On the other hand, premature acceptance of a major role for internally mediated psychological factors can have negative implications for patients. Patients feel anguish over their inability to have a positive attitude, and families conspire to worsen their guilt by demanding an upbeat stance from patients far too ill to do much except endure. The reaction of medical personnel is ambiguous. They reject a strong role for psychological causation, yet they are privately intrigued. Some clarification was suggested by a paper that differentiated a belief in control over the cause from control over the course of the cancer. The former was associated with anxious preoccupations about cancer, while the latter was associated with the beneficial fighting spirit. Another clinically useful distinction was made between weak and strong believers in psychological causation. Strong believers give psychological factors primary importance in determining their prognosis, equaling or superior to the role of conventional treatment. Weak believers view them as modifiers and do not experience as much anguish over their own inability to maintain a relentlessly positive attitude. Unfortunately, even seasoned psychiatrists find it difficult to move self-punitive patients from the strong to the weak category. Given the current state of the art, it would seem best to work actively to improve patients' quality of life, while at the same time encouraging them to enjoy these improvements for their own sake, independent of any effect on survival time. Group interventions are particularly desirable because they tap into the well-demonstrated protective effect of social supports, even as they address their other stated goals. If survival is improved, so much the better. If it is not, patients will be spared unnecessary guilt.

ALTERNATIVE TREATMENTS

The use of unproved methods of treatment is deeply entrenched in human history. The scientific developments described above have blurred the boundary between them and traditional treatment, and many have moved into the mainstream. The role of diet in cancer risk is now well respected. Programs that use meditation and lifestyle changes are being reimbursed by third-party payers who view them as effective, safe, and inexpensive adjuncts to traditional treatment. So-called integrative or complementary medicine clinics are being opened in a rapidly growing number of tradition medical centers. They often occur in the setting of an intense charismatic relationship, with a great emphasis on faith, support, and encouragement. Patients regard this experience alone as valuable.

The motives that drive providers range from mercenary ones to idealistic beliefs about the power of mind over body. The motives that drive patients include universal concerns, such as the often justified fear of failure of traditional treatment, the hope for a miraculous cure, and the desire to achieve mastery and control. The stigma of cancer propels people irresistibly into magical thinking. The toxicity of traditional treatments also makes patients so anxious that other options become compelling. The out-of-pocket expense of nontraditional treatment is in the billions. In one study, a large percentage of patients at a tertiary medical center was seeking alternative treatment, now called complementary medicine, while still in traditional treatment. They did so early in their course, took both simultaneously, dropping the traditional treatment before they dropped the alternative one. Educated and wealthy patients were best represented. The main treatments were physical ones to cleanse and strengthen the body; special diets to purify, fortify, and avoid harmful substances; immune therapies, faith healing; and psychological methods to improve mental attitudes and reinforce the body's defenses.

Many such treatments give patients a sense of purpose and control. Faith healing harnesses the great power of religious belief. The last category, improving attitudes, is most troubling to the psychiatrist, because it leads so readily into blaming the victim. Patients are told that they can influence their cancer by mental efforts. The unspoken corollary is that further disease will be due to inadequate efforts and, worse yet, that they caused the cancer in the first place. This plays directly on attribution mechanisms to which cancer patients are already universally prone. One can also see desperate family members grasping at these explanations and trapping the patient ever deeper in a web of guilt and responsibility as a means of coping with their own grief and frustration, or an angry patient blaming a family member for causing the cancer.

The psychiatrist must remember that many patients are secretly involved in alternative care, which makes them embarrassed and distant if they cannot share it. As time passes, if their condition worsens, the burden of failure and guilt makes a greater contribution to psychic distress. Hence clinicians must encourage disclosure and help patients extract something positive from the experience. This is difficult to do if patients and families retreat into anger at the establishment and reduce cognitive dissonance by clinging desperately to their alternate beliefs. However, this picture is in a place of rapid change.

SPIRITUAL BELIEFS AND HEALTH BEHAVIORS

The inclusion of a section on religious or spiritual problems in DSM-IV is but one sign of increasing awareness of the importance of this area to patients, families, and many staff as well. Several studies have shown that religious beliefs are often associated with mature and active coping methods, and the field of psychological and spiritual interfaces in the experiences of acutely ill patients is spawning a whole new area of psychological research within the traditional medical establishment. The psychiatric consultant should inquire about faith, its meaning, associated religious practices, and impact on the coping response. It can be a source of strength or guilt at all stages of the disease, ranging from the earliest “What did I do to cause this?” through “Will God give me only what I can carry?” to the poignant life review of the late stage. It is often a primary factor in the reaction to suicidality and in attitudes toward terminal care decisions. Mental health professionals should be prepared to deal with these areas in an unselfconscious, uncondescending manner, enabling patients to fully integrate this aspect of their personality into the current crisis. They should also work in harmony with the patient's spiritual guide, if one is available. Sometimes an experienced, effective chaplain working with the appropriate patient can achieve positive results more directly than any psychotherapy. Also, sometimes chaplains should call for psychiatric help at the proper moment.

The study of the psychological aspects of cancer continues to lead to many fundamental human issues, starting with bedrock existential confrontations with death and the sense of self. The recent work on families illuminates our interdependence upon one another. The issues surrounding genetic counseling, assisted-suicide, and other terminal-care dilemmas underline the grinding moral inadequacies of our social institutions. Ironically, half of the problem could be eliminated by altering a few personal habits, yet we nearly ignore this, while clinging to wisps of evidence about the “power of the mind to cure cancer.” This highlights the need for continuing

efforts to understand and alter the human response to the trauma of severe illness.

SUGGESTED CROSS-REFERENCES

Psychoneuroendocrinology is discussed in Section 1.1, the neuropsychiatric aspects of tumors in Section 2.2, cognitive-impairment disorders in Chapter 10, schizophrenia in Chapter 12, mood disorders in Chapter 14, anxiety disorders in Chapter 15, somatoform disorders (including pain management) in Chapter 16, and sexuality in Chapter 19. Death, dying, and bereavement are discussed in Section 28.5. Personality disorders are discussed in Chapter 24, noncompliance with treatment in Section 27.1, and suicide in Section 29.1. Psychotherapies are discussed in Chapter 30 and biological therapies in Chapter 31. Disruptive behavior in children is discussed in Chapter 40, and children's reactions to illness, hospitalization, and surgery are discussed in Section 49.5. Psychiatric problems in the medically ill elderly are discussed in Section 51.3a and the psychiatric aspects of long-term care in Section 51.6a. Legal issues are discussed in Section 54.1 and ethics in Section 54.2.

25.12 CONSULTATION-LIAISON PSYCHIATRY

JAMES J. STRAIN, M.D.

Consultation-liaison (C-L) psychiatry is the study, practice, and teaching of medical (Axis III) and psychiatric (Axis I and II) comorbidity. The dimension of this subspecialty of psychiatry ranges from screening, a spectrum of problem-level diagnosis to disorders, interventions, outcome, random control trials, costs, and ethical implications. A flow sheet for these crucial steps in the C-L process was developed to be a template to assist the consultant to include the steps in the process of the consultation, for example, screening, history taking, assessment scales, treatment approaches, and when drugs are used to have access to random control-trial results, drug-drug interactions, critical laboratory studies, technical reports with new findings, compliance measures, and documented patient outcome results (Fig. 25.12-1). Such a carefully orchestrated flow sheet would also assist in documenting that the consultation met quality assurance standards and legal requirements and assure that appropriate consents were obtained after capacity, and competence were established. Reliable and valid instruments that may help to document that the critical steps have been executed (e.g., diagnosis and outcome have been verified by appropriate measures) are also outlined (Fig. 25.12-1). As the steps of the consultation are completed, alerts occur to remind the psychiatrist that certain key issues must be addressed (e.g., noncompliance of the patient or nonadherence of the consultee to the suggested recommendations). This method ensures that crucial steps in the consultation process are completed and documented, and data are available for clinical and research purposes.

FIGURE 25.12-1 Computer-assisted physician management system. (Reprinted with permission from Strain JJ, Hammer JS, Caliendo G, Mayou R, Smith GC, Malt U, Lyons J, Kurosawa H: Further evolution of a literature data-base: Content and Software. Gen Hosp Psychiatry *18:*294 , 1996.)

Since C-L psychiatrists may be asked to consult on any patient in the outpatient or inpatient medical or surgical setting they may encounter any medical disorder or Current Procedural Terminology (CPT) intervention in the ninth revision of *International Statistical Classification of Diseases* (ICD-9) and any of the thousands of pharmaceutical agents that this broad spectrum of patients may be prescribed. The C-L psychiatrist must be conversant with interactions between psychotropic and medical and surgical drugs. Consequently, practitioners of this subspecialty must possess or have access to a monumental database if they are to manage their patients in a safe, therapeutically effective manner together with their medical and surgical colleagues. Possession of this knowledge base—psychological, psychiatric, medical, surgical—is essential for one of the missions of this subspecialty: teaching physicians, nurses, social workers, and patients.

The pedagogic functions of the C-L psychiatrist cannot be overstated. C-L psychiatry is the linchpin between psychiatry and the other medical specialties. The C-L role as teacher and purveyor of psychiatric skills in the medical setting maintains psychiatry as the *discipline of record* to assist with psychological, psychiatric, and psychophysiological morbidity in the medical setting. The C-L psychiatrist in many ways is the ambassador for psychiatry in the acute care and teaching hospital for tomorrow's doctors. Whether tomorrow's doctors turn to psychiatry or other mental health professionals for assistance (e.g., social work, psychology, clergy) depends upon their experiences with psychiatry in their formative years of training as medical students and house staff. Thus the C-L psychiatrist needs both the necessary knowledge base and the teaching skills to impart this knowledge and skill effectively to nonpsychiatric physicians.

The knowledge base in medicine is doubling every 5 1/2 years. In fact, 6000 to 7000 publications occur daily in science, and many of these pertain to medicine. Clearly, C-L psychiatrists need help in accessing and processing this outpouring of new information that concerns the optimal approach to the patient. Medical informatics, artificial intelligence, archives of clinically relevant information, and reference databases of seminal investigations are needed for clinical decision making. Whereas most subspecialties in psychiatry by their distinct focus limit the information with which they must be conversant, C-L psychiatrists must maintain an enormous range of information because they may be asked to consult on a patient with any physical disorder, who may be taking any medical drug, and who may be in any medical or surgical setting—a situation resembling that of primary care physicians.

COMORBIDITY IN THE MEDICAL SETTING: RATIONALE FOR C-L PSYCHIATRY

Psychosocial disability and psychiatric disorders are prevalent in the population and more often encountered in medical inpatient and outpatient settings than in psychiatric settings. One-month and point-prevalence studies found that 16 percent of community cohorts exhibited psychiatric morbidity. It is estimated that 21 to 26 percent of medical outpatients have psychiatric disorders. The age- and sex-adjusted prevalence of mental disorders was 25 percent in patients with a chronic medical condition and 17.5 percent in those without. Lifetime prevalence of a mental disorder in chronically physically ill patients reached 42 percent (most often substance abuse and mood or anxiety disorders) compared to 33.0 percent in those who did not have long-term physical disability. Finally, 30 to 60 percent of those in short term general medical or surgical inpatient settings have significant psychosocial or psychiatric morbidity.

Medical patients have a much higher morbidity for specific mental disorders than those in the general population: delirium in 15 to 30 percent of those hospitalized, depression (2 to 3 times higher), panic and somatization (10 to 20 times higher), and substance abuse (3 to 5 times higher). Thus the medical setting—where patients have already put themselves within a medical facility—is an excellent venue for screening, triage, and confronting psychiatric morbidity. In fact, the medical setting is an important de facto mental health setting from which to launch an effort to ameliorate mental suffering.

In addition, psychiatric morbidity is associated with high utilization of general medical services and an increase in several parameters of health services utilization. Investigators found that 50 percent of high utilizers had psychiatric morbidity: major depressive disorder or dysthymic disorder (40 percent), anxiety disorders (21.8 percent), somatization disorder (20 percent), panic disorder (12 percent), alcohol or other substance abuse (5 percent). Depressed patients in the medical setting use three times more health resources, encounter twice the costs, and make seven times more visits to the emergency facilities than those not depressed. Patients with panic disorder visit the emergency room 10 times more often than those without (70 percent of those with panic disorders encounter 10 or more doctors before a correct diagnosis is achieved). The need for short-term hospitalization can triple when asthma patients experience comorbid anxiety disorders.

Patients with alcohol abuse or dependence have twice the total health care costs of those without, and, one-fourth to one-half of patients with alcohol disorders are not identified as such when admitted to an acute care medical and surgical hospital. Patients with diagnosed depressive disorders used more health care resources than those not depressed ($4246 vs. $2371). Similar differences were found in those with anxiety disorders and those without ($2390 vs. $1397). When patients with specific illnesses are investigated the economic consequences of psychiatric morbidity in the medical setting become even more pronounced: Mean rehospitalization costs in patients with cardiac disease and psychological distress versus those without were $9504 and $2146, respectively. In a review of 26 studies, a significant association was found between length of hospital stay and psychiatric morbidity in 89 percent of studies with sample sizes above 110 patients. This increased health services use involved the emergency room, hospitalization, and rehospitalization, and it continued for at least 4 years after the first hospital discharge.

Psychiatric morbidity compromises patients' functional status and quality of life. The Medical Outcomes Study states that depressive morbidity carries profound physical impairment equivalent to that observed in several other chronic medical conditions (e.g., diabetes, hypertension, arthritis, coronary artery disease), and the social impairment is even greater. (Studies such as that of David Spiegel and coworkers observed improved quality of life after a C-L psychiatric intervention. Improved quality of life is an important research agenda.)

Since the majority of medical, surgical, obstetrical, and gynecological patients receive most of their medical care (including attention to their psychosocial needs and psychiatric morbidity) in the primary care setting, methods are needed to transfer knowledge and skills to this nonpsychiatric setting on a continuing basis. In fact, 44 percent of patients with mental disorders receive their only mental health care in the general health setting, and detection rates in primary care for substance abuse, alcohol abuse or dependence, anxiety disorders, and depressive disorders are only about one-third to one-half. In the general hospital, less than half of the inpatients with depression, delirium, dementia or alcohol abuse or dependence are identified (and detection without appropriate treatment and follow-up does no good). Rand studies demonstrate insufficient mental health care in the general medical setting: minimal psychopharmacological intervention for depression with subtherapeutic dosage; inadequate information to the patient, prompting too-early drug discontinuation; inadequate number of visits and lack of attention to long-term monitoring resulting in half of the patients with depression treated by primary physicians remaining symptomatic months later.

By and large, the venue of primary care does not lend itself to encouraging enough attention to psychiatric issues. The physician must direct a significant effort to ensuring that there are no physiological abnormalities, and payment for services is geared to cover only modest amounts of the physician's time for mental health screening and treatment. Patients may not readily expose their psychiatric problems, but rather emphasize somatic complaints that encourage the doctor to perform repetitive physiological examinations. Through the process of *somatization* (expressing mental feelings and conflicts via the body), neither the patient nor the primary care physician may be aware that the physical complaints emanate from psychological mechanisms. Mind-body dualism prevails, with patients and their doctors locked into endless examination of the soma in order to not miss something that could be life threatening. But they may miss another mechanism for the somatic disturbances—that is, psychiatric morbidity. They are practicing the biomedical model rather than the biopsychosocial interactional model espoused by George Engel in 1977.

SCREENING

Medical students and physicians need practical training and education in clinical diagnosis and treatment of mental disorders, particularly in the medical and surgical environment. Appropriately trained physicians are the best screening tools for mental pathology in the medically ill; however, as an interim measure, easily administered screening devices have been developed. Such devices become more necessary when mental health care is placed within the context of primary care. Most patients with comorbidity first appear in the general medical setting, and these physicians must identify the patient in need of a psychiatric consultant if they cannot treat the patient themselves. Reliable and valid screening instruments are needed by nonpsychiatric physicians and their assistants to facilitate detection of mental disorders, but adequate diagnosis and appropriate treatment must follow. Screening is only the beginning of a process.

David Goldberg developed one of the first mental health screening devices for the medical and surgical setting, the General Health Questionnaire, which has had numerous iterations and forms since its introduction in 1974. However, it is a measure of morbidity and is neither syndrome nor medical disorder specific. It identifies subthreshold states, disturbance of mood, and decreased well-being. Such broad inclusiveness will identify too many individuals beyond those with psychiatric morbidity. It has been superseded by contemporary instruments, some of which can even be administered over the telephone from home before arriving at the doctor's office or hospital, for example, Symptom Driven Diagnostic Scale (SDDS) developed by Eugene Broadhead, A.C. Leon, Myrna Weissman, and coworkers. The SDDS has a computer-based format—the CATI—that provides a telephone or admission screening result with a scored statement of the potential risk for a specific or multiple psychiatric morbidity; depression, panic, obsessive-compulsiveness, anxiety, and suicidality are automatically forwarded to the physician as a mental health alert. Presenting this alert to physicians before they evaluate the patient should focus history taking to confirmation the suspicion of a psychiatric disorder. This instrument can also be used for diagnostic and follow-up evaluation of psychiatric morbidity during and after a course of treatment.

However, it is only a screen and as such requires confirmation of the presence of the essential attributes of a diagnostic algorithm from the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) namely, the vegetative signs and symptoms should not be secondary to physical causes. Such an alert would mandate further examination by history, physical examination, and mental status assessment for the presence of core psychiatric disorders and save the physician initial triage for every patient. Only those at risk for the disorders are further screened by the history and physical investigations. Thus, much like the hematocrit, which alerts one to an anemia that requires further exploration, the screen points to the need for a mental health workup, treatment, and follow-up of the patient. No patient should leave the medical setting with a known hematocrit of 30 or less without an anemia workup, and no individual should leave a medical setting with undetected depression, anxiety, panic, suicidality, or substance abuse and lacking expert management. The screening assessment does not require the physician's time or presence for its completion, thus accommodating the significant demands and time constraints of contemporary medical and surgical practice.

The PRIME-MD, developed by Robert Spitzer, is another commonly used screening device. Such instruments allow modestly skilled persons to develop a profile of patients at risk for mental morbidity and immediately bring it to the attention of those who can perform a more rigorous clinical evaluation and provide the necessary mental health treatment.

Screening devices must be used with caution. The assessment of cognitive dysfunction by two commonly used instruments—the Mini Mental Screening Examination and the Cognitive Capacity Screening Device—are confounded by the frequent occurrence of false-positive and false-negative results, up to 25 percent in some studies. In the former case the patient may be exposed to an unnecessary workup, and in the latter (the false-negative result), critical assessment to determine the underlying mechanism for cognitive dysfunction (of which even the patient may be unaware) is overlooked, at times a life-threatening omission. The first challenge is developing a mechanism to screen every patient entering the health care system for psychosocial and psychiatric morbidity, with valid tools to alert the caregiver to the potential presence of mental states that must be addressed, which is of cost and risk benefit. The second step is confirming or ruling out this suspicion. The third requirement is formulating a diagnostic and treatment plan to ensure that the mental morbidity is properly identified and treated.

Concomitant medical illness confounds screening for mental illness. Reliability and validity are challenged by the presence of physical symptoms that can emanate from either the physical or mental sphere. However, the source is not always known and for illnesses such as depression, anxiety, and somatization it is essential that physical symptoms that emanate from physical causes are not counted in the diagnostic algorithm. The instruments commonly used to assess for the presence of mental disorders (e.g., Beck Anxiety Inventory, Beck Depression Inventory, Hamilton Rating Scale for Depression or Anxiety Scales) do not sufficiently take into account the contamination of their scores by physical symptoms that result from physical illness (e.g., anorexia, insomnia, decreased energy, diminished libido) or ideational signs that commonly accompany physical illness (e.g., guilt over smoking and helpless or hopeless feelings in cancer), all of which are expected human responses to serious medical morbidity and its treatment.

PROBLEM-LEVEL DIAGNOSIS

In the C-L psychiatric setting interaction with the patient usually begins with a problem-level diagnosis (the chief complaint). The patient may be referred for noncompliance, poor coping, strange or bizarre behavior, confusion, or staff conflicts. It may be difficult for the consultee to be more specific, especially in the face of acute or life-threatening physical illness. Primary care medicine has long known and respected the problem-level of diagnosis, knowing that many patients will not meet the criteria for a specific diagnosis; as many as 50 percent of those seen in the ambulatory setting do not receive a physiological, psychological, social, or combined diagnosis but remain at the reason-for-visit–level or problem-level of diagnosis.

Diagnosis proceeds along a continuum: (1) understanding the stated reason for the patient's visit or referral; (2) assessing the reason for contact; (3) formulating (if possible) a diagnosis or multiple diagnoses with a known cause and prognosis. The patient can be managed (treated) at any point on this continuum. The patient with acute chest pains or a bizarre psychotic reaction is managed (e.g., hospitalized) and medicated even before the underlying problem has been definitively diagnosed,

if it ever is. The patient could be signed out with chest pain of unknown origin and no more specific diagnosis. Noncompliance or phase of life problem may not be differentiated into a depressive, anxiety, or psychotic disorder but be left at the V-Code level of diagnosis (i.e., conditions that may be the focus of clinical attention).

On the other hand, use of computerized clinical database assessment techniques showed that many of the consultee's problem-level diagnoses (e.g., noncompliance) could be further reduced to specific psychiatric categories such as depressive disorders, anxiety disorders, or cognitive disorders. Such differentiation was not possible by the primary care physician. Less than 50 and 22 percent, respectively, of alcohol and delirium, dementia and amnestic and other cognitive disorders were properly identified by the consultee in the inpatient medical or surgical setting. Several reasons may explain the difficulty the primary physician has with identification. The clinical state may be at a subthreshold level and has not reached criteria for an apparent psychiatric diagnosis. Primary care physicians may not switch hierarchical levels from the physical to the psychological mechanism of causality; it may be difficult for them to discern the interrelation between somatic and mental phenomena and incorporate such mechanisms into their diagnostic formulations (e.g., delirium due to metabolic causes). Even the identification of biological, psychological, social dysfunction (triaxial diagnostic systems) does not mean the physician is aware of the interactions among the systems to arrive at a higher-order, more complex, or multiple interactional diagnosis, such as a depressive disorder due to cancer of the pancreas, psychotic disorder due to multiple sclerosis. Therefore, some cases remain diagnostic problems for the primary care physician, while others can be further specified when the medical morbidity improves and allows the psychiatric morbidity to be more apparent or disappear.

DISORDER-LEVEL DIAGNOSES

To ensure appropriate treatment within the medical model, the clinician strives for diagnostic certainty. The major dilemma is the attribution of physical symptoms, since the decision-making rules of DSM-IV state that physical symptoms secondary to a medical illness should not be counted in the algorithm for mental disorders. However, it is difficult to ascertain whether a symptom emanates from the body or has a psychological origin or both.

Three pain disorder categories are now available to the diagnostician: (1) pain associated with psychological factors, (2) pain disorder associated with both psychological factors and a general medical condition, and (3) pain disorder associated with a general medical condition (in which case the pain diagnosis is placed on Axis III and not Axis I). This classification takes into account that the most common reason for psychiatric consultation is combined psychological and physical pain, that it was an appropriate reason for referral, and that it is a knowledge and skill area in which the psychiatrist should be trained (e.g., a part of the residency curriculum). It also incorporates the reality of diagnostic uncertainty in physical symptoms that may emanate from a mental or physical sphere. The traditional somatoform-conversion pain disorder was relatively rare compared with the psychiatrist's need to assist with combined pain. The old classification had no Axis I for coding or billing purposes for appropriate psychiatric consultative effort. A similar conundrum obtains for the somatoform disorders, psychiatric disorders that present with physical symptoms, which the patient is convinced have a somatic origin. Somatization disorder (Briquet's disorder) patients besiege the primary care physician to find the physical source of their plight. They have numerous examinations and frequent emergency room visits, become high medical-resource utilizers, and continue to have negative physical findings in one workup after another. They drive themselves and their doctors to distraction and are outraged with each other.

> A 32-year-old black unmarried woman came to the physician for recurrent chest pain, after seeing several clinic and emergency room physicians for assistance in relieving the pain. Despite countless examinations and two hospitalizations, the patient insisted that something was physiologically wrong and that she must have a serious illness that the doctors could not diagnose. Finally, she was sent to a prestigious medical facility in a neighboring state, where a different set of physicians performed a complete, extensive workup and found no discernible pathology. The patient wanted one more computerized tomographic (CT) or magnetic resonance imagery (MRI) scan, and even wanted to have a surgeon look into her chest to find the disease. With increasing despair and mounting depression, the patient threatened to kill herself and blamed her family and physicians for her plight. Despite being a highly educated professional, she could not function or leave her apartment except to see the next physician, and she believed that her life was over. Observation and treatment on a psychiatric unit considerably diminished her physical complaints as she underwent cognitive-behavioral treatment, physical rehabilitation, and psychotropic medication, and was reassured that nothing had been missed (reframing her understanding of her significant pain that would in time be reduced), that gradually she would gain greater control over her body, and that she did not have a life-threatening illness. The psychiatrist knew that at times she had unbearable physical symptoms, that she would learn to manage them better and better, and that in time she would resume her previously productive and rewarding life.

These patients are certain that they have physical illness and often eschew any reference or referral to psychiatry. Close collaboration of the primary care physician and the psychiatrist is needed to shift the focus to psychological processes and conflicts without discounting the bodily symptoms and the patient's concern.

Factitious disorder patients are aware that they are causing the symptoms but do not know why they are compelled to do so.

> A 26-year-old registered nurse was admitted to the medical ward with a fever of unknown origin. Extensive workup revealed no physiological mechanism. On her fourth hospital day her primary care nurse found her injecting herself in the thigh. When questioned, the patient was embarrassed and tried to hide the syringe. The nurse took the syringe, and when its contents were examined, she learned that the patient had been injecting herself with her own feces to incite a fever and restart the process of a fever workup, which had confounded the staff for the last 2 years. When questioned about her need to do this, the patient had no explanation. Despite recurrent psychiatric consultations, she remained oblivious to the mechanism underlying her behavior and demanded to leave the hospital against medical advice. Having been exposed, she wanted to leave that medical setting and had no interest in learning more about her need to hurt herself or what was behind her self-destructive behavior.

Factitious disorders can occur with physical symptoms, mental symptoms, or by proxy where the patient has a perpetrator who claims the patient (the victim) has physical symptoms (e.g., mother of a child, or an adult child of an elderly parent, in which the perpetrator wants the victim (to be ill).

Finally, *malingering* (i.e., the feigning physical symptoms for secondary gain, in which the patient displays self-simulated symptoms) is a problem-level (V-code) diagnosis demanding attention by the psychiatrist, usually within the medical setting. This diagnosis requires proof of simulation and indentification of the secondary gain.

Unfortunately, patients who present with physical symptoms with no detectable physiological origin are too often labeled malingerers. The differentiation of the somatoform disorders, factitious disorders, and malingering is problematic not only for the psychiatrist but for the primary care physician in particular. In fact, this triad challenges the most experienced clinician and highlights the diagnostic dilemma for the psychiatrist in the medical setting when unexplained physical symptoms are under deliberation. Unfortunately, malingering is too often the default diagnosis for unexplained physical symptoms. In addition, once real malingerers are found to be simulating for secondary gain (and exposed), they usually leave that medical environment and simply move on to the next physician, with their behavior unchanged.

Physical symptoms are common in the entire spectrum of mental disorders. It is medically unsafe to categorize a symptom as psychological simply because no organic attribution can be established. If the disorder does not reach the threshold for a mental disorder, then the symptoms must remain at the problem level of diagnosis, with their cause regarded as uncertain. The adjustment disorders themselves are problematic because they have no symptom checklist but rather rely on the presence of a maladaptive response to a stressor (which may be medical illness), with the descriptor taken from the prevailing mood. Since there are no valid or reliable criteria to reach threshold for these diagnoses (so commonly used in the medical setting) and since maladaptation may include problems in mental functioning or bodily competence, this ubiquitous diagnosis in medically ill patients remains problematic. Because the standard instruments of assessment have not included calibrations for the physical symptoms they assess (e.g., 13 of 20 on the Hamilton Rating Scale for Depression) the likelihood of scoring depression in the medically ill is extremely high. Similarly, such instruments for anxiety disorder, which itself has many physical symptoms, and those for somatization disorder confront the diagnostician with, at times, insurmountable validity questions.

Nor are dementia and other cognitive disorders, mental disorders due to a general medical condition (e.g., stroke, multiple sclerosis, systemic lupus erythematosus) and substance–related disorders immune from the confounds of diagnosing psychiatric morbidity in the medical setting.

> A 72-year-old patient with alcohol abuse seen in the intensive care unit after surgery for the extravasation of a subdural hematoma was delirious postoperatively, had experienced blood loss, anesthetic agents, analgesic drugs, and exposure to a strange and confusing environment. Classification of the patient's delirium is problematic, since it could be secondary to substance abuse, medical drugs, blood loss, detoxification, or the foreign environment, and the acute state observed could cover an underlying chronic state such as dementia.

Therefore, diagnosis in the medical or surgical setting remains a process requiring initial impressions and follow-up observations to document the mental status as

medications change, the medical condition evolves (including the diminution of pain), the environment becomes more familiar and less frightening, and underlying personality traits and chronic coping styles and strategies emerge. Even in retrospect, diagnostic certainty may be elusive. Yet, this does not preclude interventions to enhance behavioral control and compliance and diminish anxiety in the medical care setting.

TREATMENT

Treatment follows the best diagnosis possible given the potential confounding factors. In recent years, treatment guidelines have been developed on the basis of the best evidence available.

According to the Institute of Medicine's *Guidelines for Clinical Practice: From Development to Use*, developers of guidelines should incorporate eight attributes: (1) validity, including strength of the evidence and estimated outcomes; (2) reliability and reproducibility; (3) clinical applicability; (4) clinical flexibility; (5) clarity; (6) multidisciplinary process; (7) scheduled review; and (8) documentation. These attributes were incorporated into the American Psychiatric Association's guidelines for the treatment of depression in primary care. The United States Department of Health and Human Services, Public Health Service, Agency for Health Care Policy and Research (AHCPR) has sponsored over 19 guidelines for treatment, many of particular importance to the C-L psychiatrist. For example, guidelines on management of cancer pain, acute pain management in adults: operative procedures, managing early HIV infection, acute low back pain, post stroke rehabilitation, cardiac rehabilitation, smoking cessation, Alzheimer's disease, anxiety and panic disorder, and chronic headache pain were constructed by incorporating these same attributes, among which one of the most important is scheduled review and constant updating and reconsideration of the strength of the evidence.

It is anticipated that guidelines can become the textbook of tomorrow, incorporating new findings and being published in a few weeks to months for rapid updating, almost the way medical journals are now distributed but even more efficiently. Amendments can be distributed overnight to update diagnostic and treatment approaches, using electronic alerts to translate new findings into therapeutic strategy and tactics for the clinician. The C-L psychiatrist must be aware of these guidelines and provide feedback to developers and promoters to enhance their utility. (Many guidelines have few psychiatric or behavioral statements or recommendations). Therefore, guidelines not specifically geared to psychiatry (e.g., Diagnosing and Managing Unstable Angina, Urinary Incontinence in Adults, Benign Prostatic Hyperplasia: Diagnosis and Treatment) may benefit from the input of C-L psychiatrists to augment the psychosocial or psychiatric morbidity component. Specialty organizations such as the American Psychiatric Association have also developed important guidelines to be used for comorbidity in the medical setting such as Practice Guideline for Major Depressive Disorder in Adults. These guidelines developed with the psychiatric patient must be amended to incorporate conditions and modifications for individuals who have psychiatric and medical comorbidity. They, like the assessment instruments described above, too often lack the dimensionality considerations that concurrent medical illness superimposes on psychiatric morbidity. Tomorrow's guidelines for the treatment of psychiatric morbidity must include algorithms and parameters to account for medical illness, which may add risks and injunctions to treatment in the medical setting.

The strength of the evidence for treatment has been codified and enhanced by the Cochrane Collaboration, Oxford University, funded by the United Kingdom's National Health Service, which has established criteria for the assessment of validity of random control trials or treatment trials. This is the highest level of assessment, promulgated in the Cochrane Database of Systematic Reviews which includes “Stroke Unit Trialists' Collaboration: A Systematic Review of Specialist Multidisciplinary Team (Stroke Unit) Care for Stroke Inpatients,” “Elective versus Caesarean Delivery of the Small Baby,” “The Effects of Family Intervention for Those with Schizophrenia,” and “Support from Caregivers for Socially Disadvantaged Mothers.” These meta-analytical studies by clinical experts in a given discipline offer the C-L psychiatrists a cross-comparison of studies that heightens the strength of the evidence and thus should have an important impact on treatment and clinical decision making. New reviews are continually being developed, and in time such efforts will help move the world's repository of random control trials to a more refined definition of reality than exists in most medical treatment areas to date. This effort goes well beyond one research team or one finding. These reviews are labor intensive; they require hand examination of journals.

PSYCHOTROPIC-MEDICAL DRUG INTERACTIONS

One of the most critical areas for the C-L psychiatrist involves medical drug–psychotropic drug interactions. In addition, the C-L psychiatrist must understand pharmacokinetics as it relates to end-organ dysfunction (kidney, liver, lung, heart) and the aging process. Since, by definition, most patients in the C-L setting present with physical illness, prescription of psychotropic drugs entails knowing the pharmacokinetics and interactions of the medical drugs their consultation patients are taking. Thus authors, Gina Caliendo and Carol Himelein have developed an approach to (1) review the literature, (2) codify and describe the most important psychotropic drug–medical drug interactions, and (3) access and update new findings from a variety of sources not customarily used by the psychiatrist. Many psychotropic medications have not been tested against medical drugs, especially newer ones such as protease inhibitors for human immunodeficiency virus (HIV) infection. Thus, the C-L psychiatrist must have access to technical reports and a way to update their knowledge of potential interactions. There is a lag time from publication to inclusion in the MEDLINE system, and as stated above, many published studies do not appear in MEDLINES. Updates on medical drug–psychotropic drug interactions are often in the form of case reports and letters to the editor. Although C-L psychiatrists may not have ready access in their offices to the following materials, they must know about them and where to access them (usually the pharmacy department of the hospitals in which they practice).

