lower-than-expected dosage or therapeutic efficacy at a lower antidepressant dosage than expected. However some drug-drug interactions have only silent side effects that may go unnoticed. Ultimately, the pharmacokinetic interactions must be considered in terms of pharmacodynamic

consequences.

Inhibition of the cytochrome P450 system by antidepressants is receiving increasing study. The cytochrome P450 system is a collection of more than 30 different hepatic isoenzymes that show peak absorbance at 450 nm in a spectrophotometer after exposure to carbon monoxide. These isoenzymes metabolize endogenous substances, substances found in food and the environment, and drugs. Although a number of isoenzymes have been identified by molecular biological techniques, only a small proportion have been well characterized. Each isoenzyme has a three-character name: a number that denotes the family, a letter denoting the subfamily, and another number, which specifies the gene. This is seen in the names of the most commonly described isoenzymes such as CYP 1A2, 2D6, and 3A4. Genetic polymorphism of certain of these isoenzymes results in some individuals who are totally or relative deficient (i.e., poor metabolizers) in a particular isoenzyme. The extent of isoenzyme polymorphism across various ethnic groups has not been extensively studied.

Antidepressants are typically divided into groups with high, medium or low potential isoenzyme inhibition, as shown in Table 31.25a-3. A number of commonly prescribed medications and the isoenzymes that metabolize them are shown in Table 31.25a-4. Note that some medications such as the tertiary tricyclic drugs have multiple pathways of metabolism. Examples of medication interactions include fluvoxamine and theophylline (Theo-Dur) via the CYP 1A2 isoenzyme; clozapine (Clozaril) and fluvoxamine (CYP 1A2); sertraline, fluoxetine, or paroxetine (CYP 2D6); and paroxetine, fluoxetine, and sertraline with tricyclic drugs through the CYP 2D6 isoenzyme.



CYP 1A2
Antidepressants: tertiary tricyclic drugs, fluvoxamine
Antipsychotics: clozapine, haloperidol, olanzapine, thioxanthenes, phenothiazines
Others: caffeine, theophylline, tacrine, verapamil, acetaminophen
CYP 2C
Antidepressants: amitriptyline, citalopram, clomipramine, imipramine, mirtazapine, nortriptyline, trazodone, sertraline, fluoxetine, paroxetine, venlafaxine
Antipsychotics: chlorpromazine, clozapine, perphenazine, haloperidol, risperidone, thioridazine, olanzapine
Antiarrhythmics: mexiletine, flecainide, propafenone, encainide
β-Adrenergic receptor antagonists: labetalol, metoprolol, propranolol, timolol
Opioids: codeine, hydrocodone, oxycodone
Others: dextromethorphan, amphetamine, diphenhydramine, loratadine
CYP 3A
Benzodiazepines: alprazolam, clonazepam, midazolam, triazolam, diazepam
Antihistamines: astemizole, terfenadine, loratadine
Calcium channel blockers: diltiazem, felodipine, nifedipine, verapamil
Antidepressants: tertiary tricyclic drugs, nefazodone, sertraline, venlafaxine
Antiarrhythmics: amiodarone, disopyramide, lidocaine, quinidine
Others: clozapine, carbamazepine, cisapride, dexamethasone, cyclosporine, cerivastatin, tamoxifen, estradiol, macrolide antibiotics

† Note that some medications such as tertiary tricyclic drugs and clozapine have more than one metabolic pathway.

Table 31.25a-3 Commonly Prescribed Medications That Are Substrates of the Cytochrome P450 1A2, 2C, 2D6, or 3A4 Isoenzymes

Relative Rank	CYP 1A2	CYP 2C	CYP 2D6	CYP 3A
Higher	Fluvoxamine Grapefruit	Fluoxetine Fluvoxamine	Paroxetine Fluoxetine	Fluvoxamine Nefazodone Troleandomycin Grapefruit
Moderate	Tertiary amine tricyclics Fluoxetine	Sertraline	Secondary amine tricyclics Sertraline	Fluoxetine Sertraline
Low or minimal	Paroxetine Venlafaxine Nefazodone Sertraline Bupropion Mirtazapine Citalopram	Venlafaxine Paroxetine Citalopram	Fluvoxamine Venlafaxine Nefazodone Bupropion Mirtazapine Citalopram	Venlafaxine Paroxetine Mirtazapine Citalopram

Table 31.25a-4 Interaction Potentials of Antidepressant Drugs at Cytochrome 450

Whether or not isoenzyme inhibition has clinical relevance depends on a number of factors. Patients taking multiple medications are at risk if those medications have a low therapeutic index or do not have alternative pathways of metabolism or if the patients have clinically significant renal or hepatic disease. Other risk factors include the presence of highly potent isoenzyme inhibitors such as quinidine (Duraquin) at the 2D6 isoenzyme or ketoconazole (Nizoral) at the 3A4 isoenzyme. An informed awareness of potential drug-drug interactions and monitoring for them is the best way to maximize clinical care and minimize avoidable risks.

The SSRIs are safe, well-tolerated medications that have benefited millions of patients worldwide. Dosing is less complicated than with tricyclic drugs, and initial dosing at a low level with gradual escalation is a successful and well-tolerated strategy for most patients. Administration with meals at initial dosing helps minimize nausea, which is perhaps the most common early adverse effect of the SSRIs. Sexual dysfunction was poorly recognized during early clinical trials but is now recognized to affect a significant number of patients. Taken together, the risk-benefit relationship with this class of medications is favorable in the vast majority of patients.

SUGGESTED CROSS-REFERENCES

Additional information regarding monoamines and their receptors appears in Section 1.4. The basic electrophysiology of neurons is discussed in Section 1.9. The neurobiology of mood disorders is discussed in Section 16.4, and biochemical aspects of anxiety disorders are covered in Section 15.3.

31.25 SELECTIVE SEROTONIN REUPTAKE INHIBITORS

31.25B CITALOPRAM

JEFFREY E. KELSEY, M.D., FH.D., AND CHARLES B. NEMEROFF, M.D., FH.D.

HISTORY

Citalopram (Celexa) is the most recently approved selective serotonin reuptake inhibitor (SSRI) in the United States, though it has been available for a number of years in over 50 other countries worldwide. Currently, citalopram is approved by the Food and Drug Administration (FDA) for the treatment of major depressive disorders but as with the other SSRIs, data suggest efficacy in dysthymic disorder, anxiety disorders, and bipolar disorder depression.

CHEMISTRY

The molecular formula of citalopram is $C_{20}H_{22}BrFNO_2$, with a molecular weight of 405.35. The chemical designation is (±)-1-(3-dimethylaminopropyl)-1-(4-fluorophenyl)-1,3-dihydroisobenzo-furan-5-carbonitrile, and citalopram is a racemic mixture of the hydrogen bromide salt. The structure of citalopram is shown in Figure 31.25b-1.

FIGURE 31.25b-1 Molecular structure of citalopram.

PHARMACOLOGICAL ACTIONS

Absorption Citalopram demonstrates good absorption orally, with approximately 80 percent of a 40-mg dose being absorbed systemically relative to an intravenous dose. Food does not interfere with the absorption of citalopram, and peak plasma concentrations are achieved approximately 4 hours following oral dosing. Citalopram is available in the United States as tablets and is also available as an intravenous solution in other parts of the world.

Distribution The volume of distribution of citalopram is about 12L/kg. In vitro, citalopram and two metabolites, demethylcitalopram (DCT) and didemethylcitalopram (DDCT) are approximately 80 percent bound to serum proteins. The rate of plasma clearance is about 330 mL/per hour for citalopram, of which 20 percent of the clearance is due to renal excretion of the citalopram itself.

Metabolism and Elimination Citalopram is a racemic mixture of *R*-citalopram and *S*-citalopram in equal proportions. The *S*-enantiomer of citalopram as the primary component that demonstrates inhibition of serotonin reuptake and appears to be metabolized at a slightly faster rate than the *R*-enantiomer. After intravenous administration of the racemic mixture, citalopram is metabolized to DCT, DDCT, and citalopram-*N*-oxide. There is also a pharmacologically inactive propionic acid derivative that is presumably formed by deamination of citalopram, DCT, or DDCT. The *N*-demethylation of citalopram occurs in vitro via the cytochrome P450 (CYP) 3A4 and CYP 2C19 pathways. The parent compound, citalopram, is the predominant molecule found in the systemic circulation, with concentrations of DCT and DDCT being about 50 and 10 percent of those of citalopram, respectively. Citalopram is eight times more potent than its metabolites in inhibiting serotonin reuptake.

The elimination half-life of citalopram is close to 35 hours, with hepatic metabolism as the primary pathway. The pharmacokinetics of citalopram are linear and dosage-proportional over the usual dosing range of 10 to 60 mg a day. At steady state, mean plasma concentrations of citalopram are approximately 120 and 367 nmol/L for subjects receiving 20 and 60 mg a day, respectively. The expected steady-state concentration of citalopram in plasma is approximately 2.5 times that following a single dose.

Geriatric patients, defined in the pharmacokinetic studies as patients 60 years of age or older, show reduced clearance of citalopram. The citalopram area under the concentration-time curve (AUC) and half-life were increased by 23 to 30 percent and 30 to 50 percent, respectively, across single-dose and multiple-dose studies in geriatric patients. The recommended dosage for most geriatric patients is 20 mg a day. One small study ($N = 32$) suggested that women have a greater AUC for citalopram than men; however, this finding was not reproduced in larger studies ($N = 625$). Impairment of hepatic function is associated with impaired metabolism of citalopram, with a resultant 37 percent decrease in clearance of orally administered citalopram and a twofold increase in the half-life. In contrast, mild-to-moderate renal impairment resulted in only a 17 percent decrease in citalopram clearance. There are in sufficient data to determine the extent of changes in clearance in patients with more severe renal impairment. Dosages of 20 mg a day are usually considered to be the maximum dosage for geriatric patients or those with hepatic impairment; a dosage adjustment is usually not necessary for mild-to-moderate renal impairment.

PHARMACODYNAMICS

Mechanism of Action The therapeutic activity of citalopram is believed to be due to specific serotonin reuptake inhibition at the presynaptic serotonergic nerve terminal. Citalopram, the most selective of the SSRIs, shows more than a 3000-fold higher potency for blocking serotonin reuptake than norepinephrine reuptake, with Kis in vitro of 1.3, 4000, and 28,000 nmol/L for serotonin, norepinephrine, and dopamine, respectively. Citalopram lacks any clinically significant receptor affinity for muscarinic cholinergic, histamine type 1 (H_1), a_1-a_2-, and b-adrenergic, dopamine type 1 (D_1) or D_2, serotonin (5-hydroxytryptamine [5-HT]) subtype 1a ($5\text{-}HT_{1A}$) or $5\text{-}HT_{2A}$, g-aminobutyric acid (GABA), and benzodiazepine receptors.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

A number of clinical trials have investigated the efficacy of citalopram in major depression, in which thousands of patients have received the compound. Citalopram is available as both an intravenous infusion and tablets for oral administration.

Major Depressive Disorder A fixed-dose, double-blind, placebo-controlled 6-week trial of citalopram at 10, 20, 40 or 60 mg in 650 outpatients with revised third edition of *Diagnostic and Statistical Manual of Mental Disorder* (DSM III-R) major depression showed superiority of the active drug at both 40 and 60 mg a day. Study participants all had a 1-week placebo run-in period and then, if still eligible, were randomized to placebo or one of the citalopram dosing arms. Subjects in the 10- and 20-mg a day group started treatment at that dosage, those in the higher dosage groups were titrated from a starting dosage of 20 mg a day for days 1 to 3, and 40 mg a day for days 4 to 6. Study participants randomized to the 60 mg a day dosage had the final dosage increase on day 7. Using a last observation carried forward (LOCF) analysis, the two lower dosages, 10 and 20 mg a day, did not separate from placebo by week 6 in Hamilton Rating Scale for Depression (HAM-D) scores. The two higher dosages, 40 and 60 mg a day, were both statistically superior to placebo at endpoint but did not differ from each other.

A second recent outpatient study used a flexible dosing strategy and raised the dosage of citalopram to 80 mg a day, or if that was not tolerable, to the highest tolerated dose. In this study, the average dosage of citalopram was 30 mg a day at week 1 and 52 mg a day at week 4. There was an overall response rate of 80 percent in the citalopram-treated group.

Citalopram prevented relapse following improvement in a short-term trial. In one study, patients who responded to open-label treatment with citalopram (20 to 60 mg a day) as evidenced by a score on the Montgomery Asberg Depression Rating Scale (MADRS) of 12 or less, were randomized to either placebo or ongoing citalopram. After the 24-week double-blind phase, 18 of 74 (24.3 percent) patients receiving placebo had relapsed, compared with only 21 of 152 (13.8 percent) who continued to receive citalopram. Relapse was defined as a score of 25 or above on the MADRS. A second 24-week maintenance study comparing citalopram at doses of 20 or 40 mg a day demonstrated less relapse with active drug than with placebo treatment.

A comparison study of citalopram and sertraline (Zoloft) in a general practice setting suggested no differences in efficacy between the two drugs. The mean doses of citalopram and sertraline were 34 and 82 mg a day, respectively. Both drugs were well tolerated. Studies comparing citalopram with either fluvoxamine (Luvox) or fluoxetine (Prozac) in depressed outpatients have also suggested equal efficacy and tolerability. An inpatient study conducted by the Danish University Antidepressant Group suggested that the tricyclic antidepressant clomipramine (Anafranil), which inhibits both norepinephrine and serotonin reuptake, had better efficacy than citalopram in an inpatient setting when the criterion for response was a HAM-D score of 7 or less. In contrast to this finding, a comparison of citalopram, an SSRI, to maprotiline (Ludiomil), a norepinephrine-selective tricyclic drug, found no difference in efficacy between the two in 29 hospitalized patients.

Comparison of orally or intravenously administered citalopram in a small study (*N* = 30 per group) suggested that intravenous administration for the first 10 days, at a dosage of 40 mg a day, produced a more rapid response than oral administration at the same dosage. Both routes of delivery were equally well tolerated.

Trichotillomania A small open-label study in patients with trichotillomania showed only a 38.5 percent response rate (Clinical Global Impression [CGI] of 2 or less) after 12 weeks of treatment. The mean dosage of citalopram in the 11 of 12 subjects who completed the trial was 36.2 mg a day.

Obsessive-Compulsive Disorder A small (*N* = 29) open-label study examined the efficacy of citalopram in obsessive-compulsive disorder. Dosages of 40 to 60 mg a day were reported to have efficacy in about 75 percent of subjects.

Panic Disorder Citalopram treatment of eight patients at a dosage of 20 mg a day significantly decreased the frequency of panic attacks induced by a cholecystokinin tetrapeptide challenge.

Social Phobia An open-label trial of 22 patients with social phobia found an 86 percent response rate among study participants after 12 weeks of treatment at 40 mg a day.

Substance Dependence A placebo-controlled comparison trial of citalopram (20 mg a day) and fluvoxamine (150 mg a day) in detoxified alcoholics reported them to be equipotent in maintaining abstinence when combined with cognitive behavioral therapy. Citalopram-treated patients also reported reduced craving for alcohol. Another study, however, found citalopram to be better than placebo only in a subgroup of males below the group median of alcohol consumption. In this group of 30 men with mean alcohol consumption of 111 ± 51 grams a day of pure alcohol, only those with the lower daily consumption (mean 85 ± 15 grams a day of pure alcohol) derived more benefit from citalopram than from placebo.

Fibromyalgia A placebo-controlled trial of citalopram, up to 40 mg a day, revealed no superiority of the SSRI over placebo treatment. Twenty-two patients with fibromyalgia were randomized to 20 mg a day of citalopram or placebo, with the option to increase to 40 mg a day after 4 weeks if there was no response. A variety of outcome measures including self-report and physician assessment failed to differentiate the two groups.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Respiratory System No adverse respiratory effects noted with citalopram have differed significantly from those observed with placebo in premarketing trials. Allergic reactions to citalopram have been reported with the potential for respiratory involvement.

Cardiovascular System The premarketing clinical trials database showed a heart rate 1.7 beats per minute lower in subjects receiving citalopram than in those receiving placebo. Such clinically insignificant decreases in heart rate have been seen after treatment with other SSRIs. There were no changes in cardiac conduction as measured by electrocardiographic (ECG) changes associated with citalopram treatment. Animal studies in beagle dogs reported sudden death in 5 of 9 dogs treated with citalopram at a dosage of 8 mg/kg a day for 17 to 31 weeks. Elevated DDCT concentrations were considered responsible for QTc prolongation and subsequent fatal arrhythmias. The metabolism of citalopram differs to a great extent in beagles and humans with the former exhibiting markedly higher levels of DDCT. Specific analysis of the QTc in premarketing clinical trials failed to reveal any abnormalities associated with citalopram treatment.

No significant changes in supine or orthostatic blood pressure have been observed in association with citalopram treatment. However, premarketing clinical trials generally exclude patients with preexisting cardiac disease.

An analysis reported from Sweden suggests that with a single drug overdose of citalopram, some patients who ingest more than 600 mg exhibit ECG conduction changes. Doses exceeding 1900 mg invariably produce ECG changes.

Blood Citalopram has been rarely associated with reports of abnormal bleeding. Medications that inhibit serotonin reuptake are believed to inhibit platelet aggregation, which may produce bleeding or bruising in susceptible individuals.

Gastrointestinal System Citalopram, like the SSRIs, has the potential to produce nausea. The incidence of nausea in the premarketing clinical trials was 21 percent in the citalopram-treated group and 14 percent in the placebo-treated group. In 1036 patients receiving citalopram, nausea was the most common adverse event associated with discontinuation, with a rate of 4 percent. Nausea with this class of medications is usually dose related and transient. Dosing citalopram with meals initially or starting at a reduced dosage of 10 mg a day often reduces the incidence of nausea. Short-term treatment trials with citalopram (6 to 8 weeks duration) were associated with a weight loss of 1.1 pounds on average. The long-term effects of citalopram on body weight are not known.

Skin Rashes or pruritus were reported in the premarketing clinical trials at a rate of at least 1 percent.

Central Nervous System Tremor was reported by 8 percent of clinical trial participants receiving citalopram and 6 of those who received placebo. Dizziness was cited as the reason for study discontinuation by 2 percent of study participants receiving citalopram in premarketing trials.

THERAPEUTIC INDICATIONS

Citalopram currently has been approved by the FDA for the treatment of major depressive disorder. A variety of clinical experiences ranging from placebo-controlled, double-blind trials to case reports points to the efficacy of citalopram in other affective and anxiety disorders.

PRECAUTIONS AND ADVERSE REACTIONS

The most prevalent adverse events associated with citalopram treatment, mostly reported from non-U.S. trials, include nausea, dry mouth, somnolence, sweating, tremor, diarrhea, and ejaculatory dysfunction. This side-effect profile is typical of SSRIs, and in general, citalopram is quite well tolerated.

Sexual dysfunction was reported in the premarketing trials at a low rate, but the actual incidence in clinical practice is thought to be higher, similar to that with the other SSRIs.

DRUG INTERACTIONS

Evidence indicates that citalopram has the lowest potential for untoward drug-drug interactions of the SSRIs, probably because of its benign effects on the cytochrome P450 isoenzyme system. Citalopram is considered to be a weak inhibitor of the CYP 1A2, 2C19 and 2D6 isoenzymes, with no appreciable activity on the CYP 3A4 isoenzyme. Nevertheless, drug-drug interactions have been reported with cimetidine (Tagamet) and metoprolol (Lopressor). Cimetidine increases the AUC and maximum serum concentration of citalopram. In contrast, citalopram, 40 mg a day for 22 days, approximately doubled the serum concentration of metoprolol, a b-adrenergic receptor antagonist CYP that is metabolized by the CYP 2D6 isoenzyme. Citalopram displays lower protein binding (80 percent) than the other SSRIs but not as low as venlafaxine (Effexor) (27 percent). Good clinical care requires being aware of the potential for drug-drug interactions, especially when a new medication is added to a treatment regimen.

Citalopram should not be combined with monoamine oxidase inhibitors (MAOIs), because of the potential for developing the serotonin syndrome. The manufacturer recommends a washout period of 14 days between citalopram and MAOIs when switching from one to the other.

LABORATORY INTERFERENCES

Citalopram does not appear to interfere with any laboratory testing.

DOSING AND ADMINISTRATION

Citalopram is available in 20- and 40-mg scored tablets. The tablets contain copolyvidone, cornstarch, crosscarmellolose sodium, glycerin, lactose monohydrate, magnesium stearate, hydroxypropyl methyl cellulose, microcrystalline cellulose, and polyethylene glycol. The 20-mg tablets also contain titanium dioxide and iron oxides as coloring agents.

The suggested starting dosage of citalopram in patients with major depression is 20 mg a day. Effective dosages for the treatment of major depression have ranged from 20 to 80 mg a day in dosage-finding trials, though there were reports of failure at 20 mg a day in some trials in which higher doses were successful. In general, if a nongeriatric patient tolerates a dosage of 20 mg a day and does not demonstrate the desired response, it is reasonable to increase the dosage to at least 40 mg a day, assuming intact hepatic function. Some patients with sensitivity to citalopram or other SSRIs may do best at a starting dosage of 10 mg a day for 4 to 6 days before increasing the dosage. Steady-state concentrations of citalopram are achieved after about 1 week of treatment. There are insufficient clinical trial data to suggest target dosages for other disorders. SSRIs as a class are generally used at higher dosages to treat obsessive-compulsive disorder and panic disorder than to treat major depression. Because patients with panic disorder are generally more sensitive to adverse effects of medications than those with major depression, gradual dosage titration is of paramount importance in this group.

Geriatric patients, age 65 or older, composed 24 percent of the patient population (1034 of 4422 subjects) in citalopram premarketing trials. The most common dosing range in this population was between 20 and 40 mg a day. Citalopram clearance is reduced in the geriatric patient. Insufficient clinical data exist to suggest dosing strategies in children, though one might expect dosages to be similar to those for healthy adults, but adjusted for body mass.

SUGGESTED CROSS-REFERENCES

Additional information regarding monoamines and their receptors appears in Section 1.4. The basic electrophysiology of neurons is discussed in Section 1.9. The classification of mental disorders is discussed in Chapter 9, and mood disorders in geriatric patients in Section 51.3d. The neurobiology of mood disorders is discussed in Section 14.4. Lithium therapy is discussed in Section 31.18 and the biological treatment of mental illness in elderly adults in Section 51.4a to Section 51.4g.

31.25 SELECTIVE SEROTONIN REUPTAKE INHIBITORS

31.25C FLUOXETINE

JEFFREY E. KELSEY, M.D., FH.D. AND CHARLES B. NEMEROFF, M.D., FH.D.

HISTORY

Approximately 10 years ago, fluoxetine (Prozac), a selective serotonin reuptake inhibitor (SSRI) was introduced into the United States. Since that time, fluoxetine has become the most commonly prescribed antidepressant in the United States. Although initially approved for the treatment of major depression, fluoxetine currently also has Food and Drug Administration (FDA) approval for the treatment of obsessive-compulsive disorder and bulimia nervosa. Evidence suggests that it is effective in the treatment of dysthymic disorder, panic disorder, social phobia, premenstrual syndrome, and bipolar disorder depression.

CHEMISTRY

Fluoxetine's empirical formula is $C_{17}H_{18}F_3NO \cdot HCl$ and it has a molecular weight of 345.79. Its chemical designation is (±)*N*-methyl-3-phenyl-3[(a,a,a-trifluoro-*p*-toylyl)-oxy]-propylamine hydrochloride and its structure is shown in Figure 31.25c-1.

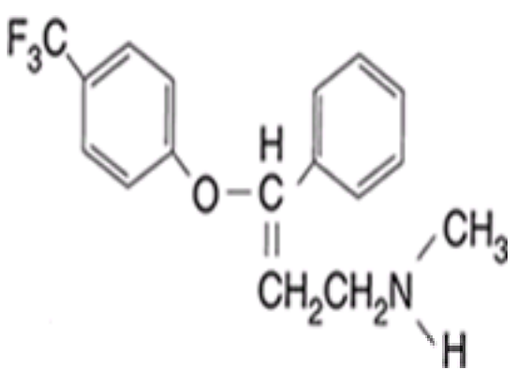

FIGURE 31.25c-1 Molecular structure of fluoxetine.

PHARMACOLOGICAL ACTIONS

Absorption Fluoxetine is well absorbed orally, with 72 to 90 percent systemic availability reflecting the combination of almost complete absorption and first-pass metabolism by liver hepatocytes. Maximum plasma concentration is achieved within 6 to 8 hours of ingestion following a 40-mg dose and is not affected by food. Fluoxetine is available as either pulvules (10 or 20 mg) or oral concentrate. Both forms have equal rates of absorption.

Distribution In vitro, fluoxetine is approximately 95 percent bound to serum proteins (albumin and a_1-acid-glycoproteins) at concentrations of 200 to 1000 ng/mL. The volume of distribution for fluoxetine and norfluoxetine, the biologically active metabolite, range from 20 to 45 L per kg. The rate of plasma clearance is 20 and 9 liters per hour for fluoxetine and norfluoxetine, respectively. Fluoxetine is widely distributed, including excretion into breast milk.

Metabolism and Elimination Fluoxetine is a racemic mixture of *R*-fluoxetine and *S*-fluoxetine in equal proportions. Both are approximately equipotent in serotonin reuptake inhibition activity, though the *S*-fluoxetine enantiomer is more slowly eliminated and is therefore the predominant form in plasma at steady state. Fluoxetine undergoes demethylation in the liver to norfluoxetine and a number of other unidentified minor metabolites of fluoxetine, though norfluoxetine is the only metabolite identified that possesses biological activity. In animals, the *S*-enantiomer of norfluoxetine is essentially equivalent in activity to *R*- or *S*-fluoxetine, but *R*-norfluoxetine has significantly less activity. Inactive metabolites produced by hepatic metabolism are excreted by the kidneys.

The elimination half-life of fluoxetine is 1 to 3 days after short-term administration and 4 to 6 days following long-term administration. Norfluoxetine has an elimination half-life of 4 to 16 days, independent of the duration of administration. Steady-state levels of fluoxetine are higher than would be predicted on the basis of single-dose administration. This is likely due to saturation of the cytochrome P450 (CYP) 2DG isoenzyme and subsequent metabolism by alternate nonsaturable pathways. Steady state is achieved because of these nonsaturable pathways. Norfluoxetine in contrast, demonstrates a linear dose-proportion relationship. The long half-lives of both fluoxetine and norfluoxetine indicate the possibility of drug-drug pharmacokinetic interactions for a sustained period of time after treatment with the drug is discontinued.

Impaired hepatic function is associated with impaired metabolism of fluoxetine. In a series of subjects with cirrhosis of the liver, the mean half-life of fluoxetine was increased to 7.6 days, compared with 2 to 3 days for normal subjects. The half-life of norfluoxetine was similarly increased to a mean of 12 days, compared with 7 to 9 days for normal subjects. This suggests the necessity of dosage reduction in individuals with significant liver disease.

Renal disease does not appear to impair the metabolism of either fluoxetine or norfluoxetine in single-dose studies. However, data on repeated dose administration as occurs in clinical practice are not available and a reduction in dosing size or frequency may be indicated for patients with renal impairment.

PHARMACODYNAMICS

Mechanism of Action The therapeutic activity of fluoxetine is believed to be due to specific serotonin reuptake inhibition at the presynaptic serotonergic nerve terminal. Using an in vitro synaptosomal assay system, fluoxetine is 23 times more potent in blocking serotonin uptake than in blocking norepinephrine uptake, with K_{is} of 12 and 278 nmoles, respectively. In contrast to the tricyclic drugs, fluoxetine essentially lacks any significant affinity at the muscarinic cholinergic, type 1 (H_1), histamine, a_1-adrenergic and serotonin (5-hydroxytryptamine [5-HT]) type 1 ($5\text{-}HT_1$) or $5HT_2$ subtypes. This translates into a significant reduction in adverse effects produced by receptor blockade, compared with the older antidepressants. Fluoxetine, unlike tricyclic drugs, also lacks affinity for cardiac fast sodium channels and thus demonstrates a superior safety profile with regard to cardiac toxicity. Fluoxetine has no effect on monoamine oxidase (MAO) activity.

Blood Concentrations and Relation to Action In contrast to many tricyclic drugs, there appears to be no significant relation between blood concentrations of fluoxetine and subsequent therapeutic response in major depressive disorder. A study of patients with obsessive-compulsive disorder failed to reveal any relation between fluoxetine or norfluoxetine plasma concentrations after 20, 40, or 60 mg a day of fluoxetine and clinical response. However, the assays used failed to differentiate between *S*-norfluoxetine, the more potent 5-HT reuptake inhibitor, and the less active *R*-norfluoxetine.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Major Depressive Disorder Thousands of patients have participated in dosage-ranging studies and active comparator trials of fluoxetine. Most studies have involved outpatients between 18 and 65 years of age, the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) or the revised third edition (DSM-III-R) at least moderate depression severity with major depression meeting criteria of Hamilton Rating Scale for Depression [HAM-D] ³ 20). Few placebo-controlled trials have studied the geriatric and inpatient populations.

The early dose-finding studies compared 20, 40, or 60 mg a day of fluoxetine with placebo. There were 363 randomized subjects, of whom 61 percent were female, and the average baseline HAM-D score was approximately 25 for all groups. All three dosages of fluoxetine showed approximately equal efficacy, with separation from placebo at weeks 4 and 6, as assessed by Clinical Global Improvement Scale. Patients treated for at least 3 weeks exhibited response rates (50 percent or more decrease in HAM-D) of 33, 72, 71, and 64 percent in the placebo, 20, 40, and 60 mg a day groups, respectively. The 60 mg a day dosage had nearly three times the dropout rate due to adverse events (25 vs. 8 percent) as the 20 mg a day group. A second dosage-finding study using lower doses (5, 20, or 40 mg a day) found equal efficacy for all three dosages of fluoxetine, and each was superior to placebo. The 5 mg a day dosage was superior to placebo at weeks 1 to 6 and the 20 or 40 mg a day groups were superior at weeks 3 to 6. These studies suggest that a wide range of dosages is effective in the treatment of moderate or severe depression. The effects of fluoxetine in milder depression (HAM-D scores of 15 to 19) were investigated using doses of 20, 40, or 60 mg daily. Endpoint analysis failed to reveal any difference between fluoxetine and placebo. Completer analysis revealed improvement for the 40 and 60 mg a day groups compared with the placebo group, assessed by clinical global improvement only.

Comparator trials with fluoxetine have included amitriptyline (Elavil), doxepin (Sinequan) imipramine (Tofranil), moclobemide (Aurorix), paroxetine (Paxil), and venlafaxine (Effexor). Doxepin has been compared with fluoxetine in geriatric and nongeriatric patient groups. In the geriatric population, fluoxetine (20 to 80 mg a day) demonstrated efficacy equivalent to that of doxepin (50 to 200 mg a day). Scores on the HAM-D decreased from 25.2 to 16.3 (fluoxetine) and 25.9 to 16.6 (doxepin) in a 6-week trial, a trial length many investigators consider too short to demonstrate maximal efficacy in a geriatric population.

A preliminary report with relevance to this population suggests that in geriatric females, estrogen replacement therapy in conjunction with fluoxetine treatment is more efficacious than fluoxetine alone (HAM-D score improvement of 40.1 and 17 percent, respectively). This retrospective analysis of a relatively small number of study participants did not control for factors that may have led to hormone replacement.

In the nongeriatric study (average age, 41.9 years for the fluoxetine treatment group; 44.4 years for the doxepin treatment group) doxepin and fluoxetine displayed equal efficacy, with baseline HAM-D scores of 26.1 reduced to 16.7 after fluoxetine treatment, and baseline HAM-D scores of 25.5 reduced to 13.4 after doxepin treatment. In general, the comparison trials with amitriptyline and imipramine show efficacies equal to that of fluoxetine, but fluoxetine clearly possesses a superior side-effect profile. Fluoxetine and paroxetine have similar efficacy in outpatients with major depressive disorder of at least moderate severity. Fluoxetine (20 to 40 mg a day) and moclobemide (300 to 600 mg a day), the reversible inhibitor of monoamine oxidase (MAO) type A (RIMA), demonstrated equal efficacy in 122 outpatients with major depressive disorder.

Too few inpatient comparator studies exist to permit firm conclusions. Fluoxetine was compared with imipramine with median dosages of 80 mg a day (fluoxetine) and 200 mg a day (imipramine). There was a nonsignificant trend ($P = .063$) toward greater improvement with imipramine. When fluoxetine was compared with moclobemide in inpatients, both agents demonstrated equal efficacy. One multicenter inpatient trial in France compared fluoxetine and venlafaxine; venlafaxine showed greater efficacy at weeks 4 and 6. Unfortunately, none of the comparator inpatient trials to date have been placebo controlled.

Limited data exist to provide general guidance on how to proceed after nonresponse to fluoxetine. When should a practitioner change the treatment (e.g., by increasing the dose)? Another issue is how to deal with the loss of an initial therapeutic response. In an open-label study, 108 patients with major depressive disorder were treated with fluoxetine (20 mg a day). Patients who failed to respond after 3 weeks were randomized to continue treatment with the same dosage or at 60 mg a day for an additional 5 weeks. At the end of 8 weeks of treatment, both groups demonstrated improvement, with no statistically significant differences between the two groups that were randomized or the group that showed an initial response in the first 3 weeks of treatment. Another study was designed to address the issue of predicting outcome after 8 weeks of fluoxetine treatment, based on responses to the drug at 2, 4, or 6 weeks. In this open-label study, 143 outpatients with DSM-III-R major depression received a fixed dosage of 20 mg a day of fluoxetine. The proportion of patients who failed to show a 20 percent decrease in their HAM-D scores by weeks 2, 4, or 6 but went on to have a 50 percent or greater decrease at week 8 were calculated by survival analysis. The proportion of those who did not demonstrate a 20 percent improvement by weeks 2, 4, or 6 but did respond by week 8 was 36.4, 18.9, and 6.5 percent, respectively, suggesting that there is less than a 20 percent chance of responding to fluoxetine in those who have not responded at all by 4 weeks of treatment. In yet another study, comparing fluoxetine and moclobemide, patients (both inpatients and outpatients) showed equal response rates after 6 weeks of treatment (fluoxetine, 20 to 40 mg a day or moclobemide, 300 to 600 mg a day). Those who failed to respond to the lower dosage by 3 weeks of either drug had their dosage doubled. The higher dosage of moclobemide (600 mg a day) was nearly twice as effective as the higher dosage of fluoxetine (40 mg a day) as assessed by the Clinical Global Impression Scale. The issue of what to do if an initial response is lost has also been examined. Eleven of 18 patients who relapsed on fluoxetine (20 mg a day) (61 percent) exhibited a salutary response during follow-up after the dosage was increased to 40 mg a day.

A common dilemma for the clinician is deciding what course of action to take if a first adequate antidepressant drug trial fails. Unfortunately, limited data address the question of whether switching to a second SSRI after failing a first is indicated. In an open-label, non-placebo-controlled trial of treatment failures or nonresponders to sertraline (Zoloft) who were then switched to fluoxetine, 40 to 70 percent responded. In the absence of placebo-controlled trials, it is difficult to determine how switching within a class compares with the efficacy of switching to a different class.

The efficacy of fluoxetine in the treatment of major depression in children and adolescents (ages 7 to 17 years) was evaluated in a double-blind, placebo-controlled trial. Using the intent-to-treat sample, 56 percent of the patients treated with fluoxetine and 33 percent of those receiving placebo were rated as “very much” or “much” improved. Complete symptom remission was observed in 31 and 23 percent of the fluoxetine and placebo-treated patients, respectively.

Bipolar Disorders Fluoxetine, like other antidepressants, can induce mania in patients with bipolar disorders. Induction of hypomania or mania was reported at a rate of approximately 1 percent in the premarketing major depressive disorder and obsessive-compulsive disorder trials, a rate comparable to that with other antidepressants. A treatment trial comparing 6 weeks of fluoxetine, imipramine, or placebo in depressed patients with bipolar disorder showed improvement in 86, 57, and 38 percent of those receiving fluoxetine, imipramine, and placebo, respectively. During the 6-week trial and extension phase, none of the subjects receiving fluoxetine switched into mania. In this same trial, 4 of 25 patients who were treated with fluoxetine after failing to respond to imipramine or placebo treatment experienced mania.

Comparison of antidepressant-induced mania and spontaneous mania suggested that the latter is more severe. Another group, analyzing treatment-emergent switches into mania by bipolar patients found that SSRIs were associated with a 3.7 percent rate, compared with 11.2 percent for tricyclic drugs and 4.2 percent for placebo.

Dysthymic Disorder The data on treatment of dysthymia with fluoxetine are relatively sparse. In a placebo-controlled trial, 35 subjects with dysthymic disorder (primary dysthymia without a current major depression episode) exhibited response rates of 62.5 percent (10 of 16) in the fluoxetine group and 19 percent (3 of 16) in the placebo group. Response was defined as a 50 percent or greater decrease in the HAM-D scale and a Clinical Global Improvement Scale improvement of 1 or 2. No difference, however, was seen on the Hopkins Symptom Checklist or Cornell Dysthymia Rating scale. In this study, the mean patient age was 36.2 years, and 62.5 percent reported the onset of depressive symptoms in childhood. A similar 60 percent response rate was found in an open-label trial of fluoxetine in elderly patients with dysthymic disorder in an 11-week trial of active medication following a 2-week placebo lead-in period. Data on the effectiveness of fluoxetine after long-term treatment in dysthymia are needed.