One important source for updates in this crucial area is the *F-D-and-C Pink Sheets*, a weekly publication that highlights regulatory issues for new drugs and those soon to be approved and important labeling changes. Computerized methods of accessing important pharmacological literature exist; most hospital pharmacy services have access to these instruments and will assist the C-L psychiatrist with queries regarding psychotropic drug–medical drug interactions. MICROMEDEX is a computerized database compiled from multiple drug information systems. DRUG-REAX is a subsection of MICROMEDEX that searches multiple drugs simultaneously for drug-drug, drug-food, and drug-disease interaction data. DRUGDEX is a software system that contains drug monographs with drug interactions obtained from case reports and drug interaction references. In addition, many journals and publications include information on medical drug-psychotropic drug interactions: *Pharmacotherapy, Annals of Pharmacotherapy, Clinical Pharmacology and Therapeutics, Drug Safety, and Drugs* . Monitoring services include *Clin-Alert; Reactions, Clinical Abstracts/Current Therapeutic Findings; Current Contents/Adverse Reactions and Excerpta Medical/Adverse Reactions*; and *American Journal of Health-System Pharmacy, Current Literature* (a section of the *Journal of the American Society of Health-System Pharmacists)*. Most of these resources are not known or used by psychiatrists but are the information systems of pharmacists and consultants. Most large institutional settings (e.g., university teaching hospitals) have established drug information centers within their pharmacy departments. Trained pharmacists with access to the information sources above are more adept at determining potential medical drug–psychotropic drug interactions or can provide the best advice given the state of current knowledge. Pharmaceutical companies also have information services and can often assist with potential or reported interactions with their products. These in-house information services cull data from the published literature, clinical trials, foreign databases, and unpublished spontaneous case reports from medical professionals. An example of one hospital's attempt to systematize psychotropic drug–medical drug interactions is given below and described in Table 25.12-1 and Table 25.12-2.

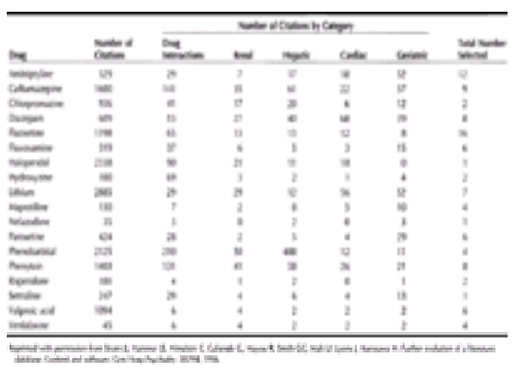

Table 25.12-1 Sample of Search Results Psychotropic Drug Medical Drug Interactions

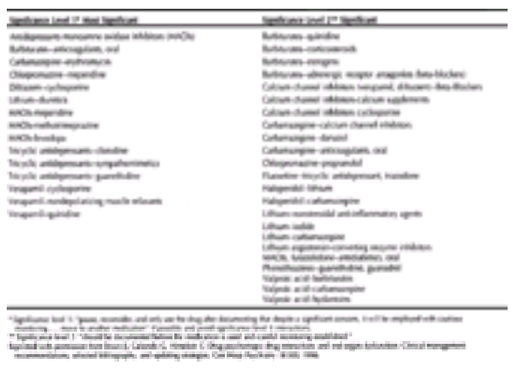

Table 25.12-2 Psychotropic-Medical Drug Interactions and Significance Level

Interaction: Carbamazepine–Erythromycin Significance Level 1: Most Significant

Advice to Practitioner: Erythromycin may inhibit the hepatic metabolism of carbamazepine and toxicity may result. Interactions of this type present problems when the drug that alters hepatic metabolism is added after a patient is stabilized on the affected drug. A problem may also arise if a patient is stabilized on the affected drug while receiving an enzyme-altering drug and that enzyme-altering drug is discontinued. Interactions of this type may take a few days to become evident and resolve because effects of the enzyme altering agent may take a few days to become evident or dissipate. If a patient is stabilized on the combination, there is little need to alter therapy. If a patient is on erythromycin and carbamazepine is added, the dosage of carbamazepine will be determined by serum concentrations and clinical efficacy, and no additional intervention is required. If a patient is on carbamazepine and erythromycin is added, serum concentrations of carbamazepine may increase during combination therapy, and may result in toxicity. An alternative antibiotic should be used if possible.

Action: Monitor carbamazepine serum concentrations when erythromycin is added to carbamazepine, and an alternative antibiotic is not required.

Alan Stoudemire and T.M. Brown have an important publication that addresses the issue of psychiatric adverse effects of prescription and over-the-counter medications, which may also be useful to the C-L psychiatrist.

COMPLIANCE

Not only research but clinical care is undermined by noncompliance in the patient, the consultee, or the consultant; the patient may fail to comply with the prescribed regimen; the consultee may fail to follow the consultant's recommendation (*nonconcordance* with recommendations); while the consultant may not comply with the suggested treatment protocol, algorithm, or guideline *(nonadherence)*. Any of these three behaviors leads to error measurement in the outcome results of research. For the patient, noncompliance may mean less than optimal behavioral changes that at times can be life saving (e.g., tearing out intravenous lines in the intensive care unit because of a delirious agitated state).

One study found that consultees used the C-L psychiatrists' recommendations for psychopharmacology, consultations, and diagnostic labeling on 71, 43, and 39 percent of the prescribing occasions, respectively. It is not surprising that consultees may be reluctant to prescribe medications that they are unfamiliar with or for a frail or especially vulnerable patient, those with the recent acute surgery, elderly patients, or those with nascent trauma. The C-L psychiatrist needs to tell the consultee about expected adverse effects of psychotropic drugs as well as central nervous system (CNS) manifestations that may accompany medical drugs; for example, many of the antiviral, anti-infection, and antineoplastic chemotherapeutic agents used to combat (HIV) (e.g., zidovudine (Retrovir) affect mood and cognition (Table 25.12-3). The consultant must also encourage the use of indicated psychotropics when there is reluctance on the part of the consultee because of inadequate information, misguided beliefs, or inadequate understanding.

Table 25.12-3 Psychiatric and Neurological Side Effects of Medications Used in Treating AIDS

Just as diagnostic impressions must be confirmed with reliable and valid rating scales and treatment strategies must be titrated against specialty-developed guidelines, compliance must be assessed as a part of the consultation process by consulting with the patient, the caregivers, and the medical chart. Until it is confirmed that the recommendations were invoked, assessment and the meaning of outcome are in peril of error measurement. Since noncompliance in all its forms is ubiquitous in medicine and since it may have such a pernicious effect on preferred outcome, it becomes an essential attribute of the consultation process, and the fate of recommendations must be documented. Currently, compliance is seldom commented upon, and its documentation in the consultant's note is even rarer.

PATIENT OUTCOMES

Patient outcome studies from C-L psychiatric interventions in the inpatient or outpatient medical setting have shown important contributions to the well-being of patients and often decreased costs of medical treatment.

Inpatients Steven Saravay and Mark Lavin examined 26 outcome studies (17 U.S.) on the effects of psychiatric morbidity and hospital length of stay. Eighty percent of the studies selected and 89 percent of those with a sample size larger than 110 reported a significant association between increased length of hospital stay and psychiatric morbidity, and that depressed mood, impaired cognition, and other personality variables were associated with increased length of hospital stay and greater utilization of rehospitalization and general medical services for up to 4 years after discharge from an initial hospitalization.

C-L psychiatric intervention studies for acutely hospitalized medical or surgical patients demonstrated improved patient status and decreased costs. When psychiatrists became part of the orthopaedic team and examined every elderly patient admitted during 1 year for the surgical repair of an acute hip fracture and treated those requiring psychiatric intervention, patients (1) were found to have significant diagnosable DSM-III-R disorders (most commonly, organic mental and mood disorders, 56 percent), (2) were discharged with less psychiatric morbidity, (3) left the hospital on average 2 days sooner than those in comparison groups, (4) had fewer rehospitalizations, and (5) needed fewer rehabilitation treatment days. There was no evidence of cost shifting to ambulatory settings. A $20,000.00 C-L psychiatric intervention cost saved $167,000.00 hospital-stay dollars on one illness in 1 year. Other studies demonstrated that early discharge planning and timely, focused interventions for psychosocial factors that affect length of hospital stay produced significant financial savings. Since inpatient hospital care remains the most expensive delivery component of medical service in our health care system, the Health Care Financing Administration has been issuing guidelines since 1979 in an

attempt to limit length of hospital stay to only what is medically necessary.

With both the high incidence of psychiatric morbidity in the general, short-term care, inpatient, medical and surgical hospital setting and the demonstration that a C-L psychiatric intervention increases recognition of morbidity, improves patients' status upon discharge, and decreases costs, provision of C-L psychiatry in these settings appears to offer a significant cost-to-benefit ratio and should be a mandatory service for high-risk patients (e.g., elderly persons with hip fracture, persons with HIV infection, and those with acute myocardial infarction with depression).

Outpatients In a review, G. Richard Smith found the prevalence of somatization disorder in the primary care outpatient setting to be 9 percent, three times higher than that in the general population. Somatization disorder patients also had more significant functional impairment (e.g., sick days, days in bed, physical restrictions, poor psychological health, impaired parenting) than patients with medical illness alone, and somatization dysfunction is additive to what may be experienced from physical morbidity per se, which results in seriously impaired and dysfunctional patients.

PRIMARY CARE PHYSICIANS

Wayne Katon and his coworkers used double-blind, controlled intervention studies to determine what training algorithms are required to promote better patient outcome for depression treated by primary care physicians. Screening for depression, informing the physician of its presence, and a brief concurrent intervention by the psychiatrist with the patient and the primary care physician had little impact on physician behavior or patient improvement. A more comprehensive intervention by the psychiatrist with the primary care physician, which included joint interviews, educational efforts for the physician and patient, and repeat visits with physicians, did improve psychiatric morbidity. This conjoined evaluation, treatment, and educational paradigm was effective when lesser interventions did not ameliorate the depression.

By analyzing massive databases of three large health studies (the Health Insurance Experiment, the Medical Outcomes Study, and the Prospective Payment System Quality of Care Study), Kenneth Wells and his collaborators found that both outcomes and quality of care of depressed patients in primary care treatment settings are inadequate. For example, 40 percent of depressed patients were treated with subtherapeutic dosages of medication; prepaid care had lower rates of detection and referral for psychosocial treatments for depressed patients than fee-for-service programs. Significant numbers of depressed patients cared for in primary care experienced inadequate interventions and exhibited marginal improvement.

Spiegel demonstrated that women with metastatic breast neoplasia (stage IV) who were treated in an ongoing group therapy protocol lived 18 months longer than controls and had a better quality of life. This important study is now under replication at several national and international sites. Fawzy Fawzy observed that patients with metastatic melanoma who were entered into group and educational therapy protocols survived longer and had better quality of life than matched controls. These studies suggest that a psychosocial or psychiatric intervention not only improves life, but also prolongs it.

The current literature indicates that psychiatric morbidity in both outpatients and inpatients in the medical setting is generally undetected, and that these patients use more health resources, increase the cost of health care, and have more-impaired functional status than patients with medical illness alone. Lower-intensity interventions (e.g., notifying the primary care physician of psychiatric morbidity) are of minimal consequence in effecting change. Structural change in the pattern of health care provided by primary care is needed to ensure that adequate C-L psychiatric involvement occurs at every phase of treatment: assessment, treatment, and follow-up. The liaison skills—case-finding, education, and training of medical caregivers—of the C-L psychiatrist need to be incorporated into the structure of primary care so that appropriate screening, triage, treatment, and follow-up are accomplished early in the patient's encounter with primary care, whether in the inpatient or outpatient setting.

RANDOM CONTROL TRIALS: FUTURE RESEARCH AGENDA

Random control trials are confounded by psychiatric and medical comorbidity. Two recent random control trials in chronic fatigue syndrome and in patients with medically unexplained physical illness found significant lessening of symptoms of those receiving cognitive-behavioral treatment compared with placebo controls. The Spiegel and Fawzy studies of psychiatric interventions for stage IV breast cancer patients and melanoma patients, respectively, used random control trial methodology, but questions of severity of medical illness and comparability of medical treatment remain. Controlling for severity of psychiatric illness and medical illness is difficult. Measures of both spheres have many questions about reliability and validity at this time. Most measures of physical illness have not been standardized to take into account psychiatric morbidity, and psychiatric rating scales have not been modified to correct for potential challenges to validity by concurrent medical illness. How one random-control trial compares with another examining the same issue is the key to legitimizing the value of even this highest form of rigor in scientific endeavor. Since it is difficult to ascertain the reliability and validity of some psychiatric diagnoses in the medical setting and whether a psychosocial or psychiatric intervention has been fully implemented is often uncertain, errors in measurement often occur. If the random control trial is to be a system intervention (e.g., a structural consultation–liaison psychiatric change on one inpatient ward versus another, a new technique on one ward in contrast to a traditional technique on another unit), the study may be compromised by nonrandom admissions on one unit or the other. Hospitals cannot afford to hold a bed open for random assignment of a study patient. Random control trials may be approached more easily in the outpatient setting, but standardization of medical treatment and complete delivery of the psychiatric intervention enhance uncertainty and raise questions about the integrity of the therapeutic arm of the study.

An important new venue of care for comorbidity that needs to be studied with random control trial methodology is the psychiatry-medical unit (if under the Department of Psychiatry), or the medical-psychiatry unit (if it is a unit of the Department of Medicine). Roger Kathol has developed this genre of care facility at the University of Iowa to one of the highest levels in the United States. This inpatient care facility attends to medically ill patients too psychiatrically ill to be on a medical ward and too medically ill to be on a psychiatric inpatient unit. It studies chronic pain patients, somatization disorder, chronic fatigue syndrome, and those with profound somatic presentation of psychiatric symptomotology. These patients with diagnostic dilemmas and the need for short-term care for both their psyche and their soma require special physicians, nurses, and a ward structure that can address diagnoses and therapeutics in both dimensions.

Empirically, it makes sense to have a setting that can optimize care in both spheres of the human being. However, these units are costly to maintain, require staff competent in both domains (not easy to locate), and must deal with patients that abuse the medical system with their constant complaints and dissatisfaction with medical care. The effects of these units on their unique patient cohort and the cost-benefit ratio in the use of health care resources have yet to be subjected to random control trials. Until then, they are experimental, and short-term care hospitals should not universally set out to establish psychiatry-medicine units, as they have currently for coronary care, intensive care, and respiratory intensive care without ascertaining the effect size on patient outcome and comparing costs with those of traditional medical or psychiatric care units. Furthermore, existing psychiatric units need to expand their capacity to care for more seriously medically ill, neurologically complex, and elderly patients, in essence becoming de facto psychiatry-medicine units.

Transplantation services exist in many university teaching hospitals. Their medical effectiveness has been sufficiently proved to warrant payments by the Health Care Financing Administration and many third-party payers. What remains to be determined is the place of psychiatric consultation and treatment for this special cohort of patients. Although many transplant units have psychiatrists attached and have psychiatric assessment built into the selection procedure for organ transplantation, the contribution of the psychiatrist to selection, treatment, and patient outcome remains in question. No study has compared outcomes with and without psychiatric assessment in a cohort of patients receiving liver, heart, lung, pancreas, kidney, bone marrow or intestine transplants.

However, the psychiatric assessment is so essential to selection in some academic teaching hospitals that an indication of inability to comply or insufficient capacity to maintain a scarce resource (the organ) can eliminate a candidate for transplantation, and this usually means the patient will die. In such settings the psychiatrist holds as much power as the surgeon in deciding whether or not a patient will receive the life-saving liver. Random control trials of the psychiatric contribution to clinical decision making and patient outcome are essential in transplantation medicine, in which scarce resources mandate using vital organs in persons who can maintain them with the greatest likelihood of their and the organs' survival. The behavioral capacity of the organ recipient to comply with complex and demanding treatment protocols and the presence of a support system to assist in this compliance may be as important to the successful outcome of the transplantation as the optimal donor-recipient match itself. The additional cost of psychiatric assessment and treatment is a minimal part of the cost of a liver transplant (estimated to be $250,000 in New York City in 1997) if it demonstrably benefits patient outcome.

The ability to substitute one mental health specialist for another, *product substitution,* has not been studied under rigorous conditions in the medical setting or with patients with comorbidity. Random control trials comparing the ability of psychologists, social workers, clinical nurse specialists, primary care physicians, and gerontologists to diagnose and effect biological and psychological intervention strategies for biopsychosocial problems in patients with comorbidity, which may include psychotropic drug–medical drug interactions, end-organ dysfunction, and somatic and pharmacological effects on the CNS (including cortical-cognitive-affective functioning) have yet to be undertaken. As managed care replaces mental health specialists on the basis of least cost, it is compromised by a paucity of outcome

studies showing which mental health professionals optimally perform what functions. The C-L psychiatrist who manages comorbidity in the intensive care unit, with patients emerging from surgery and anesthesia who are on multiple drugs in strange and spectacular environments, and who may have impaired cognition, including orientation, from the admixture of all the above etiological agents and mechanisms, and so demand psychopharmacological intervention, needs the knowledge and skills of a highly trained physician. Without studies demonstrating that the C-L psychiatrist makes a significant difference in patient outcome, health maintenance organizations will use the least costly and lesser-skilled professional in their efforts to contain costs.

Finally, it will be important to conduct a random control trial comparing consultation (awaiting referral) with C-L psychiatry, in which the psychiatrist becomes a member of the medical-surgical team and makes rounds on all patients. Although there has been considerable debate about the virtue of these two forms of psychiatry, no study has compared their cost-benefit ratios or their effects on screening, diagnosing, treating, and outcome on a medical or surgical service. Studies such as the one on hip fracture in elderly persons and their length of hospital stay demonstrate clearly the superiority of liaison over pure consultation psychiatry, but random control trials comparing the two structures are needed not only to foster optimum patient care in the medical setting, but also to convince third-party payers of their gain from structural changes and intervention expenditures. Such studies would enhance the funding potential for C-L psychiatry as part of the team or hospital care centers, following the path of social work services who are paid from the hospital budget to be on every ward, clinic, and emergency service. This would ameliorate the current attrition of this subspecialty of psychiatry from lack of support from departments of psychiatry. It would promote autonomy, and allow the C-L psychiatrist to work at a more advanced level rather than waiting to be called by the consultee and being funded (often marginally) by third-party payers. It would also allow access to the entire hospital population to screen and triage psychiatric morbidity that cannot be referred to the consultant because it is not identified and therefore not treated by the primary care physician or a mental health specialist.

ETHICS AND ETHICS COMMITTEES

An increasing function of C-L psychiatrists is their participation in, and often chairing of, ethics committees in the general hospital setting. To this end the psychiatrist needs to be aware of basic ethical principles and theories and their application in the medical setting. The rules of autonomy, beneficence, distributive justice, and malfeasance are essential to ethical decision making and are recurrent themes encountered in the medically ill. Capacity to make decisions (e.g., respect for autonomy versus paternalistic medicine, truth telling), do no harm, prima nocere (e.g., not offering procedures that carry risk and offer little to no benefit), and the optimum use of scarce resources (e.g., what to do when two persons need the same liver to preserve their lives) are the common issues for of the C-L psychiatrist. The understanding of these dilemmas is coupled with the need in the medical setting to translate manifest content into latent meaning so that the physician can know what the patient really feels and wishes to communicate. Manifest statements by patients that they want to kill themselves may really be conscious expressions of a wish to not be abandoned, not be left in chronic pain, and not be sent to a hospice but rather be permitted to die at home. It is necessary to try to interpret patients' refusal for a procedure, chemotherapy, hospitalization, or surgical intervention.

> A painter having a one-man show on Madison Avenue heard command hallucinations that he must cut off his painting hand with an ax on the bumper of his car in a mall parking lot for sins he had committed on the astral plain some 50,000 years ago. The patient followed the admonitions of the internal voices, placed his belt around his severed wrist, put the hand in a paper bag, and brought it to the emergency room. He yelled at the doctors that if they touched him or tried to sew the hand back on or repair his arm in any way he would kill them, sever the hand again, injure it by smashing it against the wall, and the doctors would never operate again. Understandably, the surgeons were initially reluctant to begin the surgery. This was all manifest behavior and easily observed. However, the patient's presence in the emergency room with his severed hand was a latent statement to disregard his manifest verbal comment and not let him harm himself. When the patient was no longer psychotic he was most grateful that the doctors had not listened to him and had disregarded his manifest pleas to be left alone.

C-L psychiatrists need to add ethical decision-making skills to their psychological armamentarium to assist in clinical decision making that extends to moral and ethical reasoning. The psychiatrist does not judge behavior, but attempts to explain it both in psychological terms and within an ethical dimension that considers the rights and duties of both patients and their doctors. Ethical issues, such as whether to treat or not to treat; use of scarce resources; denying treatment on the basis of mental capacity (in contrast to denying autonomy on the basis of the legally derived decision of lack of competency); confidentiality; surrogate decision making; and evaluating the patient with regard to wanting to die, will only gain in importance as technological advances enhance the array of possible interventions and their risks and benefits. Western society values self-determination highly, and these conflicts—to tell, not to tell, to favor autonomy or bow to beneficence—are more current, and patients are expected to make their own choices. Critical reasoning may be mastered by working with medical ethicists, enrolling in courses, and reading cases that highlight the central problems in critical thinking. The synthesis of psychological and ethical decision-making knowledge and skills positions the C-L psychiatrist to assist patients and their caregivers with the ethical dilemmas their illness and its treatment engenders.

SUGGESTED CROSS-REFERENCES

The neural sciences are discussed in Chapter 1 and neuropsychiatry and behavioral neurology in Chapter 2. The role of epidemiology in psychiatry is detailed in Section 5.1. Information regarding the evaluation and workup of the patient is examined in Chapter 7. Specific attention is directed to Section 7.7 on medical assessment and laboratory testing in psychiatry. Cognitive disorders and mental disorders due to a general medical condition are discussed in Chapter 10, adjustment disorders in Chapter 23, anxiety disorders in Chapter 15, somatoform disorders in Chapter 16, mood disorders in Chapter 14, factitious disorders in Chapter 17, and psychological factors affecting medical condition (psychosomatic disorders) in Chapter 25. Biological therapies are discussed in Chapter 31 and psychotherapies in Chapter 30; of special interest is cognitive therapy, Section 30.6. Psychiatric problems in the medically ill elderly patient are discussed in Section 54.4k. The recurrent themes of the patient's competence and participation in decision making are discussed in Section 51.6b, forensic issues, and Section 54.1, legal issues in psychiatry.

CHAPTER 26. RELATIONAL PROBLEMS

JOHAN M. F. VERHULST, M.D.

A person's psychological health and sense of well-being depends to a significant degree upon the quality of one's relationships, that is, upon patterns of interaction with one's partner and children, parents and siblings, friends and colleagues. Close relationships are relied upon for personal growth, need fulfillment, and support. Problems in the interaction between significant others may lead to clinical symptoms and impaired functioning among one or more members of the relational unit. Relational problems can also exacerbate the course or complicate the management of a mental or general medical condition. Conversely, an individual's medical or psychiatric condition may provoke dysfunctional patterns of interaction with significant others. Relational problems are often chronic and progressive, with increasing impairment in the functioning of the couple or family unit itself.

Relationships have been the object of a growing number of research studies. Certain aspects of relational functioning have been extensively investigated. The relative frequency and patterning of the interactions between intimate partners have been analyzed. Approach-avoidance, problem solving, communication deviance, behavioral control, and coercive processes have been studied. There is an extensive literature on sexual interactions and on gender issues in relationships. Cognitive elements such as interpersonal attributions and schemas have been studied, as well as the expression and regulation of emotional tension between partners and in the family. A remarkable continuity of attachment patterns in adult relationships has been demonstrated. Researchers have explored the development of partner relationships, differences between distressed and nondistressed couples, and predictors of divorce. Attempts have been made to classify relationships on the basis of resources exchanged, rules established, roles played by the participants, and styles used in conflict resolution. Unfortunately, few investigators have developed a culturally oriented understanding of observed interaction patterns, and the research findings are generally not applicable across cultures. Furthermore, the field lacks a coherent unifying theoretical framework within which the various lines of investigation can be integrated. Many important theoretical contributions developed in the clinical practice of couples and family therapy have not yet been empirically tested.

Relational problems may be a focus of clinical attention (1) when a relational unit is distressed and dysfunctional or threatened with dissolution and (2) when the relational problems precede, accompany, or follow other mental or general medical disorders. Indeed, medical or psychiatric symptoms are influenced by the relational context of the patient. Conversely, the functioning of a relational unit is affected by a member's medical or psychiatric illness. Relational disorders require a different clinical stance than other disorders. Instead of focusing on the link between symptoms and the workings of the individual mind, the clinician has to focus on interactions between people and how these interactions are related to the medical or psychological symptoms in a meaningful way.

DEFINITION

According to the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), relational problems are patterns of interaction between members of a relational unit that are associated with symptoms or significant impairment in functioning in one or more individual members, or with significant impairment in the functioning of the relational unit itself. DSM-IV distinguishes five categories of relational problems. The first category, relational problem related to a mental or general medical condition, deals with the association between relationships and health. The other categories focus on problems in specific relational units: parent-child relational problem, partner relational problem, sibling relational problem, and relational problem not otherwise specified. In addition, DSM-IV features in appendix B the Global Assessment of Relational Functioning (GARF) Scale (see Table 7.8-4), which allows the clinician to rate the degree to which a relational unit meets the needs of its members.

ETIOLOGY

People communicate not only about personal issues and external events but also about their relationship. Interpersonal problems are generally related to interactions that deal with the various components and functions of the relationship itself. The topics of these interactions (i.e., what they are about) are classified in broad categories. It is hypothesized that all close relationships must at least deal with issues of (1) attachment, (2) ranking order, status, and dominance, (3) autonomy and territorial control, (4) sexuality and gender, (5) boundaries and loyalties, and (6) cognitive interpretations of the world. The list is somewhat arbitrary and not exhaustive. Interestingly, except for cognitive interpretations, all other issues can also be observed in interactions among nonhuman primates.

Attachment A core issue in all close personal relationships is the establishment and regulation of the affiliative connection between the participants. In a typical attachment interaction, one person seeks more proximity and affection and the other either reciprocates, rejects, or disqualifies the request. A pattern is shaped through repeated exchanges. Attachment behavior between an infant and its primary caregiver will lead to the development of an *attachment style*, which is a relatively stable communication pattern exhibited in close relationships. Distinct attachment styles have been observed in children and adults. Adults with an *anxious-ambivalent* attachment style tend to be obsessed with romantic partners, suffer from extreme jealousy, and have a high divorce rate. People with an *avoidant* attachment style are relatively uninvested in close relationships, though they often feel lonely. They seem afraid of intimacy and tend to withdraw when there is stress or conflict in the relationship. Break-up rates are high. People with a *secure* attachment style are highly invested in relationships and tend to behave without much possessiveness or fear of rejection.

Ranking Order Interactions that center on the acquisition of status and dominance (i.e., on decision-making power and control over the partner) can be called ranking-order interactions. Though the bases of interpersonal influence are diverse and difficult to specify, power and dominance are always an issue in close relationships. People tend to resent strategies of influencing to which they are particularly susceptible. Some partners are sensitive to threats of withdrawal of affection, others to guilt induction, and so on. Functional relationships require a balance of power that is satisfactory to the participants and facilitates conflict resolution rather than leading to interactional gridlock. Acute power struggles usually involve a (perceived) challenge to an existing dominance structure. An example of an especially dysfunctional exertion of power is the verbal or physical assault of a child with supposedly noncompliant behavior or of a spouse perceived as being insufficiently obsequious. Violence is less likely to occur in egalitarian relationships.

Territory People develop a sense of ownership over their own bodies, their personal space and possessions, their areas of responsibility, and the privacy of their minds. Territorial interactions deal with personal autonomy and control over resources and center on the acquisition, management, and defense of ownership rights. Effective parenting requires a gradual transfer of territorial control from the parents to the increasingly autonomous child. Especially important is the progressive validation of children's sense of ownership and control over their bodies (who can touch? who controls food intake?). Issues of personal autonomy often come to a head in adolescence. Many conflicts in couples are about territorial issues such as privacy, control over one's time, responsibility for tasks and chores, and financial control. The person who performs the quality control over an area is considered the owner of the territory, which is why comments, advice, and criticism are often resented. In healthy relationships each partner is able to relinquish autonomy and territorial control at times of stress and illness. Problems arise when such dependency is not tolerated, but also when it is systematically encouraged and maintained. Contentious territorial interactions are also common in the work environment when a person's area of responsibility is expanded to an unmanageable level or when a competing colleague threatens it.

Sexuality and Gender Communications that express gender role expectations or signal the presence or the absence of sexual attraction are a part of most close relationships. Sexual interactions center on the expression of sexual interest and on the management of sexual tension between potential partners. Cultural norms and individual maturity dictate the relationships in which sexual interactions are allowed and those that must be kept desexualized. Clearly, parents and older adults carry the responsibility of neutralizing the sexual tension that can arise in the relationship with children. Many sexual partner relationships are challenged by differences in desire (with women's sexual drive being less insistent than men's) and by the task of synchronizing individual sexual rhythms and maintaining sexual tension in the relationship.

Boundaries and Loyalties Relationships are constantly influenced by other people, by external pressures, and by each partner's outside activities and experiences.

A marriage can be undermined by an adulterous relationship as well as by excessive jealousy about a partner's emotional involvement with an outside person or activity. Loyalty conflicts involving one's spouse and one's family of origin are common in the beginning of a marriage. Work is often experienced as competing with the relationship. Even a medical condition can be seen as a rival when the patient seems to prefer the emotional involvement with symptoms and treatments to involvement with the partner. Every close relationship has to define its boundaries (e.g., the acceptable degree of outside interference as well as the acceptable degree of each partner's involvement with outside elements).

Cognitive Interpretations Humans live in a symbolic world, the world of language, ideas, values, and goals. A major socialization task of parents is transmitting this symbolic world to their children. One's sense of belonging depends upon the social validation of one's values and interpretations of the world. One's sense of identity is, to a large degree, a summary description of how one has been defined by others. Differences in worldview, values, and beliefs tend to cause interpersonal conflicts. Differences in how a conflict is interpreted by the participants tend to maintain it. A psychological mechanism that has consistently been found to create problems is that people tend to interpret their own behavior as *state-dependent*, (a normal response to the circumstances) and their partner's behavior as *trait-dependent* (determined by stable character traits). Another consistent finding is that of gender differences in thinking about relationships. Women think about relationships more and with more complexity than men do. They are more distressed about problems and more likely to take action to resolve them. Conceivably, women carry more than an equal share of the responsibility for relationships because they are defined by society as the relationships experts.

These interactions can take place without the participants paying conscious attention to them. They often consist of an exchange of nonlinguistic signals while the overt communication is focusing on something completely different and relationship neutral. For instance, while discussing vacation plans, a couple may use tone of voice and nonverbal messages to also exchange information about who is going to be in charge. These subtle exchanges may confirm or challenge the existing power structure. If enough tension develops, the issue may be brought to the forefront and discussed openly.

It is useful to distinguish between *conflicts of interest* and *conflicts of meaning.* In conflicts of interest the partners agree on what the interaction is about, but each one pursues a different outcome. In conflicts of meaning, the partners see the interaction from a different perspective and give it a different meaning. For instance, one partner may have a need for intimate conversation; the other partner has had a rough day and wants to be left alone. The first partner may experience the other's reluctance to talk as a refusal to engage in intimacy, while that partner may experience the insistence to talk as an insensitive invasion of privacy. Such misunderstanding can escalate and lead to distorted global interpretations of the partner and the relationship.

RELATIONAL PROBLEM RELATED TO A MENTAL DISORDER OR GENERAL MEDICAL CONDITION

According to DSM-IV:

> This category should be used when the focus of clinical attention is a pattern of impaired interaction associated with a mental disorder or a general medical condition in a family member.

Studies indicate that satisfying relationships may have a health-protective influence and that relationship distress tends to be associated with an increased incidence of illness. The influence of relational systems on health has been explained through psychophysiological mechanisms that link the intense emotions generated in human attachment systems to vascular reactivity and immune processes. Stress-related psychological or physical symptoms can be an expression of family dysfunction.

A person who feels ill will first turn to the members of the family. Their opinions will influence whether a person sees the symptoms as trivial or as a cause for concern, as requiring home remedies or professional attention. The family also participates, directly or indirectly, in the ongoing discourse between patient and physician, which defines the type of medical problem the patient is suffering from, how it should be dealt with, and what the family's role should be in managing the illness and supporting the patient. To a large extent, the psychological meaning of the illness and the patient's cooperation and compliance with treatment depend on the outcome of these interactions. Family dynamics influence an individual's course of illness. Conversely, the illness of a family member influences the family's interactional dynamics.

If the disease process is chronic, an adjustment of family members' roles and responsibilities is likely to be needed. The patient's identification with the sick role and the concomitant regression and disability are strongly influenced by family dynamics. In some cases the family joins with the patient in a struggle against physicians and others who appear to refuse to acknowledge the patient's disability and deny financial benefits. Sometimes medical symptoms are recruited to play a meaningful role in the interactional dynamics of the relational unit (e.g., stabilize the patient's family, regulate closeness and distance among family members, or communicate information that cannot be openly expressed).

The role of marital and family interactions in the onset and course of psychiatric disorders has been extensively studied, in particular for mood and anxiety disorders, schizophrenia, substance-related disorders, eating disorders, and personality disorders. Attempts were made to link distinct family dynamics to specific disorders. On the other hand, the following outline provides a somewhat simplified and generalized summary of the observed interactions.