Seasonal Affective Disorder The efficacy of fluoxetine in winter seasonal affective disorder (mood disorder with seasonal pattern) was evaluated in 68 outpatients with DSM-III-R recurrent major depression, seasonal (winter) type. Participants were randomly assigned to fluoxetine (20 mg a day) or placebo for 5 weeks. Both

groups exhibited clinical improvement, though the fluoxetine group had a higher rate of clinical response (defined as a 50 percent or greater reduction in the 29-item HAM-D scale between initiation and termination), 59 percent compared with 34 percent for placebo. Those who did not demonstrate some improvement by weeks 2, 4, or 6 but did respond by week 8 were 36.4, 18.9, and 6.5 percent of the patient population, respectively, suggesting that similar to observations with major depression, additional fluoxetine treatment after 8 weeks does not lead to subsequent recovery.

Trichotillomania Two placebo-controlled, crossover studies have failed to demonstrate efficacy of fluoxetine over placebo. The longer was a 31-week trial with an initial 2-week placebo washout period, followed by a 12-week treatment period with either fluoxetine or placebo, a 5-week washout with no placebo capsules, followed by a crossover for 12 additional weeks with the other treatment.

Obessive-Compulsive Disorder Fluoxetine was the first SSRI approved for the treatment of obsessive-compulsive disorder in the United States. Two multicenter, placebo-controlled trials in 355 outpatients between the ages of 15 and 70 years with DSM-III-R obsessive-compulsive disorder demonstrated the efficacy of fluoxetine. A 1-week placebo lead-in period was followed by randomization to placebo or 20, 40, or 60 mg of fluoxetine daily; patients in the 60 mg a day group received 40 mg a day for the first week. All three dosages of fluoxetine produced significant improvement over placebo by week 5. Only the 40 and 60 mg a day dosages demonstrated significant improvement over placebo at all weeks from 5 onward. The 20 mg a day group was superior to placebo at weeks 5, 11, and 13. Improvement in the Yale Brown Obsessive Compulsive Scale (Y-BOCS) from baseline to week 13 was –0.7, –4.7, –5.4, and –7.6 for the placebo, 20, 40, and 60 mg a day groups, respectively. There was a trend toward greater improvement with the higher dosages, though there was also a higher incidence of adverse events. In the authors' experience, patients with obsessive-compulsive disorder tend to have a higher tolerance for adverse effects than those with affective or other anxiety disorders. Completion rates for subjects who completed week 1 were 86, 87, 78, and 76 percent for the placebo, 20, 40, and 60 mg a day groups, respectively. All three dosages were effective, and a reasonable approach may be to initiate therapy at 20 mg a day and increase the dosage as needed.

The rate of therapeutic response to fluoxetine and other SSRIs by patients with obsessive-compulsive disorder is considerably slower than that by patients with depression. This issue was addressed by a continuation study of fluoxetine after the initial 13 weeks of double-blind treatment. Treatment responders continued double-blind treatment, and nonresponders had their dosage increased in an open-label fashion. Those in the blinded condition (receiving a dose of fluoxetine or placebo equal to that in the initial 13 weeks) continued to improve. Nearly two-thirds of open-label participants demonstrated a clinical response in the additional 24 weeks of treatment.

Fluoxetine has been compared with the tricyclic drug clomipramine (Anafranil), also approved for the treatment of obsessive-compulsive disorder. In a double-blind, randomized trial, fluoxetine (40 mg a day) and clomipramine (150 mg a day) demonstrated comparable efficacy in 55 patients with DSM-III-R obsessive-compulsive disorder.

Bulimia Nervosa Daily dosages of 60 mg (but not 20 mg) of fluoxetine, have been shown effective in the treatment of women with bulimia nervosa. An 8-week double-blind, placebo-controlled trial in 387 women with bulimia nervosa aged 18 years or older demonstrated that fluoxetine (60 mg a day) is superior to placebo in decreasing the frequency of binge-eating and vomiting episodes. Fluoxetine treatment also decreased depression, carbohydrate craving, and pathological eating attitudes and behaviors. Baseline HAM-D scores were not associated with outcome, suggesting that improvement was not simply an epiphenomenon of treating depression. Although the response rates (³50 percent improvement) to 60 mg a day were 63 and 57 percent for binge-eating episodes per week and vomiting episodes per week, respectively, less than 25 percent of subjects exhibited complete remission.

Panic Disorder Published studies examining the efficacy of fluoxetine in the treatment of panic disorder suggest that fluoxetine, like other SSRIs, is effective in the treatment of panic disorder. Panic disorder often requires smaller initial dosages than those used in depression, and many of the reports used starting dosages of 5 mg a day. This can be accomplished by using the liquid preparation (20 mg/5 mL) or by dissolving the contents of the pulvules in juice and having the patient drink an aliquot of the juice each day. Individuals with panic disorder treated with fluoxetine at a dosage of 20 mg a day often report worsening of panic attacks initially and exhibit a correspondingly high discontinuation rate.

Social Phobia Fluoxetine has been suggested to be effective in treating social phobia in a series of letters and one published open-label trial. No controlled trial data have been published.

Substance Dependence Fluoxetine was found effective in preventing relapse in male veterans with severe alcohol dependence in a small placebo-controlled trial. In another study investigating the use of fluoxetine in crack cocaine dependence, 32 subjects were randomized to either fluoxetine (40 mg a day) or placebo in addition to standard outpatient treatment. Subjects in the fluoxetine group stayed in treatment longer (median 11 weeks versus 3 weeks for placebo), but there was no difference in cocaine use or craving between the two groups in weeks 1 to 6. Because of poor retention of subjects in the placebo group, no longer-term comparisons could be made.

Premature Ejaculation Sexual dysfunction is a common adverse effect of medications that inhibit serotonin reuptake into the presynaptic neuron. This potential adverse effect has been put to therapeutic use in the treatment of males with premature ejaculation. In an 8-week open-label study, 11 male patients were treated with fluoxetine (20 to 60 mg a day) following a 2-week placebo washout. A within-subjects repeated measures design demonstrated increased intravaginal ejaculation latency as well as improved self-reported and partner's reported satisfaction. A larger double-blind, placebo-controlled trial comparing fluoxetine (20 to 40 mg a day) with placebo in 17 males with premature ejaculation demonstrated greater improvement (assessed by latency to intravaginal ejaculation) in the fluoxetine treated group.

Chronic Fatigue Syndrome A study of fluoxetine treatment of chronic fatigue syndrome with 96 patients randomized to placebo or fluoxetine (20 mg a day) and stratified by presence or absence of depression showed no between-group differences after 8 weeks of treatment.

Fibromyalgia A small-sample (*N* = 42), double-blind, placebo-controlled study that compared fluoxetine (20 mg a day) with placebo in the treatment of women with fibromyalgia found the SSRI to have no efficacy after 6 weeks of treatment.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Respiratory System No adverse respiratory effects noted with fluoxetine have differed significantly from those seen with placebo in premarketing trials. Occasionally, allergic reactions may involve the respiratory system, and dyspnea is a prominent symptom. Anaphylactoid events have also (rarely) been reported after fluoxetine treatment.

Heart and Blood Pressure Fluoxetine was not found to have any significant effects on either systolic or diastolic blood pressure. There may be a minor decrease in heart rate, with an average slowing of about 3 beats per minute observed in premarketing trials. In depressed patients without cardiac disease, fluoxetine elicited no changes in cardiac conduction in dosages up to 80 mg a day, in comparison to amitriptyline. Another study compared fluoxetine with doxepin; fluoxetine produced no adverse electrocardiographic effects. In contrast, doxepin increased the heart rate an average of 12 beats per minute and prolonged the corrected QT interval from 417 ± 36 to 439 ± 28 msec. These studies were all conducted in individuals without cardiac disease.

In one small study (*N* = 16) fluoxetine was used to treat resistant vasovagally mediated episodes of hypotension and bradycardia in individuals who are tilt-table positive. Of the 13 patients who tolerated fluoxetine, 7 (53 percent) had a negative repeat tilt-table test result and were asymptomatic for 19 ± 9 months of follow-up.

Blood Fluoxetine has rarely been reported to produce bleeding and bruising in some individuals. SSRIs as a class are believed to inhibit platelet aggregation, which may underlie this effect. Prospective small-sample studies of a number of hematological parameters following administration of fluoxetine have failed to show any differences. However, because individuals with fluoxetine-induced bruising or bleeding were not included in these studies, it is difficult to know how to interpret the results. The ability of SSRIs to reduce platelet aggregation may be an important intervention for patients with occlusive coronary and cerebrovascular artery disease and deserves study.

Gastrointestinal System Fluoxetine, like other SSRIs, can produce nausea. This is usually dose related and, in most patients, subsides with time. Initial administration of fluoxetine with meals, or in a sensitive individual, at a lower starting dosage often reduces the incidence. Diarrhea and anorexia are also experienced more often with fluoxetine than with placebo. Occasionally weight loss is seen with fluoxetine, and a minority of patients will report weight gain.

Skin Approximately 4 percent of more than 5600 subjects in premarketing trials developed either a rash or urticaria. Nearly a third of these individuals were withdrawn

from treatment because of the rash, urticaria, or both. Excessive sweating has been reported with fluoxetine at a rate about double that seen with placebo.

Central Nervous System (CNS) Potentially important CNS adverse effects seen with administration of fluoxetine include nervousness, insomina, drowsiness, anxiety, tremor, dizziness, and fatigue. Less than 7 percent of patients in premarketing clinical trials in the United States discontinued treatment because of CNS adverse effects of nervousness, anxiety, insomnia, or dizziness. Abnormal or more vivid dreams are occasionally reported by patients taking fluoxetine, as with the other SSRIs.

In the early 1990s a debate arose about whether fluoxetine treatment was associated with increased suicidal ideation and suicide attempts in some patients. A comparison of the emergence of suicidal ideation in patients receiving fluoxetine, tricyclic drugs, or placebo suggested that fluoxetine-treated patients had less emergent suicidal ideation than those treated with tricyclic drugs. Both antidepressant groups showed less emergent suicidal ideation than the group treated with placebo. Fluoxetine produces symptoms resembling akathisia in some patients, often described as restlessness by patients.

THERAPEUTIC INDICATIONS

Fluoxetine currently has FDA approval to be marketed for the treatment of major depressive disorder, obsessive-compulsive disorder, and bulimia nervosa. A variety of clinical experiences ranging from placebo-controlled, double-blind trials to case reports points to the efficacy of fluoxetine in dysthymic disorder, atypical depression, bipolar disorder depression, panic disorder, social phobia, and other anxiety disorders as well as obsessive-compulsive spectrum disorders.

PRECAUTIONS AND ADVERSE REACTIONS

The most prevalent CNS effects include headache, nervousness, insomnia, drowsiness, anxiety, and tremor. Akathisia, though qualitatively different from that observed with antipsychotic drugs, has occasionally been reported. In premarketing testing, the seizure incidence was 0.2 percent, which is similar to the rate seen with other antidepressants.

Common gastrointestinal system adverse effects include nausea, diarrhea, dry mouth, anorexia, and dyspepsia. In clinical practice, less nausea is often seen than was reported in the premarketing trials, and it can be minimized by coadministering the drug with food and reducing the initial dosage in sensitive individuals. Tolerance to nausea usually develops over time.

Sexual dysfunction was reported to occur at a low rate in the premarketing trials, but this was based on spontaneous patient reports. The actual incidence in clinical practice is much higher and consists of delayed ejaculation or impotence in men, delayed orgasm or anorgasmia in women, and decreased libido in both sexes. A number of strategies have been suggested to deal with this effect including decreased dosage, drug holidays for shorter-half-life SSRIs, or addition of buspirone (BuSpar), yohimbine (Yocon), amantadine (Symmetrel), cyproheptadine (Periactin), or bupropion (Wellbutrin). No controlled studies of the effects of any of these strategies are available.

DRUG INTERACTIONS

Fluoxetine may interact pharmacodynamically or pharmacokinetically with other medications. The potential for the serotonin syndrome characterized by autonomic instability, abdominal pain, diarrhea, confusion or delirium, increased motor activity, and myoclonus, or in severe cases, the potential for hyperpyrexia, cardiovascular shock, or death, is perhaps greatest when fluoxetine is combined with MAO inhibitors (MAOIs). The prudent washout period between starting fluoxetine treatment after an MAOI is at least 2 weeks. Five weeks is the minimum recommended interval between stopping fluoxetine treatment and administering an MAOI, because of the long half-life of norfluoxetine. l-Tryptophan in combination with SSRIs also can produce the serotonin syndrome.

Potential pharmacokinetic interactions involve protein binding (poorly characterized as to clinical significance) and the cytochrome P450 system. The manufacturer warns that fluoxetine may displace other tightly protein-bound drugs such as warfarin (Coumadin) or digitoxin (Crystodigin). Good clinical care calls for careful monitoring of potential increased concentrations of agents when tightly protein-bound drugs are coadministered, especially if one agent has a low therapeutic index.

In the cytochrome P450 isoenzyme system, fluoxetine is considered to be a relatively potent inhibitor of the CYP 2C and 2D6 isoenzymes, with no appreciable activity in the CYP 3A4 system, though norfluoxetine does demonstrate some inhibition of CYP 3A4 in vitro. Table 31.25a-4 contains a partial listing of cytochrome isoenzyme substrates.

Fluoxetine may produce hypoglycemia in patients with diabetes who are treated with insulin or oral hypoglycemic drugs. Dosage reduction of the hypoglycemic drug or insulin may be required.

LABORATORY INTERFERENCES

Fluoxetine does not appear to interfere with any laboratory testing.

DOSING AND ADMINISTRATION

Fluoxetine is available in 10- or 20-mg pulvules. The pulvules also contain F D & C Blue No. 1, gelatin, iron oxide, silicon, starch, titanium dioxide, and other inactive ingredients. A liquid solution with a concentration of 20 mg/5 mL is also available.

The suggested starting dosage of fluoxetine in patients with major depression is 20 mg a day. Effective dosages for the treatment of major depression have been reported to range from 5 to 80 mg a day in dosage-finding trials. Because of its long half-life, achieving a new steady state after dosage adjustment takes longer than with most other antidepressants. Decreasing the dosage to treat emerging adverse effects, particularly several weeks after initiation of treatment or the last dosage adjustment, is a reasonable approach.

Preclinical trials showed fluoxetine (60 mg a day) to have greater efficacy in bulimia nervosa than placebo. Treatment of obsessive-compulsive disorder also commonly uses higher dosages than those used in major depressive disorders with dosages of 20 to 80 mg a day most common. The long half-lives of fluoxetine and norfluoxetine make interpretations of the least effective dosage somewhat complicated. Fortunately, because fluoxetine is generally well tolerated, this is less of an issue than it may be with older antidepressants such as tricyclic drugs.

Treatment of panic disorder is often initiated with less than 5 to 10 mg a day, with a gradual upward dosage titration. Treatment of social phobia or premenstrual syndrome is often started at 10 to 20 mg a day. Dosage is adjusted upward as needed.

Starting dosages of 10 mg a day are often used in treating children, adolescents, or elderly patients. Adjustment upward is based on clinical response and tolerance of adverse effects.

SUGGESTED CROSS-REFERENCES

Depression is discussed in Chapter 14, anxiety disorders in Chapter 15, and eating disorders in Chapter 20. Behavior therapy is discussed in Section 30.2, and tricyclic drugs in Section 31.30.

CHAPTER 31. BIOLOGICAL THERAPIES

31.25 SELECTIVE SEROTONIN REUPTAKE INHIBITORS

31.25D FLUVOXAMINE

JEFFREY E. KELSEY, M.D., FH.D. AND CHARLES B. NEMEROFF, M.D., FH.D.

HISTORY

Fluvoxamine is currently approved in the United States for the treatment of obsessive-compulsive disorder but has been used for many years in other countries to treat depression. The efficacy of fluvoxamine is believed to be due to the reuptake inhibition of serotonin into the presynaptic serotonergic nerve terminal.

CHEMISTRY

Fluvoxamine, a structurally unique antidepressant, is a member of the 2-aminoethyloxime ethers of the aralkylketone family. The empirical formula of fluvoxamine is $C_{15}H_{21}O_2N_2F_3 \cdot C_4H_4O_4$, and it has a molecular weight of 434.4. The chemical designation is 5-methoxy-4'-(trifluoromethyl) valerophenone-(*E*)-*O*-(2-aminoethyl) oxime maleate (1:1), and the structure is shown in Figure 31.25d-1.

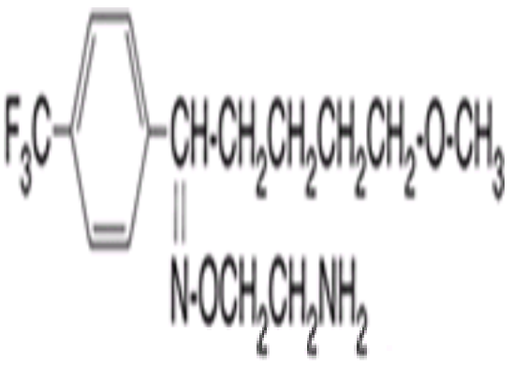

FIGURE 31.25d-1 Molecular structure of fluvoxamine.

PHARMACOLOGICAL ACTIONS

Absorption The bioavailability of fluvoxamine maleate is 53 percent, and its absorption is not significantly affected by food. At steady state, maximal plasma concentrations are achieved 3 to 8 hours after dosing.

Distribution In vitro, fluvoxamine is approximately 80 percent bound to serum proteins, predominantly albumin, at concentrations of 20 to 2000 ng/mL. The volume of distribution for fluvoxamine is approximately 25 L/kg. The extent of excretion of fluvoxamine into breast milk is unclear at this time.

Metabolism and Elimination Fluvoxamine is primarily metabolized by oxidative demethylation and deamination in the liver. The main human metabolite, as determined by radiotracer studies, is fluvoxamine acid, which along with its *N*-acetylated analogue accounted for about 60 percent, of urinary products. In this same assay, fluvoxethanol made up about 10 percent. Fluvoxamine acid is 10 to 100 times less potent in an in vitro assay of serotonin reuptake inhibition.

Fluvoxamine does not demonstrate linear pharmacokinetics. In 30 normal volunteers receiving fluvoxamine at 100, 200, or 300 mg a day for 10 days, the maximum plasma concentrations were 88, 283, and 546 ng/mL, respectively. This represents increases of 160 and 207 percent for the 200- and 300-mg dosages, respectively, over what would have been predicted from the lowest dose. The mean plasma half-life at steady state is 15.6 hours in young healthy volunteers receiving 100 mg a day and 13.6 hours for a 50-mg daily dosage. After repeated dosing, the half-life increases to 17 to 22 hours. Steady state is typically achieved in about 7 days.

Elderly patients show a prolonged half-life of fluvoxamine. Compared with younger patients, in elderly patients the half life at 50 mg a day goes from 13.6 to 17.4 hours and from 15.6 to 25.9 hours for 100 mg a day dosing.

Hepatic dysfunction is associated with a 30 percent decrease in fluvoxamine clearance compared with that in healthy controls. In contrast, renal impairment (creatinine clearance of 5 to 45 mL per minute) was not associated with decreased clearance.

CLINICAL STUDIES

Obsessive-Compulsive Disorder In a multisite, double-blind placebo-controlled trial of fluovoxamine in obsessive-compulsive disorder, 169 patients were randomized to fluvoxamine (100 to 300 mg a day) or placebo. Efficacy evaluations were available for 78 patients in each group, and fluvoxamine was more effective than placebo as measured by the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS), National Institute of Mental Health Obsessive-Compulsive scale, and the Global Improvement item in the Clinical Global Impression scale. From week 6 onward, 33.3 percent of the fluvoxamine group but only 9.0 percent of the placebo group were rated as much or very much improved on the Global Improvement item.

Fluvoxamine (100 to 250 mg a day) was compared with clomipramine (Anafranil) (100 to 250 mg a day) in 66 outpatients aged 18 to 65 with obsessive-compulsive disorder in a multicenter study. Mean reductions in the Y-BOCS of 33 and 31 percent were observed for the fluvoxamine and clomipramine groups, respectively.

A second comparison study with fluvoxamine (100 to 300 mg a day) and clomipramine (100 to 250 mg a day) was conducted in 79 patients with obsessive-compulsive disorder in a 10-week active treatment trial. Study completion rates were 78 percent for fluvoxamine and 64 percent for clomipramine-treated patients. At the conclusion of the treatment trial, the response rate (defined by a 25 percent or greater decrease in the Y-BOCS) was identical between the two groups, 56 and 54 percent for the fluvoxamine and clomipramine groups, respectively.

Fluvoxamine demonstrates efficacy in the treatment of obsessive-compulsive disorder in children and adolescents. A 10-week, parallel-design, multicenter study of children and adolescents, 8 to 17 years of age, compared fluvoxamine with placebo treatment. The fluvoxamine-treated group showed a mean drop of about 6 units on the Children's Y-BOCS, compared with a drop of about 3 points in the placebo-treated group. Post hoc analysis suggested a more robust response in the

8-to-11-years-of-age group than in the 11-to-17-year-old group. The significance of this is not clear, though it may suggest the need for earlier treatment.

Major Depressive Disorder Fluvoxamine has been compared with a number of different antidepressants. In a comparison with imipramine (Tofranil) (up to 240 mg a day) or placebo, fluvoxamine (up to 150 mg a day) was more efficacious than placebo in this study of 150 outpatients with major depressive disorder. Among those with more-severe depression (Hamilton Rating Scale for Depression is ³30), there was a suggestion of better efficacy for fluvoxamine. Fluvoxamine has been compared with fluoxetine in a trial of 100 outpatients with major depressive disorder. Fluvoxamine (100 to 150 mg a day) and fluoxetine (20 to 80 mg a day) produced comparable improvement in the 21-item Hamilton Rating Scale for Depression score of close to 60 percent over the course of 7 weeks of study medication.

Panic Disorder In addition to demonstrating efficacy in panic disorder, fluvoxamine decreased anxiety following intravenous yohimbine (Yocon) as a pharmacological challenge in patients with panic disorder after 8 weeks of treatment with fluvoxamine. The posttreatment challenge with yohimbine produced significantly less anxiety than the initial pretreatment exposure.

Social Phobia Fluvoxamine was studied in a small double-blind, placebo-controlled trial of patients with revised third edition of *Diagnostic and Statistical Manual of Mental Disorder* (DSM-III-R) social phobia. Fluvoxamine (150 mg a day) produced improvement in 7 of 15 patients, compared with 1 of 15 in the placebo group, following 12 weeks of treatment.

Other Conditions Fluvoxamine has been used in patients with binge-eating disorders and psychogenic excoriation disorders.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Respiratory System Fluvoxamine appears to have no clinically significant effect on respiratory function. However a drug-drug interaction between fluvoxamine and theophylline (Theo-Dur) is of potential importance in treating the patient with asthma or chronic obstructive pulmonary disease. Increased cough and sinusitis were reported to be frequent (incidence of 1 in 100 or greater) adverse effects in premarketing trials.

Cardiovascular Blood pressure, pulse rate, and electrocardiographs showed no significant difference between patients receiving fluvoxamine and those receiving placebo in premarketing trials. Hypertension, hypotension, syncope, and tachycardia were observed at a frequency of 1 in 100 or greater in premarketing trials.

Blood Administration of fluvoxamine does not appear to have any clinically significant effect on hematological indexes or blood chemistries.

Gastrointestinal Fluvoxamine, like the other SSRIs, may produce nausea, especially with initial dosages. The incidence of nausea in premarketing trials was 40 percent in the fluvoxamine-treated group and 14 percent in the placebo-treated group. Diarrhea or constipation may be less frequent with fluvoxamine than with some of the other selective serotonin reuptake inhibitors (SSRIs). Elevated liver transaminases were reported at a frequency of 1 in 100 or greater in premarketing trials.

Skin Increased sweating is seen in a small percentage of patients receiving fluvoxamine.

Central Nervous System The most commonly observed central nervous system reactions occuring with fluvoxamine treatment are somnolence, insomnia, dry mouth, nervousness, dizziness, tremor, and anxiety. Headache occured at a rate of 22 percent in the fluvoxamine-treated group in premarketing trials which is comparable to an incidence of 20 percent in the placebo-treated groups. Mania or hypomania was observed at a rate of 1 percent, and seizures at a rate of 0.2 percent in premarketing studies among patients receiving fluvoxamine. Both rates are comparable to those seen in trials of other SSRIs.

THERAPEUTIC INDICATIONS

Fluvoxamine is currently indicated for use in the treatment of obsessive-compulsive disorder in both children and adults. Fluvoxamine is approved for use in the treatment of major depression in numerous other countries.

PRECAUTIONS AND ADVERSE REACTIONS

The most common adverse effects observed in premarketing trials were nausea, somnolence, headache (though not at a significantly greater rate than in the placebo-treated group), insomnia, dry mouth, asthenia, nervousness, dizziness, and constipation. In general, the side-effect profile of fluvoxamine is comparable to those of other SSRIs. Patients should be warned of potential medication interactions with fluvoxamine and drugs that are metabolized by the cytochrome P450 (CYP) 1A2 and 3A4 isoenzyme system.

DRUG INTERACTIONS

Fluvoxamine is less tightly protein bound than the other SSRI medications and may be less likely to displace tightly protein-bound drugs. In the P450 system, fluvoxamine is an inhibitor of CYP 1A2, CYP 2C9, and CYP 3A4 isoenzymes. Theophylline, aminophylline (Mudrane) warfarin (Coumadin), propranolol (Inderal), and caffeine metabolism is inhibited through CYP 1A2 by fluvoxamine. Warfarin metabolism is also inhibited through the CYP 2C9 system. Benzodiazepines including alprazolam (Xanax), clonazepam (Klonopin), triazolam (Halcion), and midazolam (Versed) are metabolized by hepatic oxidation via the CYP 3A4 isoenzyme. Approximately twofold elevations in serum concentrations of alprazolam have been observed following coadministration of fluvoxamine. Increased serum concentrations of carbamazepine (Tegretol), clozapine (Clozaril), methadone, propranolol, amitriptyline (Elavil), clomipramine, and imipramine have been reported following the addition of fluvoxamine treatment. The manufacturer warns against the coadministration of fluvoxamine with terfenidine (Seldane), astemizole (Hismanal), or cisapride (Propulsid). All three compounds are inactive prodrugs upon ingestion and require CYP 3A4 activity to produce the active metabolite. Inhibition of metabolism produces an accumulation of precursor that may produce cardiac conduction delay and a potentially fatal torsades de pointes type arrhythmia.

In premarketing trials, smokers demonstrated a 25 percent higher fluvoxamine metabolism than nonsmokers, presumably through induction of CYP 1A2.

Fluvoxamine should not be administered within 14 days of discontinuing treatment with a monoamine oxidase inhibitor (MAOI). A 2-week period should elapse after stopping fluvoxamine treatment and initiating treatment with an MAOI. Caution should be used when combining fluvoxamine, like other SSRIs, with other serotonergic drugs such as sumatriptan (Imitrex) or l-tryptophan.

DOSING AND ADMINISTRATION

Fluvoxamine is available in 25-, 50-, and 100-mg scored tablets. Treatment of adults with obsessive-compulsive disorder is often started at a dose of 50 mg administered at bedtime. The dosage may be increased by 50 mg every 4 to 7 days. The effective dosing range in premarketing trials with obsessive compulsive disorder was 100 to 300 mg a day. The manufacturer suggests dividing the daily dosage if it exceeds 100 mg a day, though many patients tolerate doses larger than 100 mg. Initial upward titration often is easier with a split-dose regimen.

Treatment of obsessive-compulsive disorder in adolescents and children should start at 25 mg a day with 25 mg a day increases every 4 to 7 days. The effective dosing range in premarketing studies was 50 to 200 mg a day. The manufacterer recommends administering 50 mg as a total daily dose and no more than 50 mg as a split dose.

Treatment of elderly patients and those with comorbid medical or hepatic disease should be started at a lower dosage than typically used for adults.

Dosing for disorders other than those for which fluvoxamine is approved in the United States is usually initiated at 25 to 50 mg a day. Patients with major depression typically respond over the range of 100 to 300 mg a day, though often in the range of 100 to 200 mg a day. Treatment of panic disorder is best started at a dosage of 25 mg a day for most patients because of increased sensitivity to adverse effects in this population. The typical effective dosage is usually 100 to 200 mg a day.

CHAPTER 31. BIOLOGICAL THERAPIES

31.25 SELECTIVE SEROTONIN REUPTAKE INHIBITORS

31.25E PAROXETINE

JEFFREY E. KELSEY, M.D., FH.D. AND CHARLES B. NEMEROFF, M.D., FH.D.

HISTORY

Paroxetine (Paxil), the third member of the selective serotonin reuptake inhibitor (SSRI) family approved for use in the United States, became available in 1993. Although initially approved for the treatment of major depression, paroxetine is currently also approved for the treatment of obsessive-compulsive disorder and panic disorder. It is also used for the treatment of social phobia.

The therapeutic efficacy of paroxetine is thought to be due to the reuptake inhibition of serotonin into the presynaptic serotonergic nerve terminal.

CHEMISTRY

Paroxetine is the hydrochloride salt of a phenylpiperidine compound and is structurally distinct from other antidepressants. Paroxetine is designated as (–)-*trans*-4*R*-(4'-flourophenyl)-3*S*-[(3', 4'-methylenedioxyphenoxy) methyl] piperidine hydrochloride hemihydrate. The empirical formula is $C_{19}H_{20}FNO_3 \cdot HCl \cdot 1/2H_2O$, and the molecular weight of the free base is 374.8. The structure of paroxetine is shown in Figure 31.25e-1.

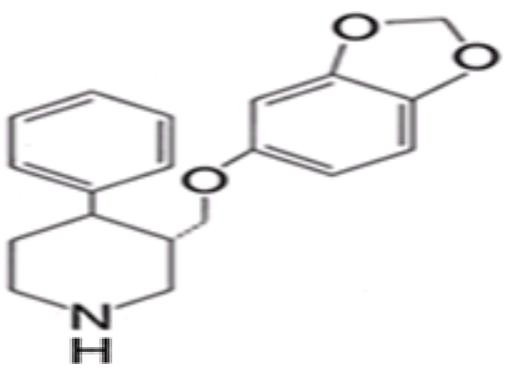

FIGURE 31.25e-1 Molecular structure of paroxetine.

PHARMACOLOGICAL ACTIONS

Absorption Paroxetine is well absorbed orally, and food does not alter absorption. Maximum systemic concentration is achieved approximately 5.2 hours after ingestion.

Distribution Paroxetine, like sertraline (Zoloft) and fluoxetine (Prozac) is tightly bound to serum proteins in vitro, with binding of 95 and 93 percent at plasma concentrations of 100 and 400 ng/mL, respectively. Paroxetine has not been reported to alter the in vitro protein binding of warfarin (Coumadin) or phenytoin (Dilantin). The volume of distribution is about 15 L/kg, and the rate of plasma clearance is close to 79 liters per hour. Most individuals achieve steady state plasma concentrations within 5 to 10 days of dosing.

Metabolism and Elimination The principle path of metabolism for paroxetine is oxidation and methylation. A number of major metabolites have been identified, though none appears to be any more than 1/50th as potent as the parent compound in the in vitro reuptake inhibition of serotonin. A test dose of paroxetine (30 mg) was recovered as 64 percent in the urine (2 percent as parent compound and 62 percent as metabolites over 10 days). In the feces, 36 percent was excreted, with less than 1 percent as the parent compound.

Paroxetine saturates the cytochrome P450 (CYP) system 2D6 isoenzyme and thus exhibits nonlinear pharmacokinetics. Steady-state plasma maximal and minimal concentrations were elevated 6 and 14 times over single-dose values after reaching steady state. This translates into a 24-hour area-under-the-curve value close to eight-fold higher at steady state than would be predicted from a single dose.

In elderly patients, dosing of paroxetine at 20, 30, or 40 mg a day produced plasma concentrations approximately 70 to 80 percent greater than those observed in younger patients. Patients with a creatinine clearance below 30 mL per minute demonstrated a fourfold elevation in plasma concentrations compared with healthy controls. More-moderate renal impairment (creatinine clearance of 30 to 60 mL per minute), as well as patients with moderate hepatic impairment, had a two-fold increase in plasma concentrations. All of the above groups should receive reduced starting dosages of paroxetine (e.g. 10 mg a day).

PHARMACODYNAMICS

Mechanism of Action Paroxetine is believed to exert therapeutic activity by means of serotonin reuptake inhibition within the central nervous system (CNS). The reuptake inhibition of norepinephrine into rat hypothalamic synaptosomal membranes requires a concentration of paroxetine 320 times that necessary for serotonin reuptake inhibition. However, paroxetine is the most potent of the SSRIs in inhibiting norepinephrine, and is in fact more potent than venlafaxine (Effexor), a serotonin-noradrenaline reuptake inhibitor, in this regard. Evidence indicates that at clinically relevant dosages, paroxetine inhibits norepinephrine reuptake. Paroxetine, like other SSRIs also depletes serotonin from blood platelets. In contrast to many tricyclic drugs that downregulate of b-adrenergic receptors in the CNS, paroxetine, like the other SSRIs does not. Terminal serotonin autoreceptors are downregulated following long-term administration of paroxetine, which reflects paroxetine facilitating serotonergic neurotransmission by increasing extracellular fluid serotonin concentrations. This has been posited to play a role in its antidepressant effect and be a critical step in the signal transduction to cellular events that result in altered patterns of gene expression, messenger ribonucleic acid (mRNA) translation, or protein modification.

Paroxetine is essentially devoid of clinically significant affinity for the a_1-, a_2-, or b-adrenergic, dopamine type 2 (D_2), histamine type 1 (H_1), serotonin

(5-hydroxytryptamine [5-HT]) type 1 (5-HT_1) and 5-HT_2 receptors. Paroxetine does have the greatest affinity for muscarinic cholinergic receptors of the available SSRIs, and produces dry mouth, constipation, blurred vision, or urinary hesitancy in a small percentage of patients. However the affinity of paroxetine for muscarinic receptors as measured by inhibition of [^{3}H] quinuclidinylbenzilate binding is 15-fold less potent than that of amitriptyline (Elavil), and its anticholinergic properties may underlie its lack of the diarrhea and loose stools observed with other SSRIs and its occasional sedating properties. Paroxetine is inactive at the cardiac fast sodium channels and has no effect on cardiac conduction. Paroxetine does not inhibit monoamine oxidase activity.

Blood Concentrations and Relation to Action No data suggest the presence of therapeutic concentrations of paroxetine or any correlation between plasma concentrations and subsequent clinical response. Therefore paroxetine plasma concentration determinations are useful clinically only to confirm compliance.

DESIGN AND INTERPRETATION OF CLINICAL TRIALS

Major Depressive Disorder

Clinical Trials Paroxetine has been studied in a large number of subjects with major depression, both in placebo-comparison studies and in those with established antidepressants as the comparison group. Most of these studies have involved healthy outpatients between the ages of 18 and 65. Paroxetine has demonstrated superiority to placebo in several controlled trials in patients with depression. In a pooled analysis of 4 trials involving 273 patients with major depression, paroxetine was superior to placebo in measures of both anxiety and depression. Paroxetine separated from placebo by week 2 and sustained this difference throughout the 6-week trial.

Comparison Trials A number of different trials have compared paroxetine with imipramine (Tofranil). Pooling six studies of similar design in which outpatients with major depression were randomized to treatment with paroxetine (10 to 50 mg a day), imipramine (65 to 275 mg a day), or placebo, both active treatments showed superiority over placebo. Both drugs were equal in efficacy and superior to placebo by week 2, but paroxetine was much better tolerated than imipramine.

Paroxetine has been compared with clomipramine (Anafranil) in a large, international, multicenter study involving 1019 patients with major depression (Montgomery-Asberg Depression Rating Scale [MADRS] score ³20) and associated anxiety (Clinical Anxiety score ³11) randomized to paroxetine 20 to 40 mg a day or clomipramine 75 to 150 mg a day. Only 41 percent of the patients receiving paroxetine and 33 percent of those receiving clomipramine had dosage increases above 20 or 75 mg a day, respectively. After 12 weeks of treatment, assessment with the MADRS and Clinical Anxiety scores demonstrated equal efficacy in the two groups. This contrasts with a Danish study of inpatients with major depression randomized to receive 40 mg a day of paroxetine or 150 mg a day of clomipramine. The clomipramine group demonstrated greater efficacy than the paroxetine group as measured by the Hamilton Rating Scale for Depression (HAM-D). Another comparison study with paroxetine and amitriptyline was performed in 153 hospitalized patients with major depression in Austria and Germany. The average duration of the current episode for most patients was 1 to 3 months. The baseline HAM-D score was 28.6 for the paroxetine group and 28.9 for the amitriptyline group. The mean doses of paroxetine and amitriptyline were 33.3 and 166 mg a day, respectively. Overall improvement was equivalent in the two groups, with response rates (HAM-D reduced to £14) of 66 and 64 percent for the paroxetine and amitriptyline groups, respectively, after 6 weeks. Paroxetine also showed efficacy comparable to that of fluoxetine in a study investigating the treatment of revised third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) major depression in 178 inpatients randomized to receive paroxetine or fluoxetine, both dosed at 20 mg a day. Subjects were from 18 to 65 years of age, with a baseline MADRS score of 24 or above. At the end of 6 weeks the response rates (MADRS score £11) were 67 percent for the paroxetine group and 64 percent for the fluoxetine group.

Paroxetine and nefazodone (Serdone) were compared in the treatment of DSM-III-R major depression in 206 outpatients with moderate severity (18-item HAM-D score ³17). The average age of patients was approximately 38. Paroxetine (mean dosage, 32.7 mg a day) and nefazodone (mean dosage, 472.0 mg a day) showed equal antidepressant efficacy.

The treatment of geriatric depression with paroxetine was compared with treatment with fluoxetine in a 6-week double-blind study of 106 depressed geriatric (age 65 years or above) outpatients. Patients were randomly assigned to paroxetine (20 to 40 mg a day) or fluoxetine (20 to 60 mg a day) following a 3- to 7-day washout period. At week 3, the paroxetine group showed greater improvement in the HAM-D than the fluoxetine group; however, the two groups showed no difference in efficacy by week 6. HAM-D scores at baseline were approximately 29 for the paroxetine group and 28 for the fluoxetine group. Following 6 weeks of treatment, scores of the the paroxetine group had decreased to approximately 20 and of the fluoxetine group to about 23 in the last observation carried forward analysis. Six weeks is generally believed to be too short a time to obtain optimal treatment results in a geriatric population.

Most antidepressant treatment trials involve 4 to 8 weeks of active medication, often following a variable placebo run-in period. Data indicate that paroxetine is effective in sustaining improvement for at least 12 months with efficacy comparable to that of imipramine but with a considerably more favorable side-effect profile. In this continuation study, patients who had responded to paroxetine, imipramine, or placebo were eligible to continue receiving the same drug for 12 additional months. After 1 year, both antidepressants were more effective than placebo in maintaining euthymia, but the imipramine group had twice the rate of dropout due to adverse experiences of the paroxetine group. Recognizing that full improvement often does not occur with 6 weeks of pharmacotherapy, another long-term extension analysis with paroxetine demonstrated continued improvement after the initial 6-week treatment phase. The baseline HAM-D score of 27.9 declined to 13.5 after 6 weeks of paroxetine treatment. After 12 months, the HAM-D score was 6.9 with no new emergence of adverse effects.

Obsessive-Compulsive Disorder Paroxetine has been compared with clomipramine in the treatment of obsessive-compulsive disorder. A randomized, placebo-controlled trial of 406 subjects with obsessive-compulsive disorder of at least 6 months duration found paroxetine (mean dosage 37.5 mg a day) equal in efficacy to clomipramine (mean dosage, 113.1 mg a day) but better tolerated in terms of adverse effects. In this study 51 percent of the paroxetine group received 60 mg a day, and 51 percent of the clomipramine group received 150 mg a day or more. Dosage-finding studies of paroxetine found dosages of 40 and 60 mg a day (but not 20 mg a day) more effective than placebo, as determined by decreases in Yale Brown Obsessive Compulsive Scale (Y-BOCS) scores. Patients with moderate-to-severe obsessive-compulsive disorder with baseline Y-BOCS scores of 23 to 26 demonstrated a mean decrease of 6 and 7 points for the 40 and 60 mg a day dosage, respectively, following 12 weeks of treatment. This was significantly better than the 4-point decrease in the 20 mg a day group or the 3-point reduction observed in the group receiving placebo.

Panic Disorder Three large-scale, placebo-controlled studies demonstrated the efficacy of paroxetine in DSM-III-R panic disorder with or without agoraphobia. The efficacy of paroxetine in reducing the mean number of panic attacks is shown in Figure 31.25e-2. In a 10-week dosage-finding study comparing placebo with 10, 20, or 40 mg a day, only the 40 mg a day dosage demonstrated superiority to placebo. Endpoint analysis showed 76 percent of patients receiving 40 mg a day of paroxetine to be free of panic attacks, compared with 44 percent of the group receiving placebo. In an extension of this study responders continued for 3 months in a double-blind arm of their original treatment and were then randomized to paroxetine 10, 20, or 40 mg a day or placebo for an additional 3 months. Those randomized to paroxetine were significantly more likely to remain in remission than those in the placebo group. A 12-week flexible-dosing study found that paroxetine (10 to 60 mg a day) eliminated panic attacks in 51 percent of participants, compared with 32 percent of the placebo group. The mean paroxetine dosage for study completers was 40 mg a day. A third 12-week flexible-dosing study compared the efficacy of paroxetine (10 to 60 mg a day) plus cognitive behavioral therapy with placebo plus cognitive behavioral therapy in the treatment of panic disorder. At the endpoint of the study, 33 percent of the paroxetine group had 0 to 1 panic attacks per week, compared with only 14 percent of the placebo group. The mean paroxetine dosage for study completers was 40 mg a day.

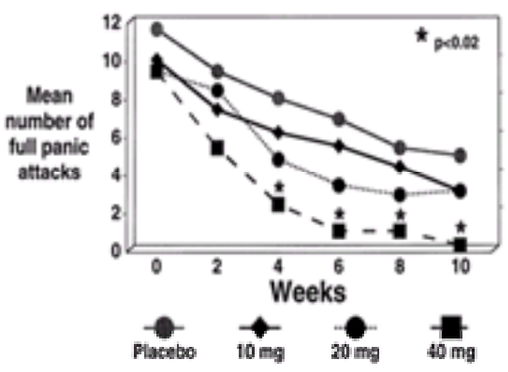

FIGURE 31.25e-2 Paroxetine in the treatment of panic disorder and the mean decrease in number of full panic attacks following treatment with placebo, or paroxetine 10, 20, or 40 mg a day.

Social Phobia An open-label trial of paroxetine (mean final dosage, 36.6 ± 15.0 mg a day) showed efficacy of the SSRI in 15 of 18 subjects rated moderate or marked responders. In another open-label study of paroxetine over 11 weeks, 23 of 30 subjects were considered responders on the basis of a Clinical Global Impressions rating of “very much improved” or “improved.” The mean final dosage of paroxetine was 47.9 ± 6.2 mg a day. Unpublished data derived from placebo-controlled, randomized, double-blind trials reveal the efficacy of paroxetine in the treatment of social phobia. These data are currently being evaluated for submission to the Food and Drug Administration (FDA) to seek approval for the treatment of social phobia.

Premenstrual Dysphoric Disorder Paroxetine has been studied as a treatment for premenstrual dysphoric disorder. In a small, open-label trial, 14 women with moderate-to-severe fourth edition of the DSM (DSM-IV) premenstrual dysphoric disorder with anger and irritability as a central feature were treated with paroxetine. After three active treatment cycles, 7 of 14 patients were given “very much improved” or “much improved” Clinical Global Impressions ratings. The average paroxetine dosage was 22 ± 10 mg a day. In a placebo-controlled comparison study with maprotiline (Ludiomil), a selective norepinephrine reuptake inhibitor and tetracyclic antidepressant, paroxetine (*N* = 22) at a median dosage of 20 mg a day was superior to placebo (*N* = 22) in symptom reduction. Paroxetine was superior to maprotiline (*N* = 22) in reducing symptoms of irritability, increased appetite and carbohydrate craving, bloating, and breast tenderness.

Premature Ejaculation Sexual dysfunction, a common adverse effect of all the SSRIs, takes the form of delayed ejaculation in men and delayed orgasm or anorgasmia in women. In a placebo-controlled trial, paroxetine (40 mg a day) was shown effective in treating premature ejaculation in men.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Respiratory System In placebo-controlled clinical trials, patients receiving paroxetine had rates of yawning and rhinitis of 4 and 3 percent, respectively, compared with 0 percent in the placebo treated group.

Heart and Blood Pressure Paroxetine has not shown any significant effects on heart rate or blood pressure. In a comparison of cardiac effects of paroxetine (20 mg a day) and amitriptyline (150 mg a day), 24 patients with major depression and 24 age and sex matched normal controls were evaluated across a number of cardiac measures. No significant differences were found between the depressed patients and healthy controls in heart rate variability while resting or during deep breathing, spectral analysis of heart rate, the Valsalva test or Posture index. The 24 patients with depression were then randomized to treatment with paroxetine or amitriptyline. Paroxetine elicited no change in any of the indexes in contrast to amitriptyline, which elicited a decrease in all measures but increased heart rate. In a study of patients with comorbid ischemic heart disease and major depression, paroxetine in contrast to nortriptyline (Aventyl, Pamelor) produced no significant alterations in blood pressure, heart rate, cardiac rhythm, or other adverse cardiovascular events.

Blood Paroxetine does not appear to produce any adverse hematological effects.

Gastrointestinal System Nausea is the most common gastrointestinal adverse effect of paroxetine, as it is for the other SSRIs. The incidence of nausea in placebo-controlled trials of paroxetine was usually about 25 percent in the SSRI-treated group. The placebo-treated groups had an incidence of nausea ranging from 9 to 17 percent. Nausea seems to be dose related, and slower escalation of the dosage and ingesting the medication with meals often reduce its incidence. In contrast to other SSRIs, paroxetine seems more likely to produce constipation than diarrhea.

Central Nervous System Like other SSRIs, paroxetine displays CNS adverse effects. Sedation, insomnia, dizziness, and tremor are the most common CNS side effects seen with paroxetine treatment. Both sedation and insomnia can often be easily managed by administering paroxetine at bedtime or in the morning, respectively. Examination of cognitive and motor function have shown no deleterious effects of paroxetine. Paroxetine does not alter the metabolism of alcohol, but as with any CNS active agent, patients should be cautioned about combining the antidepressant with alcoholic beverages.

THERAPEUTIC INDICATIONS

Paroxetine is approved by the FDA for the treatment of major depressive disorder, obsessive-compulsive disorder, and panic disorder. Like many of the other SSRIs it is used in other anxiety and mood disorders such as dysthymic disorder, depression in bipolar disorders, premenstrual dysphoric disorder, social phobia, generalized anxiety disorder, and posttraumatic stress disorder.

PRECAUTIONS AND ADVERSE REACTIONS

The most prevalent CNS effects include headache (although not more frequently than in the placebo group), somnolence, insomnia, and asthenia. In premarket testing, the seizure incidence was 0.1 percent, which is similar to the rate seen with other SSRI antidepressants. Common gastrointestinal adverse effects include nausea, dry mouth, and constipation. Sexual dysfunction was reported to occur at a low rate in the premarketing trials. The actual incidence in clinical practice (as with the other SSRIs) is much higher and consists of delayed ejaculation in men and delayed orgasm or anorgasmia in women as well as occasionally decreased libido. A number of strategies have been suggested to deal with this adverse effect including decreased dosage, drug holidays for shorter-half-life SSRIs, or addition of buspirone (BuSpar) yohimbine (Yocon), amantadine (Symmetrel), cyproheptadine (Periactin), or bupropion (Wellbutrin).

DRUG INTERACTIONS

Potential medication interactions with paroxetine include protein-binding interactions or enzymatic inhibition mediated by the cytochrome P450 isoenzyme system. Paroxetine, like most other SSRIs, is tightly protein bound and may potentially displace other highly protein bound drugs such as warfarin (Coumadin) or digitoxin (Crystodigin). The manufacturer warns that there may be a pharmacokinetic interaction between paroxetine and warfarin that prolongs bleeding, though the prothrombin time is unchanged. Addition of paroxetine (like other SSRIs) to a drug regimen in which tightly protein-bound medications are concurrently prescribed warrants careful observation during dosage adjustment.

Paroxetine is a relatively potent inhibitor of CYP 2D6 but appears to lack clinically significant effects at CYP 1A2, 2C, or 3A4. Coadministration of paroxetine with other medications that are substrates of CYP 2D6 should be approached cautiously, with an awareness of potential increases in serum concentrations of drugs that primarily use CYP 2D6 for metabolism. Examples of CYP 2D6 substrates (see Table 31.25a-3) include the type 1c antiarrhythmics encainide, flecainide (Tambocor), propafenone (Rythmol), and mexiletine (Mexitil) and b-adrenergic receptor antagonists labetalol (Normodyne) metropolol (Lopressor), propranolol (Inderal), and timolol (Blocadren). Atenolol (Tenormin), a cardioselective b-adrenergic receptor antagonist, is renally excreted and exhibits no pharmacokinetic interactions. Codeine is inactive as an analgesic and requires metabolism to morphine via CYP 2D6 to be effective in reducing pain. Inhibition of CYP 2D6 can result in loss of analgesic properties. Paroxetine is both a substrate and an inhibitor of CYP 2D6, but an alternative pathway for its metabolism exists that is not saturated.

Paroxetine, like other SSRIs, should not be administered within 14 days of discontinuing treatment with a monoamine oxidase inhibitor (MAOI). At least 14 days should pass before paroxetine treatment is started after treatment with an MAOI is stopped.

LABORATORY INTERFERENCES

Paroxetine is not known to interfere with any commonly performed laboratory assays.

DOSING AND ADMINISTRATION

Paroxetine is available as 10-, 20-, 30-, and 40-mg tablets. The 20-mg tablets are scored. Treatment for major depressive disorder or obsessive-compulsive disorder is usually initiated at a dosage of 20 mg a day. Taking paroxetine with meals, at least initially, reduces the incidence of nausea, and most patients find this adverse effect transient. Patients with major depressive disorder who do not respond to 20 mg a day can have their dosage increased by 10 mg intervals up to 50 mg a day. In studies that established paroxetine to have efficacy in maintenance treatment, patients received a mean dosage of about 30 mg a day.

The target dosage of paroxetine in the treatment of obsessive-compulsive disorder is 40 mg a day, with most responders receiving 40 to 60 mg a day. The patient's response to treatment of obsessive-compulsive disorder is often slower than that seen in major depressive disorder.

Patients with panic disorder usually tolerate the adverse effects of paroxetine, like antidepressants in general, if paroxetine treatment is started at a lower dosage than is typically used in treating depression. Most panic disorder patients do better if started at an initial dosage of 10 mg a day with gradual titration to a target dosage of 40 mg a day. Dosage increases can be made at the rate of 10 mg a week. The maximal dosage studied in premarketing clinical trials of paroxetine was 60 mg a day.

Other disorders are usually treated with an initial dosage of 10 to 20 mg a day gradually titrated upward. Paroxetine, like the other SSRIs, is well tolerated over a wide dosing range.

SUGGESTED CROSS-REFERENCES

Information relevant to understanding the biochemistry of paroxetine can be found in Section 1.4, on mononamine neurotransmitters, and Section 1.10, on basic molecular neurology. A more general discussion of the biochemistry of mood disorders is found in Section 14.3. Section 14.7 provides an overview of the many treatments for depressive disorders. Section 31.25c and Section 31.25f discuss two other SSRIs, fluoxetine and sertraline. Finally, the use of SSRIs in the treatment of psychiatric disorders is discussed in the relevant chapters (e.g., Chapter 14 on mood disorders, Chapter 15 on anxiety disorders, and Section 51.3d on geriatric mood disorders).

CHAPTER 31. BIOLOGICAL THERAPIES

31.25 SELECTIVE SEROTONIN REUPTAKE INHIBITORS

31.25F SERTRALINE

JEFFREY E. KELSEY, M.D., FH.D. AND CHARLES B. NEMEROFF, M.D., FH.D.

HISTORY

In 1992 sertraline (Zoloft) was the second selective serotonin reuptake inhibitor (SSRI) approved for use in the United States. Initially approved for the treatment of major depression, sertraline is currently also approved for the treatment of obsessive-compulsive disorder and panic disorder.

Sertraline is a member of the SSRI class of compounds that were developed on the basis of the theory that dysregulation of serotonergic circuits within the central nervous system (CNS) occur in depression and that alterations of serotonergic activity by antidepressant compounds mediate their therapeutic responses.

CHEMISTRY

Sertraline's empirical formula is $C_{17}H_{17}NCl_2 \cdot HCl$; it has a molecular weight of 342.7. The structure of sertraline, distinct from that of other SSRIs, is a napthylamine derivative. The chemical designation is (1*S*-*cis*)-4-(3,4-dichlorophenyl)-1,2,3,4-tetrahydro-*N*-methyl-1naphthalenamine hydrochloride and is shown in Figure 31.25f-1.

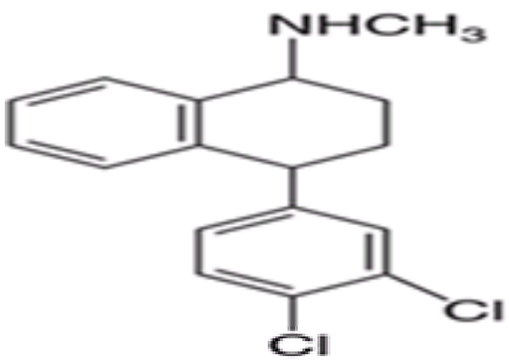

FIGURE 31.25f-1 Molecular structure of sertraline.

PHARMACOLOGICAL ACTIONS

Absorption Sertraline is well absorbed orally, with equivalent absorption from tablets or liquid formulation. Maximum systemic concentration is achieved within 4.5 to 8.4 hours of ingestion following 14 days of dosing in the range of 50 to 200 mg daily. When administered with food, the mean peak plasma concentration is increased by 25 percent, and the peak plasma concentration is achieved 5.5 hours after ingestion rather than 8 hours. Whether this food-related increase in sertraline plasma concentrations is clinically significant in terms of adverse events is unclear.

Distribution In vivo, sertraline is approximately 98 percent bound to serum proteins at concentrations of 20 to 500 ng/mL. The volume of distribution for sertraline is approximately 20 liters per kilogram, and the rate of plasma clearance is 96 liters per hour. The distribution of sertraline into breast milk has been studied in detail. The data suggest that sertraline is present in breast milk and in infant serum, albeit in low concentrations.

Metabolism and Elimination Sertraline undergoes demethylation in the liver to *N*-desmethylsertraline. The half-life of sertraline is 26 hours, and that of *N*-desmethyl sertraline is 62 to 104 hours. However the metabolite is 5 to 10 times less potent in inhibiting serotonin reuptake than the parent compound. Desmethylsertraline displays a five- to nine-fold increase in area under the curve and peak and minimum plasma concentrations following 14 days of sertraline administration. In healthy volunteers, sertraline demonstrates linear pharmacokinetics over the range of 50 to 200 mg a day. Using radiolabeled sertraline in two healthy male subjects, unchanged sertraline was found to constitute less than 5 percent of the plasma radioactivity. After 9 days, 40 to 45 percent of the radioactivity was recovered in urine, but no unchanged sertraline was detected. Another 40 to 45 percent was recovered in feces, of which 12 to 14 percent was unchanged sertraline.

Liver disease is associated with impaired metabolism of sertraline. In a series of subjects with mild, stable cirrhosis of the liver, the mean half-life of sertraline was increased to 52 hours, compared with 22 hours for normal subjects. This suggests the necessity of dosage reduction in individuals with hepatic disease.

Insufficient data are available to assess the effect of renal impairment on sertraline metabolism.

Aging is associated with decreased sertraline clearance. In 16 elderly patients treated with sertraline (100 mg a day for 14 days), the clearance of sertraline was 40 percent lower than that observed in younger (25 to 32-year-old) subjects. Desmethylsertraline clearance was decreased in older males but not females.

PHARMACODYNAMICS

Mechanism of Action The antidepressant effect of sertraline is believed to be due to serotonin reuptake inhibition at the presynaptic nerve terminal. Sertraline is a weak inhibitor of dopamine reuptake but has no effect on norepinephrine reuptake. Sertraline inhibits platelet serotonin reuptake in normal male volunteers in a dosage-dependent fashion. Sertraline also inhibits *p*-chloramphetamine-induced serotonin depletion in the rat brain, which further supports the mechanism of serotonin reuptake inhibition as a mode of action. Short-term administration (hours) of sertraline reduces serotonin turnover in rats, but this effect is not seen following long-term administration. Long-term administration in rats reduces hydrolysis of phosphatidylinositol 4,5-biphosphate, the second messenger that mediates serotonin (5-hydroxytryptamine [5-HT] type 2) ($5\text{-}HT_2$) signal transduction, but without downregulating the receptor. In humans, sertraline at therapeutic dosages (50 to 200 mg a day) does not seem to produce stimulation, sedation, or changes in psychomotor performance.

Like many other drugs in the class, sertraline is essentially devoid of any clinically significant receptor antagonistic properties at the muscarinic cholinergic, histamine type 1 (H_1), a_1-, a_2-, or b-adrenergic, and $5\text{-}HT_1$ or $5\text{-}HT_2$ receptors. Sertraline is about 4 times less potent than paroxetine and 60 times less potent than amitriptyline at inhibiting [3H]quinuclidinylbenzilate binding, which is a measure of muscarinic cholinergic receptor antagonism. Sertraline tends to be significantly better tolerated

than tricyclic drugs. Sertraline also lacks the cardiac fast sodium channel blockade seen with tricyclic drugs and thus demonstrates a superior safety profile with regard to cardiac toxicity than these older agents. Sertraline has no effect on monoamine oxidase activity.

Blood Levels and Relation to Action There does not appear to be a clear relationship between plasma concentrations of sertraline and subsequent therapeutic response.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Major Depressive Disorder Sertraline has been extensively studied in subjects with depression in comparison to placebo and to other antidepressants. Most of these studies have involved healthy adult outpatients 18 to 65 years of age. In a dose-ranging study comparing sertraline at 50, 100, or 200 mg a day with placebo in 369 outpatients with third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) depression, all three dosages in the evaluable patients group (taking study medication for 11 days or more) showed efficacy superior to that of placebo. Females constituted 53 percent of the study population and the mean age of subjects was 37.6 years. Among patients who completed the study, there was a trend for greater improvement in the 100 or 200 mg a day groups, though this did not attain statistical significance. When the data for all patients (as contrasted to study completers) were analyzed, all three sertraline dosage groups had equal efficacy. This may partly be an artifact, since the higher-dosage group had fewer completers (43 percent) than the 50-mg group (62 percent).

Comparison With Other Antidepressants Some 186 outpatients with DSM-III major depression were studied to compare sertraline with the tricycle drug amitriptyline (Elavil). Sertraline (50 to 200 mg a day) was comparable to amitriptyline (50 to 150 mg a day) and had a more benign adverse-effect profile in an 8-week trial. Sertraline was comparable to dothiepin and amitriptyline in two other studies of outpatients with major depression and showed somewhat greater efficacy than imipramine in one study of outpatients with major depression. Sertraline was also demonstrated to possess efficacy comparable to that of moclobemide (Aurorix) in depressed outpatients. In a double-blind, 6-week study of 286 outpatients with revised third edition of DSM (DSM-III-R) major depression (unipolar or bipolar), sertraline (50 to 100 mg a day) and fluoxetine (20 to 40 mg a day) showed equal efficacy.

Depression is a recurrent disorder for many patients. The efficacy of sertraline in preventing the recurrence of a major depressive episode was studied in a comparative study with fluvoxamine (Luvox). Sixty-four patients with a mean age of approximately 50 years and an average of seven lifetime episodes of depression were randomized to receive sertraline 100 mg a day or fluvoxamine 200 mg a day. If a patient's depression worsened (functional impairment and a Hamilton Rating Scale for Depression [HAM-D] score above 15) sertraline was increased to 200 mg a day or fluovoxamine increased to 300 mg a day. The agents were equally effective in this population, with only 7 of 32 sertraline- and 6 of 32 fluvoxamine-treated patients experiencing a recurrence during the 24 months of the study.

Dysthymia Sertraline was shown effective in the treatment of dysthymia. Some 416 patients with revised third edition of DSM (DSM-III-R) dysthymia (271 females, 145 males, aged 25 to 65 years) of at least 5 years duration and without current major depression were randomized to 12 weeks of treatment with sertraline, imipramine (Tofranil), or placebo. The mean duration of illness for all groups was approximately 30 years, with an average age of onset of 12 years of age. The baseline HAM-D scores (17 item) were 12.7 ± 4.0, 13.4 ± 3.8, and 12.7 ± 3.9 for the sertraline, imipramine, and placebo groups, respectively. Both sertraline and imipramine were superior to placebo in improving depression severity ratings, psychosocial function, and quality of life. The mean final dosage of sertraline was 139.6 ± 58.5 mg a day, and of imipramine, 198.8 ± 91.2 mg a day. Sertraline appeared to be better tolerated, with discontinuation rates due to adverse events of 6 percent for sertraline and 18.4 percent for imipramine.

Obsessive-Compulsive Disorder Sertraline is approved by the Food and Drug Administration (FDA) for the treatment of obsessive-compulsive disorder. A placebo-controlled, randomized trial with 50, 100, or 200 mg a day of sertraline in 324 patients with obsessive compulsive disorder without comorbid depression demonstrated efficacy of the 50 and 200 mg a day dosages in a 12-week treatment trial following 1 week of placebo lead-in. Individuals who met entry criteria (National Institute of Mental Health Global Obsessive Compulsive Scale Score ³7 and HAM-D, excluding item 21-obsessions, score £17, and a score of £1 for the depression item) after 1 week of placebo were randomized to 50, 100, or 200 mg a day of sertraline or placebo. Subjects in the two higher dosage groups were titrated upward in dosage to reach 100 mg a day by day 5 and 200 mg a day by day 14. The 100 mg a day dosage differed from placebo in efficacy measures only for the National Institute of Mental Health Global Obsessive Compulsive Scale. A higher dropout rate obtained in the 100 mg a day group (27 of 81) than in the 50 mg a day (17 of 80), 200 mg a day (21 of 80), or placebo groups (24 of 84), which may account for the lack of efficacy in the 100 mg a day group.

Panic Disorder The efficacy of sertraline in panic disorder with or without agoraphobia was assessed in three double-blind, placebo-controlled trials. In two studies, sertraline at mean dosages of 131 and 144 mg a day, was superior to placebo in change from baseline for number of full panic attacks. Sertraline was more effective than placebo in improvement and severity as assessed by the Clinical Global Impression Scale. A third, fixed-dosage study also demonstrated superiority over placebo in panic attack frequency.

Premenstrual Dysphoric Disorder SSRIs are generally considered effective in the treatment of premenstrual dysphoric disorder. In a multicenter, placebo-controlled, double-blind trial with 162 subjects, sertraline produced a positive response (“very much” or “much improved” with the Clinical Global Impression Scale) in 68 percent of patients, compared with 40 percent of those in the placebo group. Dosing of sertraline was 50 mg a day in cycle 1, and the mean dosage were 82 mg a day in cycle 2 and 108 mg a day in cycle 3. By the end of the study 18 percent were receiving 50 mg a day, 48 percent received 100 mg a day, and 34 percent received 150 mg a day of sertraline. In an open-label comparison trial with desipramine (Norpramine) in 32 women with premenstrual syndrome, desipramine (mean dosage, 110 mg a day in the second cycle studied) and sertraline (mean dosage 87 mg a day in the second cycle studied) both improved symptoms. There was a trend (not statistically significant) in favor of sertraline, and the adverse-effect profile favored the SSRI.

Postpartum Depression Sertraline has efficacy in the treatment of postpartum depression. In an open-label trial, 20 of 21 study completers had a decrease of 50 percent or more from baseline in the structured interview for the 21-item HAM-D. Fourteen women obtained remission (HAM-D < 7, CGI = 1, and Global Assessment of Function > 80). The mean daily dosage for the 21 study completers was 109 ± 37 mg a day of sertraline after 8 weeks of treatment.

Posttraumatic Stress Disorder Sertraline had reported efficacy in posttraumatic stress disorder in a pilot, 12-week, open-label study. The mean dosage was 105 mg a day, and 4 of 5 study completers responded. Patients were adult female rape victims with chronic posttraumatic stress disorder, and the completers were on average 41.6 years old and 15.6 years postassault. A large-scale, double-blind trial is currently under way.

Premature Ejaculation Sexual dysfunction, a common adverse effect of all SSRIs, is characterized by delayed ejaculation in males and delayed orgasm or anorgasmia in females. Like fluoxetine (Prozac), sertraline has been studied as a possible treatment for premature ejaculation. In a double-blind, placebo-controlled trial 52 males with self-reported premature ejaculation were randomized to either placebo or sertraline (50 to 200 mg a day) for 8 weeks. Sertraline was more effective than placebo in prolonging latency to ejaculation (self-report), number of successful attempts at intercourse, and overall self-rated improvement.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Sertraline appears to be quite well tolerated in general, with only 15 percent of over 2500 patients in premarketing trials discontinuing because of adverse events. The higher dosages had more dropouts than the lower doses, which may partly reflect forced titration schedules, which are often more aggressive than those in clinical practice.

Heart and Blood Pressure Sertraline has not been found to alter cardiac rhythm or blood pressure significantly. Individuals with existing cardiac disease were excluded from premarketing trials, but no changes on electrocardiograms were noted with treatment. Treatment with sertraline in premarketing trials was associated with a 3 percent increase in total cholesterol and a 5 percent increase in triglycerides.

Blood Abnormal bleeding or bruising has been reported in patients taking SSRIs, including sertraline, but appears to be relatively rare. In premarketing trials sertraline possessed a weak uricosuric effect, with a mean decrease in uric acid of 7 percent. The clinical significance of this, if any, is unclear. Hyponatremia has been re ported after treatment with sertraline and other SSRIs; this effect is reversed upon discontinuation of sertraline and may be secondary to the syndrome of inappropriate antidiuretic hormone secretion. Groups at risk include elderly patients, patients concomitantly treated with diuretics, and patients who were volume depleted.

Gastrointestinal System The incidence of nausea in controlled clinical trials is higher for sertraline than for placebo (26.1 vs. 11.8 percent). In a pooled analysis of placebo-controlled trials about 4 percent of patients taking sertraline experienced an increase or decrease of 7 percent of body weight or more; however, the difference from the placebo groups was not statistically significant. Sertraline also was associated with a higher (17.7 percent) incidence of diarrhea than placebo (9.3

percent) in premarketing trials and likely higher than that observed with fluoxetine or paroxetine.

Skin Approximately 2.1 percent of participants and 1.5 percent of the placebo group in premarketing trials experienced rash. Excessive sweating was reported with sertraline at a rate three time (8.4 versus 2.9 percent) that seen in the placebo treatment groups.

Central Nervous System In premarketing trials, sertraline produced no greater incidence of headache (20.3 vs. 19.0 percent) than placebo. Insomnia, somnolence, agitation, nervousness, anxiety, yawning, and impaired concentration were all reported more often in the sertraline group than the placebo group. The incidence of dizziness, tremor, twitching, hypoesthesia, and hypertonia were also all greater in the sertraline treated group than in the placebo group.

Sexual Dysfunction The reported incidence of sexual dysfunction in sertraline-treated individuals was 15.5 percent for males (2.2 percent in placebo group) and 1.7 percent for females (0.5 percent), though in clinical practice, it is now clear that sertraline and all other SSRIs produce significantly higher rates of sexual dysfunction.

THERAPEUTIC INDICATIONS

Sertraline is currently approved by the FDA to be marketed for use in major depressive disorder, obsessive-compulsive disorder, and panic disorder. Like other newer-generation antidepressants, sertraline is also used in other affective and anxiety disorders including dysthymia, premenstrual syndrome, social phobia, posttraumatic stress disorder, and generalized anxiety disorder.

PRECAUTIONS AND ADVERSE REACTIONS

The most commonly experienced CNS effects include headache (but not greater than placebo), insomnia, somnolence, dizziness, and tremor. Common gastrointestinal system adverse effects include nausea, diarrhea, and dyspepsia. Nausea is generally tolerated over time and can be minimized by administration with food, even though this strategy increases maximal serum concentrations of sertraline. Sexual dysfunction was reported at a low incidence in the premarketing trials. The actual incidence in clinical practice is much higher and consists of delayed orgasm or anorgasmia as well as decreased libido. A number of strategies have been suggested to deal with this important adverse effect including decreased dosage, drug holidays for shorter half-life SSRIs or addition of buspirone (BuSpar) amantidine (Symmetrel), yohimbine (Yocon), cyproheptadine (Periactin), or bupropion (Wellbutrin).

Drug Interactions Sertraline, like fluoxetine and paroxetine (Paxil), is tightly bound to serum proteins, and the manufacturer warns about a potential interaction between sertraline and other tightly protein bound drugs such as warfarin (Coumadin) and digitoxin (Crystodigin). Good clinical practice dictates checking serum concentrations or activity when an antidepressant with high protein binding is added to a tightly protein bound drug with a low therapeutic index. Most assays do not differentiate between bound and free drug, so functional assays such as prothrombin time with warfarin are a better indicator.

Sertraline should not be combined with a monoamine oxidase inhibitor (MAOI). At least 14 days should pass after discontinuation of treatment with an MAOI before sertraline is taken. Similarily, MAOI treatment should not be started in someone taking sertraline until the SSRI has been discontinued for at least 14 days.

Sertraline inhibits the cytochrome P450 (CYP) 2D6 isoenzyme. Inhibition of CYP 2C has potential clinical significance when sertraline is coadministered with tolbutamide (Orinase), an oral hypoglycemic drug. It does not inhibit either CYP 1A2 or CYP 3A4.

LABORATORY INTERFERENCES

Sertraline does not interfere with any laboratory measures.

DOSING AND ADMINISTRATION

Sertraline is available in scored tablets of 25-, 50-, and 100-mg strengths. Initial dosing for major depression and obsessive-compulsive disorder is typically 50 mg a day, with escalation to 100 mg a day after 4 to 7 days of treatment. Patients may require higher dosages. In a 6-week trial of sertraline in major depression the mean dosage for study completers was 145 mg a day. However, in a double-blind, placebo-controlled, continuation trial after 8 weeks of open-label treatment, the mean dosage for study completers after 44 weeks was 70 mg a day. Studies of sertraline in double-blind, placebo-controlled trials for obsessive-compulsive disorder have had mean dosages of approximately 185 mg a day.

Patients with panic disorder often require lower starting dosages of antidepressants than do others. A starting dosage of 25 mg a day with sertraline for 4 to 7 days followed by upward dose titration is a reasonable approach. The mean dosage of sertraline in double-blind, placebo-controlled trials for panic disorder was approximately 140 mg a day.

The dosage range of sertraline in most patients who have affective or anxiety disorders is 100 to 200 mg a day, though some patients respond to 50 mg a day. More-gentle titration is required for the very anxious patient or one who is very sensitive to adverse effects. Initial administration with meals often decreases initial and transient adverse effects.

SUGGESTED CROSS-REFERENCES

Additional information regarding monoamines and their receptors appears in Section 1.4. The basic electrophysiology of neurons is discussed in Section 1.9. The classification of mental disorders is discussed in Chapter 9, and mood disorders in geriatric patients in Section 51.3d. The biochemical basis of mood disorders is discussed in Section 14.4. Lithium therapy is discussed in Section 31.18, and the biological treatment of mental illness in elderly adults in Section 51.4.

31.26 SEROTONIN-DOPAMINE ANTAGONISTS

DANIEL P. VAN KAMMEN, M.D., FH.D., AND STEPHEN R. MARDER, M.D.

After more than 40 years of dopamine receptor antagonists with often unavoidable extrapyramidal side effects, newer antipsychotic drugs have become available that have no or minimal extrapyramidal adverse effects, and greater efficacy. These are the serotonin-dopamine antagonists (SDAs), named for their alleged mechanism of action. These agents will have a wider utility in psychiatry than the traditional antipsychotic drugs and could be used as mood stabilizers.

Clozapine (Clozaril) was the first antipsychotic agent with negligible extrapyramidal adverse effects and enhanced efficacy to be available in the United States. Introduced in 1990, it heralded a new era in the treatment of schizophrenia, even though clozapine had been available in Europe from the early 1970s. Fortunately for our patients, the animal models for antipsychotic efficacy based on dopamine receptor blockade were not fully established at that time. If cataleptogenic, antiamphetamine and antiapomorphine animal models had been used to test the agent for potential antipsychotic effects, the test results could have led to the rejection of clozapine for clinical trials.

The success of clozapine has inspired development of new and safer antipsychotic agents. The many unpleasant adverse effects, weekly blood sampling, and high cost of clozapine treatment made alternative drugs attractive. Several other drugs are now available, such as risperidone (Risperdal), olanzapine (Zyprexa), and quetiapine (Seroquel), and others will be approved soon (e.g., aripiprazole). Sertindole (Serlect, Serdolect) is available in Europe but not in the United States. Similarly, ziprasidone was not approved in the United States. Other agents with different mechanisms of action are currently being developed. The terms *typical* and *atypical* will lose their meaning, as these new agents become the treatment of choice. The terms *traditional, conventional*, or *first-generation drugs* for the preclozapine dopamine antagonists and *novel* or *second-generation* antipsychotic agents for SDAs may be preferable to the *typical* and *atypical* agents.