At first, the psychiatric symptoms displayed by a family member elicit concern and care. The roles within the family are adjusted, often with other family members taking charge and assuming some of the patient's duties and responsibilities. Family members define the patient's problem, give advice, propose solutions, and encourage the patient to overcome the difficulties, seek help, or both. When the patient fails to improve, however, the family members may feel increasingly frustrated. Indeed, psychiatric symptoms are often hard to live with, and they can undermine the family's energy and morale. The mentally ill family member often behaves in a way that discourages social interaction and increases interpersonal conflict. The extra efforts and tasks required of the other family members become more burdensome over time. In addition, they may hold psychiatric patients more responsible for their symptoms than they would medical patients. As frustration mounts, the family members have limited options for dealing with their feelings. Direct expression of anger, disapproval, and criticism is likely to aggravate the psychiatric condition. On the other hand, if family members withdraw and exclude the patient from activities, the patient may feel neglected and abandoned. Finally, family members may feel guilty about their feelings of frustration and try to compensate for this with self-sacrifice, overprotection, or overidentification with the patient. Such overcompensation indirectly expresses the underlying hostility.

These understandable family adaptations represent behaviors that are rated high on scales for hostility, criticism, and overinvolvement, a constellation that has come to be known as “expressed emotion.” Expressed emotion is a significant and robust predictor of relapse in several psychiatric conditions, including schizophrenia, mood disorders, and eating disorders. High expressed emotion might also be associated with a worsening of the course of Alzheimer's disease and may even play a role in medical conditions such as diabetes. The interactional mechanisms that account for the different expressed emotion response styles of family members are unknown.

The relationship between family interaction patterns and psychiatric illness is likely to be bidirectional. There is some suggestion that when a vulnerable family member feels excluded or rejected and treated with criticism and overinvolvement, psychiatric symptoms may develop. For instance, the risk of developing depression has been found to be 10 times greater for individuals experiencing relationship distress than the risk for individuals in nondistressed relationships.

The mechanisms described above do not support the notion that families cause mental illness or relapse. Indeed, neither the research data nor the complex and recursive nature of family interaction patterns warrants such a conclusion. And yet mental health professions have in the past either neglected the families of patients in the name of confidentiality and therapeutic alliance or blamed them for causing the illness. The clinician must appreciate the dedication of most families, their need to be involved in treatment decisions that affect them, and the fact that they are entitled to assistance with the considerable burden of family caregiving. Indeed, families are the primary caregivers of the sick and the disabled, and it is estimated that half to two-thirds of the persistently mentally ill population live with families. Caregiving is stressful, and the burden of caring for ill family members falls disproportionately on the women in a family. Family members who live with mental illness report high levels of stress, anxiety, depression, and resentment. They cite increased marital strain, disrupted social life, and hardship for siblings. In recent years, research into the stress of caregiving and how to alleviate it has been initiated, partly in response to the advocacy of support organizations such as the National Alliance for the Mentally Ill.

PARENT-CHILD RELATIONAL PROBLEM

According to DSM-IV:

> This category should be used when the focus of clinical attention is a pattern of interaction between parent and child (e.g., impaired communication,

> overprotection, inadequate discipline) that is associated with clinically significant impairment in individual or family functioning or the development of clinically significant symptoms in parent or child.

Parents differ widely in sensing the needs of their infants. Some quickly note their child's moods and needs, others are slow to respond. Parental responsiveness in interaction with the infant's temperament affects the quality of the attachment between infant and parent. A considerable body of research links an infant's attachment style with social and emotional adjustment in childhood. *Securely* attached children showed enhanced resilience in a high-stress environment. *Insecure* children are more likely to be anxious, aggressive, and low on social competence. Furthermore, attachment-related factors such as maternal deprivation, major separations, and loss of attachment figures and the development of disorganized-insecure attachment in response to maltreatment have been found to be risk factors in the development of psychiatric disorders.

Research on parenting skills has isolated two major dimensions: (1) a permissive-restrictive dimension and (2) a warm-and-accepting versus cold-and-hostile dimension. A typology that separates parents on these dimensions distinguishes between *authoritarian* (restrictive and cold), *permissive* (minimally restrictive and accepting), and *authoritative* (restrictive as needed but also warm and accepting) parenting styles. The children of authoritarian parents tend to be withdrawn or conflicted; those of permissive parents are likely to be more aggressive, impulsive, and low achievers; the children of authoritative parents seem to be functioning at the highest level, both socially and cognitively. Switching from an authoritarian to a permissive mode may create a negative reinforcement pattern. This interactional pattern starts with increasingly aversive child behavior, such as whining or aggressive hyperactivity, in response to insistent parental demands to “stop it.” Then, the parent backs down, which rewards the child for behaving aversively. At this point the child deescalates, thus reinforcing the parent's permissive attitude. Such coercive processes have been associated with a child's lack of self-regulation, with rejection by peers, later academic failure, depression, delinquency, and antisocial behavior.

Substantial evidence indicates that marital discord leads to problems in children, from depression and withdrawal to conduct disorder and poor performance at school. This negative effect may be partly mediated through *triangulation* of the parent-child relationships. Triangulation refers to the process in which conflicted parents attempt to win the sympathy and support of their child, who is recruited as an ally in the struggle with the partner. The term has also been used for the process by which parents focus on a behavioral or general health problem of the child as a strategy for defusing marital conflicts. Marital discord can also affect the parent-child relationship in a direct way, as negative emotions begin to contaminate all family relationships. For instance, angry interactions between spouses have been linked to negative affect in the relationship between father and infant.

The parent-child relationship is greatly influenced by the marital and family environment. Divorce and remarriage stress the parent-child relationship and may create painful loyalty conflicts. Stepparents often find it difficult to assume a parental role and may resent the special relationship that exists between the new marital partner and the children from that partner's previous marriage. Single-parent families usually consist of a mother and children, and their relationship is often affected by financial and emotional problems. Women who work and pursue careers often feel guilty about not having enough time with their children, yet they are likely to spend much more time in child-rearing activities than fathers.

Normal developmental crises can also be related to parent-child problems. For instance, adolescence is a time of frequent conflict, as the adolescent resists rules and demands increasing autonomy, while at the same time eliciting protective control by displaying immature and dangerous behavior.

PARTNER RELATIONAL PROBLEM

According to DSM-IV:

> This category should be used when the focus of clinical attention is a pattern of interaction between spouses or partners characterized by negative communication (e.g. criticisms), distorted communication (e.g. unrealistic expectations), or noncommunication (e.g. withdrawal) that is associated with clinically significant impairment in individual or family functioning or the development of symptoms in one or both partners.

A partner relationship involves two people who have made a commitment to maintain their relationship. Usually the partners live together and have sexual relations with one another. Many partner relationships are socially sanctioned as marriage. Separation and divorce rates have increased rapidly in Western societies. An unexpected announcement by one spouse of a decision to divorce often elicits an acute relational crisis in which the partners desperately seek professional help. Sociologists have found that increases in the divorce rate correlate with measures of women's economic and psychological independence. A suggested explanation is that women are less willing to stay in unhappy marriages to the degree that they are no longer forced to do so for economic reasons. Nevertheless, for most women, divorce still has severe economic consequences.

Using observational methods, John Gottman has identified criticism, contempt, defensiveness, and stonewalling (e.g., withdrawal from interaction) as interactive processes that longitudinally predict which couples will separate and divorce. The best single predictor is contempt, especially the wife's contempt. There are gender differences; women tend to show more criticism than men do, and men show more stonewalling. A cascade has been proposed in which complaining and criticizing leads to contempt, which leads to defensiveness, which leads to withdrawal from the interaction. These same patterns probably occur also in gay and lesbian relationships, although comparable data have not been reported.

Relatively minor problems can escalate to dysfunctional levels as a result of natural interactional processes such as the *amplification of differences* and the *polarization of ambivalence.* Small differences between partners, such as a subtle difference in sexual need, can amplify spontaneously. Gradually, the partner with the greater need may become the only sexual initiator, overly focusing on the other's sexual availability, while the latter is likely to adopt a style of avoiding sex and focusing on the first one's sexual aggressiveness. This preoccupation with one another's sexual desire detracts from the awareness of a person's own real needs, as one person seems to always be “in the mood” and the other never. In a spontaneous process of polarization, each partner expresses an opposite position with regard to an issue about which they both feel ambivalent. An internal dilemma is thus externalized in the relationship. The polarization of a couple's ambivalence about commitment or about the decision to have children can lead to chronic emotional conflict.

Many partners expect the other to regularly provide proof of commitment. This may result from insecurity or concerns about the power balance in the relationship. Indeed, the person who is more committed to and dependent on the relationship may feel powerless in the face of threats of divorce. Violent behavior can be an attempt to deny dependency and exert power. Being rejected by an intimate partner can elicit traumatic memories of past attachment experiences and lead to impulsive suicide attempts or to violence toward the partner.

An issue with special importance for partner relational problems is *passionate love*, defined as a special state of mind characterized by emotional dependence on the person one is in love with and by symptoms such as an intrusive preoccupation with that person, an intense desire for reciprocity of feelings, idealization, and an uncanny ability to see hope even when there is none. “Falling in love” can occur at any age and has been described in all cultures. Unrequited love can lead to depression and suicidality. Distress and alienation in one's primary relationship puts one more at risk for falling in love with someone else.

Violence can be associated with relational problems. A pattern of wife beating, however, indicates individual impulse-control problems, impaired socialization, and usually alcohol and substance abuse. Wife beating is found in every class and at every income level. Pregnancy is an extremely high risk time for domestic violence toward the woman. Being subjected to violence often results in depression and learned helplessness. The patient may feel inhibited about divulging the secret of domestic violence; thus clinicians must develop an appropriate sensitivity to the possibility of spousal abuse.

SIBLING RELATIONAL PROBLEM

According to DSM-IV:

> This category should be used when the focus of clinical attention is a pattern of interaction between siblings associated with clinically significant impairment of family functioning or symptoms in one or more of the siblings.

Sibling relationships tend to be characterized by competition, comparison and cooperation. Intense sibling rivalry can occur with the birth of a child and may persist as the children grow up, compete for parental approval, and measure their accomplishments against one another. Alliances between siblings are equally common. Siblings may learn to protect one another against parental control or aggression. In households with three children, one pair tends to become closely involved with

one another, leaving the extra child in the position of outsider.

Parents tend to be more empathetic with the child who has the same sibling position that they experienced. Relational problems can arise when siblings are not treated equally; for instance, when one child is being idealized while another is cast in the role of the family scapegoat. Differences in gender roles and expectations expressed by the parents can underlie sibling rivalry. The notion that a child's resentment directed at a parental figure or a child's own disavowed dark emotions can be projected onto a sibling and fuel an intense hate relationship is an interesting psychodynamic hypothesis. As people grow older they often experience a desire to reconnect with brothers and sisters, and they may take great effort to resolve long-standing sibling conflicts.

A child's medical or psychiatric condition always stresses the sibling relationships. Parental concern and attention can elicit envy in the siblings. Chronic disability can leave the sick child feeling devalued and rejected by siblings, who may develop a sense of superiority and feel embarrassed about having a disabled brother or sister.

RELATIONAL PROBLEM NOT OTHERWISE SPECIFIED

According to DSM-IV:

> This category should be used when the focus of clinical attention is on relational problems not classifiable by any of the specific problems above (e.g. difficulties with coworkers).

People become emotionally involved in peer relationships at school or at work, in relationships with teachers, superiors, students, and employees. They develop intensive friendships and engage in complex interactions around avocational interests and goals. In such relationships, conflicts are common and can bring about stress-related symptoms.

Many relational problems of children occur in the school setting and involve peers. Impaired peer relationships can be the chief complaint in attention-deficit or conduct disorders, as well as in depressive and other psychiatric disorders of childhood and adolescence.

Racial, ethnic, and religious prejudices cause problems in interpersonal relationships. In the workplace, sexual harassment is often a combination of inappropriate sexual interactions, displays of power and dominance, and expressions of negative gender stereotypes.

SUGGESTED CROSS-REFERENCES

Child psychiatry is the subject of Chapter 32. Couples and family therapy are discussed in Section 30.5. Child physical and sexual abuse and neglect is dealt with in Section 49.4. Physical and sexual abuse of adults is discussed in Section 28.7. Chapter 19.1a deals with normal human sexuality and sexual disorders.

CHAPTER 27. ADDITIONAL CONDITIONS THAT MAY BE A FOCUS OF CLINICAL ATTENTION

27.1 TREATMENT COMPLIANCE

BARRY BLACKWELL, M.D., F.R.C.PSYCH.

Although noncompliance with treatment is relegated in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), as a condition that may be the focus of clinical attention, no problem is more ubiquitous in practice or better illustrates the scope of psychiatry in understanding the biopsychosocial influences and interventions that determine treatment outcome. DSM-IV also indicates that our professional involvement may be related to the treatment of mental health and medical disorders directly as providers or indirectly through consultation. For this reason and because those who suffer from mental illness are people first, this review includes the entire medical domain as a background to understanding the specific problems of compliance in psychiatric disorders.

HISTORY

Interest in compliance has fluctuated through history with concerns about physician authority and patient autonomy. During the first half of the twentieth century, biomedical advances and technology rendered patients subservient to physicians. Moving toward the millennium, the social, political, and scientific zeitgeist shifted back in the direction of patient autonomy. Distrust of authoritarianism after World War II ushered in the civil, women's, and patient rights movements. The physician's unique prerogative to prescribe was eroded by other professions. Acute diseases were controlled by modern drugs, and chronic conditions predominated, raising concerns about risk reduction, disease prevention, and lifestyle change. This resulted in complex, long-term treatment regimens that created quality-of-life concerns for consumers.

In 1975 the term “patient dropout” was replaced by the word “compliance.” This coincided with an upsurge of research on the topic, and international conferences on compliance were held at McMaster University in 1974 and 1977. In the last quarter-century, over 12,000 publications have appeared, reaching a plateau in 1989 of about 800 articles a year. Almost half contain original data; the remainder are reviews.

Interest in compliance is likely to continue and increase for many reasons. Aging populations afflicted with chronic conditions are seeking longevity and improved quality of life. As more and more people (including those receiving Medicaid and Medicare) are placed in managed-care organizations, compliance will become a compelling social policy issue when the economics and quality of care are closely scrutinized.

New developments will sustain the field into the next century, including microchip circuitry and computer technology. A recent report in the *New England Journal of Medicine* argued that the Internet may become a valuable tool for transforming the delivery of medicine:

> Responsibility for decisions could be shared by the patient and physician. The patient could tap into authoritative medical data bases including textbooks and newsletters formulated expressly for lay audiences. If done right, the online computer system would function as a ‘virtual physician' in a new kind of house call.

DEFINITION

The most resilient definition of compliance is that adopted at the First International Conference, which states: “Compliance is the extent to which a person's behavior (in terms of taking medications, following diets or executing lifestyle change) coincides with medical or health advice.” This definition, which places the patient in a passive role, does not meet contemporary demands for a less subservient consumer. Soren Holm, an ethicist, noted: “It is not patients who should comply with their doctors' demands but doctors who should comply with their patients' informed and considered desires.”

The term *noncompliance* subsumes manifold behaviors, including reluctance to seek help, rejection of screening procedures, and failure to attend initial appointments. Later problems may include irregular attendance, premature termination, or failure to follow advice. These may involve diet, lifestyle, or drugs. Faulty compliance with medication may include errors of purpose, timing or dosage, partial or total omission, or use of inadvertent combinations.

Noncompliance with treatment is included in DSM-IV as a condition that may be a focus of clinical attention. DSM-IV states:

> This category can be used when the focus of clinical attention is noncompliance with an important aspect of the treatment for a mental disorder or a general medical condition. The reasons for noncompliance may include discomfort resulting from treatment (e.g., medication side effects), expense of treatment, decisions based on personal value judgments or religious or cultural beliefs about the advantages and disadvantages of the proposed treatment, maladaptive personality traits or coping styles (e.g., denial of illness), or the presence of a mental disorder (e.g., Schizophrenia, Avoidant Personality Disorder). This category should be used only when the problem is sufficiently severe to warrant independent clinical attention.

MEASUREMENT METHODS AND PROBLEMS

In the compliance field, simple measures are not accurate and accurate measures are not simple. Both patients and providers minimize the scope and understate the severity of the problem. Pill counts are unreliable, and biological markers are often only qualitative. New and more precise electronic methods are now available that use time-recording microcircuitry installed in pill containers or eye droppers. Only this last method circumvents a problem that pervades all compliance research—noncompliance disappears under scrutiny because people invariably modify their behavior to conform with the observer's expectations.

Compliance is often described in vague terms as “good, fair or bad,” but the most accurate descriptions use index measures that take into account receiving the most appropriate treatment in adequate amounts to achieve a defined outcome. Deviation from this ideal may be consistent, intermittent, or sporadic.

How much compliance is required also depends on the nature of the illness, the individual, and the treatment. For example, control of hypertension is often achieved with 80 percent compliance, but this level of adherence to a weight loss regimen usually results in failure. Even if a person is 100 percent compliant, a regimen may fail if the person takes an ineffective drug, metabolizes it slowly, excretes it rapidly, or is exposed to conditions that aggravate the disorder (e.g., stress).

One property of a medication that influences the outcome of noncompliance is “forgiveness.” This concept is illustrated by contrasting two psychotropic medications, alprazolam (Xanax) and fluoxetine (Prozac). Alprazolam is metabolized rapidly and induces its effect by immediate receptor binding. Its action is dramatic, and the effects of cessation are almost immediate. By contrast, fluoxetine is metabolized slowly and acts by delayed receptor regulation. Its effects are insidious, and the results of cessation are delayed and prolonged. A missed dose of alprazolam is noticed immediately, while an occasional missed dose of fluoxetine is immaterial.

OTHER TERMINOLOGY

Some cultures in which authority is seldom questioned lack words to convey the concept of compliance; more egalitarian societies consider the term coercive. One researcher noted the disfavor attached to the word compliance: “Because it conjures up images of patient or client sin and serfdom.” The alternative word “adherence” has been used but appears in less than 1 percent of articles published. Alvan Feinstein made the tongue-in-cheek observation that “adherence seems too sticky,

fidelity has too many connotations, and maintenance suggests a repair crew."

Irrespective of terminology, the concept of compliance has taken firm hold. Holm, notes: "New terminology will not be enough, a change of underlying attitudes is absolutely necessary." This change has begun; the slogan adopted by the National Council on Patient Information and Education is "communicate before you medicate." Further along still is the suggestion by B. A. Merrill that rehabilitation therapists like "successful salespeople know their product, learn the patient's dominant buying motive, combine facts with benefits and present arguments that fit the person's belief system and norms."

COST OF NONCOMPLIANCE

The costs of noncompliance can be computed in both social and individual terms. From a social perspective, there is always a balance between the cost incurred by the iatrogenic consequences of overuse of procedures or medications (an estimated 20 percent of health expenditures) and the economic effects of poor compliance, which have been estimated to exceed 100 billion dollars annually in lost work productivity, unnecessary hospitalizations, and premature deaths. A society that shuns preventive methods to check the spread of the human immunodeficiency virus (HIV) infection embraces genocide.

The individual costs of noncompliance were insignificant when most treatments were panaceas, but as therapy has become more effective, personal costs can be considerable. An individual denied a scarce kidney or heart transplant because of suspected compliance problems receives a death sentence. Recent research in a number of disorders has shown that patients who are compliant with placebo have better outcomes than noncompliant patients treated with an active drug. This is presumably due to the fact that people who are compliant with pill taking are more committed to all aspects of the treatment regimen (exercise, diet, and lifestyle). In another possible manifestation of this phenomenon, each of three different interventions was equally effective in the treatment of alcoholism if the type of treatment was matched to the needs and expectations of the patient; in other words, steps taken to ensure compliance with *any* intervention may be a more powerful determinant of outcome than differences between interventions.

At the same time, attempts to improve compliance are not without potential adverse consequences. Intervention at the work site to improve compliance with antihypertensive treatment increases absenteeism and decreases productivity, presumably because it increases the individual's sense of vulnerability and sick role behavior.

RESEARCH

Types Over 50 different diseases or conditions have been studied, and although no single disorder accounts for more than 10 percent of the output, the two most commonly studied areas throughout the past quarter-century have been pediatrics and psychiatry. Hypertension, smoking, asthma, diabetes, and screening programs are the other areas of common interest. Organ transplantation and HIV infection are of increasing contemporary concern while interest in seat belt use has declined.

All aspects of therapy have been studied including disease factors, referrals and appointments, treatment regimen, patient-provider interaction, and patient characteristics. What has been easiest to study has been most studied—disease and sociodemographic characteristics. Far more attention has been paid to patient characteristics and behaviors than to those of providers.

Attempts to study and understand compliance have employed five major models. The oldest and most basic is the biomedical model, which focuses on technical and mechanistic issues such as the treatment regimen. The second, the operant behavioral model, emphasizes structuring environmental rewards and teaching people specific skills. A third model is educational and aims to enhance information exchange between patient and provider. The fourth, particularly popular, is the health beliefs model based on an appraisal of the benefits and barriers to complying with treatment. The fifth and final model is the self-regulatory systems approach, which considers the patient's own models of illness and treatment and seeks to obtain congruence with providers in respect to action and coping behaviors.

Problems Research design in compliance has often lacked sophistication, and less than half of all studies have yielded positive findings. Psychosocial variables have tended to do so much more than demographic or disease characteristics. Even positive findings often lack generalizability. For example, factors that influence clinic attendance differ from those that determine medication taking. Even within a specific compliance behavior, no variable studied (e.g., marital status) has a universal or consistent impact on outcome.

Another problem is that most research is cross-sectional, while life is longitudinal. An individual's compliance may alter radically across the life cycle or between episodes of illness. A juvenile diabetic who is passively compliant with parental wishes during latency may rebel by rejecting treatment in adolescence. In early adulthood the rewards of a healthy lifestyle may be compelling, but in old age the burdens of treatment may exceed the benefits of longevity.

UNDERSTANDING COMPLIANCE

The determinants of compliance are kaleidoscopic and everchanging. There is no stereotypical noncompliant person or situation. Nonetheless, there are areas of consensus.

Noncompliance is more common and roughly double among outpatients than among inpatients. Medication compliance is more readily achieved than modification in lifestyle.

Compliance is a particular problem in disorders that have no symptoms, are persistent, and have no method for self-monitoring such as hypertension, diabetes, and glaucoma. Glaucoma presents the most difficult problem because currently there is no home tonometer to measure intraocular pressure corresponding to the sphygmometer and glucometer that measure blood pressure and blood sugar concentrations, respectively.

Compliance decays across time in disorders that are chronic or long lasting. Compliance generally (but not invariably) improves when patients' expectations are met, when they are satisfied, and when they are supervised. It helps if patients view their disease as a serious one to which they are susceptible and if they have developed compliance strategies of their own. Supportive family members or friends are important. Factors that generally (but not invariably) impede compliance are complicated regimens, troublesome adverse effects, social stress, isolation, and alcohol dependence.

Technological devices have been introduced recently to increase compliance such as special pillboxes, electronic alarms, and beepers that flash messages to take the prescribed medication. Another device is a pill-bottle cap fitted with a computer chip that records when the bottle is opened and closed. These are expensive and have not been tested adequately.

INFLUENCING COMPLIANCE

Two principles apply to choice of interventions. First, parsimony is important; some changes are more simple to make. Examples include modifying the treatment regimen, reducing waiting times, and combining written and verbal instructions. Other factors are more difficult to influence such as memory impairment or a person's attitudes and beliefs about illness, treatment, or quality of life.

Secondly, although single interventions may contribute to outcome, sustained success often requires a multimodal approach. Table 27.1-1 illustrates the types of intervention, intermediary goals, and final outcomes that are part of a truly comprehensive approach.

Intervention		Intermediary Goals	Final Outcome(s)
Education	Didactic Interactive	Knowledge Congruence	Composite compliance (to criterion) and Autonomy (at ideal)
Supervision	Professional Social	Appointment keeping	
Convenience	Regimen Access to Care	Medication taking	
Skills training	Tailoring Risk Reduction	Risk reduction	
Patient participation	Monitoring Self-Management	Active patient	

Table 27.1-1 Categorization of Interventions and Outcomes

The interventions can be conceptualized in three stages. An initial phase of information exchange (education) is followed by a negotiated alliance (supervised compliance) that consists of supervision, convenience, and skills training, leading to an ideal of autonomous self-care (active patient participation).

Education is necessary but seldom sufficient to sustain compliance. Excessive use of fear-provoking messages may also be counterproductive, because they cause anxiety and encourage avoidance. What works best is a negotiated alliance in which information is shared and congruence is reached between the provider's and the patient's beliefs about illness, treatment, and recovery. Some form of support or supervision is often essential from providers, family members, peer groups, or significant others. Although autonomy is an ideal, not everyone is eager to assume complete independence, and not all physicians are comfortable relinquishing control.

COMPLIANCE IN PSYCHIATRIC DISORDERS

The published rates of noncompliance are very similar for medical and psychiatric disorders, partly because it is such a multiply determined behavior that similarities and differences tend to average out in overall outcome. Nevertheless, these similarities and differences are worth considering in both understanding and influencing compliance in individual patients who suffer from a psychiatric disorder. Factors in the disorder, the patient, and the medications, influence compliance.

Disorders Most psychiatric disorders have two features that facilitate compliance: they are symptomatic in ways that diminish the patient's quality of life and they are episodic or intermittent. Unlike asymptomatic and persistent medical disorders (e.g., hypertension, diabetes, and glaucoma) these two features create an opportunity for the patient to learn ways in which treatment can decrease symptoms and improve overall quality of life. In addition to these features of illness, most psychiatric disorders have their peak prevalence early in life when there is less medical comorbidity, cognition is relatively intact, and social connections are preserved.

Each major mental disorder may also impose unique burdens on the individual's adaptation to treatment. Impaired concentration, poor memory, thought disorder, or anxiety all interfere with effective information exchange. Delusional ideas (particularly paranoid or grandiose types) can erode the trust necessary for a working alliance. Depression, apathy, and the negative symptoms of schizophrenia are barriers to the motivation and persistence necessary for long-term treatment. Lack of awareness or acceptance of illness (insight) is a particular problem in some patients with bipolar disorder or schizophrenia. Insight is a complex construct, difficult to define or measure. It is also misused at times to describe differences of opinion or underlying attitudes and beliefs that are part of the patient's personality or value system, not their illness.

Of great practical significance are the difficulties encountered by patients with extreme forms of symptom sensitivity (somatization disorder) or bodily preoccupation (conversion disorder). Some of these individuals suffer from panic disorders with episodic autonomic arousal that create fears about being allergic to medications. As a consequence, they are often attracted to homeopathic or alternative therapies.

Added to these problems is comorbidity with substance abuse. This is a risk factor for all forms of noncompliance but is a special problem when the effects of the substance may interfere with the therapeutic action of medication or may be used by the patient to stifle psychotic symptoms or alleviate depression.

Special problems are posed by people who have developmental disorders, since a crucial aspect of their treatment is encouraging independence and autonomy. This can conflict with simplistic notions about compliance.

Patient All long-term illness, medical or psychiatric, imposes generic burdens on those who suffer. These challenge the core human needs to feel in control, autonomous, intact, and connected to others. Severe mental illness arouses feelings of ambiguity, loss of integrity, dependence, and stigma or isolation. Irrespective of the specific disorder, these needs must be addressed before treatment recommendations of any kind can prove acceptable.

Like physicians, patients possess unique beliefs, attitudes, and experiences relating to illness, which may include its cause, treatment, and outcome. People with strong psychological or spiritual beliefs may resist medication. Patients in homeless clinics often report bruising experiences with uncaring or coercive providers that make them reluctant to accept help. Many people share a belief that the body sometimes deserves a rest from medication and as a result they take drug holidays.

Medication Psychoactive drugs possess several properties that may appear counterintuitive to the patient and so invite noncompliance. Because the brain is well protected, large amounts are required to pass the liver and penetrate the blood-brain barrier. The receptors with which drugs interact are also present elsewhere in the body so that adverse effects are virtually inevitable, with disturbances in cardiovascular, sexual, or gastrointestinal function that compromise quality of life. The newer, more selective compounds are less prone to this drawback, but the cost-benefit balance is always an issue.

Secondly, changes in brain chemistry often occur slowly because of up- or down-regulation of receptors. People are used to the immediate mind-altering effects of alcohol, nicotine, caffeine, and cocaine. The fact that therapeutic effects of psychotropic drugs are delayed (while many side effects are immediate) is an incentive to poor compliance.

Finally, the natural history of psychiatric disorders and their response to treatment may conflict with commonsense lay experience. In most acute illnesses people take medicine until they feel better and then stop. In major psychiatric disorders, treatment must continue beyond the restoration of normal function, often for many months. Because repeated episodes generate the likelihood of recurrence (kindling), long-term maintenance or prophylaxis is often desirable, but it may be resisted by those who fear dependency on medication.

Clinicians To facilitate compliance the treating psychiatrist must accomplish three objectives: developing an alliance, enabling a support system, and tailoring the regimen to fit the convenience and lifestyle of the patient.

Alliance A physician's need for control and instantaneous cure may confront a patient's desire for autonomy and independence. Although psychotic illness can sometimes diminish a person's decision-making capacity or ability to make informed choices, attempts to evoke fear or use coercion are seldom successful and usually elicit resistance or regression. Even when safety is an issue, the short-term protective benefits of coercion quickly dissipate over the long-term management of an illness. Coercion is not limited to obvious forms of involuntary confinement or outpatient commitment procedures; it can be a subtle and pervasive influence over many of the interactions between a provider and patient.

To negotiate a productive alliance the physician must explore the patient's knowledge, attitudes, and beliefs about the disorder and its treatment. These can often be accommodated without sacrificing the essential ingredients of effective treatment. Persons who believe in megavitamin therapy experience no harm if they also take traditional medicine.

Not every patient seeks or is willing at first to accept complete responsibility for coping with the burden of illness. The physician must explore resistance or regression, avoid an overly parental approach that may provoke these defenses, and discourage passive adoption of the sick role. The patient's ability to assume control may

also depend on the phase and severity of the illness. In acute episodes, psychotic symptoms, cognitive impairment, and poor impulse control are impediments. Later, apathy or negative symptoms may interfere. Moves toward autonomy should be gradual; an individual who initially receives monthly parenteral injections is slowly weaned toward daily or weekly attendance for oral medication. For the physician to relinquish control and encourage autonomy may involve calculated risks including the possibility of relapse or recurrence of dangerousness to self and others.

Patients must learn for themselves that medication stifles voices or impulses and must calculate the personal benefit of these improvements with the discomfort of side effects. The physician's advice and predictions are just that—inexact but (one hopes) well-informed guesses. The more often they are accurate, the stronger the patient's trust and the better the likelihood of later acceptance of suggestions in the lifelong course of a relapsing illness. As patients make their own decisions, they develop a stronger sense of self and personal responsibility.

Support System A physician's tolerance of ambiguity and risk is bolstered when the patient has a strong attachment to others. The presence of concerned persons is among the most potent facilitators of participation in treatment. Support may be provided by relatives, friends, other health care providers, a case manager, or a payee. Critical, coercive, or intrusive involvement may be counterproductive and can provoke relapse in vulnerable individuals. At most health care clinics and shelters for homeless persons, staff strive to create a nurturant and optimistic environment in which encouragement is gentle but persistent. Failed appointments are followed by telephone calls, and people who live on the streets or in shelters can attend daily or are given weekly supplies of medication in pill containers. Social, medical, and psychiatric needs are cared for simultaneously, and people receive hot drinks, snacks, and clothing as well as pills. Communication with case managers and payees is especially productive since they encounter clients on a regular basis and can monitor medications and be alert for use of other drugs or alcohol that interfere with medication taking or its efficacy.

Whenever possible, involvement with family members is crucial to improving compliance and monitoring medication taking or side effects. The dynamics of family interactions should be respected, but lack of involvement is sometimes due to the spurious use of confidentiality as an excuse to avoid the time and trouble required to communicate effectively.

Treatment Regimen Treatment must be tailored to the convenience and lifestyle of the patient. Taking medications can be cued to repetitive daily events. Although pharmaceutical companies have gone to considerable trouble to develop once-daily medications, compliance is not usually compromised unless the patient is taking multiple medications or medications are prescribed more than three times daily, because most people use meal time as their reminder. The benefits of medication are often unclear unless the physician explains them in plain language. This can include restful sleep, increased energy, clear thinking, and absence of voices or alien ideas. The physician should also try to explain and minimize adverse effects—for example, by timing sedative drugs to facilitate sleep.

The linkage between relief of symptoms and taking medication can sometimes be demonstrated by keeping a daily checklist of symptoms, adverse effects, and predicted benefits. This may be particularly helpful with symptom-sensitive people, since record keeping capitalizes on their compulsive skills and need for control.

Randolph was a 30-year-old former intravenous drug abuser with a diagnosis of schizoaffective disorder who was recently informed that he had tested positive for HIV infection. During a recent hospital admission for medical treatment, the nursing staff felt he was paranoid and depressed. Randolph had previously rejected offers of medication or had grudgingly accepted but never taken it. On this admission his urine tested positive for cocaine. When questioned at the bedside, he freely admitted using this to counter feelings of “disgust.” Randolph also agreed that after each brief euphoric interlude he was back again in the real world, feeling even more suspicious and disgusted.

The psychiatrist began with a detailed analysis of why Randolph used cocaine, what it did for him, and how he thought it worked. Based on his experience, Randolph agreed that chemicals could alter mood and behavior but at some cost. It was suggested that he might consider the alternative of prescribed medications. The point was made that unlike cocaine, these worked slowly with gradual benefit but that also unlike cocaine, the results persisted. If he was willing to attempt an experiment, chances were he would feel less suspicious and disgusted. In addition, he might no longer crave cocaine. Randolph agreed it was worth a try. After discharge, he came to the homeless clinic and was given an antidepressant and an antipsychotic. Two weeks later he was pleased and surprised to report that his voices were slowly fading away and he was sleeping soundly and feeling much less disgusted with life. His urine tested negative for cocaine and other substances of abuse.