Compared with the traditional agents, all second-generation agents have a higher ratio of serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT $_2$) to dopamine type 2 (D_2) receptor blockade and a greater specificity for the mesolimbic than the striatal dopamine system. These new agents showed selectivity for the limbic system in electrophysiological studies (percentage of silent dopamine neurons with chronic treatment) and animal tests (low catalepsy in rodents, and low extrapyramidal adverse effect liability in nonhuman primates). In contrast, traditional antipsychotic agents affect both the limbic and striatal dopamine neurons, which frequently results in extrapyramidal effects at therapeutic doses.

All the new agents are first-line drugs, except clozapine because of its adverse effects and the required weekly blood sampling. Preliminary data show that negative symptoms may respond better to the newer agents (at least risperidone, olanzapine, ziprasidone, sertindole, and quetiapine). Because negative symptoms are a critical determinant of the social and vocational outcome of schizophrenia, these newer agents should improve quality of life. However, whether the difference results from some intrinsic effects of the drug or can be accounted for by the lack of striatal dopamine type 2 (D $_2$) blockade is unclear. The SDAs are more expensive than conventional agents, which has lead to extensive campaigns to ensure that these agents are available for patients who need them. The high costs of the new agents require justification for their usage. Initial pharmacoeconomic studies of these agents suggest that increased efficacy (e.g., decreased rehospitalization rates and bed days of care) may offset the higher costs, particularly in the second year of treatment (e.g., with clozapine and risperidone). Other studies question this decrease in other costs.

Some intriguing observations, such as lower suicidality (during clozapine treatment), less smoking, lower water intoxication risks; continued improvement potential up to 2 years; and decreased or absent risk of tardive dyskinesia require careful evaluation. Additional benefits include the possibility of better long-term outcomes than with conventional agents, diminished relapse risk, and improved quality of life. So far weight gain has been the major adverse effect of the SDAs. This chapter considers clozapine and five other SDAs in order of their historical appearance on the market, not their potential importance. Because clozapine and risperidone have been on the market for the longest time, more is known about these drugs than about the others.

CLOZAPINE

Clozapine was the first SDA to be approved. Its greater efficacy in schizophrenia, effect in treatment-resistant patients, and low risk for extrapyramidol effects changed the thinking about what antipsychotic drugs could do in schizophrenia. However, the adverse effects of clozapine, ranging from dangerous (agranulocytosis and seizures) to clearly uncomfortable (e.g., constipation, sedation, hypersalivation), created the need to search for similar agents. Its adverse-effect profile keeps it from being prescribed for first-episode patients. At this time clozapine remains the gold standard for treatment of treatment-resistant patients. Studies will soon appear that will show whether clozapine nonresponders respond to other SDAs.

History Clozapine was discovered in 1958 in Bern, Switzerland. Clozapine was first studied in animal experiments in May 1960. In 1972 clozapine was put on the market in Switzerland and Austria. Soon after clinical trials with clozapine began, the drug appeared to be an effective antipsychotic agent that did not cause extrapyramidal effects. The first studies showed that patients became calmer in the first 5 days, and psychotic excitement decreased from day 5 on. Day 20 effects on psychosis were substantial, and negative symptoms improved at 40 days. However, the drug had significant hematological toxicity. In 1975, clozapine was introduced in Finland, where 16 of 1600 treated patients developed granulocytopenia (£1600 cells per mm ^{3}). Eight of the 13 patients in whom granulocytopenia progressed to agranulocytosis died of infectious diseases. After 50 patients around the world had died, clozapine was withdrawn from most European markets, and research with this drug came to a virtual halt. Some patients who were receiving clozapine before its withdrawal from the market continued to receive the drug because of its clear advantages over prior treatment. Regular monitoring of white blood counts in these individuals showed that clozapine-induced agranulocytosis was reversible when drug use stopped. In addition, controlled trials in Europe showed that clozapine was more effective than conventional agents for treating schizophrenic patients who were either severely ill or resistant to other antipsychotic agents.

Discussions with the Food and Drug Administration (FDA) led to a US multicenter trial to determine whether clozapine was effective for treatment-refractory patients. The effectiveness of clozapine was compared with that of chlorpromazine (Thorazine) in 268 schizophrenia patients with thoroughly documented failure to respond to conventional antipsychotic agents. Because of this trial, the FDA approved clozapine in 1990 for schizophrenia patients who are resistant to treatment with other antipsychotic drugs or who are unable to tolerate conventional drugs because of extrapyramidal effects or severe tardive dyskinesia. Treatment resistance is not a well-defined concept and may include patients with distressing residual symptoms. This is important because patients with schizophrenia who improve substantially with traditional antipsychotics frequently retain positive and negative symptoms that impair their adjustment in the community. Such residual symptoms make these patients eligible for clozapine. The clinician and patient are left with the difficult task of weighing clozapine's substantial advantages against its problems, which include the risk of agranulocytosis and sudden death, seizure, adverse effects such as sedation and weight gain and weekly blood monitoring. The newer agents should probably be tried first.

Chemistry Clozapine is a five-membered heterocyclic compound, 8-chloro-11-(4-methyl-1-piperazinyl)-5 *H*-dibenzo-[*b,e*][1,4]diazepine (Fig. 31.26-1). Its chemical formula is $C_{18}H_{19}N_4Cl$, and molecular weight is 326.8. Substitutions for the A-ring have led to other clinically effective clozapine-like agents; however, loxapine (Loxitane), an antipsychotic agent with a clozapine-related molecular structure, has a clinical and adverse-effect profile similar to that of other traditional antipsychotic drugs. Recent studies suggest that loxapine may be effective in lower-than-recommended dosages and may actually be an SDA. Other clozapine-derived antipsychotic agents are olanzapine and quetiapine, but being a derivative does not mean similar efficacy.

Pharmacological Actions

Pharmacokinetics The pharmacokinetic profiles of clozapine and other SDAs in special populations are summarized in Table 31.26-1.

Drug	Elderly	Renal Impairment	Hepatic Impairment	Ethnic
Clozapine	↓ dosage	No ↓ dosage	↓ dosage	↓ dosage women
Risperidone	↓ dosage	↓ dosage	↓ dosage	↓ dosage Asians/ CYP 2D6
Olanzapine	↓ dosage (33%)	No ↓ dosage	No ↓ dosage (preliminary)	↓ dosage women ↓ dosage Asians/
Sertindole	No ↓ dosage PD concerns	No ↓ dosage	↓ dosage (1/2)	↓ dosage women CYP 2D6 polymorphism
Quetiapine	NO PK ↓* ↓ dosage ↓* PD	No ↓ dosage	Slight ↓ dosage	No ↓ dosage
Ziprasidone	No ↓ dosage	No ↓ dosage	No ↓ dosage	?

Abbreviations: PD, pharmacodynamic; PK, pharmacokinetic; ↓, change in; CYP2D6, cytochrome P450 system 2D6 polymorphism (three drugs may delay the therapeutic response in CYP2D6, poor metabolizers. Poor metabolizers indicated by this genetic polymorphism include 4 to 10% of whites and smaller proportion of Asians and African-Americans.
*Increased adverse reactions (as thioridazine)
Modified from Hendlin Y: Pharmacokinetics and drug interactions: Update on new antipsychotics. J Clin Psychiatry 57(Suppl 11), 1996.

Table 31.26-1 Changes in Pharmacokinetics: Special Populations

ABSORPTION Clozapine is only available as an oral preparation. As with other antipsychotic agents, peak plasma concentrations are reached approximately 2 hours after oral administration (range, 1.1 ± 0.5 to 3.0 ± 1.5 hours). The elimination half-life is about 12 hours (between 10 and 16 hours; range, 6 to 33 hours). As a result, twice-daily dosing results in steady-state plasma concentrations in less than 1 week. Based on animal studies, coadministration of highly protein bound drugs may increase free clozapine concentrations, although the total concentration (free plus bound) may be unchanged.

DISTRIBUTION Clozapine has a lower volume of distribution than other antipsychotic drugs, but it is large, with a mean of 2.0 to 5.1 L/Kg (range, 1.0 to 10.2 L/Kg).

METABOLISM AND ELIMINATION Clozapine undergoes extensive first-pass metabolism in the liver and gut. Absolute bioavailability (the percentage of clozapine reaching the systemic circulation unchanged) after oral administration varies from 27 to 47 percent. Demethylation and oxidation of the terminal nitrogen of the piperazine side chain form the two main metabolites. These *N*-demethyl and *N*-oxide metabolites are cleared as fast as or faster than clozapine. Reportedly, 80 percent of administered clozapine appears in the urine or feces as metabolites. Less than 5 percent of the parent compound is found unchanged in the urine.

Pharmacodynamics

MECHANISM OF ACTION Clozapine is considered a novel, or atypical, antipsychotic drug because of its biological and clinical profile. It has a relatively low affinity for D_2 receptors and a high affinity for 5-HT_2 receptors, with a low propensity for extrapyramidal adverse effects. Preclinical studies in rats showed that clozapine blocks the conditioned avoidance response, indicating that the drug has potential antipsychotic activity. On the other hand, it did not produce catalepsy in animals, suggesting that it is unlikely to produce extrapyramidal symptoms in man. This made it different from conventional antipsychotic medications, which all cause extrapyramidal effects as a direct result of their D_2 dopamine receptor blockade in the forebrain. The relatively low affinity for D_2 receptors (Fig. 31.26-2) may explain clozapine's lack of extrapyramidal effects. Positron emission tomography (PET) scan studies have shown that with doses comparable to 10 mg of haloperidol (Haldol), more than 80 percent of striatal D_2 receptors are occupied. Higher doses do not increase receptor occupancy further. Clozapine in clinically effective dosages occupies only 40 to 50 percent of D_2 receptors. This weak effect at the D_2 receptor site may be related to clozapine's unusual biological profile that combines a low D_2 affinity with activity at a number of other receptor sites including serotonergic (e.g., 5-hydroxytryptamine [5-HT]) type 2 (5-HT_2), 5-HT_{1c}, adrenergic, and cholinergic sites.

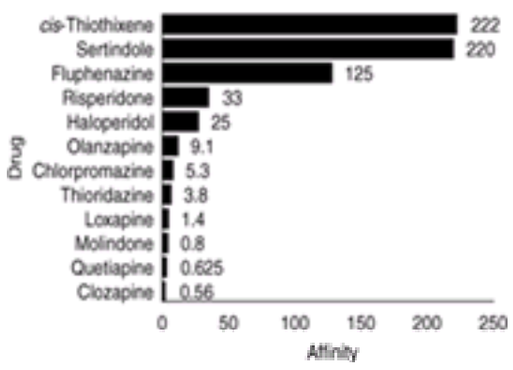

FIGURE 31.26-2 Neuroleptic and dopamine D_2 receptor blockade. Affinity is expressed as 10^7 $1/K_d$, where K_d = equilibrium dissociation in molarity. (Reprinted with permission from preclinical pharmacology of neuroleptics. J Clin Psychiatry *57*(Suppl):5, 1996.)

Several hypotheses address the mechanism of action of clozapine. Because its D_2 receptor activity is lower than that of traditional antipsychotic agents and its 5-HT_2 receptor blockade is stronger than that of haloperidol, Herbert Meltzer has proposed that the differential antipsychotic effect of clozapine is related to its low D_2 to 5-HT_2 ratio. Clozapine's affinity for the 5-HT_2 receptor is among the highest for antipsychotic agents. An alternative hypothesis proposes that clozapine is effective because it has a selective preference for the mesolimbic dopamine system. D_2-receptor blockade in the striatum by conventional agents may interfere with their antipsychotic effects and induce negative symptoms. Others have focused on clozapine's stronger 5-HT_3 blockade and its stronger a_1-adrenergic receptor and a_2-receptor blockade. Other differences include its stronger affinities for histamine type 1 H_1 receptors and for acetylcholine muscarinic receptors but lower affinity for sigma receptors than haloperidol (Table 31.26-2). All values are expressed as nanomoles of the drug needed to replace 50 percent of the radio-labeled receptor ligand (i.e., the inhibitory constant [IC_{50}]). IC_{50} values may vary between laboratories and are sometimes conflicting. Clozapine also has a 10-fold higher affinity for the

D_4 dopamine receptor than other antipsychotic agents. The D_4 receptor is present in the cortex and less so in the striatal areas. Which receptor system is responsible for the clinical difference between conventional and novel antipsychotic agents remains unknown.

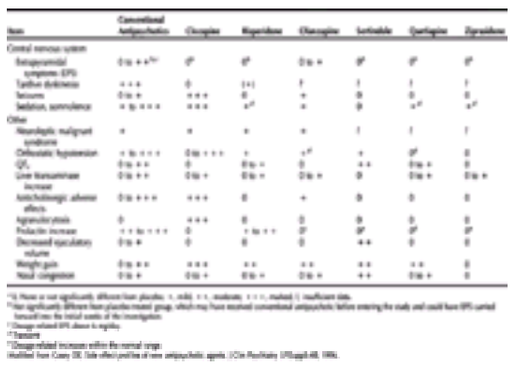

Table 31.26-2 Adverse Effects of Antipsychotic Agents[a]

BLOOD CONCENTRATIONS AND RELATION TO ACTION As with most antipsychotic drugs, patients display considerable variability in their clozapine plasma concentrations—about 45-fold among patients receiving the same daily dose. This probably results from differences in both absorption and metabolism. Variability is also observed within patients, which is presumably related to variable absorption rates rather than changes in hepatic metabolism and clearance. Some reports show that women have slightly higher plasma concentrations, and smokers slightly lower (20 to 30 percent). Older adults may have twofold higher levels than young adults.

Several investigators studied the relation between plasma concentrations of clozapine and clinical response. Their findings suggest that monitoring the clozapine concentration in plasma may be useful under certain conditions. A wide range of clozapine concentrations appears to be associated with clinically meaningful response. Plasma concentrations of clozapine average about 10 to 80 ng/mL per mg of drug given per kilogram of weight. Thus, a typical daily dosage of 300 to 400 mg (about 5 mg/kg) is associated with plasma concentrations ranging from 200 to 400 ng/mL. Studies indicate that patients are more likely to respond when their clozapine plasma concentrations exceed 350 ng/mL. If patients with a plasma concentration of 250 ng/mL have not responded by 6 weeks, the clinician should adjust the dosage to raise the concentration to approximately 350 ng/mL. The likelihood of response to concentrations above 350 ng/mL is small; therefore, patients with high concentrations who exhibit adverse effects may benefit from having their dosage reduced. The correlations between plasma concentration and clinical improvement or adverse effects are weak, as is observed with other antipsychotic agents.

Design and Interpretation of Clinical Drug Studies

Design Open clinical trials conducted in the early 1970s suggested that clozapine was an effective antipsychotic drug that lacked extrapyramidal effects. Double-blind trials then provided further evidence of this drug's unique properties; however, to date no double- blind trials comparing clozapine with a placebo have been reported. In 79 percent of the controlled trials that compared clozapine with another antipsychotic drug, clozapine was superior. In reviewing these studies Ross Baldessarini cautions that the differences between clozapine and the comparison drug were relatively small. Nevertheless, certain patterns emerge. One comparison with chlorpromazine found a small advantage favoring clozapine when a heterogeneous group of patients was studied, but differences favoring clozapine were greater when the most severely ill subgroup was studied. Another study compared haloperidol use with clozapine use in more severely ill and treatment-refractory patients and found a clear advantage of clozapine over haloperidol. One study comparing clozapine with risperidone found no differences in clinical response at the end of 6 weeks. Response to risperidone came sooner, but some extrapyramidal effects were observed with risperidone. Few treatment-refractory patients were included. In summary, these studies suggest that clozapine may be particularly effective for a subgroup of schizophrenic patients who are both severely ill and refractory to treatment with conventional drugs. Whether or not clozapine is more effective in acutely psychotic patients who are likely to respond to conventional antipsychotics is unclear. A study from New York suggests, however, that clozapine also has advantages in these patients. In a US multicenter study of patients who had tardive dyskinesia or were sensitive to extrapyramidal effects, clozapine was superior to chlorpromazine. Double-blind comparison studies with clozapine are difficult to do. The weekly blood sampling and the adverse-effect patterns make it difficult to maintain the double blind with drugs that have so few side effects. Clozapine and other SDAs tend to show their greatest advantages over traditional antipsychotic agents during the second year, when lower hospitalization rates and fewer cognitive effects are noted; however, compliance may improve when patients experience fewer adverse effects.

Efficacy in Treatment-Refractory Patients Clinical experience with clozapine suggested that it was more effective than conventional drugs for patients who were unresponsive to conventional antipsychotic agents. Before marketing clozapine for these patients, the FDA and the manufacturer of clozapine developed a study comparing clozapine with chlorpromazine plus benztropine (Cogentin). The 268 patients in this trial had previously responded poorly in at least three prior antipsychotic agent trials and a prospective single-blind trial of haloperidol. This study compared the effectiveness of chlorpromazine and clozapine in 248 patients who had thorough documentation of poor responsiveness to conventional antipsychotics. During this 6-week trial, the clozapine-treated patients did better on a range of measures of both positive and negative symptoms. Thirty percent of clozapine-treated patients met a priori criteria for significant improvement in contrast to only 4 percent of chlorpromazine-treated patients. Other studies show that this 6-week trial may have significantly underestimated the proportion of patients who respond to clozapine and that up to 60 percent of patients may display substantial improvement following a 6-month trial. Clozapine in this trial was superior to chlorpromazine on 14 of 18 Brief Psychiatric Rating scale items, as well as on the Clinical Global Impression and such nursing ratings as Social Competence, Social Interest, Personal Neatness, Irritability, Manifest Psychosis, and Motor Retardation. When patients were classified as having improved (by prospective criteria) to a clinically significant extent, 30 percent of clozapine patients improved within 6 weeks versus only 4 percent of those receiving chlorpromazine and benztropine ($p < .001$). Based on this trial, the FDA approved clozapine for limited use in the United States.

Long-Term Effectiveness All of the long-term studies with clozapine have been uncontrolled or retrospective. Nevertheless, they provide further support for the unique properties of this drug. For example, patients who received clozapine for up to 13 years were more likely to be discharged and remain out of the hospital. In a European study, patients who received clozapine for at least 2 years increased their rate of employment from 3 to 40 percent. However, none of the reported long-term studies included random assignment and controlled comparisons with conventional treatment or other SDA treatment. Thus the impact of clozapine on the long-term outcome of patients—one of the most compelling questions in the therapeutics of schizophrenia—requires more study. In the meantime Novartis has started a 2-year evaluation of clozapine versus olanzapine in effectiveness against suicidality.

Therapeutic Indications The second author (Steven Marder) and Ted Van Putten suggested before the arrival of other SDAs that three populations of patients with schizophrenia were obvious candidates for clozapine: (1) patients with severe schizophrenic symptoms that respond poorly to conventional antipsychotic medications; (2) patients with severe tardive dyskinesias; and (3) patients who suffer from severe extrapyramidal effects at doses of conventional antipsychotic drugs that are necessary for treating their symptoms. Because the concept of treatment resistance will change with the newer SDAs, the authors suggest that groups 1 and 2 should be replaced by patients who have not responded to other SDAs. An off-label indication may be severe suicidality.

Treatment-Resistant Patients Patients with severe positive symptoms despite treatment with adequate dosages of antipsychotic agents are probably the largest group of candidates for clozapine treatment. These patients may be inpatients or outpatients who are suffering from continuous psychotic symptoms. The findings from John Kane and coworkers' multicenter trial indicate that about one-third of these patients will show significant improvement at 6 weeks, and 60 percent will at 5 to 6 months. In the authors' experience these patients show a range of improvements. Some recover from all or nearly all of their positive symptoms. These patients are then challenging candidates for psychosocial rehabilitation programs. Others demonstrate substantial improvement in psychotic symptoms but still suffer lingering schizophrenic experiences that resist even clozapine treatment. For these patients too, clozapine is a better antipsychotic agent, with fewer adverse effects. Others fail to show substantial improvement with clozapine and may prefer the adverse effects of conventional drugs to those of clozapine and its required participation in the blood-monitoring system.

Severe Tardive Dyskinesia Patients with severe tardive dyskinesias should also be considered for a clozapine trial. Most clinical reports indicate that clozapine can suppress abnormal movements in tardive dyskinesia. This is not surprising since conventional antipsychotic agents are effective in short-term suppression of tardive dyskinesia. However, clozapine is probably less likely to cause the disorder and therefore is promising for the long-term management of patients, particularly those who already have tardive dyskinesia. Although rare cases of tardive dyskinesia have been found in patients who receive clozapine, the risk of developing tardive

dyskinesia is substantially reduced. Studies with animal models indicate that clozapine does not evoke the increased sensitivity of striatal D_2 receptors that is associated with typical antipsychotic agents, which has been theorized to result in tardive dyskinesia. It remains to be established whether a positive effect on tardive dyskinesia results from a direct effect of clozapine on certain transmitter systems or whether clozapine spares the striatal D_2 receptors, which allows spontaneous remission of tardive dyskinesia. The former interpretation is supported by the reports of a return of tardive dyskinetic movements following clozapine withdrawal. None of the SDAs has shown evidence of inducing tardive dyskinesia.

Patients With a Low Extrapyramidal Adverse Effect Threshold Another group of schizophrenic patients who may be reasonable candidates for clozapine are those who develop severe extrapyramidal adverse effects—particularly, severe akathisia—when they receive relatively low doses of conventional antipsychotic drugs. The benefits of antipsychotic treatment are often only obtained at the price of severe discomfort and dysphoria that is not adequately responsive to antiparkinson medications or propranolol (Inderal). The incidence of akathisia is considerably lower with all SDAs.

Schizoaffective Disorder, Treatment-Resistant Mania, and Severe Psychotic Depression A number of early clinical trials of clozapine that included patients with schizoaffective disorder, treatment resistant mania, and severe psychotic depression suggested that clozapine is effective. Several reports suggest that clozapine is effective in treatment-resistant mania, and a consensus is developing that mania responds well to clozapine. A recent trial in patients with psychotic depression indicates that clozapine is effective with those patients as well.

Neurological Illnesses Clozapine has also found uses in patients with neurological disorders. It has been used in idiopathic Parkinson's disease to treat psychotic symptoms that are secondary to levodopa (Larodopa). These patients may respond to relatively low daily dosages of clozapine (25 to 75 mg). Higher dosages (e.g., 100 to 250 mg a day) may exacerbate the parkinsonian symptoms. A case report described a patient with both schizophrenia and Parkinson's disease who was successfully treated with levodopa and 300 mg daily of clozapine. Other reports suggest that clozapine may be useful for tremors in Parkinson's disease, alcohol-related disorders, and benign essential tremor. Patients with Huntington's disease have also responded positively to clozapine. More studies are needed to clarify the role of clozapine in the treatment of neurological disorders. When experience with risperidone, olanzapine, quetiapine, sertindole, and ziprasidone increases, those drugs might become the preferred agents because of their more benign adverse-effect profile.

Treatment Resistance in Other Disorders Treatment-resistant patients with a pervasive developmental disorder, autistic disorder, or obsessive-compulsive disorder have responded well to clozapine, either by itself or in addition to their regular treatment. However, the data on obsessive-compulsive symptoms are somewhat in doubt because some patients may worsen, particularly with concomitant use of selective serotonin reuptake inhibitors (SSRIs). Children with these severe psychiatric illnesses may respond well also.

Severely Suicidal Patients With Schizophrenia or Schizoaffective Disorder Patients who are severely suicidal or agitated with schizophrenia, affective disorders, mental retardation, or dementia become candidates for clozapine treatment. Schizophrenia carries a 9 to 13 percent lifetime risk of suicide, with a projected 0.4 to 1 percent per year. In a 1995 study, the authors reported that suicidality decreased markedly with reduction in depression and hopelessness. Treatment resistance was unrelated to the decrease in suicides or suicidality. Novartis is presently conducting a study in schizophrenia patients with suicidal ideation.

Precautions and Adverse Reactions Adverse effects of clozapine and the other SDAs are compared in Table 31.26-2. The only contraindications to the use of clozapine are a white cell count below 3500, a previous bone marrow disorder, a history of agranulocytosis during clozapine treatment, or the concomitant use of another bone marrow suppressant drug such as carbamazepine (Tegretol). When counts are low to begin with, it will be difficult to determine whether leukocytopenia or agranulocytosis has been induced. Although the mechanism of action is unknown, a slight risk of respiratory depression or collapse may occur if treatment is initiated while patients are taking benzodiazepines.

Leukocytopenia and Agranulocytosis One to 2 percent of patients receiving clozapine develop granulocytopenia or agranulocytosis; if not for this adverse effect, clozapine could be a first- or second-line antipsychotic. These patients may have a sudden or a gradual drop in the white blood count. The risk for this adverse effect is greatest during the first 3 months of treatment, but a significant risk remains during the first year of treatment and perhaps indefinitely. Agranulocytosis due to clozapine is a potentially fatal condition that requires immediate medical attention. The mortality rate is 1 less than in 10,000. The risk for clozapine-induced agranulocytosis is 0.73 percent for the first year of treatment and 0.07 percent in the second year. Review of the clozapine register indicates that the incidence may be as low as 0.038 percent. Peak incidence occurs between 6 and 18 weeks. For neutropenia the risk is 2.32 percent in the first year and 0.69 percent in the second year. Risk of agranulocytosis increases with age and is higher in females. Therefore, before treating patients with clozapine, clinicians were required to register patients with the Sandoz Company (Novartis). Recently the FDA approved a generic form of clozapine for marketing in the United States and registration is no longer required. Until recently, clozapine-treated patients had to receive weekly monitoring of their white blood cell (WBC) counts for as long as they received the drug and for at least a month after discontinuation. Since early 1998 the weekly blood sampling requirement has been every other week after 6 months.

Current guidelines specify that any fever or sign of infection (e.g., pharyngitis) is an immediate indication for a WBC count, particularly in the first 18 weeks of treatment. If the patient has a WBC count below 2000 or a granulocyte count below 1000, clozapine must be discontinued. Reports of clozapine reexposure following hematological recovery have shown that all such patients reexperience agranulocytosis but sooner and at lower doses than before. Thus patients who develop agranulocytosis should not receive clozapine again. Although WBC count below 3500 cells per mm^3 is not a proved risk factor, clozapine should be administered cautiously to patients with such low counts because of the difficulty in early identification of agranulocytosis. Similarly, carbamazepine should not be given concomitantly with clozapine. Clozapine therapy should be discontinued whenever the total WBC count falls below 3000 cells per mm^3 or the granulocyte count below 1500 cells per mm^3. Other hematological changes have been reported with clozapine, including leukocytosis (0.6 percent), eosinophilia (1 percent), leukopenia, neutropenia, and decreased WBC count (3 percent), and rarely, thrombocytopenia.

Several hypotheses about this toxicity have been proposed. A metabolic change might lead to the production of toxic metabolites, possibly higher than usual *N*-demethylclozapine concentrations. An alternative hypothesis proposes that neutrophils and their committed stem cell precursors can metabolize clozapine into free radicals, which are cytotoxic. This has led to suggestions that vitamins E or C and other antioxidants or trace elements that are cofactors of free-radical scavenger enzymes (e.g., selenium, zinc, and copper) may be preventive.

Sialorrhea Sialorrhea is an uncomfortable but tolerable adverse effect that develops early in treatment. Hypersalivation is most profound during sleep, and patients may complain that their pillow is wet in the morning. Placing a towel over the pillow may be of some help. Although the symptom can be treated with anticholinergics, this is not recommended because of the risk of anticholinergic toxicity. It has been proposed that changes in the peripheral adrenergic tone and substance P may override the muscarinic effects of clozapine on the salivary glands. Clonidine (Catapres) (0.1- or 0.2-mg patch once a week) and amitriptyline (Elavil, Endep) have been used at bedtime to treat sialorrhea. Recent studies suggest that clozapine does not increase saliva flow, it decreases swallowing, which becomes more obvious during sleep.

Cardiovascular System The cardiovascular adverse effects most frequently observed are tachycardia and postural hypotension. The tachycardia is probably a direct effect of the vagolytic properties of the drug. It can be present in the supine position and therefore does not result from orthostatic changes. Increased pulse rates of 20 to 25 beats a minute are encountered when clozapine reaches 300 mg a day or more over a 7-day period (e.g., sinus tachycardia). Reversible nonspecific ST-T wave changes, T wave flattening, or inversions (repolarization effects) are seen infrequently but are usually of no clinical significance. These changes are similar to those with other antipsychotics and are dose dependent. Although some tolerance occurs, it will persist unless the dose is lowered. A b adrenergic receptor antagonist (beta-blocker) such as atenolol (Tenormin) but not propranolol (which may increase the risk of agranulocytosis), may be given if the blood pressure allows it.

The risk of postural hypotension progressing to orthostatic collapse is high, if the initial dose exceeds 75 mg a day. Tolerance to the hypotensive effects of clozapine often develops over time. It can usually be managed if the initial dosage is low (e.g., 25 mg a day), and the dose is increased gradually. When it occurs, lowering the dosage to the previous level and slowing titration will limit the problems. Support stockings, increased sodium intake, or fludrocortisone (Florinef) may be helpful. However, orthostatic hypotension with or without syncope can occur with clozapine treatment and may represent a continuing risk in some patients. Rarely (approximately 1 case per 3000 or 4000 patients), collapse can be profound and be accompanied by respiratory arrest, cardiac arrest, or both. Orthostatic hypotension is more likely to occur during initial titration in association with rapid dose escalation and may even occur on the first dose. In one report, initial doses as low as 12.5 mg were associated with collapse and respiratory arrest. When resuming administration to patients who have had even a brief interval within clozapine (i.e., 36 hours or more since the last dose), the authors recommend that treatment be reinitiated at 12.5 mg once or twice daily.

Paradoxically, hypertension has been observed as well (<4 percent). Clozapine induces significant changes in hemodynamic mechanisms; it should be used with caution in patients with preexisting cardiovascular disease, such as a history of myocardial infarction or arrhythmias. The authors recommend careful monitoring of

vital signs during the first few weeks of treatment.

Peripheral Anticholinergic Effects Dry mouth, blurred vision, constipation, and urinary retention are commonly observed with clozapine. Other adverse effects on the autonomic nervous system, such as increased sweating, have also been reported.

Disturbances in Temperature Regulation Occasionally, benign hyperthermia is observed during the first 3 weeks of treatment, with a peak incidence on the 10th day. The increase in temperature is usually not more than 1 to 2°F, which spontaneously resolves over a few days with continued treatment without any clinical significance. Occasionally, however, temperature readings above 101°F have been seen, which require temporary cessation of clozapine treatment and frequent hematological monitoring. Differential diagnoses include drug fever, intercurrent infection, infection secondary to agranulocytosis, dehydration, heat stroke, lethal catatonia, and possibly neuroleptic malignant syndrome. Patients who develop a high temperature can be given the drug again but with a more gradual increase in dosage. If this strategy does not work, clozapine treatment may need to be discontinued. Mild hypothermia is frequently observed (87 percent). Because this effect is observed as frequently as with chlorpromazine, it may indicate the poikilothermic effect of antipsychotic agents (see chapter on antipsychotic agents). It is presumably mediated by the hypothalamus and it might be treated with benzodiazepines or 500 µg of thyrotropin-releasing hormone, according to Garth Bissette.

Weight Changes Weight gain has been reported with clozapine as with most SDAs. The incidence may be higher because of its strong 5-HT $_1$ and histamine type 1 (H_1) receptor affinity. With the improved quality of life often associated with clozapine treatment, weight gain becomes more of a rehabilitation issue.

Gastrointestinal Disturbances Constipation, most probably due to the antimuscarinic effects of the drug, is the most common gastrointestinal adverse effect (up to 33 percent). It should be treated with stool softeners, laxatives, fiber supplements, and adequate fluid intake. The constipation can progress into intestinal obstruction if not appropriately treated. Nausea and less frequent vomiting might be managed by dosage reduction.

Liver Function Disturbances Liver function disturbances are mild and transient. Only one case of cholestatic jaundice induced by clozapine has been reported.

Urogenital Effects Urogenital effects include enuresis, frequency and urgency, hesitancy, urinary retention, and impotence. All of these are independent of dose or blood concentrations. Urinary incontinence or enuresis can be managed by setting an alarm clock to ring at night, intranasal desmopressin (DDAVP) or oxybutynin (Ditrapon) (5 to 15 mg a day). So far, a few cases of clozapine treatment–associated priapism have been noted. Because patients may not volunteer this complaint, clinicians should ask about it because it may lead to noncompliance or medical complications and affect the patients' quality of life. Prolactin concentrations are less likely to increase with clozapine than with other antipsychotic agents, and effects of hyperprolactinemia such as amenorrhea, galactorrhea, or gynecomastia have not been encountered.

Extrapyramidal Adverse Effects Clozapine has a much lower incidence of extrapyramidal adverse effects than other antipsychotic agents. Akathisia (6 percent), tremors (6 percent), and rigidity (3 percent) are considerably less frequent than with traditional antipsychotic agents. The authors are not aware of reports of acute dystonia with clozapine. Currently, there are no confirmed cases of tardive dyskinesia with clozapine; moreover, tardive dyskinesia improved with clozapine. Patients with tardive dyskinesia may benefit from a treatment trial.

Neuroleptic Malignant Syndrome Consistent with clozapine's low affinity for D_2 receptors, there have been few reports of typical neuroleptic malignant syndrome developing in patients treated solely with clozapine. A few case reports exist of patients developing this syndrome who were concomitantly treated with lithium (Eskalith). Although two patients had experienced neuroleptic malignant syndrome with conventional antipsychotic agents before, one case has been reported of a patient with a history of neuroleptic malignant syndrome who was successfully treated with clozapine. The authors recommend, therefore, that lithium not be used as adjunctive treatment with clozapine in patients who have experienced neuroleptic malignant syndrome. Because clozapine treatment is accompanied by adverse effects that resemble several signs and symptoms of neuroleptic malignant syndrome (e.g., hyperthermia, cardiovascular effects, delirium, increased sweating, elevations in creatine phosphokinase, and leukocytosis), clinicians should be alert for the development of a potential neuroleptic malignant syndrome during clozapine treatment. Some case reports have described neuroleptic malignant syndrome without rigidity in patients treated with clozapine, although the lack of rigidity could preclude the diagnosis of this syndrome.

Lowering of Seizure Threshold Like treatment with other antipsychotics, clozapine treatment carries the risk of encephalographic (EEG) changes and grand mal seizures that are dose dependent. The initial data showed that the risk of seizures increases considerably with doses exceeding 500 mg. The cumulative incidence at 1 year for dosages up to 300 mg a day is 1 to 2 percent; 300 to 600 mg a day, 3 to 4 percent; and 600 to 900 mg a day, 5 percent. A preexisting seizure disorder or head trauma places the patient at even greater risk. More-recent data from a 6-month period suggest that the crude rate of seizures is 1 to 3 percent. The real risk is probably much lower when the drug concentration in blood is kept within the recommended range and no preexisting seizure disorder exists.

Several recommendations have been made to lower the risk by 50 percent; they include monitoring clozapine concentrations in blood, an EEG before raising the dosage over 600 mg a day; combining clozapine with anticonvulsants at dosages where a seizure occurred before, and lowering the dosage after a seizure has occurred, followed by a neurological consultation. Looking for other etiologies than clozapine is important as well as avoiding combination treatment with other drugs that lower the seizure threshold. Patients who are on antiepileptic agents may need dosage adjustment according to metabolic changes induced by clozapine administration. Carbamazepine should not be combined with clozapine because of its risk of granulocytopenia. Patients who are taking carbamazepine and are candidates for clozapine should preferably be given another anticonvulsant. If anticonvulsants are required, the effects on metabolism should be included in the decision about the dosage of both clozapine and the anticonvulsant.

Other CNS Effects Sedation is the most common adverse effect of clozapine treatment. It occurs early in treatment and tolerance usually develops after the first few days and weeks. However, if the patient does not take other CNS depressants and takes most of the daily dosage at bedtime, daytime sedation may be avoided or minimized. The a_1- and H_1-receptor blocking effects of clozapine are believed to be the cause. Other CNS effects include dizziness and syncope, which may be related to orthostatic hypotension. Confusion and delirium may occur because of muscarinic toxicity.

Subtle myoclonic movements and (rarely) cataleptic-like events in which the patient experiences a sudden loss of muscle tone in a part of the body without loss of consciousness have been reported and may occur more frequently than is reported in the literature. Lowering the dosage may deal with this. Whether clozapine induces or worsens a restless limb syndrome is uncertain.

Pregnancy and Lactation No data on risks have been reported in pregnant or lactating women to date.

Drug Interactions Because the cytochrome P450 mitochondrial system is involved in the metabolism of clozapine, ethnic differences and interactions with drugs that inhibit or stimulate this system will affect clozapine concentrations in blood. For instance, caffeine N3-demethylation, which is a measure of cytochrome P450 (CYP) isoenzyme 1A2 (CYP 1A2) activity, accounts for 70 percent of the variance in clozapine clearance. This suggests that fluvoxamine (Luvox), a potent inhibitor of CYP 1A2, will elevate clozapine concentrations, while fluoxetine (Prozac) may only lead to changes in higher dosage ranges. Cimetidine (Tagamet), SSRIs, tricyclic drugs, and valproate (Depakene) decrease clearance, presumably through inhibition of CYP 1A2 and 2D6, while phenytoin (Dilantin) and carbamazepine induce CYP 2C and 3A4 hepatic isoenzymes and may decrease concentrations of clozapine (£50 percent). Furthermore, when risperidone, which weakly inhibits CYP 2D6, is added, clozapine levels may rise also. Benzodiazepines do not affect kinetics but interact rarely with clozapine; a few case reports of delirium, increased somnolence, and acute respiratory suppression have appeared in the literature. Erythromycin and ketoconazole (Nizoral) may increase clozapine concentrations.