Agnes was a 42-year-old single female well known throughout the city for frequent admissions to several hospitals over many years. She usually arrived accompanied by police, in an manic episode, combative, provocative and totally lacking any capacity to view herself as ill or in need of treatment. Although highly intelligent, Agnes was unable to hold a job and received Social Security with Medicaid health benefits. She was unpopular with the inpatient staff who viewed her behavior as “borderline.”

Her first several months with the psychiatrist were spent getting acquainted, and during this time Agnes was admitted twice to hospital. While Agnes was willing to take medication, she detested the way mood stabilizers stifled her creativity. As a result, she experimented continuously with various forms of meditation and marginal religious cults. When doing so, she gave herself frequent drug holidays. In her initial dialogue with the psychiatrist each attempted to convert the other. Agnes was sensitive to control issues; her father had been a benevolent tyrant, and her mother was critical and unloving. Agnes agreed that she found her experiences with the police and in hospital humiliating. The psychiatrist encouraged her ongoing search for spiritual meaning and nondrug methods of thought control but also maintained that these could be compatible with medication if she were willing to explore the tradeoff between a benefit she valued (staying out of hospital) and side effects she didn't (slowing of thoughts). Together they agreed on a target—to persist with medication in a sustained way until Agnes had been out of hospital longer than in any previous interlude (about 11 months).

It is now 2 years since Agnes last suffered the humiliation of hospitalization; she has found a source of spiritual solace, and she continues to complain bitterly about side effects. Together she and the psychiatrist are looking forward to a new generation of more specific psychotropic compounds that will stabilize moods without stifling her creative thought.

A paradigm shift has occurred away from a simple interest in treatment compliance to a more sophisticated understanding of the therapeutic alliance. This was brought about by the evolving systems of community outreach and support that have developed to supplement the community mental health system and to complete the process of deinstitutionalization.

Psychiatrists are now challenged to meet the needs of people striving to lead normal lives in the community despite sustained mental illness, homelessness, and substance abuse.

Prescribing is often necessary but never sufficient. Coercion is ineffective, and the current concept of compliance is inadequate. Medications are now part of an alliance that embraces each person's beliefs, experience, and lifestyle—not simply that individual's diagnosis, chemistry, or genes.

SUGGESTED CROSS-REFERENCES

Consultation-liaison psychiatry is discussed in Section 25.12, and primary care psychiatry is discussed in Section 28.1. Biological therapies are covered in Chapter 31.

27.2 MALINGERING

MARK S. LIPIAN, M.D., FH.D. AND MARK J. MILLS, J.D., M.D.

The medical concept of malingering has its origins in the philosophical dichotomy between reality and unreality, the ultimate expression of which is the question of the truth and falsity of life in general. Jesus called Satan “the father of the lie” (John); that lie has been interpreted by Christian theologians as man's denial of God who referred to the statement in John: “Who is a liar but he that denieth that Jesus is the Christ?”.

Central to philosophical moral thought has been debate of the rightfulness or wrongfulness of a person's deliberate employment of the capacity to deceive. At one conceptual extreme is Friedrich Nietzche, writing in *The Will to Power:*

> There is only one world, and that world is false, cruel, contradictory, misleading, senseless.... We need lies to vanquish this reality, this “truth,” we need lies in order to live... That lying is a necessity of life is itself a part of the terrifying and problematic character of existence.

At the opposite philosophical pole is Nicolai Hartmann, who argues in his *Ethics* that any lie “injures the deceived person in his life; it leads him astray.”

A young engineering assistant, a recent emigré from Lebanon, began to complain of burning pain in his feet. He attributed this malady to “having to walk so much at work,” where he was required to journey three or four times a day to and fro between his office and a common work space. The pain increased, and the man left the workplace on a workers' compensation disability claim.

Shortly after leaving work, and despite his “disabling” foot pain, the man embarked upon a three-week holiday to Lebanon where he visited family; did some sightseeing; and met, courted, proposed to, and married a young woman. He returned to the United States with his new wife and began the workers' compensation treatment process.

A major effort, including two podiatric surgeries and months of chiropractic manipulation, failed to improve the man's burning foot pain, and he was referred to psychiatry for “depression in the face of intractable and apparently nonphysiologic pain.”

The psychiatrist diagnosed a psychotic disorder, and began to write weekly session-based reports to the workers' compensation insurance carrier describing increasingly ominous paranoia. Over the course of several years, these reports documented escalating threats against the original employer and the insurance carrier, whom the man perceived as having deliberately produced his disabling pain, and as now toying with him by refusing to settle his case for the award of one million dollars that he felt he deserved. The psychiatrist energetically advocated giving the man his million dollars so that he might “return to Lebanon in peace.” Even as he proposed this “treatment,” the psychiatrist told of his patient bringing to therapy guns and bullets earmarked for insurance executives; appearing at sessions bloodied by deep wounds sustained “while sharpening my machete so I can cut off their feet,” and snapping out of typically docile, melancholy reveries into sudden rageful tirades directed at his alleged “tormentors”—the tirades replete with threats, vulgarities, and gory, vengeful vows.

With the help of an outside forensic consultant engaged some 3 years after psychiatric treatment began, the insurance company moved toward aggressive intervention. The man was hospitalized involuntarily at a major university center. He lost several civil commitment appeals. Faced with the probability of a court-ordered conservatorship and involuntary electroconvulsive therapy, the man miraculously ceased his threats and his bellicose behavior. His psychosis melted away, and he developed remarkable insight into not only his prior “paranoia,” but also into the psychogenic origins of his “chronic foot pain.” He even began to exercise on a treadmill. Shortly after discharge, the man's workers' compensation case was settled for a figure eminently acceptable to all. The man is not known to have interacted with the mental health community again.

HISTORY

In medicine, the tension between truth and lies has found expression in the domain of malingering and its detection. Mental illness, because it is difficult to verify objectively and is dramatic and emotional subjectively, is an age-old favorite of the malingerer. An early description of feigned madness appears in the Bible:

> And David arose, and fled that day for fear of Saul and went to Achish the king of Gath. And the servants of Achish said unto him, Is not this David the king of the land? Did they not sing one to another of him in dances, saying, Saul hath slain his thousands, and David his ten thousands? And David laid up these words in his heart, and was sore afraid of Achish the king of Gath. And he changed his behavior before them, and feigned mad in their hands, and scrabbled on the doors of the gate, and let his spittle fall down upon his beard. Then said Achish unto his servants, Lo, ye see the man is mad: wherefore then have ye brought him to me? (Samuel)

That individuals might feign or produce illness or disability for gain of some kind or to avoid duty has been known since antiquity. The Greeks considered malingering in military service to be analogous to forgery, and both offenses were punishable by death; the penalty was later mitigated to forced public exposure for three days, wearing floridly female regalia. Ulysses is said to have feigned insanity to avoid duty in the Trojan War, employing such tactics as yoking a bull and a horse together, plowing the seashore, and sowing salt instead of grain. In an early attempt at lie detection, the infant son of the King of Ithaca was placed in the furrow, directly in the line of Ulysses' oncoming plow. If the man was mad, it was reasoned, he would take no heed of the obstacle. Ulysses swerved to avoid his son, and that action was considered proof that his madness was a ruse.

In the second century AD Galen wrote a treatise, *On Feigned Diseases and the Detection of Them*, in which he described Roman conscripts who cut off thumbs or fingers to ensure unfitness for duty. In the sixteenth century Paolo Zacchias, considered by many to be the father of forensic medicine, wrote of madness, “There is no disease more easily feigned, or more difficult to detect.”

Truth versus imposture was discussed in Theodric Beck's 1823 *Elements of Medical Jurisprudence*, perhaps the first notable American text on the subject:

> In almost every age, impostors have sprung up who affect various maladies and operate on the superstition or the curiosity of the vulgar. And even the higher ranks of society, from motives as unworthy, have occasionally, like the courtiers of Dionysus and Louis XIV, given a sanction to such practices.

DEFINITION AND COMPARATIVE NOSOLOGY

Contemporary theorists share with their historical antecedents the construct that the fundamental characteristic of malingering is intentional falsity, with an underlying incentive of gain of some kind. According to the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV):

> The essential feature of Malingering is the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by

external incentives such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs. Under some circumstances, malingering may represent adaptive behavior—for example, feigning illness while a captive of the enemy during wartime.

Malingering should be strongly suspected if any combination of the following is noted: (1) Medicolegal context of presentation (e.g., the person is referred by an attorney to the clinician for examination); (2) marked discrepancy between the person's claimed stress or disability and the objective findings; (3) lack of cooperation during the diagnostic evaluation and in complying with the prescribed treatment regimen; and (4) the presence of Antisocial Personality isorder.

Malingering differs from factitious disorder in that the motivation for the symptom production in malingering is an external incentive, whereas in factitious disorder external incentives are absent. Evidence of an intrapsychic need to maintain the sick role suggests factitious disorder. Malingering is differentiated from conversion disorder and other somatoform disorders by the intentional production of symptoms and by the obvious, external incentives associated with it. In malingering (in contrast to conversion disorder), symptom relief is not often obtained by suggestion or hypnosis.

Thus, malingering is distinguished from factitious disorder in its motivation: whereas malingering is prompted by a conscious desire to obtain tangible external rewards or environmental outcomes, factitious disorder is not. In the latter, a matrix of intrapsychic needs manifesting themselves as a nearly irresistible desire to assume the sick role is thought to motivate the intentional deception of malady. The problems in diagnostic differentiation are obvious. A person might malinger to obtain tangible rewards (such as disability payments or chicken soup) associated with the sick role but might still enjoy the nurturing and care that such a role provides. A person with factitious disorder might be highly resistant to returning these financially and gustatorily satisfying aspects of being sick, while still clinging to and needing the emotional gratification that a person with this disorder is supposed to crave.

Differentiating malingering from the somatoform disorders (e.g., conversion disorder) is easier in that the somatoform disorders lack the volitional component of malingering. In the somatoform disorders an underlying emotional conflict is thought to be unconsciously transformed into a physical manifestation of some kind. No external or environmental outcome or reward is consciously sought. Rather, the defensive makeup of the person with a somatoform disorder is believed to be more tolerant of manifest turmoil in observable, extrapsychic form than of unobservable, emotional upset.

Whereas the various nosological schemes employed historically and internationally agree on the centrality of volitional deception to malingering, there is more controversy over whether malingering should be considered a mental disorder at all. That is of some importance because in most civil litigation, only mental disorders are compensable. DSM-IV classifies malingering with additional conditions that may be the focus of clinical attention, and thus, if malingering occurs in association with such mental disorders as antisocial personality disorder, factititious disorder, or a somatoform disorder, the diagnostician is enjoined to consider those diagnoses primary. In fact, a diagnosis of factitious disorder excludes a diagnosis of malingering.

Definitions of Subtypes of Malingering It has been suggested that malingering be considered not as a dichotomous variable (a condition that is either present or absent) but as falling along a continuum in terms of (1) degree of intentionality, (2) degree of symptom exaggeration involved, and (3) degree of actual impairment (if any). In keeping with the concept of a continuum, the following definitions have been proposed:

Pure Malingering Feigning a disease or disability when it does not exist to any extent.

Partial Malingering Consciously exaggerating symptoms that really exist.

False Imputation Ascribing actual symptoms to a cause consciously understood to have no relation to the symptoms.

Misattribution Ascribing actual symptoms to a cause erroneously believed to have given rise to them. Such misperception is often the product of unconscious processes that have interfered with reality testing and in its pure form, it does not constitute malingering. To the extent that the misattribution is consciously augmented (false imputation), malingering is at play.

A female police officer filed a lawsuit against her former department, alleging that sexual harassment at the workplace and wrongful termination for "whistleblowing" had resulted in psychiatric damages. Psychiatric evaluation of the case suggested that while the officer was suffering from a bout of major depressive disorder, "harassment" had not caused it. Instead, the officer was found to suffer from profound narcissistic and borderline personality disorders, and a series of inappropriate interactions and behaviors born of these disorders had given rise to the tensions and improprieties ultimately resulting in her professional demise. While the officer's narcissism did, to a great extent, cause her to distort and truly misperceive the sequence of events leading to termination (misattribution to her gender rather than to her professional failures), the officer also clearly and blatantly "invented" episodes of harassment, pointing to these fantastic events as the specific origins of her (exaggerated) symptoms (false imputation and malingering).

In addition to the various degrees of malingering, several forms of malingering have been identified and defined:

Simulation Feigning symptoms that do not exist, or the gross, conscious exaggeration of preexisting symptoms. Simulation has sometimes been referred to as *faking bad* and *positive malingering*.

Dissimulation Concealing or minimizing existing symptoms. Dissimulation has also been called *faking good, negative malingering*, and *defensiveness*. The term is somewhat confusing because it has sometimes been used to refer to medical faking in general—that is, as a synonym for malingering.

Staged Events Carefully planning, orchestrating, and executing events, with the desired result being either an actual injury or a credible explanation for a disability that will later be feigned.

Data Tampering Altering diagnostic data or records to simulate a disorder. Such alteration might take the form of self-mutilation (to influence the outcome of a physical examination), physical addition to or removal of substances from laboratory specimens (to influence the results of analyses performed on the specimens), and defacing or adjusting laboratory reports, diagnostic instruments, and medicohistoricolegal documents.

Opportunistic Malingering Exploiting a naturally occurring event or preexisting medical condition for gain. Opportunistic malingering is distinguished from partial malingering, which involves the exaggeration of specific preexisting symptoms.

Symptom Invention Falsely and consciously complaining of symptoms that are unrelated to any current or preexisting disorder or injury.

An air traffic controller was hit by a car while riding his bicycle, and thrown by the impact into a nearby ravine. Despite minimal trauma, no loss of consciousness, perfect Glasgow Coma Scale scores, and negative neurological workup, the man was diagnosed as suffering from closed head trauma and postconcussional disorder. He filed suit against the offending driver, claiming to have cognitive impairments including left-right confusions (mistaking left for right and vice versa); analogous up-down confusions, and similar object confusions (mistaking a car for a bus, a plane for a bird). His doctors judged him to be permanently disabled from work as an air traffic controller.

Although neuropsychological testing and psychiatric evaluation revealed none of the claimed impairments and, in fact, suggested malingering, the man was charismatic and appealing, and a generous settlement package was offered and accepted. Undercover investigation discovered the man 8 months later living in Iceland under a new name, once again working happily and successfully as an air traffic controller.

EPIDEMIOLOGY

In the United States, malingering is not considered as a medical or psychiatric diagnosis. Therefore, such traditional epidemiological considerations as the reliability of diagnostic criteria and the validity of the diagnostic construct are largely irrelevant. Further, estimations as to the typical age of onset, sex ratio, prevalence, or age-specific features are hampered by systematic underreporting of malingering by health care practitioners. Several concerns underlie the reluctance of professionals to label patients as malingerers and the tendency to refer instead to a vague lack of objective evidence in support of the patient's particular subjective

complaints.

Most clinicians were drawn to the mental health field out of some desire to help others; they find it distasteful and a violation of the doctor-patient relationship to call a patient a liar. Concern over legal liability also inhibits the widespread labeling of malingering: although expert testimony about malingering, given in court and in good faith, is protected by immunity, a clinical label applied in the outpatient office or emergency room is not. Finally, physicians are concerned about the anger and possibly physical outbursts that might result if a person's conscious attempts at deception are foiled and his or her conscious scheme to manipulate the system for reward is dismantled.

Nevertheless, according to some epidemiological data it is estimated that the average person in the average day lies twice, although the same person may be completely truthful at other times. A 1 percent prevalence of malingering has been estimated among mental health patients in civilian clinical practice, with the estimate rising to 5 percent in the military. In a litigious context, during interviews of criminal defendants, the estimated prevalence of malingering is much higher—between 10 and 20 percent.

Most criminals are skillful liars, and the capacity to lie develops early; about 50 percent of children presenting with conduct disorders are described as bringing to the clinician serious lying-related issues. It can reasonably be assumed that in civil lawsuits, particularly those involving child custody or evaluations pertaining to civil commitment, a similar elevation of the prevalence of dissimulation (faking good) would become apparent if the appropriate data were amassed.

Thus, although no familial or genetic patterns have been reported and no clear sex bias or age at onset has been delineated, malingering does appear to be highly prevalent in certain military, prison, and litigious populations, and, in Western society, in men from youth through middle age. Associated disorders include conduct disorder and anxiety disorders in children and antisocial, borderline, and narcissistic personality disorders in adults.

ETIOLOGY

Although no biological factors have been found to be causally related to malingering, its frequent association with antisocial personality disorder raises the possibility that hypoarousability may be an underlying metabolic factor. No predisposing genetic, neurophysiological, neurochemical, or neuroendocrinological forces are known.

During the height of psychoanalytic influence, malingering was considered to be a form of mental disease. Kurt Eissler wrote, “It can be rightly claimed that malingering is always a sign of a disease often more severe than a neurotic disorder because it concerns an arrest of development at an early phase.” Although most analysts today accept the nondisease concept of malingering, the malingerer is still thought to be as enslaved to his or her past as the neurotic is, except that the malingerer is unable to produce an actual neurotic symptom as a result of primitive ego and superego development. The malingerer acts out consciously that which the neurotic is able to convert unconsciously; the psychodynamic connection between malingering and the somatoform disorders is a close one.

At the other end of the etiological spectrum lie the theories of Thomas Szasz who has argued that malingering can be understood only in the context of the sociopsychology of games, systems, and interactions. Malingering would be meaningless in a strictly psychiatric situation limited to physician and patient; in fact, if it were to emerge only in such a context, it would have to be considered factitious disorder. According to Szasz, malingering is a relevant concept only when the physician and patient are part of a larger social structure and each are players in a social game. The patient is out to score; so is society. The physician's job is to officiate the proceedings, to prevent cheating, and to minimize any unfair advantage. As such, the prudent psychiatrist approaches every evaluation with the assumption that the patient being evaluated may stand ready to use mental infirmity to achieve questionable ends.

Social and cultural forces must be considered as etiologically relevant in any analysis of malingering behavior. Although studies showing marked differences in readiness to complain of illness among different ethnic groups have been criticized on methodological grounds, it is generally accepted that the culture of work, ethical responsibility, and duty to country in the form of military service (with the potential for self-sacrifice) varies from society to society, subculture to subculture, and epoch to epoch. How acceptable, condemnable, or laudable malingering may be within any sociocultural context will surely influence its prevalence and manifestations.

DIAGNOSIS AND CLINICAL FEATURES

In his 1823 *Medical Jurisprudence*, Beck described the three contexts that have most stimulated malingering behavior throughout history.

> Diseases are generally feigned from one of three causes—fear, shame, or the hope of gain. Thus the individual ordered on service will pretend being afflicted with various maladies to escape the performance of military duty—the mendicant, to avoid labour, and to impose on public or private beneficence—and the criminal, to prevent the infliction of punishment. The spirit of revenge, and the hope of receiving exorbitant damages, have also induced some to magnify slight ailments into serious and alarming illness.

Contemporary authors have elaborated on those core motivations and added a few more. It is thought that the twentieth-century malingerer is hoping to achieve one of the following seven ends:

Avoidance of Criminal Responsibility, Trial, and Punishment Criminals may pretend to be incompetent to avoid standing trial; they may feign insanity at the time of perpetration of the crime; they may malinger symptoms in order to receive a less harsh penalty; or they may attempt to act too incapacitated (incompetent) to be executed. The following transcript from an east-coast newspaper during the 1940s was quoted by Henry Davidson in the chapter on malingering in his *Forensic Psychiatry:*

> X and Y who acted like mad dogs in a murderous payroll robbery and like apes when brought to trial yesterday, were locked up out of the public gaze today to await their next appearance in court.... The defense lawyer contended that they were insane and they gave no outward indications to the contrary. They walked into the courtroom with an apelike gait, arms hanging loosely, heads wabbling [sic] from side to side with their chins held against their chests for pivots.... Attendants had to prod them along like animals. X poked the fingers of his hand into his mouth and gnawed them. Y ate pieces of paper from the table. X then rolled up a paper napkin and ate it. Y lowered his brow to the edge of the table and rubbed it like a horse scratching his head on a post. X took a pair of soiled underpants from his pocket and wrapped it around his neck. Then he licked it and wrapped it around his head. At recess, both prisoners had to be lifted from their chairs like sacks. They sloughed out of the room like apes....

Avoidance of Military Service or of Particularly Hazardous Duties Persons may malinger to avoid conscription into the armed forces, and once conscripted, they may feign illness to escape from particularly onerous or hazardous duty.

Financial Gain Modern malingerers may seek financial gain, in the form of undeserved disability insurance, veterans' benefits, workers' compensation, or tort damages for alleged psychological injury. In the chapter on malingering and associated syndromes in the second edition of *American Handbook of Psychiatry*, David Davis and James Weiss paraphrased Punton's description of a malingerer, circa 1903:

> A man named Moffett described his “cane and screw” racket, in which he used a specially prepared cane to loosen the floor screws on streetcars and railroad cars, over which he would then pretend to stumble and then institute a claim for injuries sustained. He stated that he made it a universal rule to employ the very best doctors, as he found, by experience, that they were the most easily fooled, while the companies he fleeced were better satisfied with their opinions. In this connection, he noted that he paid the doctors' bills promptly and willingly, even though at times he thought they were exorbitant, but this was done, he said, in order to impress them with the honesty of his actions.

In a more modern example at the cutting edge of “political correctness,” a male high school junior claimed his female drama teacher (widely regarded by students as personifying female desirability) had seduced him into a brief sexual relationship, which the boy finally ended “because it wasn't right.” The boy and his mother then sued the teacher and the school department for “ruining his life, his self-concept, his sexual identity, and his future.” At the time of the alleged affair, the student was sexually involved with a female peer; shortly after allegedly “spurning” his drama teacher, he began a new sexual relationship with a different female classmate. The young man went on to graduate from high school, enter the University of California, earn a 3.5 grade point average, and achieve considerable social success on campus. Nevertheless, he, his mother, and his therapist steadfastly reported chronic depression, social awkwardness, sexual inhibition, and irreversible identity disturbance, all the result of the alleged lust of the insatiable drama teacher.

Avoidance of Work, Social Responsibility, and Social Consequences Individuals may malinger so as to escape from unpleasant vocational or social circumstances, or to avoid the social and litigation-related consequences of vocational or social improprieties.

> A lawyer had mishandled her assets to the point of bankruptcy; she similarly mishandled her legal practice to the point of being served with several professional negligence suits as well as formal charges of misconduct by the American Bar Association. She proceeded to implement the following plan:
>
> (a) She shifted bankruptcy status so as to protect her existing assets against all her disgruntled former clients.
>
> (b) She convinced a psychiatrist that she suffered from disabling “anxiety and depression,” thereby activating her generous disability insurance policy and achieving financial independence while escaping from what had been a most unpleasant marriage to her legal practice. (A variety of data gathered by the insurance company and its psychiatric consultant confirmed the frank falsity of the attorney's claimed psychiatric difficulties.)
>
> (c) Through her psychiatrist, the malingerer convinced attorneys representing the American Bar Association that she was “incompetent” to assist in the defense of the various professional transgressions of which she was accused, thereby achieving an indefinite “stay” from facing the professional and social consequences of her alleged legal misbehavior.

Facilitation of Transfer From Prison to Hospital Prisoners may malinger (fake bad) with the goal of obtaining a transfer to a psychiatric hospital, from which they may hope to escape or in which they expect to do easier time. However, the prison context may also give rise to dissimulation or faking good: the prospect of an indeterminate number of days on a mental health ward may prompt an inmate with true psychiatric symptoms to make every effort to conceal them.

Admission to a Hospital In this era of deinstitutionalization and homelessness, persons may malinger in an effort to gain admission to a psychiatric hospital. Such institutions may be seen as providing free room and board, safe haven from the police, or refuge from rival gang members or disgruntled drug cronies who have made street life even more unbearable and hazardous than it usually is.

> A young, healthy, but disheveled-looking man presented to a psychiatric emergency room in the early morning hours. He declared that “voices told me to come down to the VA and see the doc.” Pressed to further elucidate, the patient confided, “The voices told me I should be coming on in to the hospital for a few days.” When he was confronted with the atypical nature of this hallucinatory experience, the young man became increasingly agitated, demanding, and confrontational. Ultimately, he admitted there in fact had been no voices at all; a drug deal gone sour had created a need for a safe haven and the hope that the Veterans Administration would comply.

Drug-Seeking Malingerers may feign illness in an effort to obtain favored medications, either for personal use or, in a prison setting, as currency to barter for cigarettes, protection, or other inmate-provided favors.

> A woman was rear-ended while parked at a stoplight, giving rise to a herniated cervical disc and chronic pain. A first attempted surgical intervention was botched when the wrong disc was removed and the wrong section of spine fused. A second was botched when the anesthesiologist managed to pharmacologically paralyze his patient, but failed to put her to sleep. Thus, the woman was conscious and alert throughout the entire discectomy and fusion procedure, but unable to speak or gesture to alert anyone to her plight. Several malpractice lawsuits were filed, and posttraumatic stress disorder was alleged.
>
> Frequent, impulsive wanderings across the country were held by the plaintiff's attorney to be the most disabling feature of this unfortunate woman's posttraumatic stress disorder. However, psychiatric evaluation revealed that the woman had no significant symptoms of posttraumatic stress disorder. Rather, she displayed a classic picture of substance-induced depressive disorder and manipulative drug-seeking behavior.
>
> It turned out that the plaintiff's cross-country wanderings centered around visits to random emergency departments, with desperate complaints of pain and demands for morphine. Further investigation revealed a pre-accident history of chronic polysubstance dependence, and similar cross-country drug-seeking meanderings beginning in the early teens.

DETECTION OF MALINGERING

In his article on the detection of malingered mental illness in *Behavioral Sciences and the Law*, Philip Resnick noted that clues to aid in the detection of deception have been sought for at least 3000 years. He quoted the following description of a liar, taken from a papyrus drafted around 900 BC: “He does not answer questions, or gives evasive answers; he speaks nonsense, rubs the great toe along the ground, and shivers; he rubs the roots of the hair with his fingers.”

The clinician must rely primarily on interviewing skills to detect malingering. Untrained observers seem to do little better than chance in lie detection, and some studies have found police detectives to do hardly better than undergraduates in judging guilt versus innocence. Despite conceptual and methodological flaws, David L. Rosenhan's study of malingerers faking insanity as inpatients on a psychiatric ward casts doubt on the ability of trained clinicians to differentiate real from feigned mental illness in certain contexts.

Nevertheless, several clues exist, and if properly applied, they are useful for the clinician who needs to detect malingering. The psychiatric conditions most likely to be malingered are mental retardation, organic impairment, amnesia, psychosis, and posttraumatic residua, including depression and posttraumatic stress disorder.

Detecting Deception Perpetrators' urges to confess seem greatest shortly after they have transgressed; during this period their guilt is apparently at its most burdensome and is as yet unrelieved by mental defense mechanisms. Memory has yet to be distorted, either consciously or unconsciously. Thus, every effort should be made to interview the criminal shortly after the crime.

Intentional malingering is harder to maintain as the evaluative interview becomes increasingly lengthy because of basic fatigue and a pull toward reality. Therefore, when malingering is suspected, the clinical interview should be as long, detailed, and grueling as possible.

Research on lying and malingering has shown that liars often speak in high-pitched voices, make errors of grammar, and make slips of the tongue. Students instructed to lie, hesitate or pause while lying and tend to make irrelevant, rambling, and negative comments; the negativity is thought to be related to guilt. The passive voice is more common than the active, discrepancies between verbal and nonverbal expression (blinking, dilated pupils, rubbing or stroking of the self) are frequent, and answers may appear rehearsed, overly facile, and rote. The clinician's suspicion should be aroused if an interviewee issues spontaneous assurances of veracity: “Doc, would I tell you a lie?” or “To be perfectly honest....”

Planning a lie before the fact allows the liar to rehearse more carefully. Thus, during the lie he or she requires fewer pauses for words, phrases, or ideas; has more control over tone of voice; and is able to project more confidently. Planned lies are consequently less easy to detect than unplanned ones. Among the most successful liars are those who exaggerate their feigned sentiments histrionically (*hamming*); those who have had some acting experience; those who are intelligent, creative, resourceful, and have good memories; and those who are smooth and practiced verbally.

Contrary to intuition and popular myth, facial expression and eye contact are poor indicators of truthfulness and may actually interfere with more sensitive lie-detection modalities. One study measured the ability to detect deception under three different conditions: (1) while watching and hearing a videotaped interview, (2) while listening to an audio recording of the interview but seeing no visuals, and (3) while reading a transcript of the interview. Listeners and readers were far more successful at identifying deception than were watchers, which suggests that visual cues during the interview serve primarily as distractions. At a fairly early age children learn how to control their facial expressions so as to conceal their emotions, refining those skills through game playing and social interaction; the face is particularly adept at deception.

Liars do not necessarily make less eye contact, have shifty eyes, smile or gaze less, or adjust posture more than nonliars. However, Sigmund Freud's assertion that a liar's unconscious guilt “oozes out of every pore” may at least be true below the neckline. A marked incongruity between calmness of the face and tension, fidgeting,

and active movement of the less controllable arms, hands, legs, and feet is a good reason to suspect deception.

Detection of Specific Malingered Conditions

Malingered Mental Deficiency or Mental Retardation Mental deficiency or mental retardation is difficult to feign in the United States, primarily because the educational system is so energetic in its passion to evaluate and classify intelligence. In general, the school system is paced at 1 school year for each year of mental age on the Stanford-Binet Intelligence Scale, with the first grade adjusted to a mental age of 6. Thus, a student who has completed the ninth grade should have a mental age of approximately 14 years. A sudden adult score more than 2 or 3 years out of line with that formula, in the context of prior school scores consistently adhering to the predicted pattern, should arouse suspicion. In addition, malingerers may miss easy questions on psychometric tests while correctly answering more difficult ones.

It is useful to check vocational and military records if mental deficiency is claimed. These sources may provide further corroborative or contradictory instances of formal intelligence testing, and a marked discrepancy between claimed capacity and historical accomplishment would be further cause to suspect falsity. Table 27.2-1 summarizes some clues to the detection of malingered mental deficiency or mental retardation.

1. Striking discrepancy between level of educational achievement and level of tested or reported intelligence (>3 years' difference)
2. Striking discrepancy between military and employment testing records and presenting behavior and test performance
3. Striking discrepancy between adult test performance and prior pattern of test performance
4. Failure on easy items in the face of success on difficult items during evaluative testing
5. Incongruity of vocational and social performance with presentation capabilities and behaviors

Table 27.2-1 Clues to the Detection of Malingered Mental Deficiency or Mental Retardation

Malingered Cognitive Disorders The most noteworthy discrepancy reported between those who have dementia and those who are attempting to fake a cognitive disorder has been the presence of marked perseveration in the former and its absence in the latter. If the suspected malingering follows a traumatic injury (e.g., head trauma or toxin exposure), a careful study of the known effects of that insult is necessary before the physician can compare the claimed sequelae with the plausible ones. Most persons attempting to malinger feign fairly blatant and dramatic symptoms—paranoia, morbid depression, suicidal behavior, gross forgetfulness—that may not be reasonable outcomes of a specific class of physical injury.

The patient's performance before and after the alleged incident should be thoroughly analyzed as should the patient's behavior in all spheres of function since the onset of the alleged deterioration. A person who performs well socially and when at leisure while claiming inability to work should be suspected of malingering. Table 27.2-2 summarizes some guidelines on the detection of malingered cognitive disorders.

1. Lack of marked perseveration
2. Implausible symptom profile given reported injury
3. Psychotic symptoms confused with cognitive impairments
4. Unimpaired function in social and recreational realms in the face of gross disability in domain of vocation and responsibility

Table 27.2-2 Clues to the Detection of Malingered Cognitive Disorders

Malingered Amnesia Amnesia, probably the most common clinical presentation of malingering, is claimed by 30 to 55 percent of perpetrators of homicide. It is easy to feign and is particularly difficult to detect.

At least six possible causes have been suggested for amnesia: (1) conversion disorder, (2) psychosis, (3) alcoholism, (4) head injury, (5) epilepsy, and (6) malingering. Before malingering is ascribed, the clinician should review and eliminate the other five potential causes. A good diagnostic battery would include negative results on skull X-ray, head computed tomography or magnetic resonance imaging, and electroencephalography; normal findings on a neurological examination; a life history inconsistent with either conversion disorder or alcoholism (or other causes of intoxication); and a clinical examination and history inconsistent with either alcoholic amnesia (alcohol-induced persisting amnestic disorder) or psychosis (alcohol-induced psychotic disorder).

If those tests are negative, the clinician faces the difficult task of amassing evidence, albeit inferential, of malingering. Motivation is a key indicator. Previous amnestic episodes without apparent motivational precursors lower the likelihood that the patient is malingering. Similarly, a patient with histrionic personality traits is more likely to be experiencing true dissociative amnesia than one with primarily antisocial traits.

The timing of onset and recovery, and correlation of the alleged amnestic episode with convenience, are other clues to the presence of malingering. Global amnesia is somewhat more convincing than spotty, patchy, self-serving amnesia. There have been several reported epidemics of copy-cat amnesias following famous or highly publicized cases; an eye to recent sensational litigation is prudent. Table 27.2-3 summarizes some guidelines on detecting malingered amnesia.

1. No history of amnestic episodes
2. Antisocial personality traits more prominent than histrionic personality traits
3. Spotty, episode-specific amnesia rather than global amnesia
4. Self-serving timing of onset and recovery
5. Recent, widely publicized, suspiciously familiar cases involving amnesia

Table 27.2-3 Clues to the Detection of Malingered Amnesia

In the context of forensic psychiatry and exculpation from criminal blame, a claim of amnesia following a crime is of little help to a defendant. Loss of memory following severe upset (such as committing a murder) is a fairly common phenomenon. To be useful in an insanity defense, the amnesia claimed would have to have existed for an appreciable period prior to the criminal act and would have to have continued unabated through it; confusion on that issue has precipitated the downfall of many a malingerer.

Malingered Psychosis In assessing an apparently psychotic patient, the clinician should obtain as much historical and collateral information as possible, especially if malingering is suspected. Motivation, availability of coaching, and adherence of the symptom picture to known disorder profiles are of use in assessing the plausibility of an evaluee's psychotic presentation.

Beyond these initial assessments, a number of indicators have been identified that, if present, raise the probability of malingering. Malingerers tend to overact their part, often mistakenly believing that the more bizarre they appear, the more convincing they are. The earlier example of the two ape-men is a case in point.

Schizophrenic patients tend to be reluctant to discuss their symptoms, particularly if they are in the throes of a persecutory delusional psychosis. On the other hand, malingerers may be anxious to call attention to their illnesses and to whatever outlandish belief systems they are attempting to feign. The form of schizophrenic thinking is far more difficult for malingerers to imitate than its content. Thus, it is much less likely that malingerers will mimic loose associations or tangential or circumstantial reasoning than that they will describe or act out odd beliefs.

Unsophisticated malingerers often confuse madness with dumbness, supposing that silly or childlike responses go hand in hand with bizarre, delusional experiences. Such faulty juxtaposition may be evident during clinical interviews and can be highlighted on psychological testing.

Malingerers may claim the sudden onset of a delusion. Realistically, delusional symptoms take weeks, months, or years to coalesce. Truly psychotic persons experiencing an acute episode are likely to act in direct accordance with their delusional system; malingerers claim to have done so only when such concordance is opportunistic. The discrepancy is less striking once the psychosis has become more longstanding; the burned-out schizophrenic person may not be as flamboyant in acting on delusional beliefs as a younger, more acutely psychotic person.

Malingerers are likely to contradict themselves in their accounts of the illness, and those contradictions may multiply as the interview progresses. They may be led astray by leading questions that the examiner knows are psychologically absurd, and they may make mistakes when questioned rapidly or directly confronted. Their symptoms may fit no diagnostic entity, and when caught in such a discrepancy they may sulk or laugh from embarrassment.

Malingerers sometimes attempt to take control of the interview, behaving in an intimidating and blustery manner. They are likely to repeat questions or answer questions slowly, working to give themselves more time to fabricate convincing responses. They present themselves as blameless within their feigned illness, yet they are likely to have nonpsychotic alternative motives for their behavior, such as killing out of revenge or out of paraphiliac desire.

As is true of the form of schizophrenic thinking, malingerers are unlikely to successfully imitate the subtle signs of residual schizophrenia. Blunted affect, concreteness, and odd, schizoid relatedness are presentations familiar only to the most talented malingerers. Table 27.2-4 summarizes some features of malingered delusions.

1. Abrupt onset and termination rather than gradual development and hesitant abandonment
2. Eagerness to call attention to delusions and symptoms rather than reluctance to acknowledge them
3. Behavior inconsistent with delusional content rather than reflective of delusional content
4. Thought content grossly disturbed in the face of quite conventional and goal-directed thought process

Table 27.2-4 Features of Malingered Delusions

Criminal defendants attempting to malinger psychosis most frequently fake auditory hallucinations; thus, detailed knowledge of the characteristics of genuine hallucinations and detailed questioning into the nature of the claimed experience are mandatory if the clinician suspects malingering.

HALLUCINATIONS True hallucinations tend to be associated with delusions and are often a psychotic expression of some intrapsychic need. Accusatory voices may represent unacceptable (or psychotic) guilt, horrifying creatures or threatening animals may represent unacceptable aspects of the personality, and the belief that one is giving off a foul odor may represent severe depression and self-deprecatory delusion.

Persons with schizophrenia frequently report that voices speak directly to them or pass judgment on them. Schizophrenic hallucinations tend to be intermittent rather than continuous, and over 50 percent of schizophrenic persons eventually acknowledge that they may have imagined their hallucinations. Some studies reveal that 66 percent of schizophrenic patients have auditory hallucinations and 33 percent have visual hallucinations; the visual hallucinations almost always accompany the auditory hallucinations. Visual hallucinations tend to be in color and of normal-sized people. Olfactory and gustatory hallucinations have been reported in acute episodes of schizophrenia; olfactory hallucinations are of unpleasant odors.

Auditory hallucinations are reported to come from outside the head by 88 percent of schizophrenic persons, and 75 percent report that they hear both male and female voices. The message is usually clear; it is vague only 7 percent of the time, and is accusatory about one-third of the time. About 30 percent of schizophrenic persons answer the voices that they hear.

Command hallucinations, although clinically noteworthy, are ignored by true psychotic persons up to 60 percent of the time. They are more likely to be obeyed if the voice is familiar to the hallucinator or if they are one element in a developed delusional system.

Most truly psychotic individuals have developed strategies for coping with hallucinatory episodes. Commonly helpful are changes of posture, distraction through activity or interpersonal contact, or ingestion of antipsychotic medication. Although the auditory hallucinations of truly psychotic persons tend to be general and basic, those of malingerers are often stilted, specific, and self-serving.

Alcohol-induced psychotic disorder with hallucinations, which follows the abrupt cessation of previously high alcohol intake, ordinarily produces vivid hallucinations. Although voices are extremely common, experience of noise, music, unintelligible voices, or tactile hallucinations (insects) are more frequent than in schizophrenia. Substance-induced psychotic disorders generally involve unformed, indistinct hallucinatory noises. Table 27.2-5 summarizes some features of malingered auditory hallucinations.

1. Continuous rather than intermittent
2. Vague, inaudible, or unintelligible rather than distinct
3. Free-standing rather than associated with delusions
4. Stilted in language and specific in tone rather than basic and general
5. Reported in the first person rather than in the third person
6. Uncontrollable rather than susceptible to strategies for containment
7. Irresistible rather than susceptible to indifference

Table 27.2-5 Features of Malingered Auditory Hallucinations

Malingered Posttraumatic Residua In today's litigious society, the psychiatrist may be asked to determine the veracity of psychiatric or behavioral symptoms that a person claims resulted from trauma of some sort, whether psychological or physical in nature. The actual incidence of malingered psychological symptoms following physical injury is unknown, but one study found that 48 out of 50 cases of postaccident neurosis had cleared up 2 years after the legal claim had been settled, and a United States General Accounting Office follow-up study reported in 1980 that approximately 40 percent of persons considered to be totally disabled had no disability whatsoever 1 year after that declaration.

Malingerers in personal injury cases seldom feign psychosis. Much more common are claims of depression and, now that it has been highly publicized, of posttraumatic stress disorder. Such ambulatory illnesses allow malingerers to avoid responsibility and to escape from work while sparing them the unpleasantness and the 24-hour scrutiny of hospitalization in a psychiatric setting.

In attempting to distinguish malingered from actual posttraumatic depression, it is helpful to consider subtle signs and symptoms of depression not commonly known to the lay individual. The absence of diurnal variation, of specifically early-morning awakening (as opposed to vague, generalized insomnia), of angry irritability, and of diminished sexual interest suggest uninformed imitation. Similarly, the lack of a family history of the disorder or of prior incidents is suspicious. Possibly most revealing of all is a lack of depressive withdrawal from enjoyable domains (such as social and recreational activities) in the face of apparent total incapacity in aversive ones (such as work).

Posttraumatic stress disorder has become a particularly productive field for fraud, especially since the Veterans Affairs (VA) widely publicized the posttraumatic stress disorder criteria in the early 1980s and announced that any veteran meeting the criteria was eligible for governmental compensation. In posttraumatic stress disorder claims as in posttraumatic depression claims, amassing a detailed picture of pretrauma functioning is crucial. The reasonableness of the relation between the degree of the stressor and the alleged symptom cluster, the temporal pattern, and any prior, concurrent, or subsequent symptoms and stressors figure centrally in the evaluation.

Some specific clues to the malingering of posttraumatic stress disorder exist. The patient with true posttraumatic stress disorder frequently focuses on the negative features of the disorder—the emotional numbness, indifference, and social withdrawal—whereas the malingerer may be more impressed by (and therefore hopes to impress more with) the expressionistic, flamboyant nightmares and flashbacks. In true posttraumatic stress disorder victims the nightmares tend to vary in content while hewing to the constant themes of terror and helplessness; malingerers are more likely to report reexperiencing exactly the same dream, often described as a videotape-like reliving of the alleged trauma itself. Many malingerers are misinformed about the nature of the true flashback experience, confusing it with—and describing it as—a benign pictorial memory. Particularly in posttraumatic stress disorder with its clearly delineated criteria and entirely descriptive diagnosis, a textbook-perfect presentation should raise greater suspicion than a presentation characterized by a vague, more approximate symptom cluster.

Table 27.2-6 lists a number of items suggestive of malingering of psychological distress following a traumatic incident.

1. Assertion of inability to work in the face of unimpaired capacity for pleasurable activity (recreation, social interaction)
2. Subscription to more obvious symptoms of widely publicized disorders (depression, posttraumatic stress disorder) in the face of denial of more subtle features of the disorders
3. Spotty, questionable vocational history; tendency to drift; fringe member of society
4. Evasiveness during interview; unwillingness to concretely address a return to work, responsibility, and social expectation
5. General presentation of sullenness, suspicious guardedness, uncooperativeness, or resentment
6. Refusal to comply with recommended diagnostic or treatment procedures; avoidance of direct examination
7. History of disabling injuries and unusually frequent absences from work
8. Traits common to antisocial, narcissistic, borderline, or histrionic personality disorders
9. Energetic and concerted pursuit of legal claim in the face of alleged debility caused by depression and posttraumatic stress disorder
10. Refusal of employment suggested as plausible despite alleged disability
11. Self-depiction in excessively favorable and capable terms prior to alleged trauma and behavioral collapse

Table 27.2-6 Factors Suggesting Malingering of Psychological Distress Following Trauma

Objective Testing For centuries objective measures, such as physiological reactions, have been used to differentiate the conniving from the sincere. For example, realizing that stress may cause a reduction in saliva production, the Bedouins required conflicting witnesses to lick a hot iron; the person whose tongue stuck to the iron was adjudged to be the liar. Similarly, in ancient China individuals in conflict were each required to chew on a ball of rice and then to spit it out; the person whose ejected rice was drier was considered to be the charlatan.

The more contemporary technique for measuring psychophysiological stress is the polygraph. However, the polygraph is not foolproof; at best it is 80 to 90 percent reliable, which has caused many jurisdictions to forbid its use in forensic evaluations. The polygraph seems best at detecting lying in anxious but honest individuals; it is therefore prone to false-positive results. Particularly disheartening is the boast, empirically verified, of many practiced sociopaths that they can beat the lie detector through exercises such as meditation, holding the body rigid, or the pretest ingestion of contraband benzodiazepines or other sedatives.

Amobarbital (Amytal), sometimes mislabeled truth serum, and hypnotic techniques have also proved disappointing candidates in the search for objective arbitration. About 50 percent of tested persons are able to maintain a lie under either of these relaxation techniques, and in fact, some lies can actually become solidified under botched hypnotic circumstances. There is much debate among modern practitioners of hypnosis about whether a person can be forced to reveal, experience, or accomplish anything at all under hypnotic trance that the same person is disinclined to reveal, experience, or accomplish when fully alert.

Psychological testing has proved somewhat more successful than the foregoing techniques in the detection of malingering. By far the most widely employed psychological test for the purpose, and the only one with an empirically validated indicator, is the Minnesota Multiphasic Personality Inventory-2 (MMPI-2). The useful gauge is known as the F – K scale, obtained by subtracting the K raw score from the F raw score; the higher the F – K index, the greater the likelihood that the subject is malingering. With an F – K index of +10, one would be correct about 97.5 percent of the time to assume that the entire MMPI-2 profile was malingered.

The F scale from MMPI-2 alone has also been proposed as an indicator of malingering, particularly when the score is above 100. However, an elevated F score alone could also signal simple uncooperativeness, misunderstanding of the items, a plea for help from an adversarial system perceived as adversarial, or frank psychosis. Thus, it has been suggested that the MMPI-2 may be most fruitfully consulted if both F and F – K scores are computed and the subject is then reinterviewed concerning the endorsed critical items. Such an analysis can shed further light on the reasoning that prompted the observed response pattern.

A further use of the MMPI-2 in the detection of malingering has involved an analysis of the ratio of subtle versus obvious indicators of pathology endorsed. In such an

analysis, as in the setting of a clinical interview, malingerers are more likely to subscribe to blatant, popular indicators of pathology than to more subtle ones.

How useful a Rorschach profile is to the detection of malingering remains controversial. According to conventional wisdom, the Rorschach is easily fooled and therefore is not very useful. However, John Exner, Jr., employing a highly developed scoring system emphasizing interrelations among the underlying structural indicators (texture, color, form, movement, and shading), has claimed that he is much less likely to be tricked. Exner teaches that a highly dramatized and personalized content identifies simulators, while a very constricted profile suggests dissimulation.

Neuropsychological testing has been advanced as an aid in the evaluation of head-injured patients. In one study, the Halstead-Reitan Battery, the Wechsler Adult Intelligence Scale (WAIS), and the first edition of Minnesota Mutiphasic Personality Inventory (MMPI) were administered to 16 volunteer malingerers and 16 nonlitigating head-injured patients, and the test results were sent to 10 neuropsychologists for blind ratings. Although the overall levels of impairment were equivalent in both groups, the patterns of impairment were not. The malingerers scored most poorly on the obvious items, whereas the injured individuals failed more subtle ones. Considering the results of all three tests together, the neuropsychologists correctly classified 100 percent of the malingerers and 94 percent of the nonlitigating injured patients.

Thus, although psychological and neuropsychological testing is helpful, it is not infallible. As for all clinical tests, a given test result should be considered in the context of a battery of converging objective indices, and that battery should be considered as only one entity in the overall clinical evaluative matrix.

DIFFERENTIAL DIAGNOSIS

Malingering must be differentiated from the actual physical or psychiatric illness suspected of being feigned. Furthermore, the possibility of partial malingering, which is an exaggeration of existing symptoms, must be entertained. There also exists the possibility of unintentional, dynamically driven misattribution of genuine symptoms (e.g., of depression) to an incorrect environmental cause (e.g., to sexual harassment rather than to narcissistic injury).

> A 51-year-old manager of a large department store made a critical error in his twenty-third year of service. When two department supervisors, one retiring and the other incoming, disputed who was the rightful recipient of a seasonal bonus check, the manager did not appeal to upper management for a solution. An individual with clear-cut narcissistic personality disorder, the manager took matters into his own hands. He divided the check three ways, one-third going to each supervisor, and one-third going to himself. The manager was put on suspension for inappropriate dispensation of company funds.
>
> This episode was only the most serious of an escalating series of poor decisions, and the company suggested that the manager allow himself to be psychiatrically evaluated at company expense. Outraged at the suspension “after all these years of devoted service” and the suggestion that “I would do anything wrong,” the manager instead quit his position, and sued the company for race discrimination (he was Hispanic) and age discrimination. Psychiatric examination revealed a man suffering from depression, clearly the product of a narcissistic wound, but who appeared utterly convinced of the truth of the misattribution of his misfortune, which had been dynamically driven outward. A diagnosis of malingering would have been as inappropriate in this case as were the plaintiff's allegations of race- and age-motivated discrimination.

It should also be remembered that a real psychiatric disorder and malingering are not mutually exclusive.

> A patient was admitted to a VA hospital with complaints consistent with posttraumatic stress disorder. Although he denied auditory hallucinations, he was troubled by recurrent nightmares and frightening flashback experiences, both involving a terrifying event he had witnessed while serving with the infantry in Vietnam.
>
> Time, and growing trust in the therapist, resulted in an admission by the patient that he experienced persecutory auditory hallucinations and had for years; in fact, his history became increasingly clearly that of a schizophrenic person, and he was assigned that diagnosis. Antipsychotic agents greatly relieved his symptoms.
>
> Ultimately, it was discovered that the patient had never served in Vietnam, had never witnessed any life-threatening trauma, and had never experienced flashbacks or recurrent nightmares. He did, however, continue to benefit greatly from treatment with antipsychotics and was eventually discharged with the diagnosis of chronic paranoid schizophrenia.

Potentially confused with malingering are factitious disorder, Ganser's syndrome, and somatoform disorders (especially conversion disorder). Factitious disorder is distinguished from malingering by motivation (sick role versus tangible pain), whereas the somatoform disorders involve no conscious volition. In conversion disorder as in malingering, objective signs cannot account for subjective experience, and differentiation between the two disorders can be quite difficult; Table 27.2-7 lists some variables that may aid in distinguishing between these two conditions.

1. Malingerers more likely to be suspicious, uncooperative, aloof, and unfriendly; patients with conversion disorder likely to be friendly, cooperative, appealing, dependent, and clinging
2. Malingerers may try to avoid diagnostic evaluations and refuse recommended treatment; patients with conversion disorder likely to welcome evaluation and treatment, “searching for an answer”
3. Malingerers likely to refuse employment opportunities designed to circumvent their disability; patients with conversion disorder likely to accept such opportunities
4. Malingerers more likely to provide extremely detailed and exacting descriptions of events precipitating their “illness”; patients with conversion disorder more likely to report historical gaps, inaccuracies, and vagaries

Table 27.2-7 Factors Aiding in the Differentiation Between Malingering and Conversion Disorder

Ganser's syndrome, or the syndrome of approximate answers, is rare and described primarily in prison populations. It involves the production of answers to questions that are relevant but not quite correct, such as stating that the product of 7 times 4 is 29. It is classified in DSM-IV as a dissociative disorder not otherwise specified, but it has variously been regarded as a factitious disorder, an hysterical phenomenon, a psychotic disorder, and frank malingering. Several studies of undergraduates instructed to feign madness resulted in the malingerers producing approximate answers strikingly reminiscent of Ganser's syndrome. That finding lends credence to Frederick Wertham's 1949 assertion that “A Ganser reaction is a hypothetical pseudostupidity which occurs almost exclusively in jails and in old-fashioned German textbooks. It is now known to be almost always due more to conscious malingering than to unconscious stupefaction.”

COURSE AND PROGNOSIS

Malingering persists as long as the malingerer thinks it to be productive of the desired rewards. In the absence of concurrent diagnoses, once the rewards have been attained, the feigned symptoms disappear. In some structured settings, such as the military or prison units, ignoring the malingered behavior may result in its disappearance, particularly if an expectation of continued productive performance despite complaints is made clear. In children, malingering is most likely associated with a predisposing anxiety or conduct disorder; proper attention to that developing problem may alleviate the child's propensity to malinger.

Malingerers are unlikely to comply with disorder-specific treatments that are offered. If they are confronted with their malingering directly, they are likely to seek out other doctors until they can find a physician who unwittingly complies with their manipulations. Symptoms are likely to abate only when the desired outcome has been achieved or when it becomes clear that the malingering is futile. At that point, malingerers are likely to discontinue treatment abruptly. However, as would be expected, the more the malingering has been reinforced, the more likely it is to recur. Successful malingerers are apt to malinger repeatedly throughout their lives, on

just as many occasions as society willingly rewards them for doing so.

TREATMENT

In his 1940 *Behind the Scenes of Murder*, Joseph Catton describes how he added whiskey to the food of an individual arrested for committing a murder while intoxicated, a defendant who had remained persistently mute and was now consequently a patient. “The insanity defense,” wrote Catton, “was dissolved in five ounces of the same liquid that precipitated the killing.”

Malingerers do not wish to be treated; the last thing they desire is to have their condition diagnosed. They are consciously gaming the system, manipulating it in the hopes of achieving personal gain of some kind.

The appropriate stance for the physician is initial clinical neutrality. If malingering is suspected, a careful differential investigation should ensue. If, at the conclusion of the diagnostic evaluation, malingering seems most likely, the patient should be tactfully but firmly confronted with that outcome. However, he or she must not be abruptly shunned; the reasons underlying the ruse should be elicited and possible alternative pathways to the desired outcome explored. Coexisting psychiatric disorders should be thoroughly addressed. Misattribution patterns and their characterological underpinnings should be gradually exposed. Only if the patient is utterly unwilling to interact with the physician under any terms other than manipulation should the possibility of an ultimate, positive therapeutic outcome be abandoned.

SUGGESTED CROSS-REFERENCES

The somatoform disorders, including conversion disorder, are discussed in Chapter 16; further differentiation of those disorders from malingering may be found in that chapter. Factitious disorders are discussed in Chapter 17. Disturbances of perception, including hallucinations, and of experience, including delusions, are discussed in Chapter 8 on clinical manifestations of psychiatric disorders. Schizophrenia is discussed in Chapter 12, dementia is discussed in Chapter 10, and mental retardation is discussed in Chapter 34. Dissociative amnesia is addressed in Chapter 18. Depressive disorders are reviewed in Chapter 14. Various personality disorders and traits, including borderline, narcissistic, histrionic, and antisocial personality disorder, are elucidated in Chapter 24. Psychological and neuropsychological testing are addressed in Section 7.4, Section 7.5, and Section 7.6.

27.3 ADULT ANTISOCIAL BEHAVIOR AND CRIMINALITY

KENNETH TARDIFF, M.D., M.P.H.

Antisocial behavior refers to a number of behaviors that are immoral, illegal, or both and do harm to other persons and society. Antisocial behavior often involves aggression and violence. In the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) the following statement about adult antisocial behavior appears:

> This category can be used when the focus of clinical attention is adult antisocial behavior that is not due to a mental disorder (e.g., Conduct Disorder, Antisocial Personality Disorder, or an Impulse Control Disorder). Examples include the behavior of some professional thieves, racketeers, or dealers in illegal substances.

The term *antisocial behavior* is sometimes confusing because it refers to behavior both by persons whose behavior is not due to a mental disorder and by persons who have never received an adequate neuropsychiatric workup to determine the presence or absence of a mental disorder. The violence of antisocial behavior must be differentiated from violence due to psychiatric disorders defined by DSM-IV. Physical violence is associated with a number of psychiatric disorders and varies in severity, frequency, and nature, depending on the psychopathology of the specific disorder and the environmental context of the specific incident. For some psychiatric disorders violent behavior is part of the diagnostic criteria listed in DSM-IV, such as intermittent explosive disorder, antisocial personality disorder, borderline personality disorder, and conduct disorder. In other psychiatric disorders violence may not be among the diagnostic criteria but may emerge as part of the expression of the disorder. Among these disorders are substance-related disorders, cognitive disorders, schizophrenia, psychotic disorders, and bipolar disorders.

HISTORY

Although antisocial behaviors have been part of society since history has been recorded, the medical profession's involvement with such behaviors is fairly recent. In the nineteenth century Benjamin Rush described disorders of the will, and J. C. Prichard formulated the concept of moral insanity to describe antisocial behaviors. In the twentieth century the person who committed crimes was thought to have a hereditary defect and was called a psychopath. Later, as a larger role was imputed to social factors in causing crime, such persons were called sociopaths. In 1950 Sheldon Glueck compared delinquents and nondelinquents on hundreds of traits and determined that both heredity and socioeconomic factors were related to antisocial behaviors. August Aickhorn formulated deviant behavior in psychoanalytical terms. He emphasized the faulty development of the superego and noted that psychopaths lacked anxiety or guilt feelings about their behaviors. As researchers studied criminal populations, it became apparent that criminals had a broad range of psychiatric disorders. In addition to psychopaths, persons with schizophrenia, mental retardation, psychoneurosis, and alcoholism were in prison populations.

EPIDEMIOLOGY

In 1933 the rate of homicide in the United States was 9.7 homicides per 100,000 persons. The rate of homicide declined in the 1950s but began to climb in the late 1960s and 1970s and peaked at 10.7 per 100,000 persons in 1980. From the high in 1980 homicide rate declined to a low of 7.9 per 100,000 persons in 1985. This dip was short-lived, as the homicide rate climbed steadily to a high of 9.5 per 100,000 in 1993. In contrast, rates of nonfatal assaults, monitored by the National Victimization Survey since 1973, did not fluctuate as much as the homicide rate between the early 1970s and early 1990s.

In other words, violence per se did not increase, only lethal violence increased from the mid-1980s to the early 1990s. This was probably due to a number of factors. First, there was greater access to firearms, particularly the more lethal automatic and semiautomatic weapons. Access to these weapons and carrying weapons increased especially among young males. Not surprisingly, homicide rates increased most among young males. For example, between 1965 and 1985, homicide rates for 15- to 19-year-old males were one-third to one-half the rates for men 20 to 34 years of age. Between 1985 and 1992, annual rates of homicide for 15- to 19-year-old males rose 154 percent. Victims of these young perpetrators were more likely to be strangers or acquaintances than family members. The rise of crack cocaine from the mid-1980s was associated with chaotic drug dealing, with violence related to territorial disputes and robberies and death of drug dealers, customers, and innocent bystanders. African-Americans and Latinos are overrepresented as homicide victims and perpetrators, probably because of socioeconomic disparities, not race per se. These include poverty, low education, unemployment, and living in crime-ridden neighborhoods.

Men are more likely than women to be victims of violent crime, except rape and sexual assault. In 1994 the National Victimization Survey found the rate of nonfatal assault to be 5100 per 100,000 men and 3500 per 100,000 women 12 years and older. Rates of homicide were 18 per 100,000 men and 4 per 100,000 women. Rates of robbery were 800 per 100,000 men and 400 per 100,000 women. Rates of rape and sexual assault were 400 per 100,000 women and 20 per 100,000 men. Rates of women being victims of violent crime have increased over the past 20 years. Women are more likely than men to be attacked by intimates, relatives, or acquaintances.

There has been good news in regard to violent crime in the United States over the past few years: it is decreasing. From 1993 to 1996, overall violent crime dropped 16 percent; nonfatal assaults decreased 27 percent, rape decreased 44 percent, and other sexual assaults decreased 37 percent. According to the 1998 Federal Bureau of Investigation report, there was a downward trend in murders of about 8 percent from 1997 to 1998. Speculation about the reason for the decrease in violent crime involved more-aggressive police work with enforcement of “quality-of-life” crimes stabilizing neighborhoods and decreasing drug-dealing, particularly the violence-prone selling of crack cocaine.

Although accounting for few homicides, mass murders and serial murders receive disproportionate attention in the media. In fact, some speculate that media attention has caused an increase in these homicides over the past two decades. The first mass murder that received widespread coverage by the media in the United States was the sniper attack by Charles Whitman from a tower at the University of Texas. Since then, mass murders have been media events and the number of dead bodies are compared with that in earlier mass murders. Mass murderers who followed Whitman in the United States have acquired more-lethal weapons that are easier to carry and conceal. While Whitman lugged a case of rifles and ammunition to the top of the tower, more-recent mass murderers use small automatic pistols or automatic rifles. Consider the Long Island Railroad mass murder in which Colin Ferguson carried an automatic pistol and clips of ammunition in a small knapsack. Originally, a mass murderer was most likely to be a white man preoccupied with guns and militaristic themes. The mass murderer was often a disgruntled employee or some person who felt discriminated against and paranoid about society. Most recently, mass murderers have been children who feel ridiculed or rejected by classmates and teachers in schools and who have easy access to guns. The Littleton, Colorado, massacre in 1999 by two high school students who killed 13 people and then killed themselves may fall into this category.

Serial murderers usually kill one victim at a time over a period of time rather than a group of people at one time. Serial murderers have existed in England and Europe since the nineteenth century (e.g., “Jack the Ripper”). In the United States the first infamous serial killer in this century was Albert DeSalvo, the “Boston Strangler.” Serial murderers often kill for sexual reasons, and the victims often resemble each other. Ted Bundy raped and killed many young women who resembled a former fiancé who called off their engagement. John Wayne Gacy and Jeffrey Dahmer primarily molested and killed young men. Along with sexual themes, there may be cult or satanistic themes as in the cases of Charles Manson and David Berkowitz, the “Son of Sam” killer. Another type of serial murder involves killing elderly persons in rooming houses for pension or Social Security checks, as in the case of Dorothy Perente in California.

A third type of homicide that constitutes a small number of homicides but receives wide media coverage is the murder-suicide. As with mass murders and serial murders, those who murder someone and then commit suicide are usually men. There are several types of murder-suicide. The most common type, representing one-half to three-fourths of murder-suicides in the United States, involves amorous jealousy. Typically a man develops suspicion or knowledge of his spouse's or girlfriend's infidelity. He kills her and perhaps her lover and commits suicide with a gun. Another type of murder-suicide involves an elderly man who is in poor health or has an ailing wife. A new variant of this type is a person with acquired immune deficiency syndrome (AIDS) who kills a lover and then himself. A third type involves the murder of a spouse, children, or other family members and the suicide of a depressed male head of a household or a mother of a child. Last, a paranoid disgruntled mass murderer may kill himself or put himself in a position so that the police kill him.

ETIOLOGY

Socioeconomic Factors Criminal violence in deprived inner cities has been explained in terms of recourse to fighting as a means of achievement. The breakup of families, alienation, discrimination, and frustration are believed to be compounding factors. Some have hypothesized that blacks live in a violent subculture; others have found there is no difference between blacks and whites in domestic violence if socioeconomic status is controlled for in the analysis.

In a study that compared rates of violent crimes in large standard metropolitan statistical areas, racial inequality and stress were associated with higher rates of homicides. Economic inequality denoted not merely poverty, but also relative income differences among individuals. Violence may occur because of hostility in persons who perceive that they are economically disadvantaged relative to other persons. Some studies have found that economic inequality is not related to violence but that absolute poverty is related to violence and other criminal behavior.

These contradictory results are probably due to the use of large metropolitan areas as units of analysis. A study by the author used the smaller, more naturalistic units of neighborhoods to test the hypothesis that economic inequality is related to homicide. The study found that economic inequality and race were not related to homicide and that the prime determinants of homicide were absolute poverty and marital disruption.

The social determinants of violent crimes are interconnected. Poverty, inability to acquire the basic necessities of life, marital disruption, single- or no-parent families, substance abuse, unemployment, and lack of education lead to social disintegration, decreased social control, and violence.

Physical Factors Physical crowding is probably related to violent crime in terms of the number of buildings in a geographic area or the number of inhabitants in a building. Some believe that with increased contact in high-density areas, there is less defensible space and an increase in violence; whereas others argue that an increased density affords increased social control and decreases violent crime. The latter situation may be obtained if bystanders serve informally or formally in a neighborhood crime-watch program.

Metropolitan areas with central cities have the highest rates of homicide, followed by nonmetropolitan counties, and then metropolitan areas without central cities. It appears that the difference between urban and rural areas in primary homicides is less than the difference in secondary homicide rates, or homicides committed secondary to crime, which are higher in urban areas.

Biological Factors Genetic inheritance may be related to criminal acts in general. Studies have found more criminal behavior in monozygotic twins than in dizygotic twins. Insofar as twins share the same environmental and genetic backgrounds, further research has turned to adoption studies. In two studies reported from Scandinavia there was no support for a genetic basis to homicide and some support for an association with other crimes. There appears to be no specific chromosomal abnormality that accounts for violent behavior, and studies of inheritance support only a genetic relation for economic, property crimes, not for violence per se. There is evidence that low serotonin and corticotropin concentrations in the brain and high free testosterone concentration in cerebrospinal fluid may be associated with episodic violence.

Developmental Factors Several retrospective studies and one prospective study have shown that being abused as a child is related to becoming a physically abusive adult. Further, witnessing intrafamilial violence (e.g., spouse abuse) is related to increased problems with violence among children. Abuse as a child and growing up with domestic violence are not the sole causes of violence in adults. Other factors affect whether there is violence in a family, such as the presence of psychiatric disorders, alcohol and drug abuse, or other pathology in the perpetrator, or socioeconomic factors such as poverty, unemployment, education, or culture. The role of the media, such as violent television programs, movies, and music videos, has come under increased scrutiny as a factor in the development of violence and other antisocial behaviors.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of adult antisocial behavior is made by a process of elimination. Mental disorder must be ruled out as a cause of or factor contributing to violence by the person. The mental disorders most frequently associated with violence are intermittent explosive disorder, antisocial personality disorder, borderline personality disorder, conduct disorder, schizophrenia, other psychotic disorders, bipolar I disorder, substance-related disorders, and cognitive disorders.

DIFFERENTIAL DIAGNOSIS

Intermittent Explosive Disorder Intermittent explosive disorder is defined in DSM-IV as an impulse-control disorder manifested by several discrete episodes of loss of control over aggressive impulses, resulting in serious assaultive acts or destruction of property. The degree of aggressiveness expressed during the episodes is grossly out of proportion to any precipitating psychosocial stressors. There are few or no signs of generalized impulsiveness or aggressiveness between episodes. The person usually feels remorseful and concerned about the consequences of the violence, such as divorce and loss of a job. The episodes of loss of control are not better accounted for by antisocial personality disorder, borderline personality disorder, conduct disorder, a psychotic disorder, a manic episode, and attention-deficit/hyperactivity disorder and are not due to substance intoxication or personality change due to a general medical condition (e.g., head trauma).

A 40-year-old male lawyer sought outpatient psychiatric help for a long-standing problem with his temper. He and his wife would have serious arguments every week or so. On a number of occasions he had pushed her out of his way as he attempted to leave the house and “cool off.” After arguments he would say how sorry he felt and plead with his wife to forgive him. The arguments had increased in number and intensity since the birth of their son 2 years earlier. A recurring theme in the arguments was his concern that his wife did not care about him and paid too much attention to the son. The wife felt she had sacrificed her professional career and that her physical appearance had deteriorated after the birth of the child. A few weeks before the first consultation the patient had pushed his wife, who sustained a laceration on her head. She insisted that he leave and that they separate legally.

The patient was an only child and felt resented by his mother, who had to stop working to take care of him. His father was a successful lawyer who spent little time with the family. The patient had reading problems throughout school. He was a bully since late childhood and would get into fights with other, usually smaller boys.

Over a year of psychotherapy exploring issues of self-esteem, in conjunction with a moderate dosage of clonazepam (Klonopin), he was able to reconcile with his wife without physical attacks on her.