Dosage and Administration Clozapine treatment should begin with 12.5 to 25 mg during the day and be increased by 25 mg a day every 2 to 3 days. The rate of increase is limited by sedation and orthostatic hypotension. No dosage-response studies have been reported, but daily dosages between 250 and 450 mg are usually considered adequate; daily dosages above 600 mg are seldom indicated. In spite of its low relative potency in many animal studies, clozapine is 1 1/2 to 2 times more potent than chlorpromazine. Except for seizure risk, and possibly early sedation and hypotension, neither clinical nor adverse effects are likely to increase in severity with the dosage. Traditional antipsychotic agents can be discontinued overnight and replaced by clozapine. The authors recommend, however, that the traditional antipsychotic agent be discontinued gradually, until the clozapine dosage is increased to the desired level.

Once the appropriate dosage has been reached and the patient improves, the medication should be continued, probably indefinitely. When drug administration is abruptly discontinued in a successfully treated patient, a rebound worsening is sometimes observed, requiring dosage tapering and an early addition of the next antipsychotic agent. The rebound psychosis may be due to muscarinic supersensitivity in the changeover. An antipsychotic agent that has lower muscarinic blockade than clozapine may be perceived as less effective. The authors recommend that clozapine dosage be tapered gradually and anticholinergic agents added while

administration of the other drug is begun. Available preparations of clozapine and other SDAs are listed in Table 31.26-3.

	Tablets	Solution
Clozapine	25, 100 mg	
Olanzapine	2.5, 5, 7.5, 10 mg	
Quetiapine	25, 100, 200 mg	
Risperidone	1, 2, 3, 4 mg	1 mg/1 mL

Table 31.26-3 SDA Drug Preparations

RISPERIDONE

Results from clinical studies indicate that risperidone is an effective antipsychotic medication with a relatively mild adverse effect profile. In contrast to high-potency conventional antipsychotic agents, risperidone's therapeutic efficacy appears at lower dosages than the extrapyramidal effects, which is dose dependent. Hematological effects have not been observed. Risperidone appears to have a better antipsychotic effect than haloperidol and in all likelihood is also better for the treatment of negative symptoms. Risperidone has not been compared with low-potency antipsychotic agents such as chlorpromazine or thioridazine (Mellaril). Nevertheless, it is less sedating and does not have adverse anticholinergic effects. These particular characteristics indicate that risperidone is an appropriate first-line drug for patients with schizophrenia and other psychotic disorders when an antipsychotic agent is indicated. An early study by Eli Lilly comparing olanzapine with risperidone suggested that olanzapine was more effective; however, the risperidone dosage used was most likely too high for a good evaluation. A recent study by Janssen Research Foundation reported the opposite: risperidone was more effective than olanzapine. Many patients respond optimally to a lower dosage than the recommended 6 mg a day. Risperidone is available as a liquid. Depot formulations are expected to be developed (Phase III). Patients who are likely to need short-acting, injectable drugs may require a drug that is available for other routes of administration.

History Risperidone was the first antipsychotic agent to gain FDA approval after clozapine. Risperidone was discovered, patented, and marketed by the same company that developed haloperidol, pimozide (Orap), penfluridol (Semap), and other antipsychotics.

Chemistry Risperidone is a benzisoxizole derivative (see Fig. 31.26-1).

Pharmacological Action

Pharmacokinetics

ABSORPTION Risperidone is metabolized in the liver to 9-hydroxyrisperidone, which has the same pharmacological profile as the parent compound. After ingestion, peak plasma levels of the parent compound occur within 1 hour and within 3 hours for 9-OH-risperidone. Food does not affect the rate or extent of absorption in the gut.

METABOLISM AND ELIMINATION Risperidone has a bioavailability of 70 percent. The hepatic enzyme system that metabolizes risperidone to the hydroxy metabolite is CYP2D6, or debrisoquin hydroxylase. A genetic polymorphism is present in 7 percent of white people, leading to almost no activity in this enzyme. A much lower incidence has been seen in Asians (Table 31.26-1). Because the metabolite has an activity similar to that of the parent compound, this variance is not clinically significant.

Pharmacodynamics

MECHANISM OF ACTION Potent central antagonism of both serotonin (particularly 5-HT_{2A}) and D_2 receptors characterizes risperidone's presumed mechanism of action. Risperidone also demonstrates high affinity for a_1- and a_2-receptors but low affinity for b-receptors or muscarinic receptors. Preclinical studies indicate that while it is as potent as haloperidol in D_2 antagonism, risperidone is several times less potent than haloperidol at inducing catalepsy. This is consistent with risperidone having substantially less extrapyramidal adverse effect than conventional drugs at the recommended doses. In addition, the activity at 5-HT_2 receptors may result in greater activity against negative schizophrenic symptoms. PET studies indicated that dosages of 1 to 4 mg a day provide the required D_2 blockade for a therapeutic effect.

BLOOD CONCENTRATIONS AND CLINICAL ACTIVITY No clear evidence exists of a relation between clinical efficacy and concentration of risperidone in blood. This may well be because the dose-response curve is an inverted U.

Design and Interpretation of Clinical Drug Studies

Early Clinical Trials Several double-blind trials have compared risperidone with other drugs and placebo. In addition to providing evidence about the effectiveness of risperidone compared with that of other drugs, a number of studies have also focused on the dosage of risperidone by comparing several fixed dosages.

VARIABLE-DOSAGE STUDIES Variable-dosage studies most closely duplicate a real-life clinical setting in which clinicians individualize treatment. The first published double-blind study of risperidone was a multicenter investigation from Belgium. Forty-four patients with relatively refractory forms of schizophrenia were assigned to risperidone (mean daily dosage, 12 mg) or haloperidol (mean daily dosage, 10 mg). Although the two drugs did not differ significantly in their effectiveness for positive or negative symptoms, risperidone tended to be more effective. Risperidone patients were less likely to require antiparkinson medication.

A double-blind study that lasted 8 weeks (N = 107 schizophrenia patients) compared risperidone (mean dosage, 8.5 mg daily) and perphenazine (Trilafon) (mean, 28 mg). Although a higher proportion of patients assigned to risperidone (74 percent) than perphenazine (59 percent) met improvement criteria for total score on the Positive and Negative Symptom Scale (PANSS), the difference was not statistically significant. For positive symptoms, 69 percent of risperidone and 73 percent of perphenazine patients met improvement criteria (not significant); for negative symptoms, 76 percent of risperidone and 53 percent of perphenazine patients met criteria ($P < .05$). Extrapyramidal adverse effects did not differ between the two groups.

FIXED-DOSAGE COMPARISONS Fixed-dosage studies permit comparison of different dosages and they eliminate the effect of differences in prescribing habits among clinicians. The largest risperidone study was a multinational study that included 1362 patients who were randomized to a double-blind comparison of 1, 4, 8, 12, or 16 mg daily of risperidone or 10 mg of haloperidol. The 1-mg risperidone daily dosage was considered subtherapeutic and was therefore used as a control. All of the other risperidone doses and haloperidol resulted in greater improvement on the total PANSS than 1 mg of risperidone. The 4- and 8-mg risperidone daily dosages were the most effective, although their advantages were not statistically significant. A clear dosage-related increase in extrapyramidal adverse effects occurred with risperidone. However, all risperidone dosages were associated with less extrapyramidal effect than haloperidol. The differences in extrapyramidal adverse effects were statistically significant for all risperidone dosages except 16 mg a day.

The most important placebo-controlled trial was carried out in Canada and the United States. Acutely ill patients with schizophrenia were randomly assigned to groups that received 2, 6, 12, or 16 mg of risperidone, 20 mg of haloperidol, or placebo. The results from the United States and Canadian studies were very similar. Risperidone at daily dosages above 2 mg and haloperidol at daily dosages of 20 mg were consistently more effective than placebo for total PANSS and positive symptoms. The most effective daily dosage of risperidone was 6 mg, which was significantly more effective than haloperidol in both total PANSS and positive

symptoms. Risperidone (6 and 16 mg) but not haloperidol resulted in significant improvements in negative symptoms as measured by the PANSS negative symptoms scale. Similar results were obtained when the proportion of patients meeting criteria for improvement (20 percent or greater improvement in total PANSS or Brief Psychiatric Rating Scale [BPRS] were considered.

Risperidone resulted in a dose-related increase in extrapyramidal adverse effects. However, the proportion of patients who required antiparkinson medications was no greater at the 6-mg daily dosage—the dose at which risperidone was most effective—than on placebo. This observation suggests that patients who are treated with an effective dosage of risperidone are less likely to suffer from extrapyramidal effects than patients on high-potency drugs such as haloperidol if they are treated with dosages of 2 to 4 mg a day. In spite of early reported studies, 2 to 4 mg a day is the prefered effective dosage range.

Efficacy in Treatment-Refractory Patients Risperidone is an appropriate choice for individuals who have failed to respond to a conventional antipsychotic. In the U.S. study patients who had been in the hospital for at least 6 months prior to the study tended to show the greatest advantage for risperidone over haloperidol. This suggests that risperidone may be effective for some patients with treatment-refractory illnesses or who respond poorly to traditional agents.

COMPARISONS WITH CLOZAPINE Two published studies have compared risperidone with clozapine. In the first study, carried out in Germany, 59 acutely ill patients received 4 mg of risperidone, 8 mg of risperidone, or 400 mg of clozapine daily for 28 days. All three treatment groups improved, and there were no significant differences among the groups. The 4-mg risperidone daily dosage was the best tolerated when adverse effects were measured. However, subjects in this study were not selected for being resistant to antipsychotic medications.

Another European study compared risperidone and clozapine in treatment-refractory schizophrenic patients with a mean of six previous hospitalizations. Overall no significant difference was observed at the end of the trial. Daily dosages of 300 and 400 mg of clozapine were used compared with 4, 6, or 8 mg a day of risperidone, and at least for these dosages of clozapine, risperidone was as effective as clozapine. Patients receiving clozapine experienced more asthenia and lethargy and increased fatigability.

Replacing clozapine with risperidone does not always prevent a relapse, even when dosages are slowly tapered and given concomitantly. The authors recommend that anticholinergic agents accompany the replacement of clozapine with risperidone. Because of risperidone's lack of associated anticholinergic effects, this treatment should continue for some time after clozapine treatment has been stopped, to prevent symptoms associated with a cholinergic rebound.

Long-Term Effectiveness Evidence indicates that the effectiveness of risperidone does not decrease over time. Initial pharmacoeconomic studies indicate that risperidone may have a better record of preventing relapse and decreasing hospitalizations. Whether this is due to better compliance has not been determined.

Overview of Efficacy Taken together, these studies indicate that risperidone is an effective antipsychotic that may have advantages over conventional antipsychotics in its adverse-effect profile and in its efficacy. Large multicenter studies are most likely to detect differences in efficacy between risperidone and a comparison drug. However, both the 15-nation study and the North American trial compared multiple daily doses of risperidone with a single daily dose of a comparison drug. This type of comparison is biased for obvious reasons. However, John Davis recently analyzed pooled data from five controlled trials. The results of the meta-analysis indicated that 53 percent of risperidone patients met a priori criteria for improvement when their daily dosage exceeded 6 mg, compared with 40 percent of individuals who received a conventional antipsychotic ($P < .001$). Davis also reported that risperidone was 25 percent better for positive symptoms and 60 percent better for negative symptoms than traditional agents.

Treatment Indications

Acute Psychosis Risperidone is effective for both first and later episodes of psychosis in schizophrenia and schizoaffective disorder. There are some suggestions that risperidone is more effective than conventional antipsychotic agents, and it is certainly associated with fewer adverse effects. Other off-label use includes psychotic depression and perhaps autistic disorder. Risperidone may also have antimanic efficacy in bipolar disorder patients in add-on and monotherapy.

Maintenance Treatment in Schizophrenia and Schizoaffective Disorder Once the patient is stabilized, the dosage may be lowered. Although no long-term controlled studies of maintenance risperidone in schizophrenia or schizoaffective disorders have appeared, clinical experience indicates that it is effective in preventing relapse. Depot preparations are being studied.

Tardive Dyskinesia Case reports suggest that tardive dyskinesia may improve with risperidone. Because the disorder waxes and wanes, systematic study is needed before any conclusions can be drawn. Reports from Janssen Pharmaceutica document two cases of tardive dyskinesia in 1156 patients (0.2 percent) and a 0.4 percent risk in those treated for over 1 year. Patients treated with traditional agents have a 5 percent risk per year. A recent study in elderly agitated patients showed that risperidone was safe and efficacious, and there was a lower incidence of tardive dyskinesia than was expected in this age group. Dosages were 0.25 to 1 mg a day.

Patients With a Low Extrapyramidal Adverse Effect Threshold Patients with a low extrapyramidal effect threshold may respond to low dosages of risperidone without extrapyramidal effects.

Other Diagnoses The exploration of the clinical efficacy of risperidone has focused on schizophrenia. Controlled studies for other indications as antimanic and mood-stabilizing effects are awaited. In open studies, risperidone has been successful in patients with schizoaffective disorder, mania, psychotic depression, treatment-resistant depression, autistic disorder, and psychotic disorder due to brain trauma (i.e., hemorrhage), as well as elderly schizophrenic patients, those with acquired immune deficiency syndrome (AIDS)-related dementia and psychosis or with agitation, and psychotic symptoms in patients with dementia or substance-induced psychotic disorder. Some bipolar disorder patients with resistant mania or hypomania have responded well to low-dosage risperidone. In general these patients tend to respond to dosages below 6 mg a day (e.g., 1 to 3 mg). However, dosage increases lead to increased activation in some. Open studies indicate that elderly patients may require lower dosages (0.25 to 3 mg a day). Other case reports indicate that tics in Tourette's disorder, behavior disturbances in Huntington's disease, and levodopa–induced hallucinations may respond favorably as well. One patient with Lesch-Nyhan syndrome showed fewer episodes of self-mutilation during treatment with risperidone. Early reports of effects in children and adults with conduct disorders are encouraging in dosages between 0.02 and 0.06 mg/kg a day.

Precautions and Adverse Reactions Double-blind trials indicate that risperidone treatment is associated with a dose-dependent increase in extrapyramidal adverse effects. Although most adult patients may not experience these effects at the recommended daily dosage of 6 mg, dystonic reactions have occurred with dosages between 4 and 16 mg a day. Akathisia and occasional occurrences of tardive dyskinesia have been described. Most patients require only 2 to 4 mg a day. Risperidone induces a substantial rise in plasma prolactin concentration, a direct effect of all drugs with D_2 activity. This increase could lead to galactorrhea and menstrual disturbances in some women and sexual dysfunction in some men, but no such effects have been reported. Other common adverse effects include sedation, dizziness, constipation, tachycardia, and weight gain. A few cases of neuroleptic malignant syndrome have been reported on risperidone, which is not surprising given this drug's antidopaminergic activity. Other reported cases indicate that risperidone can produce obsessive-compulsive symptoms in some patients, an observation that has been made with clozapine and olanzapine, other drugs with substantial activity at 5-HT_{2A} receptors. One case of risperidone-induced angioedema has been reported. However, many incidents of adverse effects can be prevented if the daily dosage is kept below 5 mg.

Overdose Although antipsychotic drugs are relatively safe as a class, one fatal overdose with risperidone in a 45-year old man with schizophrenia has been reported. He ingested several hundred 1-mg tablets. At autopsy he had blood concentration of risperidone 500 times the normal therapeutic range. A 29-year-old man was brought to the emergency room 45 minutes after ingestion of 245 mg of risperidone. On examination he exhibited a cardiac conduction disturbance and an electrolyte imbalance, but he recovered fully.

Dosage and Administration

Initiation of Treatment The authors suggest a 1-mg starting dose, with 1-mg increments in twice-daily doses for the first few days. Most patients are then evaluated on 4 to 6 mg for the next 2 to 3 weeks. Although 6 mg a day may be the optimal dosage as determined by the phase III studies, new data indicate that many patients may be optimally treated with a 2- to 4-mg daily dosage. Lorazepam (Ativan) may be added during dose titration if the patient shows agitation in the early phases of treatment. Most of the improvement will occur in the first 8 weeks. If the response is not adequate, an increase to 8 mg may be indicated. The response is faster than with haloperidol; however, an 8-week trial should give an adequate assessment. Risperidone can be given once daily, which is as effective as twice-daily dosing.

Elderly and Parkinson's disease patients may need doses of 1 mg or less to prevent other side effects.

Duration of Treatment Until studies show otherwise, the rules used for traditional antipsychotic agents apply.

Drug Interactions At least two types of interactions are possible. Inhibition of CYP 2D6 by fluoxetine and paroxetine (Paxil) should block conversion to the hydroxy metabolite. Inversely, inducers of this enzyme such as carbamazepine should enhance the conversion and may require higher dosages. Raising the concentration of risperidone in blood may increase the risk of extrapyramidal effects and decrease the drug's efficacy. Because the metabolite and parent compound have the same pharmacological effects, such interactions may not be important. Risperidone is only a weak inhibitor of the enzyme and should not significantly decrease the clearance of other drugs. Clinical studies are needed to confirm the in vitro findings. Elderly persons, who are often phenotypically poor metabolizers, may require 50 to 66 percent lower dosages.

OLANZAPINE

Olanzapine is a safe and effective agent in the treatment of schizophrenic symptoms, including positive and negative symptoms, with a very favorable adverse-effect profile. It can be given in a single starting daily dose of 10 mg, with a dosage range of 10 to 30 mg a day. The benign side-effect profile includes weight gain, somnolence, some orthostatic hypotension, and constipation. Liability for extrapyramidal effects and seizures is low. No hematological effects have been observed. Preliminary studies indicate greater improvement in quality of life than with haloperidol as well as a lower rehospitalization rate than with traditional antipsychotic agents. Olanzapine is a first-line antipsychotic agent. Its efficacy in treatment-resistant patients has not been fully established; however, studies are under way to establish olanzapine's mood-stabilizing efficacy in bipolar illness.

History Eli Lilly and Company discovered olanzapine in Great Britain in 1982. It is derived from clozapine, as an agent without strong D_2 receptor blockade. In 1986 renewed interest in the compound emerged. Phase III clinical trials were completed in July 1995, and became available on the American and European markets in the fall of 1996.

Chemistry Olanzapine is a thienobenzodiazepine (Fig. 31.26-1). It can be considered a derivative of clozapine with substitution of a thieno ring for clozapine's carbonyl ring.

Pharmacological Action

Pharmacokinetics

ABSORPTION Food does not affect absorption of olanzapine.

DISTRIBUTION Peak plasma levels of olanzapine are reached in 5 hours. The half-life is 31 hours (range, 21 to 54 hours), which allows once-a-day dosing. The drug is 93 percent protein-bound plasma. Age, gender, or ethnicity effects on olanzapine concentrations are small.

METABOLISM AND ELIMINATION Olanzapine has a very weak affinity for hepatic P450 cytochromes (e.g., CYP 2D6, CYP 1A2, CYP 3A4, CYP 2C19) suggesting that it has little effect on the metabolism of other drugs, and that other drugs minimally affect its concentration in blood.

Pharmacodynamics

MECHANISM OF ACTION Olanzapine specifically blocks 5-HT_{2a}, and D_2 receptors and additionally blocks muscarinic (M_1), H_1, 5-HT_{2c}, 5-HT_3, 5-HT_6, a_1, D_1, and D_4 receptors. Its 5-HT blockade is about eight times as strong as its dopamine receptor blockade. The biochemical profile of olanzapine resembles that of clozapine more closely that those of the SDAs that are available or soon will be, without the typical clozapine adverse effects. The ratio of mesolimbic to striatal dopamine D_2 receptor blockade by olanzapine further indicates that extrapyramidal effects may occur only in some very susceptible patients. In fact, few extrapyramidal effects have been reported in clinical studies to date. Compared with risperidone, sertindole, quetiapine and ziprasidone, olanzapine has considerable M and H receptor antagonism, but less a_2-receptor antagonism. A recent PET study showed that the D_2 effect of olanzapine is greater than that of clozapine but similar to risperidone, which suggests that higher doses will be associated with a rise in prolactin and with extrapyramidal effects. Clozapine has also 5-HT_{1A} agonist properties, which may explain its antianxiety and antidepressant effects.

Olanzapine blocks phencyclidine (PCP) effects in animal studies. PCP is an *N*-methyl-D-aspartate (NMDA) receptor antagonist, that induces a syndrome reminiscent of many aspects of the positive, negative, and related cognitive symptoms of schizophrenia in humans. PCP's biochemical effects have led to the hypoglutamatergic hypothesis of schizophrenia.

BLOOD CONCENTRATIONS AND CLINICAL ACTIVITY Blood concentration studies have not yet appeared; however, side effects do not appear to be dose dependent. Women tend to have higher olanzapine concentrations than men.

Design and Interpretation of Clinical Drug Studies

Early Clinical Trials Double-blind studies compared olanzapine at once-a-day dosages (2.5 to 17.5 mg a day) with placebo and haloperidol (10 to 20 mg a day). Olanzapine was found superior to placebo and comparable to haloperidol in treatment of positive symptoms at intermediate (7.5 to 12.5 mg a day) and high (12.5 to 17.5 mg a day) dosages. Olanzapine was also superior to haloperidol in negative symptom response.

Efficacy in Treatment-Refractory Patients Olanzapine is potentially of interest for treatment-refractory patients because it has a biochemical profile similar to that of clozapine and it is more effective on negative symptoms than haloperidol. One study reported that olanzapine was as effective as chlorpromazine in treatment-resistant patients, while another found that olanzapine was superior to haloperidol in such patients. However, further studies are needed, and such patients may require higher dosages than the 25 mg a day dosages used. A patient who has not responded to one SDA may respond to another.

Long-Term Effectiveness A year-long maintenance study found less relapse with olanzapine than with placebo or haloperidol. In fact, at higher dosages of olanzapine, fewer patients dropped out of the study than with haloperidol.

Treatment Indications

Acute Psychosis Its once-a-day dosage and low side-effect profile make olanzapine an attractive agent for both first-break psychosis patients and relapsed patients who do not like antipsychotic agents because of the extrapyramidal effects. First-break patients tend to improve more with olanzapine than chronic psychotic disorder patients (65 percent vs 40 percent).

Maintenance Treatment Initial studies indicate that efficacy remains high over time and that olanzapine is well tolerated. However, weight gain (>7 percent) can be a serious problem in some patients.

Tardive Dyskinesia No cases of tardive dyskinesia have been observed in the limited time that patients have been studied. Studies of c-*fos* suggest that olanzapine has a low risk of inducing tardive dyskinesia. In all likelihood, olanzapine will be effective in patients with tardive dyskinesia.

Patients With Low Extrapyramidal Effect Threshold So far, akathisia and acute dystonias have been reported only occasionally in the large patient base studied. Because of the low risk of extrapyramidal effects, olanzapine should be a good drug for patients with a low threshold for these effects. However, c-*fos* studies in animals suggest that higher doses of olanzapine may cause extrapyramidal effects.

Other Diagnoses Olanzapine, SDAs, and typical antipsychotics are effective in patients with the same diagnoses.

Precautions and Adverse Reactions Olanzapine's adverse effects (Table 31.26-2) are transient sedation and orthostatic hypotension. The risk of extrapyramidal effects is low, but acute dystonic reactions and akathisia or neuroleptic malignant syndrome have been (rarely) observed. Moderate weight gain, which can be serious in some patients, has been observed. Fortunately, alternatives are now available. Prolactin concentrations increase only transiently and may be dose related. No hematological changes have been observed.

Dosage and Administration

Initiation of Treatment Olanzapine is effective at dosages between 7.5 and 30 mg a day. A single starting dose of 10 mg is well tolerated. The company recommends 10 mg a day for initial dosage. However, patients may need higher or lower dosages to obtain optimal results. Treatment-resistant patients or chronic patients with poor response may need higher doses (30 to 40 mg). This higher dosage range may raise prolactin concentrations and increase the risk of extrapyramidal effects. The half-life suggests that a single daily dose is sufficient.

Duration of Treatment Initial studies suggest that the efficacy increases over time. Early response predicts later response. Guidelines are the same as those for other agents.

Drug Interactions The small effects on hepatic metabolism suggest that interactions with other drugs will not be of much concern. Ethanol increases olanzapine absorption (>25 percent), which may lead to increased somnolence and orthostatic hypotension. Patients who smoke may require higher dosages. Poor extensive CYP 2D6 metabolizers show similar concentrations; thus drugs that inhibit this enzyme should have little effect on olanzapine's efficacy. Carbamazepine and phenytoin decrease olanzapine concentration moderately (£50 percent) by inducing CYP 3A. Cimetidine may increase olanzapine concentration.

SERTINDOLE

Sertindole is an effective, well-tolerated antipsychotic agent, without extrapyramidal adverse effects, and with other, mild adverse effects. It is effective in the treatment of negative symptoms. Its a_1-receptor blockade may cause initial hypotension and sinus tachycardia, nasal congestion, and decreased ejaculatory volume, which usually resolve. Weight gain is about the same or less than that with other SDAs. Prolactin concentrations are not raised to a clinically significant extent. The lack of H_1 and $M_{1–4}$ receptor blockade may explain its lack of sedation, cognitive adverse effects, or constipation. Hematological effects have not been observed. Sertindole has anti–negative symptom effects, but its efficacy in treatment-refractory patients is not yet fully established. Although the initial titration time may be a problem for some patients, the long half-life (3 days) will be helpful in partially compliant patients. Plasma concentrations do not predict therapeutic effect. Initial studies indicate a lower relapse rate than with traditional antipsychotics. Sertindole could be a first-line agent.

History Sertindole was discovered in Denmark in 1985. Abbott Laboratories licensed and brought the drug to the market. Although the New Drug Application (NDA) was filed in 1996, Abbott withdrew its application in the spring of 1998 when the FDA was not forthcoming with approval. The drug is thus only available outside the United States.

Chemistry Sertindole is an arylpiperidylindole derivative (Fig. 31.26-1).

Pharmacological Action

Pharmacokinetics The serum half-life of sertindole is 1 to 4 days, the longest of the drugs discussed in this chapter. Fifty-two (38 to 63) percent of sertindole is excreted in the urine, and 36 (5 to 40) percent in the feces. Plasma half-life is 25 to 29 hours, allowing a once-a-day dosage. The long plasma half-life may lead to a 2-week delay before steady-state concentrations in plasma are reached, which suggests that 3 to 4 weeks must pass before a lack of response is indicated. One circulating metabolite of sertindole is LU 28-092.

Pharmacodynamics

MECHANISM OF ACTION Sertindole blocks $5HT_{2c}$, $5HT_{2a}$, D_2, and a_1 receptors. In clinically effective doses it binds preferential to the mesolimbic dopamine system. Extrapyramidal effects probably require a dosage 10 to 20 times the clinically effective dosage.

BLOOD CONCENTRATIONS AND CLINICAL ACTIVITY No evidence links clinical responsiveness to sertindole to its concentration in plasma.

Design and Interpretation of Clinical Drug Studies

Early Clinical Trials Among clinical trials assessing the clinical efficacy of potential antipsychotic effects, one study stands out, the so-called landmark study with seven treatment arms. Not only did it compare three doses of sertindole with placebo, it also included three arms of haloperidol. Until this study only one dose of the comparison active agent (usually haloperidol, between 12 and 20 mg a day) had been used. All dosages of sertindole (12, 20, and 24 mg a day) and haloperidol (4, 8, and 16 mg a day) were significantly more effective than placebo after 8 weeks of treatment. While all dosages of sertindole and haloperidol were effective on positive symptoms, only sertindole (20 mg a day) was statistically more effective than placebo on negative symptoms. Sertindole and placebo did not differ statistically in extrapyramidal effects; haloperidol (as expected) did. Sertindole was well tolerated; adverse effects were mild and related to its a_1 activity. Improvement in positive symptoms with 4 mg of haloperidol leveled off after 2 weeks, and the 8-mg dosage reached maximum effect after 4 weeks; 16 mg of haloperidol reached its maximum effects in the eighth week but was less effective than the 8-mg dosage. Sertindole (20 mg a day) reached its maximum effect at the eighth week, comparable to 8 mg a day of haloperidol, which was the most effective dosage of that drug. Preliminary long-term studies suggest that patients continue to improve with this dose of sertindole after 8 weeks of treatment.

Efficacy in Treatment-Refractory Patients Seven patients partially responsive to haloperidol received clozapine, risperidone, and sertindole sequentially. Compared with haloperidol, symptoms improved on clozapine (33 percent), on sertindole (35 percent), and on risperidone (45 percent). Results from studies in treatment-resistant patients will soon be available.

Long-Term Effectiveness Studies are under way showing that the efficacy of sertindole continues over time.

Treatment Indications

Acute Psychosis The low adverse-effect profile makes sertindole a good first-line agent, especially for first-episode psychotic patients.

Maintenance Treatment The low adverse-effect profile and preliminary data suggest that maintenance treatment will be well tolerated and effective.

Tardive Dyskinesia The lack of extrapyramidal effects and the actual improvement in involuntary movements (compared with placebo) observed in the studies suggest that long-term risk of tardive dyskinesia with sertindole should be extremely low.

Patients With a Low Extrapyramadal Effect Threshold Because of the lack of extrapyramidal effects at the recommended dosages, patients who cannot tolerate traditional antipsychotic agents are obvious candidates for sertindole.

Other Diagnoses Double-blind studies with patients carrying other diagnoses (e.g., mania, psychotic depression, substance-induced psychotic disorders, dopamine stimulation–induced psychosis in Parkinson's disease, dementia with psychotic features, or substance-intoxication delirium) have not been published. Preliminary evidence from studies with risperidone in patients with obsessive-compulsive disorder suggests that these patients may be helped by sertindole.

Precautions and Adverse Reactions The most frequently observed adverse effects of sertindole are tachycardia, mild nasal congestion, decreased ejaculatory volume (20 percent of patients), mild prolongation of the QT interval, weight gain (0.5 to 1.4 kg), and nausea. In a small number of patients the decreased ejaculatory volume led to discontinuation; in others it resolved spontaneously with continued treatment. This sexual effect and the nasal congestion are attributed to its

a_1-receptor blockade. Other sexual effects observed with the traditional antipsychotic agents such as retrograde ejaculation and diminished libido and ability to experience orgasm (potency) have not been reported. Animal and human studies showed that sertindole prolongs the QT interval, but increasing the dosage does not increase the interval further. The clinical significance of this prolongation has not been established, and this increase may not differ from that observed with some conventional antipsychotic or antidepressants. No incidents of torsade de points have been observed in over 100 patient-years; continued monitoring will clarify the actual risk. However, sudden cardiac death has occurred in patients treated with sertindole. Sertindole has no antihistaminic or antimuscarinic adverse effects. The weight gain may be due to its 5-HT blockade and is similar to that observed with clozapine, olanzapine, risperidone, or quetiapine. Transient elevation of liver enzyme activity (aspartate aminotransaminase [AST], alanine aminotransamine [ALT]) has been reported (as with other agents), without any clinical consequences. Changes in WBC count or other hematological index were not observed. Prolactin concentrations increased only transiently.

Dosage and Administration

Initiation of Treatment The recommended starting dosage of sertindole is 4 mg a day, with increases of 4 mg every other day up to 20 mg a day. Some patients may require 24 mg. If initial agitation is not fully treated before the optimal dose is reached, temporary addition of benzodiazepines or a traditional antipsychotic agent may be helpful. The recommended dosage range is 12 to 20 mg a day. The pharmacokinetics are nonlinear, so that 24 mg a day produces twice the concentration in blood that 20 mg produces. Elderly persons may require much lower dosages. Intramuscular injectable forms are not available. If sertindole replaces clozapine, the authors suggest using the transient anticholinergic strategy used with risperidone.

Duration of Treatment The coming years will provide the needed data about effectiveness and relapse prevention in multiyear studies.

Drug Interactions Fluoxetine and paroxetine decrease sertindole clearance by 50 percent. The authors recommend lowering the dosage by 50 percent in patients also receiving these agents. Carbamazepine and phenytoin increase sertindole clearance by 50 percent, which may require raising the dosage of sertindole. Area under the concentration-time curve for terfendine (Seldane) blood concentrations increased nonsignificantly by 28 percent.

QUETIAPINE

Two double-blind trials with quetiapine indicate that it is a promising SDA with efficacy at least equal to that of haloperidol and chlorpromazine. Doses must be titrated to 150 mg a day and up to 750 mg a day as clinically indicated. Maximum therapeutic effects are seen with 300 mg a day. It is superior to placebo and its extrapyramidal effects do not differ from those of placebo. Adverse effects include drowsiness, increased heart rate, weight gain, and agitation. No blood dyscrasias or effects on prolactin concentrations have been observed in long-term trials. Trials in drug-resistant patients and for pharmacoeconomic comparisons are under way. Quetiapine is a first-line antipsychotic agent.

History Quetiapine was developed by Zeneca Laboratories. Its NDA application was filed at the FDA in 1996 and approved by the FDA in 1998.

Chemistry Quetiapine is a dibenzothiazepine with more potent 5-HT_2 than D_2 receptor-blocking properties. Quetiapine is related to the clozapine (Fig. 31.26-1) and fluperlapine molecules.

Pharmacological Action

PHARMACOKINETICS No difference was found between twice-daily or thrice-daily dosing, in spite of a steady-state half-life of 6.9 hours. The time to maximum concentration (T_{max}) after oral intake is less than 2 hours, with an estimated half-life of 3.0 to 5.0 hours. Steady-state concentrations are reached in 48 hours. PET studies indicated that a single clinical dose of quetiapine occupied 42 percent of D_2 receptors and 72 percent of 5-HT_2 receptors. After 8 and 12 hours, considerable receptor occupancy remained, although concentrations in blood had dropped off, supporting twice a day dosing. Quetiapine has many metabolites; and the only two active ones make up only a small percentage; 95 percent of [^{3}H]quetiapine is recovered as metabolites in urine and feces, and only 1 percent as quetiapine itself.

Pharmacodynamics

MECHANISM OF ACTION Quetiapine has a high affinity for 5-HT_2, histamine H_1, $5HT_6$, a_1, and a_2 receptors, a moderate affinity for D_2 and sigma receptors, and low affinity for D_1 receptors. It has very low affinity for M_1 and D_4 receptors. However, in vitro studies suggest that quetiapine has a much lower receptor blockade profile than other effective antipsychotic agents. An extensive examination in different animal models for schizophrenia (e.g., dopaminergic and nondopaminergic behavior models) indicated that quetiapine has potential antipsychotic and anti–negative symptom effects without significant liability for extrapyramidal adverse effects. Studies in humans suggest that quetiapine has essentially no extrapyramidal adverse effects and that it results in only transient elevations in prolactin concentration.

BLOOD CONCENTRATIONS AND CLINICAL ACTIVITY Quetiapine response is independent of dosage. Because many elderly persons have reduced oral clearance, the dosage may need to be reduced, particularly the starting dosage. Patients with impaired renal or hepatic clearance need to receive 30 to 50 percent lower dosages. No gender or ethnic differences were found in clinical activity or concentrations in blood.

Design and Interpretation of Clinical Drug Studies

Early Clinical Trials Phase II and III trials compared quetiapine at high and low doses. Effectiveness occurs over a wide dosage range, with 300 mg a day generally the optimal dosage. Quetiapine was at least equal to haloperidol in treatment of positive and negative symptoms.

Efficacy in Treatment-Refractory Patients Current trials are ongoing with no results currently available. Anecdotal evidence suggests that some treatment-resistant patients may respond to quetiapine.

Long-Term Effectiveness Although they are expected soon, no results from quetiapine long-term studies have been reported. The low adverse-effect profile and the preliminary clinical data indicate that maintenance treatment will be well tolerated and that therapeutic efficacy will be maintained. A quality of life and pharmacoeconomic study is under way.

Patients With a Low-Extrapyramidal Adverse Effect Threshold Parkinson's disease patients with dopamine agonist-induced psychosis have responded to low doses of quetiapine in open studies.

Treatment Indications Quetiapine is an effective antipsychotic agent in acutely exacerbated schizophrenic and schizoaffective patients. Preliminary data indicate that quetiapine is effective in functional and organic psychoses in elderly persons and very effective in levodopa–induced psychosis in Parkinson's disease patients. It has some effect on negative symptoms. Although not yet reported, quetiapine may be useful in the same nonschizophrenic diagnoses as other SDAs, with the advantage of not being associated with extrapyramidal adverse effects. In patients with a variety of dementias, psychotic symptoms improved with quetiapine. These potential indications require careful examination. Relapse prevention is expected but has not been reported. Response in treatment-refractory patients is being examined.

Precautions and Adverse Reactions The most frequently observed adverse effects (Table 31.26-2) are somnolence, postural hypotension, and dizziness, and tolerance quickly develops to them. Extrapyramidal adverse effects were not observed. Some constipation and dry mouth were observed despite the lack of anticholinergic effects. Prolactin concentrations were not raised after the initial doses. Small increases in heart rate were observed, with supine pulse rate increasing 3.3 to 4.9 beats a minute. Small decreases in thyroid hormone concentration occurred without increases in thyroid-stimulating hormone concentrations, but these changes were not clinically significant. An average weight gain of 1.7 to 2.3 kg (vs. 0.1 kg for placebo) occurred during acute studies. No significant continuing increase in weight was observed in long-term open-label studies. ALT activity increased transiently during the first 2 weeks. No changes in WBC count or other hematological index were observed. QT_c changes were no more likely than with standard antipsychotic agents. Adverse events were as likely on quetiapine as with placebo but less so than with haloperidol or chlorpromazine. Seven overdose incidents (more than 900 mg) were reported (1200 to 9300 mg); none was lethal. One patient developed a first-degree heart block. Occasionally inclusion bodies in the eye are observed. Quetiapine is a safe and well-tolerated antipsychotic agent.

The major risk with quetiapine is the development of cataracts, although a causal relation has not been established. Slitlamp or other sensitive methods to detect lens

abnormalities should be conducted early in treatment and every 6 months thereafter.

Dosage and Administration

Initiation of Treatment Quetiapine doses must be titrated to avoid postural hypotension and syncope. Studies are under way to show how aggressively the dose can be raised. The drug is very well tolerated even in the range of 800 mg a day. Usual titration typically reaches the effective dosage of 300 mg a day by day 4.

Duration of Treatment Most trials had a duration of 6 weeks. Longer-duration studies are under way.

Drug Interactions Interactions between quetiapine and other drugs have been studied to a greater extent than those of most of the new antipsychotic agents. No synergistic effects are noted with alcohol and lorazepam. CYP 3A4 is the major metabolic pathway, and CYP 2D6 is a minor pathway. Quetiapine does not interact with CYT 1A2, 3C9, 2C19, 2D6, or 3A4. Neither cimetidine nor antipyrine (Auralgan) induced quetiapine metabolism or vice versa. Only phenytoin caused a fivefold increase in quetiapine clearance through CYP 3A4 induction. Lithium, lorazepam (or other benzodiazepines), cimetidine, risperidone, haloperidol, fluoxetine, and imipramine (Tofranil) had no effects on the pharmacokinetics of quetiapine, and vice versa (i.e., no required dosage adjustments). Concomitant administration of thioridazine, however, increased oral clearance of quetiapine by 60 percent, which requires further study.

ZIPRASIDONE

Ziprasidone combines antagonist effects at 5-HT_{2A} and D_2 receptors without extrapyramidal, antimuscarinic, anti-a_1 or antihistaminic adverse effects. Ziprasidone is an effective drug for positive symptoms. Negative symptoms improve as well, but no information is available on the deficit state and treatment-refractory patients. Ziprasidone has a low risk of extrapyramidal adverse effects. Food increases absorption but age, gender and renal or hepatic impairments have little effect on the pharmacokinetics. Its norepinephrine and serotonin uptake inhibition may make it of interest in depressed and chronically withdrawn schizophrenic patients. Its potent $5HT_{1A}$ agonist activity suggests that it may also be useful for schizophrenic patients with anxiety symptoms and depression. It is the only SDA that is not associated with weight increase. Hematological effects have not been noted. Drug interactions are expected to be low, suggesting that the drug can safely be used in people with medical treatments and in the elderly. Besides the oral form, an intramuscular preparation would have been available for initiation of treatment. Ziprasidone could have been a first-line drug in schizophrenia or schizoaffective disorder if not for the QT_c prolongation.

History Ziprasidone was synthesized in 1987 by Harry Howard of Pfizer Pharmaceuticals. Tom Seeger screened the compound and identified the activity at D_2 and $5HT_2$ receptors. The FDA did not approve ziprasidone because of QT_c prolongation, and the company withdrew its NDA in the spring of 1998.

Chemistry Ziprasidone is a benzisothiazolyl piperazine (Fig. 31.26-1). Its chemical formula is $C_{21}H_{21}ClN_4OS{\cdot}HCl{\cdot}H_{2O}$ with a molecular weight of 467.41. The compound is not related to any now available or in late-stage development.

Pharmacological Action

Pharmacokinetics

ABSORPTION The peak levels concentrations after single and multiple dosing of ziprasidone were similar. Peak levels were reached 2 to 6 hours after dosing. T_{max} ranged from 4 to 5 hours. Absorption rates did not change from day 1 to 18. Bioavailability doubles when ziprasidone is administered with food; following administration of multiple doses of ziprasidone under fed conditions, peak serum concentrations occur in 6 to 8 hours.

METABOLISM AND ELIMINATION Steady state is attained after 1 to 3 days of dosing. Overall exposure at steady state is relative to the dose over the range of 20 to 80 mg twice a day. The mean terminal plasma half-life for ziprasidone at steady state ranges from 5 to 10 hours in volunteers and schizophrenic patients. The 0.5- to 1-hour lag in reaching peak level concentrations was attributed to delayed gastric emptying.

Age and gender or mild-to-moderate renal or hepatic impairment have no significant effects on the pharmacokinetics of ziprasidone, making dosage adjustments unnecessary. Ziprasidone is extensively metabolized, with less than 1 percent excreted unchanged in the urine or feces. In vitro studies indicate that the major metabolites are produced by CYP 3A4. The major circulating metabolites possess less than 1 percent of the binding affinity of the parent compound for D_2 and 5-HT_{2A} receptors.

Pharmacodynamics

MECHANISM OF ACTION In vitro studies show ziprasidone to be a very potent antagonist at the 5-HT_{2A} receptor, with 5-HT_{2A} to D_2 ratio of 11. PET studies in healthy volunteers confirm that 5-HT_2 occupancy substantially exceeds D_2 occupancy. Ziprasidone has potent affinity for the D_3 receptor and moderate affinity for the D_4 receptor, like haloperidol; the affinity for the D_1 receptor is 100-fold lower than that for other dopamine receptors. Ziprasidone is an agonist at the 5-HT_{1A} receptor and a potent antagonist at the 5-HT_{2C} (5 times greater than clozapine and 19 times greater than risperidone) and 5-HT_{1D} receptors. It also moderately affects norepinephrine and serotonin (and dopamine) uptake sites. Ziprasidone has only moderate affinity for the a_1 receptor and low affinity for the H_1 receptor. The biochemical profile suggests an antipsychotic drug with low risk for extrapyramidal adverse effects, efficacy in treatment of negative symptoms, and additional effects in patients with anxiety and mood disorders. Ziprasidone is the only agent with uptake inhibition of norepinephrine and serotonin. Stimulation of 5-HT_{1A} receptors is shared with clozapine.

BLOOD CONCENTRATIONS AND CLINICAL ACTIVITY With twice-daily administration of ziprasidone, estimates based on systemic exposure and PET data predict that 5-HT_2 and D_2 receptor occupancy ranges from 80 to 90 percent and 45 to 75 percent, respectively. Ziprasidone at serum concentrations of 30 to 40 ng/mL is likely to be associated with about 75 percent 5-HT_2 and more than 65 percent D_2 receptor occupancy as determined from PET scan data.

Design and Interpretation of Clinical Drug Studies

Early Clinical Trials Results from 4- to 6-week fixed-dosage, double-blind clinical trials indicate that ziprasidone is effective in the treatment of positive, negative, and affective symptoms in patients with schizophrenia and schizoaffective disorder. In two separate 4- to 6-week clinical trials in patients with acute psychotic exacerbation, ziprasidone (80 to 160 mg a day) was significantly superior to placebo, and in a 4-week trial, ziprasidone (160 mg a day) was comparable to haloperidol (15 mg a day) in reducing psychotic symptoms. Statistically significant, dosage-dependent improvements in negative symptoms as measured by the PANSS were observed with ziprasidone (80 and 160 mg a day) compared with placebo in a 6-week trial. Further evidence for efficacy in negative symptoms comes from a 4-week, placebo-controlled trial in which a significant improvement in the BPRS anergia factor was observed with ziprasidone (120 mg a day). A dosage-dependent effect was not observed, which suggests that the negative symptom reduction may be related to the lack of extrapyramidal effects. Ziprasidone (160 mg a day) also significantly improved depressive symptoms in patients with clinically significant symptoms at baseline (Montgomery Åsberg Depression Rating Scale [MADRAS] $^{3}14$; baseline mean, 23.5) compared with placebo at 6 weeks. Statistically significant improvement was also observed in affective symptoms at 4 weeks in patients with a BPRS anxiety-depression cluster baseline score of 18 or above.

Long-Term Effectiveness Recent results from a prospective, 1-year, double-blind, fixed-dose ziprasidone study in patients with chronic or subchronic schizophrenia showed that ziprasidone (40 to 160 mg a day) is associated with significantly lower relapse rates than placebo. This group of stable patients experienced a significant reduction in negative symptoms from baseline compared with placebo, as measured with the negative symptom subscale of the PANSS. This improvement in negative symptoms was maintained throughout 12 months of treatment, with a tendency toward continuing improvement in patients who completed the study. Further long-term clinical trials of ziprasidone are ongoing.

Efficacy in Treatment-Refractory Patients No data are available on the efficacy of ziprasidone in treatment-refractory patients.

Treatment Indications The available data from clinical trials show the efficacy of ziprasidone in dosages of 80 to 160 mg a day in the treatment of positive, negative, and depressive symptoms in patients with schizophrenia and schizoaffective disorder. Clinical trial data also indicate that ziprasidone maintenance therapy with

dosages of 40 to 160 mg a day is effective in prevention of psychotic relapse in patients with chronic or subchronic schizophrenia. Most studies so far have focused on chronic and subchronic schizophrenia and schizoaffective disorder. Its biochemical and clinical profile makes ziprasidone a potentially interesting agent in affective disorders with psychosis and in alcoholism and anxiety disorders. The availability of intramuscular administration will make this drug attractive for acutely agitated and psychotic patients.

Precautions and Adverse Reactions Ziprasidone has been well tolerated in short- and long-term clinical trials. Treatment-emergent extrapyramidal adverse effects have been infrequent and mild during the clinical trials. Akathisia has been notably absent. Concomitant benztropine use was significantly lower with ziprasidone than with haloperidol. The major adverse effects encountered with ziprasidone treatment include somnolence, dizziness, nausea, and lightheadedness. Orthostatic hypotension was rare. Unlike other SDAs, ziprasidone evoked a low incidence of clinically significant weight gain (>7 percent), which may be an attractive feature of this agent. Serum prolactin concentrations were not elevated during the chronic phase of the trials (day 18). AST and ALT activities were occasionally elevated but rarely of significance. Treatment-related blood dyscrasias have not been reported with ziprasidone. Prolactin concentrations returned to baseline during the dosing interval in a 4-week study.

Dosage and Administration

Initiation of Treatment Ziprasidone has been administered safely at 40 mg a day in two doses without the need for dose titration. Clinical trial data suggest that 80 to 160 mg a day given as a twice-daily dose with food is effective in acutely exacerbated patients. An intramuscular form of ziprasidone is undergoing testing; this form induces a somnolence from which patients are easily aroused.

Duration of Treatment The preferred dosage for maintenance treatment and prevention of relapse is 40 to 60 mg twice a day. Ziprasidone has been administered safely for up to 2 years, and data from a 1-year clinical trial show that ziprasidone is effective in preventing psychotic relapse.

Drug Interactions Ziprasidone has low potential for clinically significant drug interactions. In vitro studies indicate that ziprasidone is not a substrate for CYP 2D6, CYP 2C9, CYP 2C19 or CYP 1A2 and has low potential to inhibit CYP 1A2, CYP 2C9, CYP 2C19, CYP 2D6, and CYP 3A4. The lack of clinically relevant CYP 2D6 inhibition was confirmed in healthy volunteers; ziprasidone did not inhibit metabolism of dextromethorphan (a CYP 2D6 model substrate) to its major metabolite, dextrorphan. While ziprasidone is a substrate for CYP 3A4, cimetidine (a CYP 3A4 inhibitor) does not inhibit its metabolism, suggesting that significant metabolism occurs by an alternative pathway. Clinically significant interactions have not been reported with lithium, antacids (aluminum and magnesium hydroxides), or oral contraceptives in volunteers. Ziprasidone did not affect steady-state lithium concentrations or renal clearance.

OTHER INVESTIGATIONAL DRUGS

Several other SDAs are being tested in the clinic. Iloperidone is an SDA with high affinity for the 5-HT $_{2A}$ receptor and moderate-to-high affinity for D_{2s}, D_{2L}, D_3, D_4, and $5HT_{1A}$ receptors. This profile suggests that iloperidone will be a second-generation antipsychotic agent with a low liability for extrapyramidal adverse effects and efficacy against negative symptoms and anxiety. The drug is well tolerated, with extrapyramidal adverse effects similar to those of placebo and minimal elevations of prolactin concentration. The preliminary dosage is 8 mg a day.

Aripiprazole (OPC-14597) (Otzuka) is a highly lipid soluble quinolinone derivative that can be given in a once-a-day dosage (2 to 30 mg). Extrapyramidal adverse effects are similar to those with placebo. Prolactin concentrations did not increase with aripiprazole at 4 weeks. The drug stimulates dopamine autoreceptors, with a D_2 antagonism at postsynaptic D_2 receptors in the same dose range. It also blocks 5-HT $_2$ and a_1 receptors. At 4 weeks the 30-mg daily dosage was superior to haloperidol in positive and negative symptoms. Whether aripiprazole increases body weight is uncertain. No evidence of sedation, somnolence, or antimuscarinic effects has been observed.

Several other approaches (e.g., D_4, D_3 and 5-HT_3 antagonists) are also under study. The authors expect the next generation of antipsychotic drugs to have biochemical profiles that are not as solidly based in the monoamines.

IS INDUCTION OF c-*fos* RELATED TO ANTIPSYCHOTIC EFFECTS?

Induction of immediate early genes such as c-*fos* by antipsychotic drugs may assist in understanding the different profiles of the traditional and atypical agents. c-*fos* induction in the dorsolateral striatum suggests extrapyramidal adverse effect liability, and induction of c-*fos* in the prefrontal cortex and nucleus accumbens suggests antipsychotic and potentially anti–negative symptom effects. Haloperidol induces c-*fos* in the dorsolateral striatum and the nucleus accumbens, while clozapine induces c-*fos* in the medial prefrontal cortex, lateral septal nucleus, the major island of Calleja (D_3 receptor blockade), and the nucleus accumbens but not in the dorsolateral striatum. Risperidone strongly induces c-*fos* in the dorsolateral prefrontal cortex, the nucleus accumbens, and the medial prefrontal cortex. Olanzapine treatment shows a pattern like that of clozapine but with some c-*fos* induction in the dorsolateral striatum, although this drug has very low extrapyramidal adverse effect liability at the recommended dosages. Clozapine, risperidone, and olanzapine induce c-*fos* in brain areas that do not show induction with haloperidol, which suggests that these areas may be involved in the treatment of negative symptoms. Similarly, sertindole does not induce c-*fos* in the dorsolateral striatum, and induces very little in the nucleus accumbens and weakly in the medial prefrontal cortex, in spite of its clinical efficacy. Quetiapine also shows c-*fos* induction in the limbic system and ventral striatum but not in the motor areas of the brain. These data indicate that the location of the expression of the immediate early gene c-*fos* differentiates SDAs from conventional agents. The neuronal location also differs among the SDAs as well, even though the anatomical location of its induction is in principle the same. The coming years will include immediate early genes in the screening for potential antipsychotic and anti–negative symptom effects and extrapyramidal adverse effects, showing the individual characteristics of these drugs and their treatment potential.

FUTURE DIRECTIONS

The greater therapeutic efficacy and the low extrapyramidal adverse effect liability of these new agents compared with the traditional agents may be due to the relative blockade of 5-HT $_2$ over D_2 receptors. The differences between the traditional and second-generation antipsychotic agents have also altered our thinking about the biology of psychosis and the clinical indications of these agents. These differences point to neuronal circuitry changes in schizophrenia, rather than an absolute single cause of the changes in behavior. Such changes may involve dopamine, but also serotonin, norepinephrine, GABA, glutamate, and acetylcholine (including muscarinic antagonism and nicotinic receptor stimulation). All these neurotransmitters may play a role in the antipsychotic effects, as they are involved in the cortico-limbic-thalamic pathways in the brain. Conceivably, other, unknown mechanisms may be responsible for the antipsychotic effects when only moderate binding to D_2 receptors provides the optimal response.

These agents differ in their specific receptor affinities, which makes these drugs—including the ones under development—potentially more interesting than just another drug with a low D_2 to 5-HT_2 receptor blockade ratio. For example, risperidone, olanzapine, and quetiapine share a $_2$-receptor blockade with clozapine. 5-HT $_{2A}$ receptor blockade varies widely; risperidone, olanzapine, sertindole, and ziprasidone show high affinities, and quetiapine shows lower affinity. In D_2 receptor blockade, risperidone and olanzapine are similar to haloperidol. The D_4 receptor affinity of haloperidol is similar to that of clozapine, although the implication of this has been disputed. Sertindole and ziprasidone have D_2 affinities somewhat lower than that of haloperidol. Quetiapine is remarkably like clozapine in its low D_2 receptor affinity; while olanzapine has a higher D_2 affinity than clozapine or quetiapine but lower than sertindole and ziprasidone. In addition, ziprasidone is unusual in that it blocks norepinephrine and serotonin uptake, and it shares 5-HT $_{1A}$ receptor stimulation with clozapine. This makes ziprasidone potentially effective for emotional withdrawal and amotivational syndromes and in depressed patients who are psychotic or anxious. Quetiapine has low receptor affinities, with stronger 5-HT $_2$ than D_2 receptor blockade and strong antihistaminic effects. Clozapine, olanzapine, quetiapine, and ziprasidone are considered broad-spectrum, or multireceptor, antagonists, while risperidone, sertindole, and iloperidone share mainly 5-HT $_2$ and D_2 antagonism. Ziprasidone has some specific, additional effects. Sertindole and iloperidone share strong a_1 blockade with different adverse effect profiles. a_1- and a_2-receptor blockade is related to antipsychotic potency of traditional agents.

Improvement in Quality of Life Recent innovations in prescribing antipsychotic drugs have led to the hope that the outcome of schizophrenia can be substantially improved. The second-generation compounds may allow rehabilitation without cognitive impairment as observed with the low-potency agents and clozapine. Research on the effect of the SDAs on the cognitive deficits in schizophrenia has high clinical relevance, and will revolutionize how clinicians and patients will view these drugs. All the new agents are remarkably free of unpleasant side affects. Akathisia is frequently the same as with placebo. Occasionally, initial orthostatic hypotension and somnolence, dizziness (nonorthostatic), stuffed nose, and headaches are observed, while prolactin concentrations are minimally affected or not at

all. Because of their lack of bothersome extrapyramidal effects and drug-induced negative symptoms, all of the new agents may provide a chance for more successful rehabilitation and better compliance. The greater anti–negative symptom response to at least risperidone, olanzapine, and sertindole is a hopeful development. Negative symptoms may fluctuate with relapse and be secondary to positive symptoms or to striatal D_2 blockade (drug induced). Whether the deficit symptoms are responsive to SDAs is unresolved. The lack of antimuscarinic effects (e.g., cognitive interference and sedation) of the newer agents, as with clozapine, chlorpromazine or extrapyramidal adverse effect treatment, may allow better cognitive rehabilitation. Preliminary evidence suggests that cognition improves beyond what is to be expected from the lack of adverse effects. However, well-controlled and well-executed cognitive studies with the newer agents are expected. Other qualitative advantages that are not well addressed with the usual ratings scales seem to be present and require a more focused approach.

Patients with an early age of onset who did not undergo the normal adolescent peer experience and developmental tasks may be unable to deal with the demands of adult life despite absence of schizophrenic symptoms. How this deficiency should be treated is still unknown, but it suggests that therapists and case managers must deal with improvements in a realistic and supportive manner.

How Different Are These Drugs? How much these drugs differ in their clinical profile is unknown. The low adverse-effect profile of the new SDAs makes them attractive first-line agents in first-break patients. Preliminary data suggest that these drugs (e.g., olanzapine and ziprasidone) have antidepressant effects in schizophrenia patients. However, published studies have not addressed the same questions across all SDAs, and others may have similar effects. Anecdotal evidence suggests that an unsatisfactory response to one SDA may not preclude a positive response to any other and that addition of a traditional agent may increase effectiveness as well. Until more studies in treatment-resistant schizophrenic patients have been published with these newer SDAs, clozapine will remain the drug of choice in these patients. However, clinicians should try the newer agents first in chronic patients with serious residual symptoms, as they may be more effective than the traditional agents, with fewer adverse effects. They may replace clozapine for many patients for whom clozapine is considered appropriate. Comparison studies among the SDAs are needed to ascertain specific differences in clinical efficacy and adverse effects.

The authors have spoken out over the years against concurrent use of multiple antipsychotic drugs (polypharmacy). There is a clinical impression from case reports that poor responders to clozapine may do well with addition of a high-potency D_2 blocker (e.g., pimozide). Double-blind trials are obviously needed to address this question. Such additions need to be monitored closely and discontinued as soon as it is clear that they did not induce any change. Similarly, when a patient is gradually switched over to SDA treatment, the original medication can be fully withdrawn within 1 to 2 weeks of having reached the desired dose of the SDA; this is to prevent confusion and to decrease the risk of adverse events. Whether treatment response is associated with specific patient-related factors is not known. With each new agent that reaches the market, the need to identify the responder group becomes more important. The authors expect that genetic approaches to identifying responders and nonresponders to the SDAs will soon become acceptable. At the same time, the fewer adverse effects of these new drugs promise better compliance rates than before. Patients report that they like the new drugs better than conventional agents, but many patients will likely continue to be noncompliant. Initial studies show increased quality of life and increased time in the community, which make these new agents quite attractive.

Therapists' enthusiasm about improvement and unrealistic expectations of a cure must be checked. Patients may be forced into unacceptable situations and stress by the denial of how impaired many patients still are. Clozapine does improve about 30 to 50 percent of patients who did not respond to older drugs, but many patients do not respond, remain severely impaired, or cannot tolerate the drug. Unrealistic expectations of the newer drugs may lead to disappointments. Although perhaps at a lower rate, patients will continue to relapse through noncompliance, stress, or spontaneous fluctuations of the illness, regardless of the level of improvement.

The traditional agents may have some protective effects at the onset of the illness, as shown by a better outcome with a shorter psychotic pretreatment phase during the first episode. If treatment of first-break patients prevents early deterioration, the SDAs may be particularly promising. Such effects may be neuroprotective on the basis of their anti-PCP or sigma receptor binding properties. The ultimate recovery potential may remain limited in some because the major lesions in schizophrenia may have preceded the actual appearance of psychosis. On the other hand if the major lesion in schizophrenia is altered neuronal circuitry, our hope may be justified. The next 5 to 10 years will show whether the course of schizophrenia can be improved.

Some patients may not calm quickly enough with SDAs in the beginning of treatment, and addition of benzodiazepines or a traditional high-potency antipsychotic may be needed temporarily. SDAs are unavailable in short- and long-acting injectable or liquid forms, which limits their use as first-line drugs and in maintenance treatment. Several pharmaceutical companies are exploring injectable forms (e.g., ziprasidone), skin patches, liquid forms (e.g., quetiapine) or easily dissolvable wafers (e.g., olanzapine). Long-acting injectables are not expected within the next few years. The increased activity in antipsychotic drug development and marketing (e.g., treatment guidelines, patient support services, public education) means that clinicians and families will become better educated about treating patients with schizophrenia. The SDAs are being tried in a much wider diagnostic range than the traditional indication of acute and chronic psychosis. Risperidone and olanzapine are presently being developed as mood stabilizers. Preliminary reports of studies in acute mania and chronic affective disorders are encouraging.

Preliminary pharmacoeconomic studies suggest that the extra costs are sometimes offset by the greater efficacy. Even if the newer agents are more expensive, the decrease in hospitalizations, the better quality of life, the fewer adverse effects, and the great improvements in some schizophrenic patients will make treatment with these agents worthwhile. Pharmaceutical companies will continue to search for better antipsychotic compounds, which may not affect dopamine or serotonin activity. At this time, though, the new drugs promise to be real alternatives to traditional agents in first-break patients and in those who respond poorly to the traditional agents or cannot tolerate their adverse effects. The new agents have raised hope for patients and their families.

SUGGESTED CROSS-REFERENCES

Section 12.8 discusses the somatic treatment of schizophrenia. Section 31.17 provides a discussion of the dopamine receptor antagonists. Amino acid and monoamine neurotransmitters are covered in Section 1.5 and Section 1.4 respectively.

31.27 SYMPATHOMIMETICS

JAN FAWCETT, M.D.

Sympathomimetic amines are defined as naturally occurring catecholamines and drugs that mimic their actions. They are currently referred to as stimulant drugs, which can increase motivation, mood, energy, and wakefulness. While these drugs act specifically on symptoms of poor concentration and hyperactivity in children and adults, as well as being approved for use in increasing alertness in narcolepsy, they were also used to maintain wakefulness, alertness, energy, and confidence in combatants in the air and on the ground in several wars, ranging from Bavarian soldiers in the mid 1880s to extensive use in World War II and in fliers in the Gulf war, and most recently in sleep-deprived combat helicopter pilots. Because of their rapid onset, immediate behavioral effects, and propensity to develop tolerance, which leads to the risk of abuse and dependence in vulnerable individuals, they have been classified as controlled drugs and are stigmatized, and their manufacture, distribution, and use are regulated by state and federal agencies.

Despite these caveats, their use persists and may be increasing in medicine and psychiatry in specific clinical situations. Stimulants can be of great help, if appropriately prescribed and monitored, because of their effectiveness in specific clinical situations in which no other drug has been helpful. Sympathomimetics have been widely used in attention-deficit/hyperactivity disorder and narcolepsy because no other equally effective agents exist and have been found effective in certain cognitive disorders that result in secondary depression or profound apathy (e.g., acquired immune deficiency syndrome [AIDS] depression and dementia, closed head injury), as well as in the pharmacological augmentation of antidepressant medications in specific treatment-refractory depressions.

The compound *d,l*-phenylisopropylamine or amphetamine, was first evaluated in the early 1930s when the dextrorotatory isomer, dextroamphetamine (Dexedrine), was found to increase wakefulness and alertness, to promote improved physical and mental performance, and to suppress appetite. Amphetamine was used to treat narcolepsy (in divided doses of 30 to 50 mg a day) then postencephalitic parkinsonism, epilepsy, and for a while barbiturate poisoning. In the early 1940s amphetamine was thought to be useful for treating “psychopathic states and delinquency” with mixed results, which preceded its use in children with attention-deficit/hyperactivity disorder. Controlled studies in depression did not support routine use of amphetamine especially in the face of the risk of dependence and abuse in the late 1960s. In the 1960s amphetamines were used with mixed results in the treatment of obesity. In 1970, amphetamine and its derivatives were scheduled and regulated under the Controlled Substances Act. While the indications for the use of sympathomimetic stimulants have narrowed over the years and their risks have been recognized, they continue to play a growing role in behavioral medicine and psychiatry. Recently, a product that is a combination of dextroamphetamine and amphetamine (Adderall) has been marketed for the treatment of attention-deficit/hyperactivity disorder.

CHEMISTRY

Amphetamine, or racemic phenylisopropylamine, is similar in structure to the catecholamines such as dopamine and norepinephrine, but unlike catecholamines, crosses the blood-brain barrier (Fig. 31.27-1) The dextrorotatary isomer was found to be 3 to 4 times more potent in behavioral effects than the levorotatory isomer. An a-methyl group protects amphetamine from rapid breakdown by the monoamine oxidase (MAO) type A enzyme that breaks down catecholamines (Fig. 31.27-1).

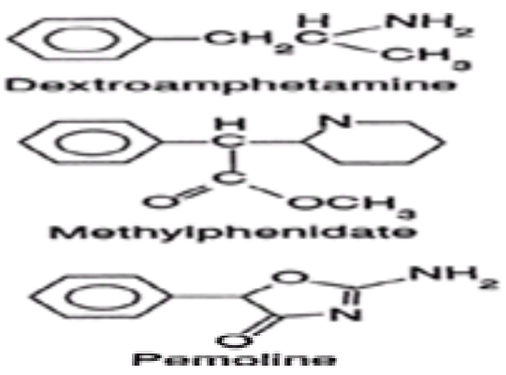

FIGURE 31.27-1 Molecular structures of selected sympathomimetics.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics Dextroamphetamine reaches peak blood levels in 2 to 3 hours, with a variable effect of several hours after oral administration. Though partially metabolized hepatically, almost half is excreted unchanged in the urine, constituting the basis for using ammonium chloride to acidify the urine, which can markedly increase excretion in the management of amphetamine overdose.

Methylphenidate (Ritalin) is a piperidine derivative, structurally related to amphetamine (Fig. 31.27-1), a mild stimulant, with some of its effects. It reaches peak blood concentrations in 2 hours and has a short half-life of 1 to 2 hours. Concentrations of methylphenidate in the brain exceed blood concentrations. Ritanilic acid is the major metabolite excreted in urine.

Pemoline (Cylert) is structurally dissimilar to methylphenidate (Fig. 31.27-1) but exerts similar mild stimulant effects. It peaks in 2 to 4 hours in blood but has a longer half-life of 5 to 7 hours in children. It is partially (about 50 percent) bound to proteins, with about half excreted unchanged in urine.

Pharmacodynamics All of the stimulants are considered indirect-acting sympathomimetics because they do not act directly on receptors as do natural cathecholamines but increase their effect by increasing release at the synapse while blocking reuptake (therefore slowing metabolism and increasing effect). Dextroamphetamine is the most potent by virtue of its ability to release both dopamine and norepinephrine and its capacity to release both newly formed soluble pools and granule-stored pools of catecholamines in nerve endings. Methylphenidate and pemoline act mainly on dopamine (not norepinephrine as well) through release of dopamine from granular pools of dopamine and blockage of the reuptake of dopamine. This may explain why amphetamine is a more powerful stimulant and is more likely to activate latent hypertension than methylphenidate.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Attention-Deficit/Hyperactivity Disorder The treatment of symptoms of narcolepsy, the treatment of attention-deficit/hyperactivity disorder, and more recently residual attention-deficit/hyperactivity disorder in adults are clinical uses that have continued to be dominant treatments since early observations of these effects with the discovery of amphetamine's actions. R.A. Barkley's 1976 review of studies involving a total of 915 child and adolescent patients (mainly treated with methylphenidate) showed that approximately three-quarters showed improvement, though he concluded that long-term psychosocial adjustment was unchanged. A

more recent review of 11 randomized, controlled, longer-term studies (mainly methylphenidate) indicated clear benefit of sustained treatment on core behavioral features of attention-deficit/hyperactivity disorder (poor sustained attention, impulsiveness, and excessive motor activity). Two most recent comprehensive reviews by different groups conclude that given adequate doses of stimulants, approximately 70 percent of those treated achieve significant improvement in cognitive function and behavioral problems; improved social interactions with family, teachers, and peers; and improved self-esteem. After reviewing the available data regarding the use of newer antidepressants, such as buproprion and ventralaxine, as well as other pharmacotherapies for attention-deficit/hyperactivity disorder, in 1997 C.W. Popper concluded that “psychostimulants remain the treatment of choice because of their unique effect on attention.”

Treatment-Resistant Depression and Medical Depression Case reports of the effectiveness of adding psychostimulants such as methylphenidate and dextroamphetamine to tricyclic drugs and serotonin reuptake inhibitors in treatment-resistant depression have been published recently. The effectiveness of these psychostimulants in modest doses in the treatment of depression in the medically ill has been documented as for the use of stimulants in the treatment of depression in the elderly. Methylphenidate has been reported to be beneficial with depressed hospice patients. Early controlled trials of amphetamine use in clinical depression failed to show significant therapeutic effect as monotherapy, but the methodology of these studies has been questioned. This, in the context of the risk of dependence and abuse, resulted in the exile of stimulants from conventional psychiatry. More recently case report data and open clinical trials have again raised the possibility of the effectiveness and usefulness of stimulants as an augmentation medication in treatment-resistant depression and as monotherapy in medical depression (patients with depression associated with comorbid medical conditions such as stroke, AIDS, and cancer pain treated with high-dose opioids, with consequent mood-obtunding effects). Several case reports of the effectiveness of adding stimulants to tricyclic drugs and serotonin-reuptake inhibitors in treatment-resistant depression have been published and have been recently reviewed by A. Nierenberg, and colleagues. The use of stimulants to augment the effects of MAO inhibitors (MAOIs) in treatment-refractory patients (many who had benefited from electroconvulsive therapy [ECT]) who constituted high suicide risks in their untreated state has also been reported. This report emphasized the importance of documenting a risk-benefit analysis, informed consent including the reports of three deaths associated with this combination in years past, as well as obtaining double consent (patient and significant other) and recognition that this combination is listed as contraindicated in the labeling of available monoamine oxidase inhibitors.

Central Nervous System Damage Increasing reports are appearing of the successful use of sympathomimetic stimulants in patients with central nervous system (CNS) damage stemming from stroke, closed head injuries, AIDS dementia, and related disorders characterized by mental dulling, apathy, cognitive decline, lack of motivation, lack of initiative, and lack of energy as well as depression. All of these reports are relatively unsupported by controlled studies, except for comparison studies of stroke patients, but three recent reports of controlled studies in 88 total patients support positive outcomes previously reported. One report of benefit in a patient improving from severe apathy following subcortical infarcts demonstrated improved frontal lobe functions by single photon emission computed tomography (SPECT) scan and reaction times. Five of six placebo-controlled studies of methylphenidate in geriatric patients with early dementia and symptoms of apathy have demonstrated effectiveness. J. Whyte and colleagues recently published positive effects of methylphenidate in traumatic brain injury patients from a randomized placebo-controlled trial. Most recently, M.A. Glen has reviewed the use of methylphenidate for cognitive and behavioral dysfunction after traumatic brain injury, C. Grabe and colleagues have recently published a placebo-controlled study of methylphenidate in post stroke recovery. Of particular interest is the recent report of C.A. Meyers and colleagues showing significant improvement in cognitive function in a study of thirty patients with brain tumor, with very few adverse effects and no seizures noted, with dosages of methylphenidate ranging from 10 to 30 mg twice daily.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Central Nervous System Amphetamine stimulates the medullary respiratory center and has excitatory effects on cortical function. Depending on personality and contextual factors, amphetamine in adults can increase wakefulness, energy, alertness, initiative, self confidence, and physical and mental performance, lessen fatigue, and produce euphoria. These effects occur shortly after dosing. Because of these sometimes dramatic, rapid-onset effects as well as the tendency for tolerance of these effects to develop, the danger of drug dependence and potential for abuse must be kept in mind. After withdrawal of the drug, patients who have been taking excessive doses may note excessive tiredness and sleepiness. More important, the patient may experience severe depression with suicidal im pulses. In children and adults with attention-deficit/hyperactivity disorder, stimulants do not produce euphoria but tend to reduce hyperactivity and help to focus and sustain attention.

Cardiovascular System Amphetamines can cause increased blood pressure (particularly in patients with hypertension), and with high doses, cardiac arrhythmias can result (particularly in patients with cardiovascular disease). Such effects are not likely at usual clinical doses in a patient without cardiovascular disease or hypertension. Amphetamine is more potent in producing cardiovascular effects than dextroamphetamine because of more potent effects on norepinephrine.

More recently, the mild stimulant phentermine (Ionamin) was frequently administered with the serotonergic drug fenfluramine in combination for weight loss; the combination was popularly known as “Fen-Phen.” Because of evidence suggesting the possibility that fenfluramine used alone or in combination may in some cases lead to pulmonary hypertension and cardiac valvular disease, fenfluramine was voluntarily withdrawn from the market. It was not determined whether phentermine increased the likelihood of these adverse effects when used in combination with fenfluramine.

Endocrine Effects Early reports suggested that both dextroamphetamine and methylphenidate might suppress growth in children. A recent controlled study of children and young adolescents found small but significant height differences evident in early (but not late) adolescent children with attention-deficit/hyperactivity disorder, unrelated to the use of psychotropic medications. This study concluded that the effects on growth seemed to be related to the disorder, not its treatment.

Hepatic Effects In the past year attention has been drawn to possible liver toxicity associated with the use of pemoline. The frequency of this risk is still debated, but it has led to recommendations for liver function monitoring and a labeling warning that pemoline should not ordinarily be considered first-line drug therapy for attention-deficit/hyperactivity disorder.

THERAPEUTIC INDICATIONS

Amphetamine is approved for use in attention-deficit/hyperactivity disorder, narcolepsy, and exogenous obesity, though tolerance develops to its anorectic effects. Food and Drug Administration (FDA)-approved uses of methylphenidate include attention-deficit/hyperactivity disorder and narcolepsy. Pemoline is also approved by the FDA for attention-deficit/hyperactivity disorder. As reviewed above, open studies and comparative studies support the usefulness of amphetamine and methylphenidate for depression secondary to medical conditions, apathy and depression secondary to CNS disease or trauma, relief of obtunding effects of opioids in cancer patients, and augmentation of antidepressant medication in some cases of treatment-resistant depression.