Antisocial Personality Disorder Patients with antisocial personality disorder repeatedly get into fights or exhibit other assaultive behaviors, including spouse beating and child beating. The assaultive behavior is usually evident by age 15 years. Other behaviors that manifest by middle to late adolescence include unlawful behaviors such as destroying property, harassing others, stealing, and pursuing an illegal occupation. The person cannot sustain legitimate employment or academic performance. The person may fail to honor financial obligations, has no regard for the truth, cannot function as a responsible parent, has difficulty being monogamous, is reckless in regard to the safety of self or others, and is generally impulsive and fails to plan ahead. By definition, in DSM-IV conduct disorder is present before the age of 15 years and is associated with a number of problematic behaviors such as physical aggression, cruelty to other people or animals, destruction of property, fire setting, lying, truancy, stealing, and forcing someone to have sexual activity. The hallmark of antisocial personality disorder is lack of remorse in regard to the violence and other antisocial behaviors.

A 20-year-old unemployed man came to the emergency room at 3:00 AM expressing vague suicidal ideation. He had recently lost his job; after being accused of stealing money from the cash register in the hardware store where he worked, he had hit his supervisor with a wrench. The supervisor lost consciousness and sustained residual neurological dysfunction. The patient had worked at the hardware store for only 2 months. A fellow employee called the police, and the patient was arrested, released on bail, and given a trial date. He claimed to have no memory of the event.

During his emergency room visit the patient sought admission to the psychiatric unit for an evaluation to determine whether mental problems could have been responsible for his attack on his supervisor. He had been arrested twice for driving while intoxicated. He had been in numerous fights, usually in bars, and bragged about injuries he had inflicted on opponents. Since late childhood he had been in fights, and he had frequent behavioral and academic difficulties in school. He quit high school in his junior year and held many jobs for short periods of time.

The patient was admitted to the inpatient unit and was discharged 2 days later with no Axis I diagnosis. During his short stay on the unit, he created conflict among patients and staff.

Borderline Personality Disorder Borderline personality disorder includes frequent displays of intense anger and lack of control of anger, which results in recurrent physical fights. Violence is only one area of impulsiveness. Persons with borderline personality disorder attempt suicide, are self-mutilating, and are impulsive in regard to spending money, sexual activity, shoplifting, reckless driving, and other aspects of living. There are problems with identity disturbance and chronic feelings of emptiness. Severe violence targeted at one person may come from intense and unstable interpersonal relationships and fear of real or imagined abandonment by that person.

A 25-year-old attractive woman had been in weekly psychotherapy with a male therapist for 2 years. The content of the sessions involved her sense of loneliness and lack of direction in her professional life. She had numerous unsuccessful relationships with men, usually older than she and married or otherwise not available. The relationships ended with increasing demands by her for attention and, on several occasions, suicide attempts. She would break dishes, vases, and other objects during rages but had never attacked people.

Over the past 3 months she had begun to talk of increasing the frequency of psychotherapy sessions. Vague references by the patient to where the therapist lived and inquiries about his marriage turned to overt insistence during one session that they should have sex because he was the first man to really understand her. The therapist abruptly terminated the session by asking his secretary to come into the office. That night the patient appeared at the therapist's home with a gun. The police were called. Before they arrived she shot out a number of windows in the therapist's house and then shot herself.

Conduct Disorder Conduct disorders can involve violence to varying degrees of severity, ranging from use of a weapon that could seriously injure others, such as a gun, knife, bat, brick, or broken bottle, to less severe physical fights with other persons in the home. Conduct disorder precedes antisocial personality disorder. Children and young adolescents with conduct disorder are truant, destroy property, steal, are physically cruel to people or animals, force sex on others, or engage in sexual activity to obtain money, drugs, or other goods. Less severe manifestations of those antisocial behaviors can be found along with the violence in conduct disorder.

A 9-year-old girl in a private school was frequently sent to the principal's office. In class she would not remain quiet and often used obscene words. She touched other students in class and picked on certain students, whom she hit or poked with pencils. Those actions resulted in fights and name calling. She was caught stealing minor items from another girl's locker. She bragged that she had seen X-rated videotapes and seemed too sophisticated about sex for her age. The family dog had been injured a number of times, and her parents suspected that she was responsible. The girl would blame others for her behavior and frequently lied to her teachers and parents.

Psychotic Disorders Schizophrenia and other psychotic disorders are associated with an increased risk of violence, but violence is not found in most cases. Violence can result from the nature of the delusional system, from hallucinations, or as part of disorganized or agitated behavior. As part of paranoid delusional thinking and hallucinations, patients may believe that other persons are threatening, persecuting, or in some way trying to harm them; the violence is a reaction to the perceived threats. Often the theme of the delusion is consistent over time. In the disorganized and catatonic subtypes of schizophrenia violence comes from psychotic disorganization and extreme agitation and excitability. Some patients may have difficulty delaying gratification and a low tolerance for frustration, with violent consequences.

Sometimes violence is caused by factors other than the schizophrenic process per se. For example, this author has observed violence as an indirect complication of antipsychotic medication when patients with akathisia restlessly move around the inpatient unit. Moreover, schizophrenic patients may have another disorder primarily responsible for violence, such as neurological impairment, substance abuse, or mental retardation. Violence may not be related to any psychiatric disorder but rather to retaliation or self-defense. Patients with delusional disorder may take violent action to right what they believe to be a wrong. Systematized, prominent, and fixed delusions of a spouse's infidelity and persecutory delusions have occasionally resulted in severe violence, including homicides.

A 27-year-old woman with a diagnosis of paranoid schizophrenia had been admitted to a number of psychiatric hospitals. Her first episode occurred during her freshman year at college; she believed her food was being poisoned. Her parents denied the seriousness of her illness and persisted in trying orthomolecular treatment.

In the hospital the patient was very psychotic and had multiple delusions regarding food intake, including beliefs that the staff and other patients were trying to poison her. That belief led to several attacks on other patients, requiring physical restraints and emergency medication. The violence subsided when she was allowed to stay in her room for long periods of time, including mealtimes, until antipsychotic medication was effective in diminishing her delusions.

A 24-year-old man with a diagnosis of paranoid schizophrenia was attending a day hospital program and was taking oral antipsychotic medication, but compliance was problematic. He continued to hear the voice of a friend telling him to cut himself and to hurt others because he liked to see blood. On the day of admission he had threatened to kill a therapist at the day hospital with a razor blade; a razor blade was found in his pocket. In the hospital his psychosis responded to antipsychotic medication, and he was no longer delusional. Nevertheless, on two occasions he was violent. On one occasion he swung a curtain rod at a nurse in a menacing manner because he was denied a pass. The next day he sought out the nurse who told him he could not have a pass. He punched her in the face and loosened two of her teeth. When asked why he did it, he replied that he wanted to get even for the denial of a pass. He was not delusional. The nurse, with the support of the administration, pressed charges, and he was arrested by the police.

Bipolar I Disorder Manic patients may experience sudden, severe episodes of violence. Often violence erupts in the early phase of treatment of the manic episode. Such a patient may respond violently to any form of containment or limit setting, whether physical or otherwise, as when a nurse insists that the patient take a dose of medication or a clinician insists on hospitalization against the patient's will.

A 48-year-old woman came to the emergency room accompanied by her husband. She had a history of bipolar I disorder. That day in church she had been singing and talking very loudly when an usher asked her to be quiet; she got into a physical fight with him. In the previous week she had become increasingly euphoric and hypersexual. She bit her husband several times on the arm when they were having sexual relations.

The patient and her husband were escorted into the psychiatric examination room and seen by a female resident. About 5 minutes into the interview, as the husband was showing the resident the bite marks on his arm, the patient grabbed the resident by her hair and began to pound her head against the wall. The resident had left the door to the room open and had asked a security guard to sit outside the door. The security guard rushed in and restrained the patient. When asked a month later why she had attacked the resident, the patient said she felt restricted in the room and was angry that the resident was talking to her husband instead of to her.

Substance-Related Disorders Substance abuse is associated with violence. Alcohol-related disorders as a primary disorder or in conjunction with other psychiatric disorders can result in violence. The violence is often the result of disinhibition (particularly in the early phase of intoxication) and of emotional lability and impaired judgment. Stimulants, particularly cocaine, can be associated with violence. The early phase of cocaine intoxication is manifested by a euphoria that can turn to irritability, agitation, suspiciousness, and violence, especially with crack or intravenous cocaine. With continued use of cocaine in a binge and with long-term amphetamine use, suspiciousness can become paranoid delusional thinking and violence. Heavy cocaine use has caused manic-like delirium with severe violence.

The craving for cocaine may result in violence as the user desperately seeks more cocaine or the money to purchase it.

Hallucinogens and dissociative drugs, particularly phencyclidine, can cause violence, suicide, and bizarre behaviors. Hallucinogens can impair judgment and cause perceptual changes and delusional thinking. Benzodiazepines and sedatives do not commonly produce violence through intoxication. However, abrupt discontinuation of the short-half-life benzodiazepines may result in irritability and agitation, so that the risk of violence may be increased. Withdrawal from alcohol may produce violence by similar mechanisms or by the delirious state.

> A 27-year-old woman had a 2-year history of using crack cocaine. Prior to that she had abused alcohol and benzodiazepines. She had been hospitalized numerous times. Before the current hospitalization she had been serving as the cooker in a crack house, converting crystalline cocaine into crack. For that service she was provided with a continuous supply of crack over a number of hours. She recalled becoming increasingly irritable and drinking wine in an effort to calm down. She became suspicious that others in the group were taking more and more of the cocaine and that she would be left without an adequate amount and would “crash.” She had no recollection of what happened next, but was told by a friend that she suddenly picked up an ashtray and hit a man on his head several times. When examined at the time of admission she was delusional but responded well to a low dose of an antipsychotic agent, which was stopped after 1 week.

Cognitive Disorders Organic brain disease can result in violence. Violence in patients with temporal lobe epilepsy is not frequent but may occur during the ictal period and, if so, is often purposeless. Some researchers have maintained that more-subtle neurophysiological dysfunction is responsible for violence in some patients. They point out that the electroencephalogram (EEG) is an insensitive measure of subcortical activity and that some patients with episodic violence respond to anticonvulsants. Others stress the effect of head trauma and other neurological and medical disorders that can affect the brain and produce violent behavior. Infections of the brain, including viral encephalitis, AIDS, tuberculosis, fungal meningitis, syphilis, and infection with human herpesvirus, may be associated with violent behavior. Other diseases of the brain associated with violence include normal pressure hydrocephalus, cerebrovascular diseases, tumors, Huntington's disease, multiple sclerosis, Pick's disease, vascular dementia, Alzheimer's disease, Parkinson's disease, and Wilson's disease, as well as postanoxic or posthypoglycemic states with brain damage.

A wide range of medical illnesses have been associated with violent behavior. Many are treatable and reversible. Among those disorders are hypoxia, electrolyte imbalances, hepatic disease, renal disease, vitamin deficiencies (e.g., B_{12}, folate, thiamine), systemic infections, hypoglycemia, Cushing's disease, hyperthyroidism, hypothyroidism, systemic lupus erythematosus, poisoning (e.g., by heavy metals, insecticides) and porphyria.

> A 29-year-old recreational therapist was brought to the emergency room by her sister. A week earlier her sister noticed that the patient did not wake up at her usual time to go to work. When awakened by her sister, the patient seemed upset and confused and could not remember where she worked. Over the next few days she spent a great amount of time sleeping, alternating with sexually inappropriate behavior such as disrobing in public. She became physically violent toward her sister, who tried to prevent such behavior and who insisted she be evaluated by a psychiatrist. Laboratory tests, including a toxicology screening test, EEG, and magnetic resonance imaging (MRI), revealed no abnormalities except an elevated erythrocyte sedimentation rate and mild anemia. Before the episode the patient had been healthy, except that 3 weeks earlier she had flu-like symptoms with a runny nose, malaise, and elevated temperature. On the inpatient unit she was impulsive and unpredictably violent. She would punch other patients, pull their hair, and knock food trays from tables. She was delusional in that she believed she was on a maternity ward and pregnant, which she was not. She responded to a low dosage of an antipsychotic agent, and her violence subsided with carbamazepine (Tegretol) therapy. The most probable diagnosis was psychotic disorder due to postviral encephalitis.

LABORATORY EXAMINATION

Laboratory tests and imaging studies are aimed at detecting underlying brain pathology, which may be localized, particularly to the temporal and frontal lobes, as well as general neurological and medical disorders in which violence is part of general disorganization, dementia, or delirium. The usual routine laboratory tests are done, including a complete blood cell count, a blood chemistry panel (to determine electrolytes; blood urea nitrogen [BUN]; glucose, creatinine, calcium, and phosphate concentrations; and liver function), thyroid function tests (serum triiodothyronine [T_3], serum thyroxine [T_4], serum thyroid-stimulating hormone [TSH]), a syphilis tests, vitamin deficiency testing (B_{12}, folate, thiamine), urinalysis, electrocardiography, and chest X-rays. This author believes that EEG should be part of the routine evaluation of the violent patient. The routine EEG should be augmented by recording with nasopharyngeal leads and by a sleep and a sleep-deprived EEG. In addition, blood and urine specimens should be taken at the time of admission for alcohol and drug assays. Because cocaine has a short half-life—about an hour—blood should be drawn as soon as possible and placed in a container with fluoride to prevent subsequent breakdown of cocaine in the tube.

The author believes that MRI should be used routinely in assessing violent patients. MRI is better than computed tomography (CT) in detecting temporal lobe pathology. CT does not require the same degree of patient cooperation and therefore can be used more easily than MRI in agitated, hyperactive patients.

Other laboratory tests are used if a specific disorder is indicated. Such tests include arterial blood gas determinations (to test for hypoxia), an assay for human immunodeficiency virus (HIV) antibodies, (to test for HIV infection and AIDS), a glucose tolerance test (to test for hypoglycemia), determination of ceruloplasmin and copper concentrations in urine and serum (to test for Wilson's disease), urine porphobilinogen assay (to test for porphyria), a heavy metal screening test (to test for poisoning), antinuclear antibody assay (to test for systemic lupus erythematosus), and lumbar puncture if intracranial pressure is not elevated (to test for infection, multiple sclerosis, and hemorrhage).

PROGNOSIS

When a patient has exhibited violent behavior in the past or threatens violence, a decision must be made about the risk of violent behavior in the future. Decisions must be made about whether to hospitalize a potentially violent patient, when to discharge a previously violent patient, and whether to warn a potential victim. As with the evaluation of suicide potential, evaluation of violence potential includes assessment of how well planned the threat or violent ideation is. Vague threats of killing someone are not as serious as well-formulated threats against a specific person. As with suicide, the availability of means of inflicting injury is important. If the patient has recently purchased or owns a gun, the clinician should take the threat more seriously.

A history of violence or other impulsive behavior often predicts future violence. The clinician should assess the degree of past injuries, the person toward whom violence was directed, and the circumstances. Often there is a repetitive pattern of violent behavior and escalation. Alcohol and drug abuse should be assessed. Central nervous system disorders have been associated with violent behavior, as have some systemic disorders affecting the central nervous system. As with suicide, the clinician should take seriously threats of violence by a psychotic person and assess the potential for violence. Compliance with treatment, for example, a paranoid schizophrenia patient receiving depot antipsychotic agents or an alcoholic patient receiving disulfiram (Antabuse), is reassuring. All of those factors are weighed in the final assessment of whether the patient poses enough risk to others to require some action (Table 27.3-1).

High degree of intent to harm
Presence of a victim
Frequent and open threats
Concrete plan
Access to instruments of violence
History of loss of control
Chronic anger, hostility, or resentment
Enjoyment in watching or inflicting harm
Lack of compassion
Self-view as victim
Resentment of authority
Childhood brutality or deprivation
Decreased warmth and affection in home
Early loss of parent
Fire-setting, bed-wetting, and cruelty to animals
Prior violent acts
Reckless driving

Table 27.3-1 Commonly Cited Predictors of Dangerousness to Others

TREATMENT

Safety The immediate and long-term management of violent patients is often made more difficult by staff emotions and fears about safety. This author has developed a model to predict the short-term risk of violence by patients. If the risk is significant the clinician is expected to make efforts to protect potential victims from violence by the patient by changing the treatment plan, hospitalizing the patient, or warning the potential victim and the police. In such situations confidentiality can be breached, and the potentially violent patient should be informed that a warning will take place. It should be emphasized that warning serves both to protect the patient from the consequences of his or her violence, should it occur, and to protect the intended victim.

The safety of the clinician and the environment in which the treatment takes place should also be considered. In emergencies the clinician should not intervene unless it is safe to do so. Adequate manpower should be available to contain violence by patients. Attention to attire is important; clinicians should remove earrings, necklaces, and neckties before confronting potentially violent patients. Heavy or sharp objects in the office and intravenous poles in the emergency room are dangerous. The clinician must feel safe as the evaluation and treatment of the violent patient proceeds or else the process will be incomplete or distorted.

Emergency Management There are three ways to manage violence or impending violence: verbal deescalation, medication, and physical restraint or containment. A decision to attempt to deescalate aggression by talking to the patient is made on an individual basis, but a psychotic patient or one with a gross organic dysfunction as the cause of violent behavior rarely responds to verbal interventions. The options then are restraint, seclusion, and emergency medication. The choice is based on clinical needs in the individual case. If the cause of the violent behavior is unknown, restraint may be indicated to maintain the patient drug free for purposes of evaluation. A violent patient may be preferentially managed with seclusion and restraint because of medical illness or drug allergies that would preclude the use of certain medications to control violent behavior.

Seclusion and Restraint Seclusion and restraint should never be used for punishment, that is, as retribution for an act when no danger exists to the patient or others. Seclusion may be contraindicated because of the patient's clinical or medical condition. If the patient is suicidal or medically unstable so that close monitoring is necessary, seclusion is not appropriate. Restraint may be preferable for delirious patients, in whom the reduced sensory input of seclusion may lead to worsening of the clinical state. Seclusion is also relatively contraindicated in patients who have just taken overdoses and need close monitoring, in patients with symptoms of serious and uncontrollable self-mutilation, and when seclusion rooms cannot be sufficiently cooled on hot days for patients receiving drugs, such as antipsychotic agents, that impair thermoregulation.

Restraint and seclusion are emergency procedures that are usually initiated by nursing staff, but a physician should see the patient as soon as possible and write an order to continue the procedure. Orders are time-limited and must be renewed periodically, depending on the institution's guidelines. The American Psychiatric Association's *Task Force on the Psychiatric Uses of Seclusion and Restraint* outlined standards for the monitoring and care of a patient in restraint and seclusion by nursing staff to ensure the patient's safety.

Emergency Medication Emergency medication may be used instead of or with seclusion or restraint. Antipsychotic medication should be used primarily in the management of violent patients with psychotic symptoms. It may also be indicated for patients who are not psychotic but who are violent, as in the case of patients with brain dysfunction, whose condition may be worsened by benzodiazepines. The procedure of rapid tranquilization (i.e., administering low doses of antipsychotic medication over 30 to 60 minutes) with the specific goal of decreasing violence is effective. A range of antipsychotic agents can be used, and there is general safety and efficacy with rapid tranquilization. The approach is effective in the emergency management of schizophrenia, manic episodes, and other psychotic disorders.

There are two strategies of rapid tranquilization: the use of high-potency antipsychotic drugs with an anxiolytic drug or other drugs for sedation, if necessary, and the use of low-potency antipsychotic drugs with both sedative and antipsychotic effects. The strategy chosen should take into consideration the patient's history and physical status. The clinician should review the patient's previous responses to medication and any coexisting medical illnesses that may predispose to or be exacerbated by extrapyramidal side effects or orthostatic hypotension. If extrapyramidal adverse effects are less acceptable, low-potency antipsychotic drugs should be used; if orthostatic hypotension and related adverse effects are less acceptable, high-potency antipsychotic drugs are indicated. The clinician should feel free to change the strategy if the patient's medical condition changes.

The benzodiazepines can be used effectively in emergency situations. Benzodiazepines may be used with antipsychotic medications in patients with schizophrenia or manic patients and patients in other psychotic states, or they may be used alone in the management of nonpsychotic patients. For patients who appear to have some degree of control, they may be offered as an oral medication. However, most emergency situations require intramuscular medication. Lorazepam (Ativan) is preferred because, unlike diazepam (Valium) or chlordiazepoxide (Librium), it is reliably and rapidly absorbed from intramuscular injection. Clonazepam is more appropriate in the long-term management of violence than in emergency situations.

Long-Term Medication Medication is used to treat the underlying disorders (e.g., antipsychotic drugs to treat schizophrenia and lithium [Eskalith] to treat manic episodes). Anticonvulsants, b-adrenergic receptor antagonists, and lithium have been used to treat violence in patients who do not have classic seizure activity or bipolar disorders.

Anticonvulsants Carbamazepine is effective in managing aggression and irritability in patients with overt seizures, in schizophrenic patients with and without EEG abnormalities, and in other patients with episodic violence, particularly those with personality disorders without gross brain damage and mental retardation. Carbamazepine rarely causes agranulocytosis or aplastic anemia, but the patient's hematological status must be monitored. A gradual increase in dosage in 100- to 200-mg increments to 600 to 800 mg a day, or a therapeutic serum concentration of 8 to 12 ng/mL, is recommended. Valproic acid (Depakene, Depakote) may be used after an unsuccessful trial of carbamazepine or if the hematological status of the patient precludes use of carbamazepine. Therapeutic levels range from 50 to 100 g/ml. Hepatic function should be monitored with both medications.

b-Adrenergic Receptor Antagonists A number of reports have indicated the effectiveness of b-adrenergic receptor antagonists (also called beta-blockers), particularly propranolol (Inderal), in the management of aggressive behavior. Most patients who responded to propranolol were those with brain disease, often with gross impairment of function secondary to trauma, alcohol use disorders, encephalitis, Huntington's disease, dementia, Wilson's disease, and Korsakoff's syndrome. Some patients with minimal brain dysfunction or attention-deficit/hyperactivity disorder have also reportedly responded to propranolol. Nearly all patients in those studies were refractory to other medications, including antipsychotic drugs, anxiolytics, anticonvulsants, and lithium. In a number of instances concurrent antipsychotic medication was used. Before propranolol is prescribed, the patient should receive a thorough medical evaluation. Propranolol should not be used in patients with bronchial asthma, chronic obstructive pulmonary disease, insulin-dependent diabetes, cardiac diseases (including angina and congestive heart failure), diabetes mellitus, significant peripheral vascular disease, severe renal disease, and hyperthyroidism. Propranolol should be prescribed with caution for hypertensive patients because sudden discontinuation of propranolol may result in rebound hypertension.

The initial dosage of propranolol is 20 mg given three times a day; the dosage is increased by 60 mg every 3 to 4 days unless the pulse rate is below 50 beats per minute or the systolic blood pressure is less than 90 mm Hg. If the patient experiences severe dizziness, ataxia, or wheezing, the medication should be held and then reduced or discontinued if the symptoms persist. Dosages above 800 mg a day usually are not needed to control aggressive behavior. Other b-adrenergic receptor antagonists such as pindolol (Visken), nadolol (Corgard), and metoprolol (Lopressor) have been used successfully to treat aggressive behavior.

Lithium Lithium has been used to treat a number of different types of violent patients. In a double-blind trial lithium was effective in treating aggression in mentally retarded adult patients. The administration of lithium was the same as that for the management of bipolar I patients. Lithium has also been reported to be effective in patients with a brain syndrome and head injury; aggressive schizophrenic persons; nonpsychotic, aggressive prisoners and delinquents; and children with conduct disorders and attention-deficit/hyperactivity disorder.

Behavior Therapy Behavior therapy has been used in the management of violent behavior in severely impaired institutional populations. It may be used for patients with chronic schizophrenia or patients with mental retardation in conjunction with other treatment approaches. In setting up a behavior treatment program on an inpatient unit, the services of a trained, experienced behavior analyst should be obtained. The behavior analyst is responsible for planning the treatment program in conjunction with the interdisciplinary staff and training and supervising staff in the implementation of the treatment program. Behavior treatment programs should be reviewed periodically by persons other than the ward personnel to ensure their quality and ethical standards. In addition, the patient should be involved as much as possible in the formulation of the plan, and informed written consent should be obtained if the patient is competent to offer it.

Dynamic Psychotherapy Long-term psychotherapy can be effective for violent patients who are nonpsychotic and whose primary diagnosis is personality disorder or

intermittent explosive disorder. If spouse abuse is the problem, couples sessions may be indicated, provided the spouse's safety can be ensured. The first goal of therapy is to evaluate whether the patient is motivated, as in situations in which divorce or loss of a job is pending. Next, the patient must identify patterns of escalation in violence and learn to disengage at the early phase of escalation. The therapist should closely monitor transference and be prepared to deal promptly with negative thoughts or threats by the patient. Countertransference must also be monitored, because violence can evoke inappropriate feelings and reactions to patients. Psychotherapy should provide insight into why the patient feels compelled to use violence as a means of expression. Often such patients have difficulty expressing their feelings and resolving conflicts verbally. Issues common in the treatment of violent patients involve low self-esteem in terms of money, sex, and authority.

PREVENTION

Because antisocial behavior often begins during childhood, the clinician should focus on delinquency prevention. Any measures that improve the physical and mental health of socioeconomically disadvantaged children and their families are likely to reduce delinquency and violent crime. Because many recurrently violent persons have sustained many insults to the central nervous system, starting prenatally and continuing through childhood and adolescence, programs must be developed to educate parents about the dangers to their children of central nervous system injury, including the effects of psychoactive substances on the brain of the growing fetus. Public education regarding the releasing effect of alcohol on violent behaviors (not to mention its contribution to vehicular homicide) may also reduce crime.

Although people disagree about the contribution of violence in the media to violent crime, there is universal recognition that the media have propaganda potential. The extent to which the media, such as television, can be used to transmit positive social values has not yet been realized.

The most successful preventive measures within the field of medicine have come from community-wide public health programs (e.g., the campaign against smoking) and from programs that detect individual vulnerabilities (e.g., individual monitoring of blood pressure). Studies of adult antisocial behavior reveal the contribution of broad cultural factors and constellations of individual biopsychosocial vulnerabilities. Prevention programs must recognize and address both kinds of factors.

SUGGESTED CROSS-REFERENCES

Material relevant to adult antisocial behavior and criminality may be found in Chapter 2 on neuropsychiatry and behavioral neurology; Section 4.2 on sociology and psychiatry; Chapter 11 on substance-related disorders; Chapter 12 on schizophrenia; Chapter 14 on mood disorders; Chapter 24 on personality disorders; Chapter 40 on disruptive behavior disorders; and Section 54.1 on legal issues in psychiatry. Child and adolescent antisocial behavior is covered in Section 49.7.

27.4 BORDERLINE INTELLECTUAL FUNCTIONING AND ACADEMIC PROBLEM

JAMES J. MCGOUGH, M.D.

According to the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) borderline intellectual functioning and academic problem are conditions, which may require clinical attention, but are not in themselves mental disorders. They nonetheless contribute substantially to utilization of mental health services. Borderline intellectual functioning and academic problem are usually recognized while individuals are in school. They can occur concurrently with a psychiatric disorder and adversely affect response to treatment or overall functioning. In these instances clinicians may devote more attention than if the psychiatric condition presented alone. Global Assessment of Functioning or V code conditions are occasionally noted when an evaluation for psychiatric causes of dysfunction has not been performed. Borderline intellectual functioning and academic problem can also present independently of any psychiatric disorder.

BORDERLINE INTELLECTUAL FUNCTIONING

Definition DSM IV describes borderline intellectual functioning as follows:

> This category can be used when the focus of clinical attention is associated with borderline intellectual functioning, that is, an I.Q. in the 71-84 range. Differential diagnosis between Borderline Intellectual Functioning and Mental Retardation (an I.Q. of 70 or below) is especially difficult when the coexistence of certain mental disorders (e.g., schizophrenia) is involved. Coding note: This is coded on Axis II.

History and Comparative Nosology The 1959 edition of Classification in Mental Retardation defined anyone with an I.Q. greater than one standard deviation below the mean (I.Q. below 85) as mentally retarded. This definition was applied without regard to functional impairment, and many individuals who fell within this range had no discernible adaptive difficulties. The 1973 edition of *Classification in Mental Retardation* redefined mental retardation as an I.Q. greater than two standard deviations below the mean (70 or below) with associated impairments in adaptive functioning. This definition of mental retardation has been retained in subsequent editions and is adhered to in DSM-IV and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). An I.Q. between 71 and 84 was “declassified” as mentally disordered and redefined as borderline intellectual functioning. Because individuals within this I.Q. range often have little impairment outside of educational settings, the diagnosis is often overlooked after completion of school. The condition may continue to be a focus of clinical attention if it impacts social functioning, vocational adjustment, or compliance with medical management. Approximately 14 percent of the general population has an I.Q. within this range; borderline intellectual functioning is similarly named and defined in ICD-10.

Etiology Performance on intelligence tests is a function of genetic and environmental factors. Twin and adoption studies support hypotheses that genes contribute to intellectual level. Early developmental experiences including infection, injury, poor nutrition, and emotional deprivation can adversely affect I.Q. No clinical syndromes have been specifically linked to borderline intellectual functioning.

Diagnosis and Clinical Features Mild developmental delays, persistent social immaturity, or pervasive academic underperformance can suggest borderline intellectual functioning. A detailed history is obtained with particular focus on developmental milestones, language, peer relations, and academic achievement. In suspicious cases administration of a standardized intelligence measure, such as the Wechsler Intelligence Scale for Children–Third Edition (WISC–III) or the Wechsler Adult Intelligence Scale–Revised (WAIS–R), confirms or rules out the condition.

A 20-year-old woman was poorly compliant with her diabetes management and suffered significant medical complications from poor blood sugar control. Her parents were increasingly angered by her unwillingness to comply with her insulin regimen, diet, and other household rules. The patient had completed high school in a special education class for the learning disabled and planned to attend junior college. Early developmental milestones were reportedly normal, but her parents described her as socially immature. Psychiatric evaluation revealed no significant depression, anxiety, or psychosis. Testing with the WAIS–R demonstrated borderline intellectual functioning with a verbal I.Q. of 80, performance I.Q. of 78, and full-scale I.Q. of 79. Feedback to her parents enabled them to set more realistic expectations for their daughter's behavior. The patient maintained improved blood sugar control after implementation of a behavioral approach to her diet and insulin management.

A 15-year-old boy was evaluated for “acting out and aggressive behavior.” Attention-deficit/hyperactivity disorder and a reading disorder were diagnosed in second grade. Since age 13 he exhibited increased difficulty with fire setting, lying, stealing, truancy, and public intoxication. Sleep and appetite were stable, and he denied feelings of depression or other mood symptoms. Stimulant medication decreased his symptoms of hyperactivity, but the patient expressed little motivation for improvement. Psychiatric evaluation was consistent with “attention-deficit/hyperactivity disorder,” conduct disorder, and reading disorder. Testing on the WISC-III revealed borderline intellectual functioning with a verbal I.Q. of 79, performance I.Q. of 77, and full-scale I.Q. of 78. The patient was admitted to a residential treatment center but his prognosis was considered to be poor.

Treatment Treatment for individuals with borderline intellectual functioning is focused on optimizing academic achievement and the capacity for successful adaptive living. Individuals in this group can have significant difficulties with school, work, and social relationships; proper school and vocational placement is essential. Children are generally placed in small, self-contained classrooms for the learning-handicapped. Interventions are student-focused and individualized. School work should emphasize mastery of academic skills appropriate to the student's cognitive capacity. Development of functional skills and guidance in vocational training are essential and behavioral interventions, such as social skills training, may be particularly helpful. Comorbid psychiatric conditions should be treated as indicated with medication or therapy; family therapy serves to educate and establish appropriate behavioral expectations in the home.

ACADEMIC PROBLEM

Definition DSM-IV describes academic problem as follows:

> This category can be used when the focus of clinical attention is an academic problem that is not due to a mental disorder or, if due to a mental disorder, is sufficiently severe to warrant independent clinical attention. An example is a pattern of failing grades or of significant underachievement in a person with adequate intellectual capacity in the absence of a Learning or Communication Disorder or another mental disorder that would account for the problem.

Academic problem is similarly named and defined in ICD-10.

Etiology Academic problem can result from factors intrinsic or external to the student. Psychiatric conditions such as anxiety or mood disorders can impair learning or lead to performance decline. Attention-deficit/hyperactivity disorder, chronic illness, and identity problems can lead to demoralization in school studies apart from any diagnosable mental condition. Family difficulties, social stressors, cultural deprivation, or poor fit between a student and teacher's temperamental style can also adversely affect scholastic performance.

Diagnosis and Clinical Features Academic problem is evidenced by a pattern of academic underachievement or a decline from a previous level of functioning. A comprehensive biopsychosocial assessment is fundamental to identification of causal factors. Particular focus should be given to past academic functioning and family and social stressors; concurrent psychopathology must be ruled out. Intelligence tests, measures of academic achievement, or language evaluation may be useful in differentiating academic problem from specific learning or communication disorders. Review of the medical history and physical examination may be useful in

identifying general medical conditions such as hearing loss, poor vision, and chronic illness that may adversely impact academic performance.

A 17-year-old student who had been getting As and Bs was active on the school football team and had a steady girlfriend. His parents were pleased when he obtained a part-time job, but after 3 months the student was failing Math. Psychiatric evaluation uncovered no evidence of depression, adjustment disorder, or other psychiatric condition. Family assessment revealed a history of financial difficulties and strong imperatives to earn money. The student modified his work schedule and repeated Math in summer school; he went on to attend college without difficulty.

A 27-year-old woman was unmotivated to complete her doctoral dissertation. Evaluation identified no symptoms of psychiatric disorder. A period of therapy uncovered fears of becoming more educated than her parents. The patient worked through this conflict and was able to obtain her degree.