PRECAUTIONS AND ADVERSE REACTIONS

Adverse effects (Table 31.27-1) noted with therapeutic doses of amphetamines include mild gastrointestinal disturbance, dryness of mouth, tachycardias, cardiac arrhythmias, insomnia, and restlessness. Headache, palpitations, agitation, confusion, dysphoria, apprehension, and delirium have also been reported. Adults and children may note depressed appetite, which develops tolerance over time, limiting these stimulants' effectiveness as anorectics with long-term use. Adverse effects can include overstimulation and precipitation of mania or psychosis (especially in vulnerable individuals). Medically unsupervised use of amphetamine can involve excessive doses, which can result in such effects as loquaciousness, overcheerfulness, restlessness, rapid and slurred speech, tension, anxiety, and irritability. Excessively dry mouth, with a tendency to rub the tongue along the inside of the lower lip, tachycardia, cardiac arrhythmias, brisk reflexes, dilation of the pupils, and a fine tremor of the limbs may occur. A paranoid psychosis in the setting of clear consciousness may occur. A rare, short-lasting confusional state may occur. There have been an increasing number of case reports of myocardial infarction, cerebral hemorrhage, and cerebral angiitis in individuals who were either abusing the drug intravenously or ingesting toxic doses. While the potential for abuse and dependence should be of concern in adults, especially those with past or family history of substance abuse or antisocial personality, there is no evidence of abuse liability in children treated for attention-deficit/hyperactivity disorder. Because this diagnosis in adults is sometimes problematic and often confounded by comorbid diagnoses of substance abuse or antisocial behavior or both, care must be taken in the use of stimulants in this instance. The possible effectiveness of noradrenergic antidepressants such as desipramine (Norpramine), venlafaxine (Effexor), and buproprion (Wellbutrin) provides alternative choices. Stimulants are relatively well tolerated by elderly patients.

Table 31.27-1 Management of Side Effects of Sympathomimetic Drugs

DRUG INTERACTIONS

Amphetamine may interfere with therapeutic effects of antihypertensive medications. In small doses, amphetamine may augment the analgesic effects of opiates. Methylphenidate may partially inhibit the metabolism of tricyclic drugs, warfarin (Coumadin), primidone (Mysoline), phenobarbital phenytoin (Dilantin), and phenylbutazone (Butazolidin). Because of three deaths from two fulminating hypertensive reactions and one case of hyperthermia reported when amphetamine was added to MAOI, this combination has been contraindicated in the labeling of MAOIs. Combination of any stimulants with MAOIs has been contraindicated by extension. The combination was reported to be effective in treatment-refractory patients in two small open series. Therefore, this combination should be used only when justified by a risk-benefit analysis and with informed consent, preferably of the patient and significant others.

LABORATORY INTERFERENCE

Amphetamines may elevate plasma corticosteroid concentrations.

DOSAGE AND ADMINISTRATION

Sympathomimetic therapy should be started at low dosages and increased in small increments every 3 to 7 days to determine the most-effective and best-tolerated dose for the individual patient. Methyphenidate is the most used drug in the treatment of attention-deficit/hyperactivity disorder, with the most studies reported. It has a lower likelihood of abuse than amphetamine. Dextroamphetamine is about twice as potent as methyphenidale. Dextroamphetamine and methylphenidate are given in divided doses, with the second dose in the early afternoon to avoid insomnia, while pemoline is given in one morning dose. The usual dosage of dextroamphetamine is 20 to 40 mg a day in doses of 5 to 10 mg two or three times daily, and 20 to 60 mg of methylphenidate daily is given in doses of 10 to 20 mg two or three times daily (Table 31.27-2).

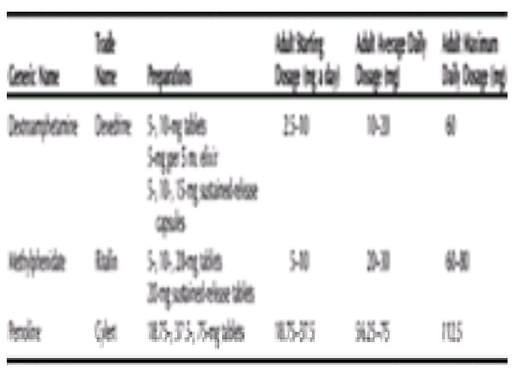

Table 31.27-2 Sympathomimetics

SUGGESTED CROSS-REFERENCES

Attention-deficit/hyperactivity disorder is discussed in Chapter 39. Amphetamine abuse is discussed in Section 11.3 and the treatment of mood disorders is discussed in Section 14.7.

CHAPTER 31. BIOLOGICAL THERAPIES

31.28 THYROID HORMONES

RUSSELL T. JOFFE, M.D.

HISTORY

The link between thyroid disease and psychiatric symptomatology, particularly depression, was well established more than 100 years ago. The clinical literature of the late nineteenth century has rich description documenting a relation between melancholic symptoms and myxedema. These observations in endocrine patients led to the logical assumption that patients with depressive illness might have abnormalities of their thyroid axis that were of etiological importance to their psychiatric illness. A concerted research effort over the last 40 years, however, has failed to demonstrate a specific abnormality of thyroid function test result in patients with primary depressive illness. Over these years, tests of thyroid function have become greatly refined and more accurate, yet they find no direct etiological link between even subtle forms of hypothyroidism and major depressive disorder. Some patients with major depression have evidence of clinical or subclinical hypothyroidism, but they are a relatively small number, and most patients presenting with depression to a psychiatric clinic are euthyroid by both clinical examination and laboratory tests. Although up to one-third of depressed patients have a blunted thyrotropin (TSH) response to thyrotropin-releasing hormone (TRH), the pathophysiological significance of this finding remains unresolved and it has limited clinical utility.

Prompted by the link established between thyroid disease and psychiatric symptomatology in the endocrine clinics and by the lack of effective psychotropic treatments, hormones in general and thyroid hormones in particular were used in the earlier part of the century to treat psychiatric illness. The results were mixed, and the practice fell into disrepute. In the 1960s, levothyroxine (Levoxyl, Levothroid, Synthroid), synthetic forms of thyroxine (T_4) and liothyronine (Cytomel), the synthetic levorotary isomer of triiodothyronine (T_3), were developed and soon replaced desiccated thyroid as the primary agents in replacement therapy in patients with thyroid disease. As a result of seminal work carried out by Arthur Prange and collaborators in the United States, beginning in the late 1960s, the modern era of therapeutic use of thyroid hormones in the treatment of depression began and became established. This effort to generate systematic data on the efficacy of thyroid hormones as psychotropic treatments has been largely confined to the mood disorders, primarily unipolar depression but also some subtypes of bipolar mood disorders.

CHEMISTRY

Two main hormones are produced by the thyroid gland, T4 and T3. The main source of circulating T_4 is the thyroid gland; T_3 is derived largely by monodeiodination of T_4 in extrathyroidal tissues. Both these hormones have been used in the treatment of mood disorders. Their structure is shown in Figure 31.28-1.

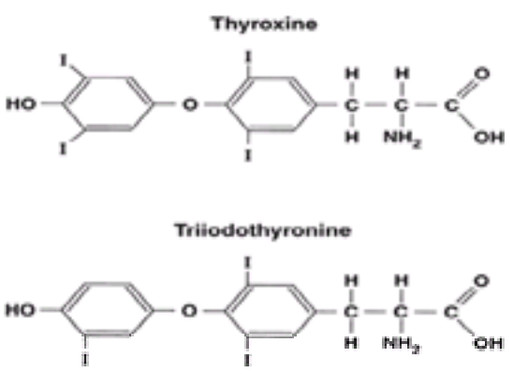

FIGURE 31.28-1 Molecular structures of thyroxine and triiodothyronine.

In addition, several other thyroid hormones are produced including reverse T_3, 3-diiodothyronines, 1-monoiodothyronine, and the acetate metabolites of T_4 and T_3, respectively, tetrac and triac. All of these hormones are produced in substantially lower amounts than either T_4 or T_3 and have uncertain physiological significance.

Secretion of thyroid hormones by the thyroid gland is regulated by the hypothalamic-pituitary-thyroid axis. Regulation of the thyroid axis is illustrated in Figure 31.28-2.

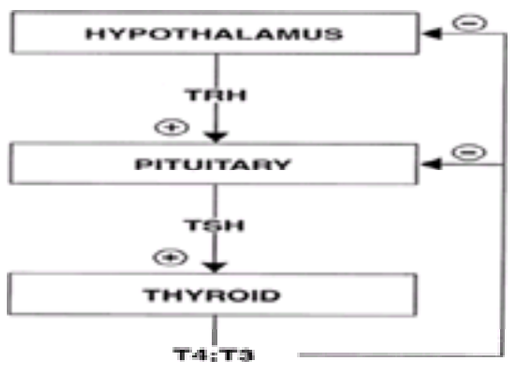

FIGURE 31.28-2 Schema of the feedback control of the hypothalamic-pituitary-thyroid axis.

Cells of the hypothalamus secrete the tripeptide TRH, which regulates the release of TSH from anterior pituitary cells via the portal venous blood system connecting the hypothalamus to the pituitary gland. The TSH is then released from the pituitary where it acts on the thyroid gland to stimulate production of T_4 and T_3. Through a negative-feedback system operating at both the level of the pituitary and of the hypothalamus, circulating levels of T_4 and T_3 regulate the activity of the thyroid axis.

In many respects, T_4 is regarded as a prohormone since its action seems to depend largely on its conversion to T_3, which then acts at the T_3 receptor to initiate the metabolic action of thyroid hormones. For the most part this conversion of T_4 to T_3 occurs in the circulation: thus the thyroid hormone available to peripheral tissues is largely T_3. The major exception is brain and to a lesser extent pituitary where the main source of thyroid hormone for action at the receptor is T_4 that gets converted

locally within the neuron to T_3 before exerting its physiological action.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics Levothyroxine and liothyronine are relatively small molecules that are easily and completely absorbed across the gastrointestinal tract. Both of these hormones are strongly bound to binding proteins and are widely distributed in tissues. There is active transport of thyroid hormones, particularly levothyroxine, across the blood-brain barrier. In addition transport mechanisms exist at the choroid plexus for movement of thyroid hormones within the central nervous system. A series of deiodinase enzymes metabolize thyroid hormones to smaller, less-iodinated molecules that are then excreted both in urine and feces. Levothyroxine has a relatively long half-life of approximately 1 week; liothyronine has a half-life of approximately 8 to 12 hours.

Pharmacodynamics Thyroid hormones have widespread metabolic effects. They are essential for brain development in the maturing infant and, in adults, play key roles in both protein synthesis and calorigenesis.

Until about 20 years ago, it was generally accepted that thyroid hormones had little if any effect on mature brain function. Considerable evidence now indicates that this is not the case and that thyroid hormones may have key roles in mature brain function. Important interactions exist between thyroid hormones and various neurotransmitter and neuropeptide systems in the brain, which may account for the putative effect of thyroid hormones on mood, behavior, and cognition in the adult. Thyroid hormones may also be important in maintaining neuronal cytoarchitecture.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

All of the hormones of the thyroid axis have been used for the treatment of depression, either as monotherapy or in combination with antidepressants. The best evidence for therapeutic efficacy is the use of liothyronine to augment therapeutic response in antidepressant nonresponders. Preliminary evidence suggests an antidepressant acceleration effect of liothyronine and a mood-stabilizing effect of levothyroxine in bipolar I disorder patients.

Various hormones of the hypothalamic pituitary thyroid axis have been used in the treatment of mood disorders. These include the highly purified TSH preparation thyrotropin (Thytropar), TRH, liothyronine, and levothyroxine. Thyroid hormones have been used in several ways including as monotherapy for depression, combined therapy with an antidepressant to accelerate the therapeutic effect of the antidepressant and augmentation therapy to enhance the effects of treatment after patients have failed to respond to a standard antidepressant.

Thyrotropin-Releasing Hormone (TRH) TRH, in addition to being released from the hypothalamus to regulate the thyroid axis, has behavioral effects independent of its effect on thyroid function. TRH affects various aspects of cerebral function including reversal of drug-induced sedation or anesthesia and stimulation of locomotor activity and also affects cardiorespiratory, gastrointestinal, and neurological functions. Because this peptide may stimulate the thyroid axis and may also have widespread effects on the central nervous system, it has been tested as an antidepressant. It has been used both as monotherapy and in combination with electroconvulsive treatment.

Several studies have examined the therapeutic effect of either intravenous or oral administration of TRH in patients with depression (Table 31.28-1). In one of the first placebo-controlled trials A. J. Kastin and collaborators reported a transient antidepressant effect in four of five patients who were administered 500 µg of TRH intravenously as a single dose. Prange and collaborators used a similar design to show that the transient antidepressant effect of TRH was superior to that of placebo in a small number of patients. Later studies have reported no effect or a very minimal therapeutic response to administration of either oral or intravenous TRH as monotherapy for times varying from one dose to several days or weeks. Results of oral and intravenous administration were not substantially different. These preliminary data suggest that TRH has no substantial antide pressant effect. The transient effects noted in some of these studies may be a nonspecific activating effect of the peptide rather than a specific antidepressant response. In another type of study, researchers used a randomized, double-blind, placebo-controlled, crossover design and administered 500 µg of TRH to eight depressed patients who were going to receive electroconvulsive therapy. TRH infusions before the electroconvulsive treatments yielded greater arousal and better cognitive functioning than placebo. TRH did not appear to have any direct effect on any seizure variables induced by the treatment. Although this study is of some interest, the data are preliminary and require replication. In particular, conclusions from this study are limited by the small number of patients and the question of whether this was a nonspecific effect of reducing the sedation associated with anesthesia rather than a true antidepressant response.

Number of Studies	Total N	Route of Administration	Result
3	36	Single intravenous dose	1 of 3 shows TRH > placebo
6	86	Intravenous doses over 3–4 days	1 of 6 shows transient effect
3	52	Oral doses for 7–30 days	1 of 3 shows no difference from amitriptyline

Table 31.28-1 Antidepressant Effect of Thyrotropin-Releasing Hormone (TSH)

Thyrotropin The rationale for investigating the use of thyrotropin was that it would stimulate thyroid function and thus have antidepressant action. Only one study to date has examined the antidepressant effect of thyrotropin. Prange and collaborators administered 10 IU of thyrotropin intravenously to 20 depressed women 1 day before beginning an imipramine (Tofranil) antidepressant trial. The thyrotropin-treated group had a more rapid antidepressant response than the saline-treated controls. Although these data are of considerable interest they require replication with larger samples and modern approaches to the diagnosis of depression, and the definition of response to treatment before one can conclude that thyrotropin accelerates response to antidepressants.

Liothyronine Liothyronine has been used in three ways to treat depressed patients. First, two early studies examined its use as monotherapy for the treatment of depressed patients. Although the data from these studies suggested some antidepressant activity, their findings are limited by methodological flaws including heterogenous patient samples; the lack of operational criteria to define the diagnoses of subjects in the studies; the open, uncontrolled nature of the trials; and the failure to provide systematic criteria for evaluating treatment response. As a result of these methodological limitations, liothyronine as monotherapy has not gained any clinical utility in the treatment of depression.

Second, Prange and collaborators used liothyronine to accelerate the response to tricyclic antidepressant treatment. In several studies they demonstrated that coadministration of liothyronine at the outset of the antidepressant trial with imipramine gave a shorter lag in onset of antidepressant response than that with placebo controls. This acceleration effect was seen in women but not in men. Several other groups replicated these findings, although some studies also gave negative results. All these studies, both positive and negative, suffer from methodological limitations including poorly defined patient samples, suboptimal antidepressant trials by current standards, and small sample sizes. Since the lag in onset of antidepressant response remains one of the great therapeutic challenges, it is puzzling that these early studies have not been followed up to determine whether liothyronine has a place in accelerating antidepressant response.

Finally, liothyronine has been used to augment the response to tricyclic drugs in patients who fail to respond to antidepressant treatment (Table 31.28-2). Both open and controlled studies using a variety of antidepressants have consistently shown that about 55 to 60 percent of patients who are nonresponsive to tricyclic drugs respond within 2 to 3 weeks after the addition of 25 to 50 µg of liothyronine. A recent meta-analysis of these studies suggest that liothyronine may increase response rates and decrease severity of depression scores in patients refractory to tricyclic antidepressant therapy. Patients treated with liothyronine augmentation were twice as likely to respond as controls. Although the meta-analysis demonstrated moderately large improvements in depression scores, the authors concluded that the generally uneven quality of the studies limited conclusions from the meta-analysis.

Study	N	Liothyronine Dosage (mg/day)	Design	Result

Joffe et al., 1993	51	37.5	Randomized, double-blind, placebo-controlled	10/17 Liothyronine = lithium > placebo

Table 31.28-2 Triiodothyronine Augmentation of Antidepressants

The findings from the open and the controlled studies of liothyronine augmentation show generally good agreement. One study, by Michael Gitlin and collaborators, failed to find a significant difference between liothyronine and placebo in the potentiation of imipramine (Tofranil). The authors, however, used a 2-week, double-blind, crossover design that is problematic in evaluating antidepressant treatment response. However, a later study found liothyronine to be more effective than placebo and comparable to lithium. Despite this study, lithium is still widely accepted as a useful clinical strategy for augmentation of antidepressants in nonresponders, whereas use of liothyronine has been met with scepticism and is less commonly used. The studies to date (Table 31.28-2) as well as the meta-analysis suggest that at least for some patients, liothyronine may be an effective means of treating antidepressant nonresponders.

Liothyronine has also been used to augment the response to electroconvulsive treatment (ECT). In a preliminary study using a double-blind, placebo-controlled design, Robert Stern and collaborators observed that fewer ECT treatments were required for antidepressant response with liothyronine augmentation than with placebo. Furthermore, patients who received liothyronine had less cognitive disturbance associated with ECT. It is unclear whether this preservation of cognitive function was a direct effect of the thyroid hormone or was related to the reduced number of ECT treatments required for response with liothyronine augmentation.

Levothyroxine Most studies of thyroid hormone augmentation of antidepressants have involved liothyronine. It has generally been assumed that because T_3 is largely derived from the extrathyroidal conversion of levothyroxine and that liothyronine would have comparable efficacy in augmenting antidepressant response. Only one study to date has directly compared the two thyroid hormones. This study found liothyronine superior to levothyroxine in augmenting antidepressant response. Clearly, this finding requires replication. Furthermore, the absence of a placebo control in this study limits the conclusions that can be drawn. Another study reported that both liothyronine and levothyroxine were effective augmentation agents in 21 patients who had failed treatment with a tricyclic drug. Seven patients responded to augmentation with levothyroxine. However, five of these seven had evidence of subclinical hypothyroidism as determined by a maximum thyrotropine response to TRH exceeding 25 µ/mL at baseline prior to thyroid hormone augmentation. Therefore it is unclear whether in this study, levothyroxine had an antide pressant augmentation effect or whether the therapeutic response was the result of T_4 replacement therapy for subclinical hypothyroidism.

A number of studies have evaluated whether levothyroxine treatment is effective in patients with bipolar I disorder. The rationale for the use of levothyroxine in this group of patients came largely from early data that suggested a higher prevalence of clinical and subclinical hypothyroidism in patients with bipolar disorders, particularly rapid-cycling. Although the specificity of hypothyroidism in rapid cyclers remains unclear, several open studies document the efficacy of high dosages of levothyroxine in patients with this disorder. Although the earlier studies used very large dosages of levothyroxine (300 to 500 µg a day), later studies used dosages that yielded serum levothyroxine concentrations slightly above the upper range of normal. Although these studies conclude that levothyroxine may have mood-stabilizing effects, particularly when used as an adjunct to other mood stabilizers such as lithium, the study findings are limited by their small sample sizes and open, uncontrolled designs. It has been suggested that the response of patients with bipolar I disorder to high dosages of levothyroxine does not appear related to their pretreatment serum levothyroxine levels, implying that the efficacy of levothyroxine may not be related to correction of underlying subclinical hypothyroidism. Preliminary data suggest that levothyroxine may also be effective in non–rapid-cycling bipolar disorders.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Thyroid hormones have ubiquitous effects on all organ systems. Until approximately 20 years ago mature brain was considered largely impervious to effects of thyroid hormone. Evidence now suggests that not only does the adult brain respond to thyroid hormones but it may be particularly sensitive to changes in concentrations of circulating T_4 and T_3. Preliminary evidence suggests that carefully regulated homeostatic mechanisms maintain brain thyroid hormone concentrations within very narrow limits.

THERAPEUTIC INDICATIONS

None of the thyroid hormones have received formal approval by regulatory authorities for use in the treatment of depression. However, a limited body of empirical data and widespread clinical experience suggest that these hormones may be useful in the treatment of patients with refractory depression and possibly refractory, rapid-cycling bipolar disorders. A substantial number of patients who receive optimum antidepressant treatment fail to respond or have only a partial response to therapy. Liothyronine remains a viable option for such patients along with other augmentation strategies such as lithium, the serotonergic agents such as buspirone (BuSpar) and pindolol (Visken) as well as the psychostimulants, among others. At present, no specific clinical or biochemical features are of use in determining which patients are more likely to respond to any one augmentation strategy. This applies as much to liothyronine as to any of the other augmentation treatments. Substantially more clinical experience and, particularly, empirical data are required to determine which treatment option should be used at what stage of treatment in individual patients. Such data will eventually lead to the rational development of algorithms for the treatment of refractory depression. Until this occurs, liothyronine remains one of many possibilities to consider for use in patients who fail to respond to their first antidepressant trial. Although its efficacy has been best demonstrated with tricyclic drugs, evidence suggests that liothyronine augments the effect of the monoamine oxidase inhibitors, the serotonin reuptake inhibitors, and several of the newer classes of antidepressant.

PRECAUTIONS AND ADVERSE REACTIONS

When liothyronine is used as an augmentation treatment, symptoms of thyroid excess or thyrotoxicosis are very unlikely. A dosage of 25 µg a day is below the replacement dosage for this hormone; thus symptoms of thyroid excess are extremely uncommon. This also applies to dosage of 50 µg a day, although this dosage is closer to the daily T_3 production rate and thus symptoms of thyroid excess could occur.

For the most part liothyronine is very well tolerated. Transient headache is the most commonly reported adverse effect, and this usually subsides spontaneously after 1 or 2 days. Allergic reactions are extremely rare. Liothyronine should be used with great caution in patients with certain medical disorders including endocrine disease and cardiovascular illness and should be avoided in pregnant patients.

If patients respond to liothyronine augmentation and it is used for a prolonged period of time, added caution should be observed in its administration. In particular, long-term thyroid hormone treatment may be associated with bone demineralization resulting in osteoporosis in women. Although this association is still controversial, one should approach the long-term use of liothyronine for the treatment of depression with caution.

DOSAGE AND ADMINISTRATION

Liothyronine is available in 5- and 25-µg tablets. It is usually administered as a single dose in the morning to avoid insomnia. There is a rationale for divided administration of liothyronine because of its short half-life, but a single daily dose is commonly used to improve compliance. Levothyroxine is available in a variety of strengths. It is administered in dosages that produce a circulating levothyroxine concentration exceeding the upper range of normal for the patient with bipolar I disorder. These dosage recommendations apply to healthy adults and should be modified for older patients. Levothyroxine should be used cautiously in elderly patients, particularly if there are concomitant medical disorders. There is no evidence for the efficacy of thyroid hormones in the treatment of mood disorders in

children.

SUGGESTED CROSS-REFERENCES

31.29 TRAZODONE

STEVEN J. GARLOW, M.D., PH.D. AND CHARLES B. NEMEROFF, M.D., PH.D.

Trazodone (Desyrel) was the first of the second-generation (“atypical”) antidepressants to be developed and marketed. Trazodone was atypical because of its lack of structural similarity to heterocyclic antidepressants. Trazodone was developed in response to the theory that major depressive disorder was caused by a paradoxical response to unpleasant and painful experiences. The compound has antinociceptive properties, and in the course of study of its preclinical pharmacology, it was found effective in animal models specifically developed to test this theory of depression. Trazodone is not active in conventional animal models of major depression where classic tricyclic drugs are effective, and tricyclic drugs are much less active in the animal model in which trazodone displays activity.

The compound was synthesized in Italy in the mid-1960s and was approved for clinical use in Europe in the early 1970s. Trazodone entered clinical trials in the United States in the late 1970s and received Food and Drug Administration (FDA) approval for use in major depression in 1981. Because of its unique pharmacological profile and relative safety, it rapidly captured a large share of the American antidepressant market. With the advent of additional sec ond- and third-generation antidepressants (e.g., selective serotonin reuptake inhibitors [SSRIs], selective-noradrenaline reuptake inhibitors [SNRIs]), the total number of trazodone prescriptions has declined.

Trazodone is a triazalopyridine derivative that had a unique chemical structure until the development of nefazodone (Serzone), a structurally related compound. Trazodone has complex and diffuse pharmacological actions in the central nervous system (CNS), with antagonist and agonist activity in the serotonergic system and antagonist activity in the adrenergic system. Trazodone is a weak inhibitor of serotonin reuptake, but it is a potent antagonist at serotonin (5-hydroxytryptamine [5-HT]) type 2A (5-HT_{2A}) and 5-HT_{2C} receptors. There is at least one active metabolite of trazodone, *m*-chlorophenylpiperazine (mCPP), which acts as an agonist at 5-HT_{2C} receptors and may act as an antagonist at 5-HT_{2A} receptors. The antidepressant property of trazodone is hypothesized to be due to both its 5-HT_2 antagonist and serotonin reuptake blocking activities. Trazodone has little or no effect on norepinephrine or dopamine reuptake. Trazodone has low affinity for muscarinic cholinergic receptors and therefore causes little in the way of anticholinergic adverse effects.

CHEMISTRY

Trazodone is a triazalopyridine derivative with some structural similarity to alprazolam (Xanax) (Fig. 31.29-1). The antidepressant activity may be due in part to the triazalo ring structure on the molecule. The chemical designation of trazodone is 2-[3-[4-(3-chlorophenyl) - 1 - piperazinyl]propyl] - 1,2,4 - triazalo[4,3 - a]pyridin-3(2H)one hydrochloride, with an empirical formula of $C_{19}H_{22}ClN_5 \cdot HCl$, and a molecular weight of 408.3. The compound is soluble in water and has a pKa of 6.7.

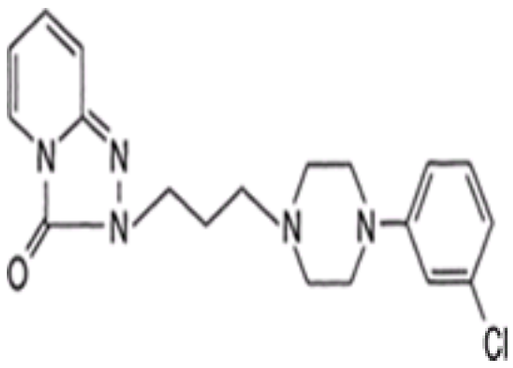

FIGURE 31.29-1 Molecular structure of trazodone.

PHARMACOLOGY

Pharmacokinetics Trazodone is rapidly and efficiently absorbed after oral administration. Peak plasma concentrations in fasting subjects are reached 1 hour after administration. Food slows the rate of absorbance but increases the total amount of drug absorbed, with peak plasma concentrations occurring 2 hours after administration and lower peak concentration values. Taking trazodone with food may minimize dose-dependent adverse effects because of the slower rate of absorbance and the lower peak serum concentration. Steady-state serum concentrations are achieved at 36 hours on a 50-mg twice a day regimen, with new steady-state concentrations being achieved in 12 hours when the dose is increased from that initial regimen. Within the dosage range of 50 to 150 mg twice a day, trazodone displays linear pharmacokinetic properties. There may be significant interindividual variation in the serum concentration of trazodone in subjects receiving the same dose. It is not clear whether there is a relationship between the serum concentration of trazodone and therapeutic response.

Trazodone is 85 to 95 percent protein bound in the blood and does not preferentially distribute to any one tissue. Both the parent compound and mCPP cross the blood-brain barrier. The drug is metabolized in the liver by the cytochrome (CYP) P450 2D6 isoenzyme. Trazodone does enter breast milk of lactating women at a low level, with the concentration in milk being approximately 10 percent of that in serum.

The half-life of the drug is from 5 to 9 hours, depending on the age and hepatic function of the patient, typically with a longer half-life in elderly persons. The elimination of trazodone is biphasic, with the initial phase having a half-life of 3 to 6 hours and the second phase having a half-life of 5 to 9 hours. Trazodone is metabolized in the liver by hydroxylation, oxidation and N-oxidation, and the hepatic metabolites are excreted by the kidneys. The metabolite mCPP has a longer half-life than the parent compound (14 hours vs. 5 to 9 hours) and is cleared more slowly.

Pharmacodynamics Trazodone has a variety of pharmacological actions measured with in vivo and ex vivo assays. Trazodone does block transport of serotonin into synaptosomal membrane preparations but has little impact on the platelet serotonin transporter of patients treated with the drug. There are minimal changes in the concentration of serotonin in the platelets of patients treated with trazodone. Trazodone has significant antagonist activity at the 5-HT_{2A} and receptor sites assayed with radioligand binding techniques on synaptosomal membrane preparations. Trazodone also inhibits a variety of behaviors in rodents produced by agonist action on the 5-HT_{2A} and 5-HT_{2C} receptor sites. Chronic administration of trazodone downregulates the 5-HT_2 receptors, causing a decrease in the number of receptor binding sites in the CNS. This effect has been hypothesized as central to the antidepressant action of the drug, because a number of other antidepressants cause downregulation of 5-HT_2 receptors.

The metabolite mCPP has both antagonist and agonist activities at a number of serotonin receptors. This compound is an antagonist at the 5-HT_{2A} receptor site but

an agonist at the 5-HT_{2C} receptor. mCPP may also be an agonist at other serotonin receptor sites. Administration of mCPP to experimental animals results in behavioral activation and enhancement of anxiety-provoking stimuli. Administration of mCPP to humans also has anxiogenic effects.

Trazodone acts as an antagonist at peripheral a-adrenergic receptors. This adrenergic receptor blockade probably accounts for the adverse effects of orthostatic hypotension, dry mouth, and priapism. Chronic administration of trazodone also downregulates b-adrenergic receptors in the CNS of experimental animals. Treatment of patients with the drug causes downregulation of b-receptors on platelets and lymphocytes. This drug has little or no activity at the noradrenergic or dopamine transporter sites in membrane preparations and behavioral assays. Trazodone has little affinity for muscarinic cholinergic receptors, histamine type 1 (H_1) receptors, and dopamine receptors.

Several studies have attempted to correlate steady-state plasma concentrations of trazodone to clinical response. The results of these studies are variable. One study in geriatric patients reported a threshold of 650 ng/mL for clinical response. A second study of geriatric patients reported an average serum concentration of 1474 ng/mL but indicated that subjects in the study who responded to trazodone had lower levels than the nonresponders. The authors concluded that this concentration may represent the top of the therapeutic window. A study of depressed patients in a primary care setting reported a threshold for response of 250 ng/mL, significantly lower than the thresholds reported in the geriatric studies. This may be due to demographic differences between the geriatric and primary care populations. Currently there has been no consistent report of a therapeutic blood level for trazodone or correlation between concentration in blood and clinical response, and there seems to be little utility in measuring trazodone blood concentrations as part of the general treatment of depression with this drug, with the exception of monitoring patient compliance.

DESIGN AND INTERPRETATIONOF CLINICAL DRUG STUDIES

Trazodone has been systematically studied for efficacy in the treatment of major depression, depression in the elderly, dysthymia, insomnia associated with depression and antidepressant treatment, schizophrenia, obsessive-compulsive disorder, anxiety disorders, eating disorders, chronic pain, geriatric cognitive disorders, developmental disorders, and male impotence. There are case reports of the use of trazodone in a large number of different psychiatric and neurological disorders. Trazodone has been studied extensively as a treatment for the depressive disorders, in which it is clearly as effective as other traditional antidepressants. The use of trazodone in the other neuropsychiatric disorders is reviewed below, though its use in these disorders has not been studied as extensively as its use in the treatment of depression.

Major Depressive Disorder The use of trazodone as an antidepressant has been studied in both inpatient and outpatient settings as well as in the primary care setting. Trazodone as a treatment for depression has been compared with imipramine (Tofranil), amitriptyline (Elavil), mianserin fluoxetine (Prozac), venlafaxine (Effexor), doxepin (Adapin), mirtazapine (Remeron), bupropion (Wellbutrin), and placebo in a variety of clinical settings and with a variety of experimental designs. In general, trazodone showed efficacy equal to the antidepressants with which it was compared, with the most significant differences between the agents being differences in their respective adverse-effect profiles and hence their tolerability. The particular subtype of depressive symptoms suffered by the subjects in the various studies also had an impact on the tolerability of trazodone. Depressed patients who experienced a great deal of anxiety and insomnia seem to benefit more from trazodone than patients suffering from significant anergia and psychomotor retardation.

Several published reviews have examined studies in which trazodone was compared with tricyclic drugs in the treatment of depression. These reviews concluded that trazodone is as effective as traditional tricyclic drugs (generally imipramine or amitriptyline) for the treatment of mild-to-moderate depression. In a meta-analysis that specifically examined those studies in which trazodone was compared with imipramine, a total of six independent reports met criteria for analysis: double-blind design, Hamilton Rating Scale for Depression (HAM-D) scores of 18 or more, and a 50 percent reduction in HAM-D score as a definition of treatment response. The meta-analysis revealed that trazodone and imipramine were equally efficacious in the treatment of depression across all six studies. Trazodone has also been compared with imipramine in the long-term treatment of moderately to severely depressed outpatients; in a double-blind study, with a 12-month blinded treatment phase, trazodone possessed equal or greater efficacy than imipramine. The authors also report continued benefit of trazodone up to 3 years after the 12-month blinded period in an open-label continuation phase.

There has been some question about the effectiveness of trazodone in patients suffering from more severe depressive disorders, as well as speculation that the anxiolytic and sedative properties of trazodone account for some or all of its antidepressant effect. In one case series in which trazodone was given to 13 endogenously depressed patients, only 3 had a positive response as defined by a 50 percent reduction in HAM-D score. This patient cohort was reported to be responsive to other antidepressant agents, and the authors concluded that the main indication for trazodone may be in treating nonendogenously depressed patients. The idea of trazodone's lack of effectiveness has been refuted in at least two different studies. In a retrospective chart review comparing 138 inpatients treated with amitriptyline with 42 inpatients treated with trazodone, the authors conclude that the trazodone-treated patients were started at dosages below the recommended dosage of 150 mg a day, with a mean starting dosage of 113 mg a day (±42 mg) and were at final dosages significantly below those reported optimal for the treatment of depression, with final mean dosage of 217 mg a day (±87.5 mg) compared with an optimal dose of 250 to 350 mg a day. The authors conclude that the apparent lack of response to trazodone may be due in part to inadequate dosing at a subtherapeutic level. In a meta-analysis that compared the effectiveness of imipramine with that of trazodone, bupropion, and fluoxetine in the treatment of depression, all four agents were deemed more effective than placebo. This analysis had very strict criteria including placebo control, double-blind design, HAM-D as a dependent measure, nongeriatric adults meeting DSM-III or Research Diagnostic Criteria (RDC) criteria for major depression, and reported means and standard deviations for responses. The analysis did not support the hypothesis that imipramine was more effective than the newer agents. The authors concluded that there are no differences in the efficacy of all four agents in the treatment of depression.

Review of all available studies of trazodone as a treatment for major depression, as well as the published meta-analyses, leads to several conclusions about the efficacy and utility of trazodone in the treatment of depression. First, trazodone is as efficacious as all other antidepressants with which it has been compared for the treatment of major depression. Second, reports of lack of effectiveness of trazodone are in part due to subtherapeutic dosing of the agent, which may be caused by intolerability of the agent in the patients deemed unresponsive. Third, the adverse-effect profile of trazodone affects its perceived tolerability and therefore its perceived utility for treating depression. Specifically, patients experiencing a great deal of anxiety, agitation, and insomnia will better tolerate the sedating effects of trazodone and in fact may benefit from these effects, whereas patients suffering from a great deal of anergia, somnolence, and psychomotor retardation may find these side effects intolerable and therefore not be amenable to treatment with trazodone.

Major Depressive Disorder in Geriatric Patients Trazodone was initially embraced with a great deal of enthusiasm for the treatment of major depression in elderly patients because of its atypical pharmacological profile, with low anticholinergic activity and negligible cardiotoxicity. As in the case of nongeriatric depression, trazodone has been compared with a number of conventional, tricyclic drugs and a number of nontricyclic agents for the treatment of major depressive disorder in elderly patients. Generally speaking, in geriatric populations as in nongeriatric populations, trazodone is an effective antidepressant agent. Trazodone is as effective as the agents with which it was compared, and the symptom complex of the patients determined the tolerability of the agent. Patients treated with trazodone reported few side effects, and in some studies reported significantly fewer side effects than patients treated with conventional agents. In two different studies comparing trazodone with amitriptyline and mianserin for the treatment of major depression in elderly patients, all three agents were found equally efficacious. Pa tients treated with trazodone had significantly fewer anticholinergic side effects than patients treated with amitriptyline and significantly fewer cardiovascular adverse effects than patients treated with mianserin.

The most frequently reported side effects of trazodone in the various studies were dizziness, orthostatic hypotension, and drowsiness or sedation. It is unclear whether the reported dizziness is in fact a manifestation of orthostatic hypotension, but this hypotensive effect can be worsened by the concomitant administration of antihypertensive agents. The hypotensive effect of trazodone is related to peak serum concentration and can be worsened by taking the drug on an empty stomach and lessened by taking the drug with food. Adjustment of the antihypertensive regimen may also decrease the occurrence of orthostatic hypotension.

As with nongeriatric depression, matching symptoms and adverse effects can improve tolerability of the antidepressant and thus improve compliance and therapeutic response. Geriatric patients who experience a great deal of anxiety and insomnia as part of their depression tolerate the sedating qualities of trazodone better than patients who experience psychomotor retardation. In fact, the sedating and anxiolytic properties of trazodone may contribute significantly to its utility in the treatment of depression in the elderly population because anxiety (often reported as “nerves”) and insomnia are common complaints of elderly depressed patients.

Insomnia Trazodone has been studied as a hypnotic agent both to treat the insomnia associated with other antidepressants and to treat the insomnia that accompanies major depressive disorder in many patients. In an open-label study, patients with major depression who had been treated with monamine oxidase inhibitors (MAOIs) and who had developed insomnia after MAOI treatment was initiated were treated with trazodone in doses of 50 to 75 mg a night. In this study, 20 of 21 patients treated with trazodone had a positive response and reported significantly improved sleep and prolonged duration of sleep. In this same study, depressed patients who had insomnia preceding treatment with the MAOI and thus unrelated to the MAOI were also treated with trazodone. Of those suffering

insomnia principally as a symptom of their depression, 26 of 27 patients treated with trazodone reported significant improvement in sleep quality and duration. Trazodone as a treatment for antidepressant-induced insomnia was examined in double-blind type studies. In one study, depressed patients treated either with fluoxetine or bupropion who were experiencing insomnia were given either trazodone or placebo; 67 percent of the patients treated with trazodone reported a significant improvement in sleep quality and duration, while only 13 percent of the placebo-treated cohort reported positive effects on sleep. This study clearly demonstrates efficacy of trazodone in the treatment of antidepressant-induced insomnia in patients with major depressive disorder.

The effects of trazodone on sleep architecture in depressed patients has been studied with polysomnographic techniques with somewhat contradictory results. In one single-blind study of depressed patients treated with trazodone at antidepressant doses, 150 to 400 mg a day, there was a significant improvement in sleep quality and duration including decreased persistent sleep latency, increased total sleep time, increased rapid eye movement (REM) latency, and improved sleep efficiency. This study reported no change in total REM duration. A second single-blind study of similar design had essentially opposite results, with significant REM suppression but no improvement in any of the other sleep parameters with the exception of increased REM latency.

Two main conclusions can be drawn from the data on the effects of trazodone on sleep. First, trazodone is effective as a sedative-hypnotic agent in patients suffering from the “primary” insomnia of major depression, as well as in those suffering from the “secondary” insomnia resulting from treatment with activating antidepressants. Second, the specific effects of trazodone on sleep architecture remain obscure because contradictory results have been reported from similar studies. The one effect that trazodone does seem to exert on sleep architecture is prolongation of REM latency.

Schizophrenia Trazodone may be expected to have both antipsychotic and antidepressant actions on the basis of its known pharmacological actions. The new generation of antipsychotic agents (e.g., clozapine [Clozaril], olanzapine [Zyprexa], risperidone [Risperdal]) all have significant antagonist action at the 5-HT_{2A} receptor. This is thought to be an essential component of their antipsychotic action and is part of the basis for their designation as atypical. Trazodone has significant antagonist action at the 5-HT_{2A} receptor and therefore may be expected to behave similarly to the atypical antipsychotic agents.

The efficacy of trazodone as a treatment for schizophrenia was examined in a double-blind, multiple crossover study that compared the efficacy of trazodone, haloperidol (Haldol), and amitriptyline in patients suffering from schizophrenia or major depression. Trazodone displayed no antipsychotic action in this study. Trazodone was found to be an effective antidepressant agent and to pose less risk to schizophrenic patients; schizophrenic patients treated with trazodone had significantly fewer instances of antidepressant-provoked psychotic symptoms than did patients treated with amitriptyline. The depressive symptoms that many of the schizophrenic patients displayed responded to treatment with trazodone, but the core psychotic symptoms did not.

In a separate study, trazodone was examined as an adjunctive therapy for treating the negative (deficit) symptoms of schizophrenia. In this study, 47 schizophrenic patients who were in a stable pattern of typical antipsychotic treatment were randomly assigned to treatment with trazodone or placebo. The patients were judged neither floridly psychotic nor depressed at entry into the randomized phase of the study. Treatment with trazodone significantly reduced the severity of two out of three measures of negative symptoms while not increasing the severity of the positive symptoms of psychosis. The improvements in negative symptoms while significant, were modest, with a 10 to 15 percent reduction in severity. Schizophrenic patients treated with typical antipsychotic agents do have some modest improvement in negative symptoms when trazodone is added to their treatment regimen. This seems to be a low-risk approach, but with the emergence of newer serotonin-dopamine antagonists such as olanzapine, the use of dopamine receptor antagonists in conjunction with trazodone would appear to be a secondary or backup strategy in the treatment of schizophrenia.

Obsessive-Compulsive Disorder The use of trazodone as a first-line treatment for obsessive-compulsive disorder has not been established. Trazodone has been reported to be efficacious in the treatment of obsessive-compulsive disorder in a number of open-label studies and case reports. In one study of 9 patients who had failed clomipramine or clomipramine plus lithium (Eskalith) treatment who were subsequently treated with trazodone, a slight but significant improvement was reported. Three of these patients were reported to have a very favorable response. In a separate open-label study, eight patients with obsessive-compulsive disorder were treated with trazodone and six were reported with significant reduction of obsessional symptoms at 4 and 10 weeks of treatment. In contrast to these studies, an open label trial in which trazodone in combination with tryptophan was administered to 11 patients suffering from obsessive-compulsive disorder showed “not encouraging” results: several of the patients were unable to tolerate the regimen, and none of those who could showed any improvement.

There has been one published double-blind, placebo-controlled study of trazodone as a treatment for obsessive-compulsive disorder. In this study, 21 patients were entered into a double-blind, parallel-design study in which trazodone was compared with placebo. There were no baseline differences in obsessive-compulsive disorder or depressive symptoms between the trazodone and placebo groups. Seventeen patients completed 10 weeks of treatment; there were no differences between the trazodone and placebo groups in terms of obsessive symptomatology after the 10 weeks. The obvious conclusion from this study is that trazodone possesses no efficacy in the treatment of obsessive-compulsive disorder. Unfortunately this was a rather small study and was not controlled with a known treatment arm (e.g., clomipramine (Anafranil), fluoxetine, paroxetine (Paxil)). Within the limitations of this study, there was no difference between trazodone and inactive placebo in the treatment of obsessive-compulsive disorder. Whether trazodone is an effective agent in the treatment of this disorder remains unresolved.

Anxiety Disorders Trazodone has been examined as a potential treatment for both generalized anxiety disorder and panic disorders. In these studies, investigators tried to separate patients who were suffering from these conditions from patients suffering from anxiety and panic comorbid with major depression, to assess directly the efficacy of trazodone as a treatment for generalized anxiety disorder and panic. The results of these studies have been somewhat mixed and contradictory.

In one report, 230 patients diagnosed with generalized anxiety disorder that was not complicated by depression or panic disorder were randomized to treatment with either imipramine (143 mg a day mean dosage), trazodone (255 mg a day mean dosage), or diazepam (Valium) (26 mg a day mean dosage) in a placebo-controlled, double-blind study. The patients fulfilled diagnostic criteria for generalized anxiety disorder by DSM-III standards, were excluded if they had a diagnosis of depression or panic disorder, and had a Hamilton Anxiety score of at least 18. The patients were treated for 8 weeks in family practice, private, and academic psychiatric settings. A bimodal treatment response was noted. Patients treated with diazepam showed significant improvement in the first 2 weeks of treatment. The somatic symptoms of anxiety were the most responsive to diazepam during the first 2 weeks of treatment. From week 3 through 8, the patients treated with imipramine and trazodone showed significant improvement, with those treated with trazodone having responses equal to those of patients treated with diazepam, while those treated with imipramine had slightly better responses than those treated with diazepam. The symptoms noted to be more responsive to antidepressant treatment were the psychic symptoms of tension, apprehension, and worry. Among those who completed the study, moderate to marked improvement was registered for 73 percent of patients treated with imipramine, 69 percent of those treated with trazodone, and 66 percent of those treated with diazepam. Clearly, this study indicates that trazodone and imipramine have important roles to play in the treatment of generalized anxiety disorder.

Somewhat contradictory results have been reported for trazodone in the treatment of panic disorder. In a single-blind trial in 11 patients with either panic disorder or panic disorder with agoraphobia, treatment with trazodone resulted in significant improvement at both 4 and 8 weeks of treatment. A different result was reported in a larger double-blind study in which 74 patients with panic disorder were randomized to treatment with either imipramine, alprazolam, or trazodone. Patients were blindly begun on active treatment after 3 weeks of placebo washout. The patients were treated for 8 weeks with active compound. A bimodal treatment response was reported in this study. Patients treated with alprazolam had significant improvement during the first week of treatment, while patients treated with imipramine exhibited a positive therapeutic response by the fourth week of treatment. Both imipramine and alprazolam were reported effective in treating symptoms of generalized anxiety, panic attacks, and phobic avoidance. Trazodone, in contrast, was reported ineffective for panic disorder in addition to being poorly tolerated. Only 17 of the trazodone-treated patients completed 4 weeks of treatment, and of these only 2 were considered to have had a good response. Thus it is unclear whether trazodone is effective for the treatment of panic disorder with or without agoraphobia.

Eating Disorders Treatment of eating disorders is one of the most challenging fields of psychiatry. Many different agents, including a variety of antidepressants, have been studied as potential treatments for both anorexia nervosa and bulimia nervosa. Patients suffering from bulimia nervosa have been reported to respond to a number of antidepressant agents including tricyclic drugs, fluoxetine, and MAOIs. While trazodone has some efficacy in the treatment of bulimia nervosa, it has not been demonstrated to have efficacy equal to the aforementioned agents. In an open-label trial, 13 patients who fulfilled DSM-III criteria for bulimia nervosa were treated with trazodone. Three of these patients dropped out of the study before receiving 4 weeks of active treatment. The remaining 10 subjects were treated for an average of 6.9 weeks with a mean maximum dosage of 410 mg a day (range, 250 to 600 mg). Six of the 10 evaluable patients had significant improvement in bulimic symptoms, with the rate of binging and purging in 4 of the subjects reduced to 0 and in the other 2 improved patients, reduced 50 to 90 percent. The only side effects reported were morning drowsiness and headache. Interestingly, the trazodone-treated patients did not experience significant weight gain, which may prove advantageous in the long-term management of these patients.

In a double-blind, placebo-controlled study, 42 women with revised third edition of DSM (DSM-III-R) bulimia nervosa, were randomized to 6 weeks of treatment with either trazodone or placebo. Trazodone was superior to placebo the frequency of binge eating and purging decreased in the trazodone-treated group. The patients

who received trazodone also reported a subjective sense of improvement. Overall, 40 percent of the patients who received trazodone had a partial or complete remission of bulimic symptoms. This is a rather modest response rate compared with that of other antidepressants, whose rate of response has been reported to be as high as 80 percent, though the “complete remission” rate for all of the different antidepressants in the treatment of bulimia nervosa is disappointingly low, generally less than 25 percent. There are case reports of bulimic patients treated with trazodone who developed delirium, but this adverse effect was not reported in the controlled trials. Thus trazodone may have a role in the treatment of bulimia nervosa, but based on the available data, it would appear to be a secondary or adjunctive role.

Chronic Pain Trazodone was initially identified as having antinociceptive properties in an experimental system designed to test a specific hypothesis of the genesis of depression. Agents that were identified with this screen were expected to possess clinically relevant antinocioceptive activity. Subsequent study of trazodone in other animal models of acute and chronic pain has yielded conflicting results. Use of trazodone in patient populations suffering from chronic pain have likewise yielded equivocal results, partially depending on the type of pain syndrome studied. There are case reports endorsing the use of trazodone to treat intractable headache, migraine, diabetic neuropathy, and other pain syndromes. Trazodone was tested as a prophylactic treatment for pediatric migraine in a double-blind, placebo-controlled, crossover study of children. This 8-month study of 40 children aged 7 through 18 had a crossover design so that patients initially treated with placebo were blindly switched to trazodone and patients initially treated with trazodone were switched to placebo; 35 patients completed the entire trial. The patients who received active compound had a significant reduction in the frequency and duration of migraine headaches. This study indicates that trazodone is an effective prophylactic treatment for pediatric migraine. There are multiple case reports documenting the efficacy of trazodone in adult migraine, but several case reports claim that trazodone treatment induced or provoked adult migraine, presumably through its mCPP metabolite.

Trazodone has been studied as a treatment for a number of peripheral pain syndromes, including chronic low back pain. In a double-blind study, 42 subjects with longstanding chronic low back pain were randomized to trazodone or placebo. The average dosage of trazodone was 201 mg a day. There were no statistically significant differences between the trazodone and placebo-treated groups in a number of self-rating and evaluator rating scales of pain. A similar result was reported for trazodone in the treatment of the dyesthetic pain syndrome resulting from traumatic spinal myelopathy. In this double-blind, placebo-controlled study, patients received either 150 mg a day of trazodone or inactive placebo during a 6-week treatment phase. There were no statistically significant differences between the trazodone- and placebo-treated groups in a number of pain measures. Significantly more patients randomized to the trazodone group dropped out of the study early because of intolerable adverse effects. The opposite result was reported in a separate study that compared trazodone with amitriptyline in the treatment of deafferentation pain, mostly due to cancer. In this double-blind study, 45 patients were randomized to receive either trazodone or amitriptyline, but there was no placebo control group. The therapeutic efficacy of the two treatments was reported to be similar. Unfortunately, because there was no placebo control group in this study, it was difficult to judge the magnitude of the therapeutic response for either treatment and whether either was better than inactive placebo. On the basis of all the available data, trazodone would appear to be ineffective in the treatment of peripheral pain syndromes.

Alzheimer's Disease and Geriatric Cognitive Disorders The use of trazodone to treat the behavioral manifestations of Alzheimer's disease and cognitive disorders has been reported in several case series. In an open-label, pilot study, 13 patients with Alzheimer's disease were treated for 10 weeks with trazodone at a dosage of 25 mg three times a day. Treatment with trazodone resulted in improvement in irritability, anxiety, restlessness, and affective disturbance. Unfortunately there was no change in Mini Mental State Examination scores nor any apparent improvement in cognitive functioning of the treated patients. This study indicates that trazodone may be helpful in alleviating some of the behavioral manifestations of Alzheimer's disease but does not treat the core cognitive deficit. Another case series on four elderly patients with severe cognitive disorders has been published. These patients had failed antipsychotic drug therapy and displayed a number of aggressive and inappropriate behaviors but did not appear to have an affective disorder. Treatment with trazodone was reported to substantially improve the behavior of all four patients. The authors relate this behavioral improvement to the “taming” effect exerted by trazodone in animal models of aggression. Less encouraging results were reported in a different case series in which seven patients with organic mental disorders were treated with trazodone. These patients also displayed a number of aggressive and inappropriate behaviors. Three of them completely ceased aggressive behavior after 4 to 6 weeks of treatment, three had no discernible change in behavior, and one patient dropped out of the study. Given trazodone's overall lack of cardiovascular toxicity and minimal anticholinergic activity, its use in behaviorally disturbed elderly patients would seem to be a reasonable option with little risk and low adverse-effect potential. A trial of trazodone may prove beneficial in achieving behavioral control in patients with dementia and other cognitive disorders.

Autistic Disorders and Other Developmental Disorders A number of case reports document the use of trazodone in the behavioral control of children and adults suffering from a number of developmental disorders. The use of trazodone has been reported in the treatment of the behavioral manifestations of pediatric and adult Down syndrome, autism, and other developmental disorders. In one open-label case series, trazodone was given to 22 hospitalized children with a variety of severe behavioral disturbances. These patients had failed other treatment regimens prior to receiving trazodone; 13 of them were judged to have benefited from trazodone treatment. There was a marked reduction in aggressive, impulsive behaviors in the responsive children. Three of the children were reported to have worsened on trazodone. Follow-up interviews with the parents of the children who had responded to trazodone treatment revealed that the beneficial activity persisted from 3 to 14 months after discharge from the hospital. Again, given the low risk of trazodone treatment, the low adverse-effect potential, and the overall safety of trazodone, a trial of its use in this type of patient seems warranted.

Sexual Dysfunction Trazodone has been systematically studied as a treatment for male impotence. There are several studies of trazodone in the treatment of primary erectile dysfunction. Between 1989 and 1994, 182 patients in a urology clinic were treated with trazodone as empirical treatment for erectile disorder, 127 of these patients were available for follow-up and retrospective analysis. The patients ranged in age from 25 to 85 years, had a number of causes for their sexual dysfunction, and received trazodone for at least 2 consecutive months. Of the patients younger than 60 years of age, 78 percent reported significant improvement in erectile ability. Patients who were older than 60 or were smokers had a poor response to treatment. Duration of erectile disturbance was also a relevant factor: those experiencing 12 months or less of erectile dysfunction had higher response rates, and those experiencing more than 60 months of dysfunction had much lower response rates. In an open-label study of 14 patients with erectile dysfunction, trazodone treatment significantly increased nocturnal erectile time, percentage of sleep with an erection, and maximal erectile rigidity. In a placebo-controlled, single-blind study of 35 patients with organic impotence, 5 weeks of treatment with trazodone (150 to 200 mg a day) resulted in significant improvement over placebo. In a self-report questionnaire, 68.6 percent of the patients reported improvement, compared with 11.4 percent of placebo-treated patients.

In a placebo-controlled, double-blind study of 79 patients who suffered from nonorganic impotence, patients were randomized to receive testosterone, trazodone, hypnosis, or placebo. The response rates were 60 percent for testosterone, 67 percent for trazodone, and 80 percent for hypnosis. The combination of trazodone with yohimbine (Yocon) as a treatment for psychogenic impotence was examined in a double-blind, placebo-controlled, crossover study of 63 patients suffering from primary sexual dysfunction. The patients were assessed for erectile function, ejaculation, interest in sex, and sexual thoughts at the end of 8 weeks of treatment and at 3- and 6-month follow-up; 55 patients completed the entire study and of these, 71 percent had a positive response. Positive responses were maintained in 58 percent of the patients at 3-month and in 56 percent at 6-month follow-up. Minor side effects were reported in 11 percent of the treated group. Trazodone was compared with ketanserin and mianserin as a treatment for erectile dysfunction in a placebo-controlled, double-blind study in which patients received 30 days of treatment. At 30 days, 62.5 percent of the patients treated with trazodone reported a positive result, compared with 19 percent of those treated with ketanserin, 31.6 percent of those treated with mianserin, and 13.6 percent of those treated with placebo. On the basis of these studies, trazodone appears to be a safe and effective agent for the treatment of psychogenic impotence, nonorganic erectile dysfunction, and possibly some types of organic erectile dysfunctions. In the absence of medical contraindications for its use, a 2- to 3-month trial of trazodone would seem to be a reasonable approach to managing patients with erectile disturbances.

Other Disorders A large number of case reports document the therapeutic use of trazodone in an assortment of psychiatric disorders. Diagnoses included in these reports are fibromyalgia; posttraumatic stress disorder; paranoid disorder; sexual paraphilias; climacteric (menopausal) symptoms; drug-seeking behavior, drug use; withdrawal symptoms of alcohol, opioid, benzodiazepines, and cocaine; and a number of anxiety of hysteric conditions. In general, none of these reports have been followed up with placebo-controlled, double-blind studies, and thus the efficacy of trazodone as treatment of any of these disorders is not known.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Few significant adverse effects were reported for trazodone in premarketing controlled trials and in postmarketing surveillance. Many of the adverse reactions have been reported in case reports or small case series. Most of the adverse effects reported are generally benign, and no lethal reactions have been directly attributable to trazodone. The adverse effects commonly reported include drowsiness, headache, nausea, and orthostatic hypotension. Trazodone is virtually without anticholinergic effects, and one multicenter analysis found no statistically significant difference between trazodone and placebo in the incidence of anticholinergic effects. Allergic reactions to trazodone have been reported. There have been few trazodone-induced hematological reactions: limited reports of mild anemia and slightly decreased neutrophil counts. There are several case reports of agranulocytosis in patients treated with trazodone. These particular reactions appear to be idiosyncratic or allergic and are rare.

A series of 10 patients was reported to suffer from trazodone-induced peripheral edema. This was a limited reaction that disappeared with discontinuation of the drug.

The cause of this effect remains obscure, but it appears to be a rare event, occurring in substantially less than 1 percent of treated patients.

Cardiovascular System Trazodone has little or no direct action on the cardiac contraction or conduction systems in experimental animals and in patients. There are individual case reports of trazodone causing significant cardiac conduction problems including ventricular tachyarrhythmias, bradyarrhythmias, and complete heart block. These reports are mostly from patients with cardiac disease preexisting initiation of trazodone therapy. In a specific double-blind, placebo-controlled study of trazodone in depressed cardiac patients, there were no arrhythmias reported in the trazodone-treated group. These results were confirmed in at least one additional study. Trazodone use in patients without preexisting ventricular arrhythmias appears to be safe, with little or no risk of inducing cardiac arrhythmias. Trazodone is not absolutely contraindicated in patients with known cardiac disease, but its use would seem unwarranted in patients with ventricular arrhythmias, given the vast array of other available antidepressants.

The most commonly reported cardiovascular adverse effect of trazodone is orthostatic hypotension. The incidence of orthostatic hypotension is directly related to the serum concentration of the agent and generally follows oral ingestion by 4 to 6 hours. This hypotensive effect can be blunted by taking the drug with food, which slows the rate of absorption and lowers the peak serum concentration. Orthostatic hypotension can be severe enough to cause syncope. This usually occurs when a large dose is taken without food or with the concurrent use of antihypertensive agents. Trazodone can potentiate the action of antihypertensive agents. Adjustment of the dosage of antihypertensive agents should be considered when coprescribing trazodone.

Genitourinary Effects Trazodone has been well documented to cause priapism, a painful unremitting erection, in a small percentage of patients. This is a true medical emergency that requires immediate medical intervention or it can lead to permanent impotence. The occurrence of priapism was first reported several months after the introduction of trazodone in the U.S. market. In the first year that trazodone was available in the United States, 11 cases of priapism were reported, 5 requiring surgical intervention. Now, with prolonged use of the drug, the rate of priapism appears to be approximately 1 in 10,000 patients treated. The exact cause of trazodone-induced priapism is not known, but it has been postulated to be due to peripheral a $_1$-adrenergic antagonist action within the circulatory system of the penis. Trazodone has minimal effects on CNS dopaminergic and cholinergic systems implicated in other drug-induced cases of priapism. In experimental animal systems, direct infusion of trazodone into the intracorporeal circulatory system causes erection.

Priapism has been reported to occur across the broad spectrum of the therapeutic dosage range of trazodone, from 50 to 400 mg. This effect generally occurs within the first 28 days of treatment but has been reported to occur after 18 months of therapy. There is no particular test or other method for predicting the occurrence of priapism.

Priapism needs to be treated on an emergent basis. Immediate discontinuation of the medication is the first intervention, and patients should be advised to discontinue taking trazodone and seek emergency treatment if they experience an erection that lasts for 1 hour or is excessively painful. Irrigation of the corpora cavernosa with an a-adrenergic receptor agonist agent such as metraminol (Aramine) or epinephrine is the first intervention. If the a-agonist agent is ineffective, then a vascular shunt must be placed, typically between the corpora cavernosa and the corpora spongiosum. If surgical shunting is required, there is a 40 to 50 percent incidence of permanent impotence. At least one case of clitoral priapism in a female patient treated with trazodone was reported in the literature. This patient required a-agonist treatment but did respond to this treatment. Trazodone has been reported to cause a number of other sexual adverse effects including increased or decreased libido in male and female patients, anorgasmia, impotence, and ejaculatory dysfunction.

Central Nervous System Trazodone's principal pharmacological actions are as a 5-HT $_{2A}$ receptor antagonist and as an inhibitor of serotonin transport. The most common neurological adverse effects associated with trazodone treatment are drowsiness, dizziness, lightheadedness, headache, and confusion or mental slowing. As many as 50 percent of patients treated with trazodone report significant drowsiness, which is the main side effect that causes patients to discontinue using this drug. On the other hand, patients with significant psychomotor agitation and insomnia do not find this particularly troublesome.

Trazodone is not known to lower the seizure threshold in patient populations or in experimental animals. There are isolated case reports of patients treated with trazodone having seizures, but this has not been observed in the large-scale clinical trials. Trazodone is not contraindicated in patients with known seizure disorders, though caution should be exercised in the dosing of these patients. Lower starting doses and slower upward titration of the dosage would be prudent when using trazodone in a patient with a known seizure disorder.

Trazodone has been reported to change sleep patterns and electroencephalogram (EEG) tracings during sleep. Generally, slow-wave sleep activity increases in patients taking trazodone. Whether these changes are meaningful is unclear.

Trazodone has been reported to precipitate mania and hypomania in vulnerable patients. The average time from initiating trazodone therapy to onset of manic symptoms is 16 days. The incidence of mania and hypomania in patients receiving trazodone appears to be lower than that reported for other antidepressant agents.

Overdose Trazodone has a favorable therapeutic index and is generally fairly benign in overdose. In the first 4 years that trazodone was available in the United States, 88 cases of overdose were reported to the manufacturer. In 73 of those patients recovery was reported as uneventful. Nine deaths were reported in this series, but all of them involved multiple pharmacological agents or alcohol. There are two case reports of patients ingesting 7.5 and 9 grams, respectively, of trazodone in overdose attempts; both recovered without incident. The symptoms of trazodone overdose are drowsiness, weakness, and prolonged unconsciousness, and general monitoring and supportive measures are the indicated treatment. Treatment with trazodone does not increase suicidal behavior or risk. There is no difference in the rate of suicidal ideation, attempted suicide, or aggressive behavior in patients receiving trazodone and those receiving imipramine, lofepramine, or mianserin.

THERAPEUTIC INDICATIONS

The FDA indication for the use of trazodone stated on the package insert is the treatment of major depressive disorder. Given its lack of anticholinergic and cardiac effects, trazodone seems particularly well suited for the treatment of depression in geriatric patients, although orthostatic hypotension is problematic in this age group. There does seem to be evidence to support the use of trazodone as a hypnotic agent both to treat the insomnia related to a depressive disorder and the insomnia associated with the use of other antidepressant agents. Evidence also supports the use of trazodone to treat generalized anxiety disorder but not panic disorder or obsessive-compulsive disorder. Evidence indicates trazodone may be an effective treatment of psychogenic impotence and organically caused erectile problems. Trazodone may have efficacy in the treatment of bulimia nervosa. Trazodone may also be useful in treating the adverse behavioral manifestations of autistic and other developmental disorders and cognitive disorders. It may be useful in the treatment of some chronic pain syndromes (pediatric migraine) but not others (neuropathic pain, low back pain). Trazodone may have an adjunctive role in the treatment of schizophrenia and is safe to use in schizophrenic patients because it does not worsen positive psychotic symptoms.

PRECAUTIONS AND ADVERSE REACTIONS

Patients should receive adequate information on the side effects and adverse reactions that can be caused by trazodone. Drowsiness is the most common side effect reported. Patients beginning trazodone therapy should be advised that the concomitant use of alcohol or other sedative agents may worsen its sedating effects. Patients, particularly the elderly and those receiving antihypertensive agents should be advised of the occurrence of orthostatic hypotension that can be severe enough to cause syncope. Ingesting trazodone with food reduces the peak serum concentration, thereby reducing the incidence of orthostatic hypotension.

The most significant side effect of trazodone in terms of excess morbidity is priapism. Patients should be well informed on the risks of developing this condition. They should be advised that an erection lasting longer than an hour or one that is excessively painful should be treated urgently and trazodone use immediately discontinued. Patients should be advised to seek immediate medical treatment if priapism develops.

The use of trazodone in patients with cardiac disease is not contraindicated. Patients with known arrhythmias should be monitored closely. Trazodone should not be a first-line agent in patients with known ventricular arrhythmias. The use of trazodone in patients with known seizure disorders is not contraindicated; trazodone dosage should be titrated slowly in patients with known seizure histories.

There is no evidence that trazodone is mutagenic in standard toxicological assays. Trazodone is teratogenic in experimental animals at high doses, 15 to 50 times the maximal human dose. There are no data on the teratogenic potential of trazodone in humans, nor are there any published data on patients exposed to trazodone in utero. Trazodone does enter breast milk. It has no affect on fertility in standard animal models, and there are no reports of alterations in human fertility in response to

trazodone treatment.

DRUG INTERACTIONS

There are case reports documenting a variety of drug-drug interactions in patients receiving trazodone. One patient who was treated with trazodone and fluoxetine had a 30 percent increase in circulating trazodone concentration. This patient experienced increased sedation and an unsteady gait, but the symptoms resolved with dosage adjustment. There are case reports documenting increased concentrations of phenytoin (Dilantin) and digoxin (Crystodigin) in patients receiving trazodone, but this has not been observed in large-scale studies.

There are no known interactions between trazodone and anesthetic agents, but given trazodone's sedating properties, discontinuation of trazodone prior to surgery would seem appropriate. While there is no evidence that trazodone affects seizure threshold, there are case reports claiming that patients on trazodone had prolonged seizures in response to electroconvulsive therapy (ECT). This has not been systematically studied. Trazodone has minimal impact on seizure threshold.

Trazodone can cause orthostatic hypotension, and this effect can be potentiated by the concomitant use of antihypertensive agents. Although this is not a true pharmacokinetic interaction, appropriate dosage adjustment of trazodone and the antihypertensive agent must be considered in patients receiving both agents.

There is evidence that trazodone is safe to use in conjunction with MAOIs. In fact there is evidence documenting the use of trazodone as a sedative hypnotic agent in patients receiving MAOI therapy. While isolated case reports of trazodone causing the serotonin syndrome exist, this reaction seems quite rare in patients being treated with trazodone in addition to other serotonergically active agents.

LABORATORY INTERFERENCES

Trazodone is not known to interfere with routine laboratory tests, including urinalysis, hematological analysis, and chemical analysis. Trazodone blood levels need not be monitored in the routine treatment of depression. There are no reliable data relating concentration in blood to therapeutic response, nor are there any data on an optimal blood concentration for therapeutic response. Monitoring blood concentrations may be a useful method of assessing patient compliance.

DOSAGE AND ADMINISTRATION

Optimal use of antidepressants necessitates matching the side-effect profile of the particular agent to the patient's symptoms. This is known to increase patient compliance, which in turn improves therapeutic response. In the case of trazodone, which is sedating and anxiolytic, patients who have significant psychomotor agitation, anxiety, and insomnia are particularly well suited for treatment with this agent. Patients who have significant neurovegetative symptomatology, anergia, and hypersomnolence would not be expected to be as responsive to trazodone, and other, more-stimulating agents should be considered.

Four controlled studies have examined the optimal dosing regimen for trazodone. They found that once-daily dosing (usually at night) is as effective as multiple daily dosing. This is somewhat unexpected given the agent's short half-life.

Trazodone therapy should be initiated at a dosage of 50 to 100 mg a day. The dosage should be increased at a minimum of 3-day intervals. Rapid dose escalation generally results in significant sedation and discontinuation of treatment. A dosage of 300 mg a day should be achieved within 2 weeks of beginning therapy. There is some controversy about the optimal dosage, with some practitioners advocating a maximum daily dosage of 300 mg, while others recommend 400 to 600 mg a day. Some have postulated a therapeutic window for this agent, but none has been definitively documented. Certainly a lack of therapeutic response at doses below 300 mg a day cannot be judged a treatment failure. Escalation of the daily dosage above 300 mg should be considered in a patient who is responding partially to the 300 mg daily dosage, but escalation of the dosage above 600 mg a day would seem unnecessary. If the patient has experienced no appreciable response at a dosage of 300 mg a day after 4 weeks, then reconsideration of the treatment regimen is in order. Most patients display a positive therapeutic response by 4 weeks of treatment, and some are appreciably improved after 2 weeks. Once-a-day dosing, in the evening, is the preferred regimen because it causes the fewest side effects and increases overall treatment compliance. Trazodone is safe and continues to be effective in the treatment of depression in long-term administration. Generally, 50 to 100 mg at night is a sufficient dose to treat insomnia.

Trazodone is available in scored 50-mg and 100-mg tablets and in 150-mg and 300-mg tablets. The larger-dose tablets can be broken into thirds or halves to facilitate dosage adjustment. There is no difference in treatment response between the regular form of trazodone and a controlled-release form available in Europe.

31.30 TRICYCLICS AND TETRACYCLICS

J. CRAIG NELSON, M.D.

HISTORY

In 1957, Roland Kuhn, a Swiss psychiatrist, reported that imipramine (Tofranil) appeared to have antidepressant effects in 40 patients with endogenous depression. This serendipitous observation was made while testing this chlorpromazine-like antihistamine for its psychoactive properties. This discovery, like those for lithium and chlorpromazine, (Thorazine) was an important landmark in modern psychopharmacology. The knowledge that this compound appeared to alleviate depression, coupled with Julius Axelrod's report of its role in blocking reuptake of norepinephrine, laid the foundation for the norepinephrine hypothesis of depression.

It is with the tricyclic compounds that the field of psychiatry explored a variety of issues involved in the drug treatment of depression. Rating scales for depression were developed. Diagnostic criteria emerged. A better understanding of drug-placebo differences evolved. The necessity for administering an adequate dose for an adequate duration was described. The physiological basis of the secondary effects of tricyclic drugs became better understood. The relationship of plasma concentrations and clinical phenomenon was explored, and the pharmacology of these compounds was investigated as it provided a “psychopharmacologic bridge” to an understanding of depression.

During the next two decades, several other compounds were developed that also had antidepressant properties. These compounds were similar in sharing a basic tricyclic structure and in terms of many of the secondary effects for which the tricyclic drugs came to be known. Later, tetracyclic compounds were also marketed which were somewhat similar in structure and had relatively comparable secondary properties.

CHEMISTRY

Tricyclic and tetracyclic compounds are categorized primarily on the basis of their chemical structure (Fig. 31.30-1). The tricyclic compounds have a three-ring structure, hence the name. The tertiary amine tricyclic compounds, such as amitriptyline (Elavil) and imipramine, have two methyl groups at the end of the side chain. These compounds can be demethylated to secondary amines, such as desipramine (Norpramine, Pertofrane) and nortriptyline (Aventyl, Pamelor). The tetracyclic compounds, maprotiline (Ludiomil) and amoxapine (Asendin) have a four-ring central structure. Five tertiary amines have been marketed in the United States–amitriptyline, clomipramine (Anafranil), doxepin (Sinequan), imipramine, and trimipramine (Surmontil). The three secondary amine compounds are desipramine, nortriptyline, and protriptyline (Vivactil).

PHARMACOLOGICAL ACTIONS

Pharmacodynamics

Reuptake Blockade The tricyclic and tetracyclic antidepressants block the transporter sites for serotonin and norepinephrine and thus reduce uptake of these amines into the presynaptic neuron (Table 31.30-1). The tertiary amines have greater affinity for the serotonin transporter. The secondary amines primarily block the uptake of norepinephrine. Because the tertiary amines are demethylated to secondary amines, during the administration of amitriptyline, imipramine, or clomipramine, secondary amines are also present, thus both serotonergic and noradrenergic effects occur.

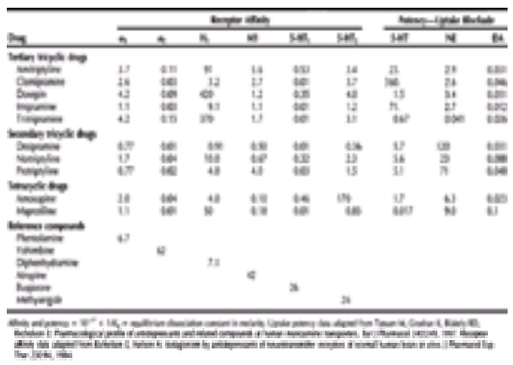

Table 31.30-1 Receptor Affinity or Potency of Cyclic Antidepressants in Human Brain

Receptor Sensitivity Changes Following the initial reuptake blockade, a sequence of events occurs. The tertiary tricyclic compounds, particularly clomipramine, inhibit the uptake of serotonin. Following reuptake blockade, the presynaptic serotonin (5-hydroxytryptamine [5-HT]) type 1A (5-HT $_{1A}$) autoreceptor reduces the firing rate of the presynaptic serotonin neuron, and concentrations of 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of serotonin, fall rapidly. Over a 2-week

period, the presynaptic autoreceptor is desensitized, which normalizes the firing rate. At this point serotonin transmission is enhanced. With chronic treatment, the tricyclic agents as a group also sensitize, or upregulate, postsynaptic 5-HT $_{1A}$ receptors. The changes in sensitivity of these presynaptic and postsynaptic receptors occur over a 2-week period and appears to be more consistent with the timing of antidepressant response than with the initial uptake blockade.