A 16-year-old high school sophomore with a long history of attention-deficit/hyperactivity disorder wished to obtain a GED. He was failing most classes in spite of having average intelligence. Evaluation demonstrated demoralization about academics, but no anhedonia or other psychiatric symptoms. He responded well to individual tutoring and parental incentives to remain in school.

A 14-year-old honors student developed anhedonia, concentration difficulties, sleep disturbance, and weight loss. She failed several classes and was increasingly behind in her school work. She enrolled in remedial course work subsequent to her response to treatment for depression.

Treatment Treatment is student focused and based on the causes of the academic problem. Classroom-based social skills training and cognitive-behavioral therapies have been found to be effective for underachieving students. Students suffering from “poor fit” with a particular teacher may require placement in a new classroom. Academic difficulties may require remedial course work or tutoring. Comorbid psychiatric conditions and psychosocial difficulties should be treated with medication or psychotherapy, as necessary.

SUGGESTED CROSS-REFERENCES

Mental retardation is discussed in Chapter 34. Learning disorders, motor skills disorders, and communication disorders are discussed in Chapter 35, Chapter 36, Chapter 37, respectively.

27.5 OTHER ADDITIONAL CONDITIONS THAT MAY BE A FOCUS OF CLINICAL ATTENTION

LEAH J. DICKSTEIN, M.D.

The fourth edition of the American Psychiatric Association *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) includes 13 conditions that are not considered true mental disorders but make up the category of additional conditions that may be a focus of clinical attention. Four of these conditions: (1) occupational problem, (2) religious or spiritual problem, (3) acculturation problem, and (4) phase of life problem are discussed in this section. The remaining 9 conditions are discussed elsewhere in this textbook: (5) noncompliance with treatment, (6) malingering, (7) adult antisocial behavior, (8) child or adolescent antisocial behavior, (9) borderline intellectual functioning (coded on Axis II), (10) age-related cognitive decline, (11) bereavement, (12) academic problem, and (13) identity problem. All except borderline intellectional functioning are coded on Axis I.

DEFINITION AND NOSOLOGY

These conditions are not considered mental disorders by DSM-IV criteria, but are related to the mental disorders in one of two ways: (1) The condition may be the focus of clinical attention, diagnosis, or treatment in the absence of a mental disorder; for example, a 90-year-old recent widower who always believed he was self-sufficient realizes after his wife's death that his physical stamina is diminishing and that he will have to move to an assisted living environment (phase of life problem). (2) The individual has been diagnosed with a mental disorder but the additional condition is unrelated to the mental disorder; for example, a 43-year-old woman with a history of specific phobia of ants finds she is unable to advance at work despite excellent ongoing periodic reviews because of gender bias (occupational problem).

When these additional conditions have led to contact with the mental health care system, the person should undergo a complete neuropsychiatric evaluation to rule out and not overlook a current additional psychiatric disorder or prodromal symptoms and signs of underlying psychiatric illness. Clearly, the distinction between an additional condition and a DSM-IV diagnosis is not always clear-cut.

OCCUPATIONAL PROBLEM

DSM-IV includes the following statement about occupational problem:

> This category can be used when the focus of clinical attention is an occupational problem that is not due to a mental disorder or, if it is due to a mental disorder, is sufficiently severe to warrant independent clinical attention. Examples include job dissatisfaction and uncertainty about career choices.

Occupational psychiatry and its expansion to include organizational psychiatry are specifically focused on the psychiatric aspects of work problems, including vocational maladjustment. Symptoms of employment dissatisfaction are varied and include blatant work errors, perceived and verbalized unhappiness and disinterest, absenteeism and tardiness, and passive-aggressive behaviors including accidents and uncooperativeness. Psychiatric symptoms include general signs of distress, anger, resentment about most work assignments, lack of confidence, and disinterest in carrying out agreed upon and expected work responsibilities.

Occupational problems often arise during stressful changes in work, namely, at initial entry into the work force or when making job changes within the same organization to a higher position because of good performance or to a parallel position because of corporate need. Distress occurs particularly if these changes are not sought and no preparatory training has taken place, as well as during layoffs and at retirement, especially if retirement is mandatory and the person is unprepared for this event. Work distress can result if initially agreed to conditions change to work overload or lack of challenge and opportunity to experience work satisfaction, if persons feel unable to fulfill conflicting expectations or feel that work conditions prevent accomplishing assignments because of lack of legitimate power, and finally if persons believe they work in a hierarchy with harsh and unreasonable superiors.

Work Choices and Changes Currently, most workers expect to change occupations at least several times during their lifetimes. Many who enter the workforce are initially unsure of their interests and potential. They often do not seek vocational counseling in high school and college and accept the first available work opportunity. Others feel parental pressures to enter certain occupations (e.g., a family business, trade, or profession).

Young adults without role models or guidance from families or those in their communities too often underestimate their lifetime potential abilities to learn a trade or earn a college degree. In addition, women and members of minority groups often feel less prepared to accept work challenges, fear rejection, and do not apply for jobs for which they are qualified. As part of initial interviews for evaluation of occupational problems, patients should be encouraged to consider their talents, long-held dreams and goals in regard to work, successes in work and school, and motivation to risk learning what they would find satisfying.

Clearly, occupational distress is inevitable following unprovoked job loss, rejection, and discrimination. Minorities and those in low-paying and low-skilled jobs too often have less job security. Downsizing, factory closings, and moves affect many, often leaving these workers feeling hopeless and helpless about future employment, on welfare, and angry.

With ongoing and often sudden downsizing of corporations and businesses, men and women continue to struggle with unexpected job loss and premature retirement, even when finances are not an issue. In addition, men, in particular, define themselves by their work roles, and thus experience more occupational distress from these changes. Women may adjust faster to retirement, but they often have less financial security than men (they earn 76 cents on the dollar for comparable work); have generally been in lower-status work positions; find themselves widowed more often than men; and are more likely to be caring for children, grandchildren, and elderly relatives. Women represent more of the single working parent group and the working poor.

Stress and the Workplace Workplace distress is implicated in at least 15 percent of occupational disability claims. Expected distress follows recognized and uncontrollable work changes: downsizing, mergers and acquisitions, work overload, and chronic physical strains, including work noise, temperature, and injuries and strain due to computer work. According to a study reported in the June 1998 issue of *Working Woman*, the top ten most stressful jobs in 1998 were (1) the U.S. president, (2) firefighter, (3) senior corporate executive, (4) race car driver, (5) taxi driver, (6) surgeon, (7) astronaut, (8) police officer, (9) football player, and (10) air traffic controller.

Work frustration can also arise from an individual worker's unrecognized (and therefore unresolved) psychodynamic issues such as working appropriately with superiors and not relating to one's supervisor as a parent figure. Other developmental issues include unresolved problems with competition, assertiveness, envy, fear of success, and inability to communicate verbally in a constructive manner.

> A 38-year-old white male has outbursts of anger when told to complete a day's tasks in a construction company. He complains to his union officer who, after investigating the worker's complaints, states that the work assignment is fair. The worker has never taken pride in completing assignments and has moved from company to company on average every 9 months since resigning from the military 6 years earlier because he tired of taking orders.

Often work conflicts reflect similar conflicts in the worker's personal life and referral for treatment, unless there is insight, is in order.

Suicide Risk Some occupations both attract persons with a high suicide risk and involve increased chronic distress that may lead to higher suicide rates. Included are

health professionals, financial service workers, and police, the first and latter groups because of easier access to lethal drugs and weapons.

Career Problems of Women Most women work outside the home out of necessity to support themselves, or their dependents (whether children or adults) or as part of a working couple. With the divorce rate remaining at the 50 percent level, many women find themselves economically poorer after a divorce than they were when married, while divorced men usually find their economic status improved. Despite three decades of increasing knowledge about, and concern for, women in the work site, unique gender issues, bias, and lack of accommodation to their life cycle needs continue when they are responsible for dependents. Women were the largest group establishing new small businesses in the past decade. Many have left large corporations where they were not valued for their efforts because of their gender, termed contra culture. Furthermore, women still experience problems when they are the sole woman in a “man's field.” Despite increasing recognition of the need for men in relationships with women to assume home/family responsibilities, less than 25 percent of men do so equitably.

Women continue to find work options limited particularly in leadership roles, because of gender bias, not because of lack of competence. A recent catalyst study revealed that women held 11 percent of director seats at 500 firms despite several decades of available, well-trained, and interested women candidates. Men and women with power (i.e., “men and women of good conscience”) must help competent women fairly attain deserved work opportunities. This process is called “taking down the impenetrable Lexan Ceiling together,” rather than women being unable to break through the supposed glass ceiling.

Women of childbearing and child-rearing ages continue to find themselves in conflict with job expectations, opportunities, and personal responsibilities. Good-quality, on-site dependent-care facilities with extended hours are rare and often out of range financially. Major unresolved work issues that are unique for women at certain life stages include flextime and paid and unpaid dependent leave options. Gender differences in attitudes toward work, life priorities, and definition of a good job persist and must be understood and respected. Furthermore, when men assume responsibilities for dependents they are applauded, while women in similar circumstances are often denigrated and passed over for deserved work opportunities. However, an increasing number of large and successful corporations highly rated as sensitive to women employees' personal responsibilities and needs are listed annually in *Working Woman* and other publications. Beyond dependent care issues, women in the workforce continue to experience distress following sexual harassment, despite its illegality and media attention. Increasingly more women have travel responsibilities, work long hours, work shifts beyond daylight hours, and are victims of personal violence. Work sites, hotels, streets, and travel must be made safer.

Among dual-career families and partners, the woman is more likely to move when the man chooses to move for a work opportunity than vice versa. Consequently, a woman's career is interrupted. Fortunately, there is less reluctance to have the two members of a relationship work for the same organization than previously, albeit usually in different departments. Work distress may also stem from continuous miscommunication, especially that based on gender. A growing and useful literature is focused on understanding gender issues in miscommunication at work. Educating women and men about this miscommunication as a major stressor can decrease work distress and improve work output and attitudes.

Working Teenagers With unemployment at an all-time low, many teenagers work part time while attending high school. Stress can arise because of less parent-teenager interaction and constructive parental control issues about use of earnings and time spent away from home and consequent behaviors both in and outside the home. When both parents or a single parent works outside the home as well as the teenager, verbal communication must be proactive and clear.

Working Within the Home Although most women with children must work outside the home, at times they may be home full time or part time or work at home. When their husbands or significant others work full time outside the home, problems may develop from each one's perceived expectations of the other. Women who care for children and their home exclusively and their partners may particularly see the woman as not only economically dependent and inferior, but not as competent and not understanding of the man's stressors and needs. Ongoing respectful listening and verbal communication must be encouraged.

Children must also be included as appropriate by age in contributing to the cooperative efforts in maintaining the home, however small their efforts may be. Furthermore, repeated studies have shown that people in organizations increasingly take work home as the work expectation increases. This work-at-home experience can and does interfere with personal lives and satisfaction, which can then have further repercussions at work.

Chronic Illness As medical treatments for chronic diseases improve, businesses have been increasingly concerned about accommodating to patients with acquired immune deficiency syndrome (AIDS), diabetes mellitus, and other disorders. The issue of mandatory testing for AIDS and substance abuse (alcohol and other illegal substances) continues to be of concern. Employee assistance programs, including general health and education, have proved timely and cost-effective.

Domestic Violence Although occurring in the home, signs and symptoms that interfere with work often trigger identification of domestic violence victims. All employees experiencing work distress must be questioned about domestic violence by trained professionals.

Loss of a Job Regardless of the reason for job loss, most people experience distress, including symptoms of normal grief, loss of self-esteem, anger and reactive depressive and anxiety symptoms, as well as somatic symptoms and possibly substance abuse and increased or onset of domestic violence. Timely education, support programs, and vocational guidance should be instituted.

RELIGIOUS OR SPIRITUAL PROBLEM

According to DSM-IV:

> This category can be used when the focus of clinical attention is a religious or spiritual problem. Examples include distressing experiences that involve loss or questioning of faith, problems associated with conversion to a new faith, or questioning other spiritual values which may not necessarily be related to an organized church or religious institution.

In an increasingly scientific world, religion or spirituality are often not acknowledged to be of major importance in people's lives. Furthermore, with ever-increasing commitments to work and other activities, together with high divorce rates and geographic distances between nuclear and extended family members, religious commitment and participation are often minimal, missing, or (with conversion) conflicted events. Faith may be lost or questioned at life-cycle crises or events, which may evolve into problems. Psychiatrists must enable and assist patients to distinguish religious thought or experience from psychopathology and, if this is a problem, encourage patients to work through it, independently or with assistance.

Religious imagery may be recognized in mental illness when persons state they believe they have been commanded by God to take a dangerous or grandiose action.

> A young professional woman finds herself in conflict when she decides to marry outside her family's religious affiliation, despite being well aware that her family has neither participated in religious activities nor spoke of religious beliefs in their home and family life. She seeks help to resolve her relationship with her family and decide on the possibilities and repercussions of her impending marriage to someone she loves and respects whose nuclear family is of another religious denomination.

Cults Cults appear to be less popular recently and less attractive to naive late adolescents and young adults seeking assistance in discovering who they are and unsuccessfully struggling to develop more mature relationships with parents. Cults are led by charismatic leaders, often out of control themselves, with inappropriate and often unethical values but purporting to offer acceptance and guidance to followers. Acceptance into the cult usually depends on complete adoption of a leader's belief system with no allowance for individual thinking and behavior. Cult members are strongly controlled and forced to dissolve allegiance to family and others to serve the cult leader's directives and personal needs. These young members often come from educated families who seek professional help in persuading their children to leave the cult and deprograming therapy to restore personal psychological stability to the former cult members. Deprograming and adjustment back into family, society, and an independent life is time intensive and long term, with resultant posttraumatic stress disorder.

ACCULTURATION PROBLEM

In DSM-IV the following statement about the acculturation problem appears:

> This category can be used when the focus of clinical attention is a problem involving adjustment to a different culture (e.g., following migration).

Culture Shock Major cultural change can evoke severe distress, termed culture shock. This condition arises when individuals suddenly find themselves in a new culture in which they feel completely alien. They may also feel conflict over which lifestyles to maintain, change, or adopt. Children and young adult immigrants often adapt more easily than middle-aged and elderly immigrants. They learn the new language more easily, and they continue to mature in the new culture, whereas those more senior have had more stability and unchanging routines in their former culture. Culture shock from immigration clearly differs from psychiatric patients' restless and continuous moving secondary to their illness.

Culture shock may occur within one's own country with geographical, school, and work changes such as joining the military, experiencing school busing, or moving across country or to a vastly different neighborhood or from a rural area to a metropolis. Reactive symptoms are understandable and include anxiety, depression, isolation, fear, and a sense of loss of identity as one adjusts. If the person is part of a family or group making this transition and the move is positive and planned, stress can be lower. Furthermore, if selected cultural mores can be safely maintained as persons integrate into the new culture, stress is also minimized.

The constant geographical moves because of work opportunities and necessity involve a large proportion of U.S. workers. Joining activities in the new community and actively trying to meet neighbors and coworkers can lessen the culture shock.

> A 29-year-old single woman moved because of a work promotion to southern California from Indiana. She joined a volunteer group working with inner-city children to share her musical talents, visited several churches, then joined one, and made concerted efforts to greet neighbors on her way to and from work.

Brainwashing First practiced on American prisoners during the Korean War by the Chinese Communists, *brainwashing* is the deliberate creation of culture shock. Victims are isolated, intimidated, and made to feel different and out of place to break their spirits and destroy their coping skills. Once the person appears mentally weak and helpless, new ideas that they would never have accepted in their normal state are imposed upon them by the aggressors. Like cult victims, upon release and return to their homes, brainwashing victims with posttraumatic stress disorder require deprograming treatment, including reeducation and ongoing supportive psychotherapy both on an individual and group basis. Treatment is usually long-term to rebuild healthy self-esteem and coping skills.

Prisoners of War and Torture Victims Prisoners who survive war or torture experiences survive because of personal inner strengths developed in their earlier lives beginning within their emotionally strong and caring families; if from troubled families, they may more likely have suicided. Prisoners must constantly cope with continued anxiety, fear, isolation from known lives, and complete loss of all control over their lives. Those who appear to cope best believe they must survive for a reason (e.g., to tell others what they experienced or to return to loved ones). Prisoners who cope best describe living simultaneously on two levels: coping in the here-and-now to survive the situation while maintaining constant mental connections to their past values and experiences and those important to them.

Beyond the surviving prisoner's personal difficulties, including posttraumatic stress disorder, if and when their survival behavior continues, it can affect their consequent families, with inordinate fear of police and strangers, overprotection and overburdening of children to replace those lost, lack of sharing of the past, continued isolation from their current communities, or inappropriate expressed anger. Another generation can thus be affected in their personal development and psychological functioning and may require psychiatric evaluation and treatment.

> A 72-year-old Jewish woman survivor of the Auschwitz Nazi concentration camp stated that as a 19-year-old married Hungarian who wanted to become a lawyer, she accepted the leadership of a women's barracks because she knew she could defend them as her father had helped the poor in their Hungarian city. She encouraged others to care for their bodies, share food and songs and stories at night, and maintain the hope they would survive to find some family and make a new life for themselves after the war. At liberation after the death march, she helped American soldiers translate, found her sister and husband, and built a new life, continuing her leadership in her new community at a hospital in Jerusalem.

PHASE OF LIFE PROBLEM

The DSM-IV description of phase of life problem includes the following:

> This category can be used when the focus of clinical attention is a problem associated with a particular developmental phase or some other life circumstance that is not due to a mental disorder or, if it is due to a mental disorder, is sufficiently severe to warrant independent clinical attention. Examples include problems associated with entering school, leaving parental control, starting a new career, and changes involved in marriage, divorce, and retirement.

Although on some level adults recognize that in the course of a lifetime, life events intrude on expected plans, unexpected, multiple, major negative occurrences, especially if they are chronic, overwhelm a person's ability to recover and function constructively. Common phase of life problems include relationship changes such as a changed significant personal relationship, job crises, and parenthood.

Because of sex role socialization and consequent cultural expectations, men appear externally better able to handle these phase of life problems, and women, the poor, and minority group members appear more vulnerable to negative experiences, perhaps because they feel less empowered psychologically. Major life changes precipitate distress in the form of anxiety and depressive symptoms, inability to express reactive emotions directly, and often difficulties in coping with life responsibilities.

Persons best able to cope with phase of life problems appear to be those with positive attitudes and mature defense mechanisms and coping styles, including basic trust in self and others, good verbal communication skills, a capacity for creative and positive thinking, and the ability to be flexible, reliable, and energetic with strong family and personal relationships. Furthermore, a capacity for sublimation, adequate financial and work status, solid values, and healthy feasible goals can enable people to face, accept, and deal realistically with life problems and changes.

SUGGESTED CROSS-REFERENCES

Cross-cultural psychiatry is discussed in Section 4.4. Section 25.9 covers stress and psychiatry. Noncompliance with treatment appears in Section 27.1, malingering in Section 27.2, adult antisocial behavior in Section 27.3, child or adolescent antisocial behavior in Section 49.7, and borderline intellectual functioning and academic problem in Section 27.4. Age-related cognitive decline is discussed in Section 51.2b on the physiological aspects of aging. Bereavement appears in Section 28.5 on death, dying, and bereavement. Section 49.10 covers identity problems and borderline disorders. Cults are discussed in Section 28.9.

CHAPTER 28. SPECIAL AREAS OF INTEREST

28.1 PRIMARY CARE AND PSYCHIATRY

MACK LIPKIN, JR., M.D.

In the 1990s primary care reemerged as the keystone of the mental health system in the United States. Primary care accounts for the most patients seen, drugs prescribed, hospital admissions, and cases of mental disorder treated.

Primary care is dominant in mental health delivery for complex reasons. Most of the general population first seeks and receives care for mental disorders at the office of the primary care physician. This is because people usually do not perceive of their own problems as mental illness and because most people prefer to avoid the personal and public stigma of seeing a psychiatrist. Of course, some do see their problems as mental and present initially to psychiatrists, but they are and will remain in the minority. Others, while recognizing they have depression or anxiety, nonetheless see their primary care doctor because they are more accessable than psychiatrists.

Primary care physicians are increasingly, although variably, trained to care for mental disorders and the psychological distress that accompanies normal development, crises, and disasters. They will increasingly care for straightforward mental problems as psychiatrists, fewer in number, focus on the sickest patients with difficult mental disorders. This will be even more true as behavioral health care gets carved out and carved up by managed care and medical corporation and easy access to psychiatrists becomes increasingly restricted.

Medical practitioners must cope with an exploding knowledge base, increased technologization, and unbridled bureaucratization—factors that have transformed and dehumanized the practice of medicine and surgery. As a result, patients and physicians face both classic and new problems in managing disease and illness. Their solutions require knowledge of the relationship of medicine and psychiatry, which integrates information and skills from not only biological but also psychological and social or systems approaches.

Psychiatry and medicine are even more inseparable than mind and body. New data increasingly demonstrate that the simple notion of single organ, single function (e.g., glands only produce hormones, nerves only transmit impulses, the brain is the site of mental disorder) no longer holds. For example, the nervous system functions not only for sensory processing, motor action, and thinking and feeling, but also as an endocrine organ and an immune organ. Every physical illness and symptom has psychological effects on the patient. Some physical illnesses for which patients seek or require medical care have psychological causes; in some severe cases, medical management makes no difference, so practitioners use psychological management. Other illnesses are related indirectly to psychological causes, psychological matters being one of several risk factors. Some psychiatric illnesses have clear physical substrates that require medical treatment.

Mental health problems represent a major and growing burden worldwide. Mental health problems account for almost 10 percent of lost years of quality life and an additional third is related to behaviorally determined illness. Depression is as significant a problem as hypertension. Substance abuse annually accounts for hundreds of billions of dollars in lost productivity and direct costs. At the same time, the mental health sector of health care is facing stagnant or diminishing resources. These burdens fall by default in the laps of primary care physicians.

The value and importance of the role of primary care in mental health care are reinforced by some (perhaps dominant) forces within modern psychiatry, which is increasingly medical and biological in approach. Modern psychiatry risks abandoning psychiatry's humanistic origins and skills to primary care. Even as new research methods show the great importance of personal development, life context, and an ecological approach to the whole person, psychiatric training and perspectives exhibit a new orthodoxy of rigid classification and scientific explanation.

The biological and reductionist views of disease as resulting from infection, toxins, genetic defects, or metabolic derangement are too narrow. Such pioneers as George Groddeck, Sigmund Freud, Franz Alexander, and George Engel, who postulated that the predisposition and timing of physical disease relate to psychological and social factors, are proving correct. Psychological factors are relevant in understanding why people get sick when they do, why the illness takes the form it does, and why some patients heal better than others. The primary contributions responsible for progress in this area have come from four research areas. Behavioral immunologists are demonstrating the behavioral conditioning of the immune response, diminished B-cell and T-cell immune function after stressful life events such as the loss of a spouse, and alteration of susceptibility to disease through specific social or psychological changes. The discovery of receptors for endogenous morphinelike substances in the brain has created an explosion of new neuropharmacophysiology. The theoretical synthesis of pain data has led to the concept of a cascade of neural gates from the individual spinal levels where sensory input occurs through higher midbrain and cortical levels. New epidemiological studies have shown that depression is an independent risk factor for death after myocardial infarction, for development of chronic disease, and for illness-seeking behavior.

DEFINITIONS

The definitions of primary care and psychiatry are formal and informal, denotative and connotative.

Primary Care Primary care is a set of approaches and functions, not a set of problems. It is often embedded in an ideology concerning the role and purpose of medicine as serving the patient and the population in a comprehensive and humanistic manner to improve both illness and disease care and health and personal well-being. Primary care can be provided by practitioners from many specialties but usually involves generalist physicians. The Institute of Medicine recently defined primary care as:

the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community.

What is new is the inclusion of integration of care by one clinician whose care is accessible, first contact, comprehensive, coordinated, and continuous in a sustained partnership. *Comprehensive* refers to inclusion of acute and chronic disease care, routine ongoing preventive care, psychiatric and psychosocial care, and referral (i.e., any problem at any stage of life). *Coordinated* refers to managing the complete problem list of the patient and serving as liaison between the various consultants and services for the patient. This includes providing quality control and help in understanding and decision making concerning what is going on and in some cases being a “gatekeeper,” monitoring access to specialist. The latter is an unpopular role for both parties. Advocacy for the patient is sometimes included as well. First contact means that a patient with a health problem first sees or calls the primary care physician. It is a necessary but not sufficient attribute of primary care practice (e.g., emergency medicine, a first-contact site, is an antipode of primary care).

A paramount attribute of primary care is that it is continuous, meaning that patient and doctor intend to stay in the relationship for several to many years. Because the average American moves every 3 to 4 years and the average doctor every 4 years, this relationship often stops for practical reasons. The most valuable feature of continuity is that each person gets to know the other and continues to learn and deepen the relationship. This permits the physician to interpret the patient's complaints accurately (“I am about to die” from a dramatic person with chest pain may be the equivalent of “nothing is really bothering me” from another more stoic person with exactly the same degree of ischemia). Continuity allows both to adapt to the other, which optimizes cooperation. This mutual adaptation makes possible the sustained partnership of a mature primary care relationship. Partnership also requires mutual respect and caring, the ability to negotiate, and an appropriate balance of power and decision making. Partnership and sharing of power are often absent in toto or in part in specialty care, including psychiatry. For example, although some psychodynamic therapists relate to their patients with respect, caring, and continuity, they seldom share power or decision making or negotiate. The average number of visits to a psychiatrist for a patient is four. Clearly, not all patients wish to make the major decisions, and not all doctors can allow their patients to

make decisions they disagree with without suffering and strenuous opposition.

Primary care theoreticians such as Ian McWhinney distinguish primary care from care of an episode of illness. Primary care focuses on patients in the context of their lives and ongoing health. It is a general, open-ended inquiry. Prevention is a priority, and helping the person is as important as managing the disease. These concepts are listed in Table 28.1-1.

Sustained partnership
Integrated
Accessible
Continuous
Comprehensive
Focused on the person rather than the episode of illness
Acute- and chronic-disease care
Preventive
First contact
Advocacy role
Care coordination role
Within context of family and community

Table 28.1-1 Definition and Functions of Primary Care

Several features of this definition pertain to mental health issues. In general, primary care doctors intend to care for most of a patient's problems, including the common mental disorders, especially those that present with physical symptoms, including depression, anxiety disorders, somatization, adjustment disorders, normal and abnormal grief reactions, substance abuse, and stress. A classification of the psychological and social issues seen in primary care is presented in Table 28.1-2. In dealing with these problems, primary care physicians to greater or lesser extents use talk therapies, psychotropic drugs, and therapies such as relaxation methods, meditation, and exercise. A complete empirical view of the extent to which primary care physicians use some or all of these methods is not available, but clearly they treat most patients with mental disorders and prescribe most psychotropic drugs. Primary care physicians refer when the diagnosis or effective response to therapy eludes them or specialized procedures or treatments are required.

Table 28.1-2 Classification of Psychological and Social Problems in Primary Health Care

Psychiatry The definition of psychiatry is both historical and functional. Formally, it is the branch of medicine concerned with diagnosis and treatment of mental disorders and related conditions. Societal attitudes about psychiatry and those of persons from other medical disciplines range from the respectful and worshipful to the magical and fearful. Unfortunately, in most parts of America and most world cultures, seeing a psychiatrist is stigmatized. People would usually rather see their own doctor, whom they trust and feel comfortable with, and neither have others know nor have to admit to themselves that they have a mental problem. Some cultures deny mental disorders to the extent that they lack words for craziness or depression (they are equally common in all major populations studied) or hide these issues in physical syndromes or euphemistic or vague terms, the equivalents of neurasthenia and anomie. This is even more true for problems that are not severe and those that are adjustments or adaptations to life and its crises and development.

The interface of primary care and psychiatry is complex and extensive. Darrell Regier has described the de facto mental health system in the United States in which 50 percent of persons with 1 of the 13 most common defined mental disorders are cared for in the primary care sector, and only about 20 percent are cared for in the mental health sector. In addition, there are more common cases in which presentations are somatized, disorders are “subsyndromal,” meaning they do not meet full criteria of the current classification.

The choices made concerning which sector of health care to use for mental-disorder–related problems are only beginning to be dispassionately studied. People with free care more often choose psychiatrists and use psychotropic drugs. Older patients, blacks, and less-educated people also use more psychotropic drugs but make fewer visits. Men use mental health specialists more, women use primary care generalists as often as they do psychological experts, and elderly persons most often see generalists. The reasons for these differences remain unknown.

The Epidemiologic Catchment Area (ECA) study and others reveal important relationships between mental health care and physical illness care. For patients with mental disorders, there is a twofold increase in the probability that they will visit a primary care physician. In fact, 58 percent of patients with mental disorders visit a generalist during any 6-month period. This author's own study found that patients visiting a mental health specialist had made 11 visits to a general internist in the previous year. In the subsequent year, they also made 11 visits, but in this case 7 of the visits were for mental health problems and 4 were for physical problems. The use of a mental health specialist did not decrease the number of visits, but the care was more appropriate. Because care was less technologically based, costs decreased.

Overall, 16 to 25 percent of all ambulatory visits in the sample of the ECA study were for a Diagnostic Interview Studies (DIS)–assessed disorder. An English study estimates that an additional 5 percent are for psychologically related or psychosomatic disorders. Although claims in the psychological literature suggest that up to 80 percent of medical visits are psychologically related, 15 to 20 percent seems relatively correct for those not in high-risk groups. For example, a comparison of surveys from developed countries shows a prevalence of psychosocial problems in primary care ranging from 4 to 32 percent of patients, with a mean of 16 percent. However, the prevalence of mental disorder and seeking care for psychological reasons goes up markedly in the lowest socioeconomic stratum and the physically ill.

INTERFACE BETWEEN PSYCHIATRY AND PRIMARY CARE

Certain conditions that are not experienced by patients as mental disorders such as somatization are especially problematic for both psychiatry and primary care. These conditions present as somatic signs or symptoms and are not perceived by the patient as mental. Thus, patients do not seek psychiatric care for them and they resist the suggestion they might be having a mental problem (“If one more doctor tells me it is all in my head I will scream!”). In other situations, somatic symptoms are masked expressions of mental disorders such as panic disorder and depressive disorder. Physical conditions (e.g., asthma, hypertension, and abdominal pain) or drug adverse effects or placebo response are precipitated, exacerbated, or extenuated by psychological considerations such as lack of social support, stress, personality style, or depression. Conversely, many medical disorders present as mental problems to psychiatrists.

Table 28.1-3 lists some of the most important situations in which primary care and psychiatry overlap and are likely to need each other's help.

Table 28.1-3 Examples of Common Interface Conditions Between Psychiatry and Primary Care

PSYCHIATRIC CONDITIONS WITH PHYSICAL CAUSE

Just as the internist who is presented with somatic complaints must consider the psychiatric or psychological causes, so must the mental health specialist or primary care practitioner consider physical causes when encountering a patient with psychiatric complaints (Table 28.1-4). Everything reasonable must be done to rule out the common physical causes of psychiatric illness. Every patient with a mood or psychotic disorder requires careful physical screening to be certain that the disorder is not based in correctable or ameliorable physical disease. When psychosis or a mood disorder is first recognized, patients must have a thorough medical evaluation by a physician aware of the disease entities that might be responsible.

Table 28.1-4 Medical Problems That Present With Psychiatric Symptoms

Mood disorders due to a general medical condition exhibit the full range of affective pathology. It is common after many viral illnesses to experience depression for days or weeks. These brief, self-limited illnesses may include suicidal ideation and vegetative signs, such as loss of appetite and libido and fatigue, which are transient and usually related to an obvious viral illness. The recently discussed chronic fatigue syndrome and Epstein-Barr virus (EBV) syndrome clearly exist in a few patients; but they are the latest examples of medicalization of adjustment disorders, depression, and somatization. A positive Epstein-Barr virus titre does not rule out a primary psychiatric problem.

Depressions related to endocrinopathies, such as hypothyroidism, may be much more extreme and dramatic; these conditions are the most often missed serious medical causes of depression. It is still possible to find patients with undiagnosed thyroid disease on the back wards of large psychiatric hospitals. Table 28.1-5 lists major categories and examples of medical conditions frequently associated with mood disorders.

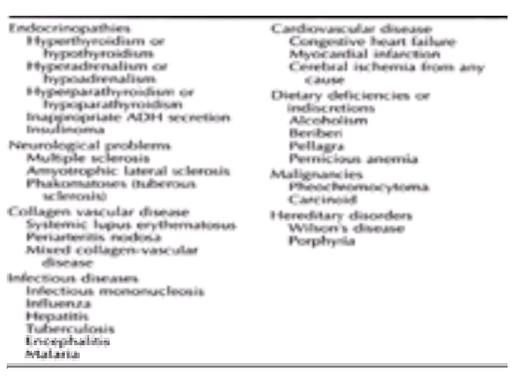

Table 28.1-5 Medical Conditions Associated With Mood Disorder

Among medications associated with the development of depression, propranolol hydrochloride (Inderal), one of the most commonly prescribed medications in the world, has an uncertain rate of adverse depressive effects but is often related to loss of libido and the development of impotence. The frequency of depression resulting from the other b-adrenergic receptor antagonists (beta-blockers) is uncertain. Many antihypertensive medications have clearer depressive effects, such as guanethidine (Esimil), reserpine and methyldopa (Aldomet). Hormones associated with depression may either cause depression directly or cause it on withdrawal. These hormones include adrenocortical steroids (cortisone and prednisone), estrogens and progestins (as in many birth control pills), and thyroid medications. Antiparkinsonian agents, including levodopa (Dopar), amantadine (Symmetrel), and bromocriptine (Parlodel), clearly cause depression. Equally, however, they allow expression of an already present depression, especially in recent-onset, severely incapacitated parkinsonian patients. The initial phases of prescription of these drugs are hazardous times, because suicide becomes physically possible for such patients. For example, one patient, upon being rescued from a decade of total immobilization in a hospital for the chronically ill, was able to leave the hospital and was driven home. One hour later, she got in her car and drove into a nearby lake. Withdrawal from stimulant drugs, such as amphetamines, cocaine, and methylphenidate (Ritalin), also may be associated with depression, as may withdrawal from adrenocorticosteroids such as cortisone and prednisone (Deltasone).

Many medical disorders are associated with psychotic states. Hyperparathyroidism and hypoparathyroidism, thyroid diseases, Cushing's and Addison's diseases, porphyria, and collagen vascular diseases, especially systemic lupus erythematosus and periarteritis nodosa, are among the most notable. Also important in this respect are seizure disorders (especially those involving the temporal lobes) and associated differential diagnostic entities, such as intracranial tumors and hemorrhage and atypical migraine. Posttraumatic conditions; sleep deprivation; the psychoses of neural degeneration, such as Alzheimer's and Pick's diseases, multiple sclerosis, and Huntington's disease; and any of the space-occupying and diffuse encephalitic conditions may be associated with, depression or psychoses. The number of conditions that can exhibit diffuse mental clouding, confusion, or delirium is enormous, but these states are less likely to be overlooked by the psychiatrist or mental health specialist because the mental status of the patient is clearly abnormal.

Drug-Related Psychosis Two main types of drugs are associated with the development of psychosis. One type is actually psychotogenic, causing frank psychosis that is related to the presence of a drug and associated with a clouded sensorium. In contrast, psychotomimetic drugs produce hallucinatory and other psychotic features while consciousness remains present and clear. Quinacrine (Atabrine) and related antimalarials may cause prolonged severe disorientation. Adrenocortical

steroids and adrenocorticotropic hormones are associated with euphoria, mania, and schizoaffective symptoms. When they are used in the treatment of systemic lupus erythematosus or other central nervous system (CNS) affecting collagen vascular diseases, the differentiation of steroid-induced psychotic disorder from CNS vasculitis challenges both psychiatric consultants and internists.

The most helpful approach is to attempt to establish baseline data that assess activity of the vasculitis process objectively. If possible, this attempt should be made premorbidly or when therapy with steroids begins rather than when the patient gets in trouble. This author has found it useful to compare the patient's electroencephalogram (EEG) findings with a baseline study; to measure complement concentration, consumption, and breakdown products; and to monitor the various antinuclear antibodies in the assessment of such cases. The psychotic collagen vascular patient often is too difficult to manage on a medical ward and requires the special services of psychiatric hospitalization. In these cases, continuity of care must be maintained by the internist or immunologist treating the vasculitis. Antipsychotic medication may be associated with a neuroleptic malignant syndrome with rapid onset of stupor, coma, delirium, mutism, rigidity, hypertension, tachycardia, and fever.

Endocrinopathies associated with psychosis include hypoparathyroidism and hyperparathyroidism and hypothyroidism and hyperthyroidism. Toxic agents are prominent offenders. Previously, mercury- and bromide-containing substances were important. Currently, those who inhale industrial hydrocarbons or abuse glue and cleaning fluids (especially adolescents) still present to emergency departments with psychoses. Many substances of abuse are associated with psychotic experiences, including all hallucinogens, (e.g., lysergic acid diethylamide [LSD] dimethyltryptamine [DMT]), phencyclidine, psilocybin, cocaine, and cannabis (marijuana). Alcohol withdrawal may result in alcohol withdrawal delirium (delirium tremens) usually easily detected because of the associated tremulousness, fever, and stigma of alcoholism. A delirium with hallucinations occurs with atropine- or belladonna-containing drugs and related compounds. When patients are taking antiparkinsonian medications, phenothiazines, or tricyclic drugs, belladonna-induced psychotic disorder may emerge. These medications also present a differential dilemma between psychosis that requires more medication and that produced by the drug itself. Here, the physical concomitants of atropinism, such as dry skin, mydriasis, tachycardia, urinary retention, and constipation, may be helpful.

The psychotomimetic drugs are associated with hallucinations, paranoia, restlessness, and altered associative processes without marked change of sensorium. They include amphetamines, LSD, cannabis, DMT, phencyclidine, and mescaline. Although any of these drugs may be suspected in adolescents with a substance abusing lifestyle, they may be missed in patients receiving these medications as part of another treatment. For example, amphetamine-like compounds are sometimes (needlessly) combined with bronchodilators in the treatment of asthma. Finally, antidepressants themselves may precipitate psychosis.

Substance Withdrawal Psychoses are associated with the withdrawal of some drugs; most prominent are the barbiturates, alcohol, and opioids. Treatment of these varied conditions requires specific knowledge of the condition or of the relevant pharmacology in the case of the substance-induced psychoses. Use of nonspecific antidotes in substance-induced psychoses may be fatal and should be avoided. Instead, creation of a supportive and reassuring environment, adequate monitoring of CNS depression and cardiorespiratory status, and time are often sufficient care. When a specific antidote is available, such as physostigmine (Antilirium) for anticholinergic-induced psychotic disorder or naloxone (Narcan) for opioid-induced psychotic disorder, it should be used.

DIFFERENCES IN THE EXPERIENCE OF MENTAL DISORDER IN PRIMARY CARE AND PSYCHIATRY

Several features distinguish the experience of the primary care physician from that of the psychiatric practitioner with respect to mental health. Most significant is that in choosing to see a psychiatrist patients must admit at some level that they have a psychiatric problem. Thus, mental health workers sometimes see persons at a higher level of awareness and acceptance. In contrast, patients can see their primary care doctor without acknowledging to themselves or the doctor that their problem is psychological. Thus, they may be less motivated, able, or willing to consider psychological explanations and treatments as relevant to their case and may strenuously reject such interpretations. While most mental health practitioners also describe problems of motivation and acceptance, these are strikingly more significant in primary care, where practitioners expect to work on these issues indirectly much of the time.

Psychological problems often present to primary care as physical complaints. Patients tend to bring all complaints to their primary care doctors initially and to focus primarily on physical complaints. Thus, of all the symptoms associated with a person's depression, the patient may highlight bodily distresses such as fatigue, impotence, or appetite or sleep change.

These considerations are especially salient with persons whose culture, religion, language, coping style, or personality are prone to deny psychological issues or to find them unacceptable, stigmatized, unsafe, or even taboo. For example, the Chinese culture lacks words for many common mental conditions and shuns discussion of negative affects. Many upper-class Anglo-Saxon communities also find such discussion distasteful. Many patients believe that if they are known to have a mental problem they will be teased or rejected and possibly lose their job or become unemployable. They fear that records are not confidential enough to prevent leakage of private information and resultant loss of privacy or insurance coverage.

Differences in Phenomenology Primary care doctors confront many psychological issues of adjustment or reaction that are not mental disorders, psychiatric illnesses, or signs of brain disease. Some of these relate to life-cycle stages—the birth of a child, puberty, adolescence, leaving home, having children, children leaving home, retirement, decline, senescence, and death—in the patient or others (e.g., death of spouse, the empty nest syndrome). Of course, mental health workers also deal with such problems, but perforce to a lesser extent.

Some common psychosocial problems presenting to primary care physicians are reactions to common events that are normal in populations of people but are experienced by the patient as unique, sometimes as disastrous (e.g., losing a job, developing a chronic illness, floods, war, or torture). Some are reactions to environmental problems such as floods or tidal waves, chronic violence, physical danger, or trauma to someone else. Here, the primary care physician is often in the best position to intervene before such issues evolve into full-fledged mental disorders (e.g., dissociative disorders, psychotic disorders, depressive disorder, posttraumatic stress disorder) or end in suicide. Recent data suggest that even 5 to 10 years after a major natural disaster, many patients still have significant depression, suicidality, or posttraumatic stress disorder.

At stressful times people develop physical symptoms, are more likely to get sick, and turn to their physicians for help. Most often, psychiatrists are not sought out in these situations because these persons do not regard themselves as mentally ill and the primary care doctor is more accessible. These conditions normally may have some anxious arousal, with symptoms of chest or abdominal pain, shortness of breath, agitation, sleeplessness or restlessness, among others.

The key to both diagnosis and treatment of defined mental disorders and psychological problems is the medical interview and the doctor-patient relationship that results. Extensive research has documented that in over 80 percent of diagnoses, the level of compliance, and patient and provider satisfaction are determined by the interview. Historically, deficiencies have existed in the teaching and monitoring of this core clinical skill. Most practicing doctors have never been observed doing a complete interview. Because how and what to teach is known and teaching is effective and durable, improving medical education in this area is a high priority.

Somatization Disorder Somatization disorder is a paradigm interface issue between the two disciplines. In this condition, patients experience psychological and social problems as physical symptoms and so seek medical care for them and resist psychological explanations for their problems. They are regularly told that their problem is mental and resent this suggestion, because they experience chest or back pain, shortness of breath, or similar symptoms. Patients with severe cases are high-stress, high-use, and high-frustration patients for both primary care physicians and those psychiatrists who do see them.

Somatization may be thought of as a transduction of psychological inputs into sensory ones, rather like synesthesia, in which sound may be experienced as smell or color (as is true for some musicians, e.g., in the blues). Such transductions occur in or accompany many mental disorders, particularly depression and anxiety. At least half of persons with major depressive disorder somatize, especially with fatigue, headache, and abdominal pain. By definition, persons with panic disorder have multiple symptoms such as shortness of breath, dizziness, chest pain or pressure, abdominal pain, and restlessness. More-disturbed persons (e.g., those with psychoses) have bizarre or distorted symptoms, so-called somatic delusions (e.g., “there is fire shooting out my ears.”).

Somatization is also a normal phenomenon in everyday life. Almost everyone does this in some ways at some times, often in culturally typical ways such as liver crisis *(crise du fois)* in France, heart symptoms in Germany, and abdominal pain *(agita)* in Italy. Somatization becomes a disorder when it leads the person to seek medical care and when it disrupts life or causes significant morbidity or disability. It is an enormous challenge for physicians because the symptoms that patients with somatization disorder experience are usually typical of other serious illnesses, and of course these patients get diseases related to physical pathology and die. One study suggested that of those diagnosed with somatization disorder about 25 percent eventually turn out to have demonstrable organic pathology in the affected system within 3 years:

Many disordered somatizers have related personality disorders, primary or secondary depression, or anxiety. Primary care doctors refer these patients to psychiatrists because they have ruled out organic problems, recognize obvious character and psychosocial pathology in the patient and the patient's illness-related behavior, or are at their wit's end. They find few psychiatrists even willing to see them in the first place and fewer who are willing to do more than rule out common mental disorders before returning the patient. Some providers get recruited in *splitting* (the behavior of some persons with character pathology to turn people they relate to against each other), in which the mental health provider accuses the primary care doctor of neglecting or failing the patient by not working up the patient's physical complaints. These patients are the best paradigm for the benefits of a team approach by mental health and primary care. When the primary care physician and the psychiatrist are working together, are physically near each other, and talk easily, the burden of these patients is lessened and splitting is less likely.

Adjustment Disorders If event or life cycle–related conditions are severe and do not resolve within a matter of weeks, they may be called adjustment disorders. These are named for the dominant psychological symptom (anxiety, depression), for example, adjustment disorder with anxious mood. If these persist for more than 6 months, they may be called chronic adjustment disorders. Some persons experience responses that do not resolve or that lead to activation or reactivation of a serious mental disorder. These are described, for example, as abnormal grief reaction (a frequent cause of somatization disorder) or adjustment disorder with depressed mood.

These conditions are more likely to be presented to the primary care physician than to a psychiatrist, but when they are severe, referral may be warranted or helpful. Making and managing such referrals must be done skillfully to avoid feelings of rejection, stigmatization, or both, and the no-show rates for such referrals are notoriously high. Here, again, physical proximity and even direct introduction of the patient to the mental health provider in the primary care physician's office or examination room can lessen losses to care. Effectively managing referrals to mental health also includes scheduling a visit back to oneself after the first visit to the mental health specialist, to emphasize that the referral is not a dismissal and to indicate an intention to participate actively in the ongoing care.

ADEQUACY OF PSYCHIATRIC TREATMENTS IN PRIMARY CARE

There is controversy about the adequacy of primary care treatment of mental disorders and of common psychological problems. Multiple data sets suggest that primary care physicians miss about 33 percent of major depressive disorder, over half of substance abuse, and at first pass, 90 percent of panic disorder. Giving the primary care doctor the results of simple screening devices used in advance of primary care visits, has little effect on the outcome of care or even in discussion of the detected problems.

Other studies suggest primary care physicians prescribe less medication, sometimes including substandard doses, for less time than do psychiatrists. This is taken as evidence of inadequate treatment. However, some data suggest that typical dosages (e.g., 150 mg of a tricyclic drug such as imipramine [Tofranil]) may not be needed in many, especially milder, cases. The cases primary care doctors miss are most often mild ones that often do not warrant drug treatment.

It is not surprising that mental disorder is missed in medical practice. One study showed that the average traditional internal medicine training program provides 2 hours a year of formal psychiatric education. Present-day primary care programs devote between 18 and 25 hours, and in some cases up to 80 hours a year, to training in psychosocial medicine. The general neglect of these issues persists despite initiatives of the American Board of Internal Medicine and other specialty boards mandating further training.

In parallel, some psychiatrists' care for primary care patients is variously criticized. Multiple studies suggest that much of the effect of psychiatric hospitalization is to increase medication use, invalidism, and time lost from work. Additional critiques have to do with a real or perceived lack of accessibility of psychiatrists. The primary care physician wants the psychiatrist to react and be helpful as soon as possible, not when there is an available opening. This is a significant cultural style issue-between the two disciplines. Psychiatrists maintain schedules and conditions of care that many patients and other doctors find impractical, which leads to patients dropping out of treatment or not making the visit. Psychiatrists, like many other types of practitioners, often find ways to eliminate from their practices the least attractive cases (e.g., unkempt, disruptive or manipulative persons) leaving the primary care system to cope with these taxing patients without backup.

Supportive Counseling in Primary Care The primary care physician facing a patient with a lifestyle or event-adjustment crisis normally uses an interview to elicit the nature and extent of the problem and then uses supportive counseling. The interview is the core tool of mental health care (Table 28.1-6). Much recent literature in primary care concerns the consensus that the interview can be conceptualized as having structures and functions. Each of the 14 structural elements (Table 28.1-7) and three functions (Table 28.1-8) is associated with specific behavioral skills that can be learned, improved, monitored, and taught.

Physician's Perspective	Patient's Perspective
Major medium of care	Major medium of care
Major time spent on interview	Major time spent on interview
Defines problem set	Defines helping set
Defines specific problems	Creates feeling of being understood
Provides context for understanding problems	Provides context for adapting to illness and understanding care
Establishes contract	Ensures goals are met
Medium of patient education	Learns how to care for self
Promotes compliance	Therapeutic alliance
Professional satisfaction	Health needs met: personally supported personal satisfaction
Interpersonal satisfaction	
Builds practice	Social needs facilitated
Facilitates healing	Comfort and cures

Table 28.1-6 Importance of the Medical Interview

Table 28.1-7 Structural Elements of the Medical Interview

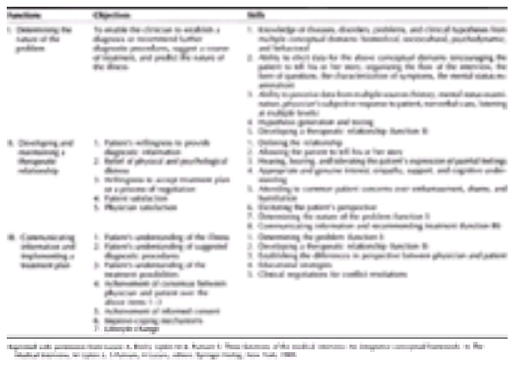

Table 28.1-8 Functions of the Medical Interview

The primary care physician in both developed and developing countries is faced with patients from a wide variety of cultural backgrounds because of differences in ethnicity, tribe, country of origin, language, and social class. It is often necessary to assess the patient's views of illness and healing to be effective in eliciting relevant information (it must be sought in culturally appropriate and sensitive ways) and in promoting patient adherence to agreed-upon plans. Arthur Kleinman has formulated a useful approach to elaborating a patient's health belief model, which is presented in Table 28.1-9 as a series of issues to consider and questions to use.

Prior illness episodes, especially of illnesses of standard severity (childbirth, renal stones, or surgery)
Cultural degree of stoicism
Cultural beliefs concerning the specific problem
Personal meaning or beliefs about the particular problem
Specific questions to ask to elicit the patient's explanatory model:
1. What do you call your problem? What name does it have?
2. What do you think caused your problem?
3. Why do you think it started when it did?
4. What does your sickness do to you? How does it work?
5. How severe is it? Will it have a short or long course?
6. What do you fear most about your sickness?
7. What are the chief problems that your sickness has caused for you?
8. What kind of treatment do you think you should receive? What are the most important results you hope to receive from treatment?
9. What have you done so far to treat your sickness?

Table 28.1-9 Assessment of Individual Illness Behavior in Becoming a Patient and Seeking Care

Normalizing the event and reaction is a first step. For example, at the loss of a spouse, one might say:

Your reactions are common. Many people feel the sorts of feelings you are having now and that feel so unique and terrible. And most people find that simply having the experiences, going ahead, and grieving, crying, or whatever works best for you, leads to gradually feeling better over weeks or months. It may take a year or two to feel yourself entirely again, and the special dates, anniversaries, birthdays, holidays, can be rough. You will never, of course, forget about your spouse, but over time the pain will lessen and the good memories will come to dominate.

Supportive counseling also involves such techniques as active listening, naming the feelings present (“sounds like you feel sad”), reflection, legitimization (“anyone who had been through that might feel as you do”), empathy (“I can really understand your pain”), and offers of support (“I will be here for you and go through this with you”). Often, the most useful act of the primary care doctor is to mobilize support, through family, neighbors, clergy, friends, employers, and nonmedical professionals such as social workers.

The primary care doctor may treat minor symptoms such as insomnia or anxiety with sedative hypnotics. Some believe that symptom-driven drug therapy interferes with the adjustment process, but such treatment is clearly indicated when the symptom interferes with vegetative functions (loss of sleep or more than transient loss of appetite), is incapacitating (“I can't do anything, I feel so agitated”), or extremely painful (Table 28.1-10).

Normalizing the feelings
Providing perspective
Suggesting a favorable resolution
Naming feelings
Reflection
Legitimization or validation
Expressing empathy
Expressing personal support
Mobilizing community and family support
Treating disruptive or damaging symptoms
Frequent visits

Table 28.1-10 Elements of Supportive Counseling

COLLABORATION OF PRIMARY CARE AND PSYCHIATRY

Psychiatry and primary care need effective partnership and mutual respect. The parallel sets of complaints highlight real problems on both sides of this critical interface. Although primary care doctors carry much of the mental health caseload in the nation, they do miss cases and often treat patients inadequately. They often find themselves in over their heads with nowhere to turn. Psychiatry as a discipline sometimes fails to care for nonremunerative patients, or to face dealing with the mental health of those in the ambulatory or medical hospital sectors. On the other side, managed care and other health insurance plans increasingly attempt to restrict direct access to psychiatrists, stipulate that care be given by social workers and psychologists, and limit the number of sessions with psychiatrists to as few as five. The two fields must cooperate. One way is to diminish the separation between the mental and the physical, so-called mind-body dualism, through mutual participation in training in both behavioral medicine and in primary care disciplines, at preclinical and clinical levels. A second technique is to have trainees at several stages of training (not just third-year clerkships) work on the other side of the fence. Of particular promise is having primary care residents do ambulatory consultations with mental health specialists and having psychiatry residents do real primary care training instead of the excessive inpatient medicine now typical.

Integrated Model of Education in Psychosocial Medicine The question of how to improve the recognition and treatment of mental disorders and psychological problems by primary care practitioners has been variously addressed. The American Academy on Physician and Patient has developed the most comprehensive approach. In this model, knowledge, skills, and attitudes are taught simultaneously, with a learner-centered style and a task orientation, in an attempt to change the behavior of the practitioner. The model has been shown to be effective and highly satisfying and to change behavior enduringly. Subjects taught have included the medical interview, communications skills, common aspects of psychiatry, somatization, pain, substance abuse, and teaching to teach, and the model has been used effectively with generalists and specialists.

Unfortunately, at this time most schools, residencies, care plans, and individual practitioners feel the time necessary to learn these complex matters is too great.

However, because missed cases generate needless testing, treatment, and iatrogenic harm, systems of care are increasingly interested in this area. For example, because each patient comorbid with depression who is hospitalized costs an additional $2500 in the ensuing year, medical care funders are interested. And because patients increasingly demand measurable effectiveness in meeting their needs, this will inevitably become a part of adequate primary care education.

Psychiatrists and Generalists Working Together What is not clear is how the various modern practice mixes of mental health and generalist practitioners will affect care outcomes and be accepted by patients. Funders want least-cost practitioners to care for mental disorders, but this is not popular with the public. Studies have suggested that having primary care and mental health practitioners physically in the same area improves referrals, outcomes, and patient and practitioner satisfaction. In one study, having selected patients alternate visits between primary care and psychiatry improved outcomes. When feedback is given concerning performance, when performance is tied to meaningful rewards, and when serious leadership attention is devoted to these issues, outcomes also improve.

There are practical and specific things to do to improve the effectiveness of individual collegial relationships between primary care and psychiatry. They boil down to good relationship skills and meticulous attention to the specifics, cultures, and feelings involved on each side. Some guidelines are outlined in Table 28.1-11.

Caring for the colleague
Cordial and polite demeanor
Intense and active initial listening
Developing a personal relationship
Taking the time to understand the other's world, preferably by training or spending time in it
Ascertaining the stated and implicit reasons for the contact
Negotiating differences
Agreeing on the mode(s) and frequency of contact
Avoiding use of jargon or insider talk
Agreeing on relative roles and responsibilities
Consulting on key decisions
Agreeing on who is to communicate what to whom (patient, family, staff)
Communicating in writing about consultations, discharges
Expressing gratitude for referral or consultation
Returning the favor of referral or consultation

Adapted from Lipkin M: Pulling together or falling apart. Prim Psychiatry, 4(1): 22, 1997.

Table 28.1-11 Guidelines for Effective Relationships Between Primary Care and Psychiatric Colleagues

When to Refer to Each Other One area in which specific guidelines may be helpful is when to call or involve someone from the complementary discipline (Table 28.1-12). Foremost, referral is warranted when the patient would benefit from partnership in the care. For primary care physicians, their ability to refer, their knowledge and skill levels, and their comfort with individual conditions each modify appropriate referral patterns. In general, referral is appropriate when the primary care doctor needs help. For psychiatrists, referral is always warranted when the patient does not have a primary care physician or when they need help with medical evaluation and treatment, especially when the patient may be somatizing.

From Primary Care to Psychiatry
When patient care would benefit from partnership
For therapeutically meaningful diagnostic uncertainty (e.g., is this patient psychotic or depressed?) but not for subtyping of depressions
When the patient does not get better on a full course of standard therapies
When the case is unduly complicated
When a specialized evaluation is needed (e.g., psychological testing)
When a specialized treatment is needed (e.g., antipsychotic medication initiation, desensitization therapy)
When the patient needs psychiatric hospitalization (e.g., decompensated, psychotic, suicidal)
From Psychiatry to Primary Care
When patient care would benefit from partnership
When the patient does not have a primary care doctor
When the patient needs a medical evaluation to complete the differential diagnosis
When the patient may have medical complications from the illness or treatment
To evaluate possible drug interactions
When the patient gets medically sick

Table 28.1-12 Referral Between Psychiatrists and Primary Care Physicians

The dominant mental health system is the primary care health system in all parts of the world including North America. This system has significant deficits in practitioner recognition and treatment of common mental disorders, psychological problems of the life cycle, and adjustment to life events including sickness and in interface areas such as somatization, psychophysiologic conditions, and stress-related disorders and complications. Remediation is possible and likely, given the existence of effective training models and social and health system imperatives that will demand more-effective care.

SUGGESTED CROSS-REFERENCES

Diagnosis, including signs and symptoms in psychiatry, is covered in Chapter 7. Clinical manifestations of psychiatric disorders is discussed in Chapter 8 and psychological factors affecting medical conditions are covered in Chapter 25. Other parts of Chapter 28 contain material related to primary care psychiatry such as chronic pain (Section 28.4), alternative medicine (Section 28.8), and death, dying and bereavement (Section 28.5).

28.2 PSYCHIATRY AND REPRODUCTIVE MEDICINE

SARAH L. BERGA, M.D., AND BARBARA L. PARRY, M.D.

Reproductive events and processes have psychological concomitants, but traditional medicine separates the treatment of reproductive events and psychological functioning and thus creates a problematic dichotomy between mind and body. This section addresses the effects of different reproductive events such as pregnancy, abortion, and menopause on endocrine and psychosocial functioning and highlights the bidirectional interaction between psyche and soma related to reproductive functioning. For instance, premenstrual syndrome—the mood, cognitive, and behavioral changes that occur in association with the menstrual cycle—exemplifies a somatopsychic disorder in which biological changes occurring in the soma trigger changes in psychological state. In contrast, hypothalamic or functional anovulation represents a psychosomatic illness that originates in the brain but alters somatic functioning. In keeping with a biopsychosocial model, key concepts about reproductive physiology are integrated into each section. The overall aim is to illustrate how the interaction between reproductive processes and psychosocial events manifests as psychiatric or gynecologic disorders.

REPRODUCTIVE DEVELOPMENT

Fetal and Neonatal Development The sex of an embryo is determined during the fertilization process. The normal chromosomal contribution of the oocyte (egg) is 23 (including an X chromosome), and the sperm contributes 23 (including an X or a Y chromosome). The translation of gonadal sex into phenotypic sex depends directly on the type and secretory activity of the gonad formed and on the responsiveness of target tissues in the developing fetus to gonadal products. The fetal testes begin to secrete testosterone and Muellerian-inhibiting substance (MIS) toward the end of the first trimester. If secretion is absent or compromised or if the fetal tissues are androgen insensitive, a spectrum of incomplete masculinization ensues. Also, excess androgen exposure at this time from maternal or fetal sources, such as occurs in fetal congenital adrenal hyperplasia, can partially masculinize a female fetus.

Sexual differentiation of the central nervous system (CNS) is believed to depend on the presence or absence of circulating levels of testosterone. The fetal testes begin to secrete testosterone in the late first trimester in response to placental human chorionic gonadotropin (hCG), while the fetal ovary does not. The organizational effects of testosterone on the developing CNS are thought to depend primarily upon in situ aromatization (the conversion of androgens to estrogens by the enzyme aromatase) of testosterone to estradiol. In contrast, estrogens from fetal or placental sources do not cross the blood-brain barrier and are not thought to imprint the developing CNS. Also, testosterone may bind directly (without conversion to estradiol) to androgen receptors in the CNS. The behavioral consequences that early exposure to testosterone has upon the developing brain are not clear, but brain areas with high aromatase activity (which thus can convert testosterone to estradiol) and androgen receptors in the nonhuman primate brain include the hypothalamus, amygdala, prefrontal visual, and somatosensory cortices. The asymmetry in exposure to testosterone also is present in early neonatal life. In late pregnancy, gonadotropin secretion is restrained by placental steroid production; when that restraint is lost at the time of birth, gonadotropin secretion rises dramatically in both sexes. In boys but not in girls, the gonadotropin rise is followed by an elevation of testosterone concentrations to adult levels. Thus, by 2 years of age, the brains and bodies of girls and boys have been exposed to dramatically different patterns of sex steroid secretion. The degree to which gender-related behavioral asymmetries are accounted for by those differences in hormone exposure is open to debate, but clearly a mechanism for inducing differences exists. In summary, the fetal sex steroid exposures exert primarily organizational effects upon the fetal CNS.

Puberty In humans, the postnatal gonadal hiatus involves the desynchronization of the hypothalamic gonadotropin-releasing hormone (GnRH) pulse generator by undetermined central mechanisms that are largely gonad independent. Puberty, the postnatal resumption of gonadal activity, is also a centrally initiated process that depends on synchronization of the pulsatile release of hypothalamic GnRH. GnRH neurons are endogenously pulsatile and active during fetal and neonatal life. In experimental conditions with primates, the entire pubertal process can be initiated and completed simply by providing exogenous pulses of GnRH or by stimulating the dormant GnRH neurons with excitatory amino acids. While prenatal exposure to sex steroids has organizational effects upon the developing brain, the reinitiation of gonadal activity during puberty is viewed as exerting activational influences upon the brain and behavior.

Gender The phenotypic sex of an individual depends upon chromosomal sex and on exposure and responsiveness of tissues to endogenous and exogenous sex steroids, but *gender* refers to the self-image and sex-role identity of that person. Gender is determined not only by exposure and responsiveness to sex steroids, but also by expectations and behavioral patterns that are learned in early childhood from parental, familial, and societal models. Gender develops across the life cycle in response to psychological and biological life events. Notions of gender direct marital, career, and other behavioral choices and may depart from biological options.

> A woman with *Muellerian agenesis* has ovaries but no uterus and vagina. Her childbearing and sexual options are constrained biologically, yet her sense of gender-appropriate behavior may drive her to pursue a heterosexual relationship and motherhood via surgical and technological advances.

Although gender is influenced by cultural expectations, each individual understands and responds to those expectations differently. To safeguard gender development, psychiatrists and psychologists must understand the medical and technological options available to individuals with disorders that alter phenotypic sexual development, while pediatricians, internists, and gynecologists must be mindful of the psychological effects of those disorders. Honesty is important, but physicians must convey information in a sensitive fashion. The clinical objective is to maintain a flexible mind-set to facilitate and support appropriate developmental choices.

Disorders of sexual development in phenotypic girls generally present at birth or at the time of expected puberty. *Adrenogenital syndrome* can be caused by congenital adrenal hyperplasia in female fetuses; the fetal adrenal secretes excess androgens, which then masculinize the external genitalia and possibly the brain. In female infants, the masculinized genitalia usually are recognized in the delivery room. Surgery to reduce clitoral size and create or widen the vaginal introitus may be necessary at a later date to restore the external appearance. However, the internal reproductive tract is normal and puberty generally occurs around the expected time if adrenal replacement therapy is adequate. Despite medical and surgical interventions, concerns over capacity for sexual function may emerge, particularly in late adolescence or young adulthood.

Turner's syndrome (XO gonadal dysgenesis) may be recognized at birth because of the associated physical stigmata, while XX gonadal dysgenesis usually presents at puberty. From a reproductive perspective, the two conditions are similar in that the ovaries do not contain responsive oocytes due to premature atresia of oocytes or failure of germ cell migration. Donor oocytes allow the option of pregnancy.

Other disorders of sexual development include *testicular feminization* and its variants; the gonads in that condition are testes, but the fetus is phenotypically female because a defect in the androgen receptor confers androgen insensitivity. Because the testes are normal, they secrete (MIS) and *Muellerian regression* occurs (regression of the anlage that would develop into the uterus and tubes). The vagina ends blindly, and the presenting complaint is usually primary amenorrhea. *Thelarche* (onset of breast development) occurs at the normal time because at puberty the testes secrete testosterone, which then is aromatized to estradiol that stimulates the growth of breast tissue. *Orchiectomy* (removal of the testes) is recommended after puberty to avoid the risk of gonadoblastoma, unless there is partial androgen sensitivity, in which case it is performed earlier to prevent the pubertal development of hirsutism and partial masculinization.

There are many types of androgen receptor defects and spectrum of clinical presentations. Some persons look phenotypically like men and may present with infertility secondary to azoospermia or oligospermia. A related disorder occurs when there is an inefficiency of the enzyme 5-a-reductase, which converts testosterone to dihydrotestosterone (DHT); DHT in turn masculinizes the external genitalia. Boys with a deficiency of that enzyme may look phenotypically female or incompletely masculinized at birth. At puberty, further masculinization, including phallic enlargement, may develop as the increased testicular secretion of testosterone partially

overcomes the enzyme deficiency and more dihydrotestosterone is made. Fertility is preserved in this condition, so it is prudent to rear the child as a male if possible. Neonatal treatment with dihydrotestosterone may help to masculinize the external genitalia.

XY gonadal dysgenesis is caused by a streak gonad that fails to secrete testosterone and MIS; generally the uterus, tubes, and vagina are present. This condition is detected when thelarche and menarche do not occur. A karyotype can confirm the XY chromosomal status. Because the gonads are inactive hormonally, they should be removed before puberty to avoid the risk of malignant degeneration. Exogenous hormone replacement is required to stimulate puberty and cause the development of secondary sexual characteristics. If donor oocytes are available, pregnancy is possible following in vitro fertilization and embryo transfer. Telling a young adolescent and her parents about the diagnosis can be difficult, but it is best to be honest, particularly since surgery will be required to remove the gonads.

A clinician who deals with patients with disorders of sexual development must have a clear understanding of the basic physiology of sexual differentiation, including that of the brain, as well as a sensitive perspective on the interactions among gender, sexuality, and reproductive capacity.

Early Sexuality The behavior of children can be understood by acknowledging the sexual motivations that, until Sigmund Freud's time, had been assumed to be quiescent until adolescence. The fact that incest, sexual abuse, and other sexual taboos that may occur in childhood have powerful after effects, even in adult life, bespeaks the importance of childhood sexuality in establishing healthy relationships.

In puberty, the overriding influence on sexuality is the dramatic change in the hypothalamic-pituitary-gonadal axis that occurs in both males and females at that time. Major hormonal changes, combined with the issue of identity diffusion, contribute to the characteristic tension in relationships, particularly between male and female peers and between adolescents and their parents.

In adulthood, one of the major indicators of maturity is the capacity to establish healthy sexual relationships. When in harmonious relationship to other components of the self and to others, sexuality is an integral component of the adult character.

Adolescence Carol Gilligan has noted in her longitudinal studies of girls before and during adolescence that there appears to be a marked decline in self-esteem occurring after puberty. Preadolescent girls exhibit a sense of self-confidence and a belief that they can influence the course of events in their lives. During adolescence, however, that self-esteem and belief in their own efficacy appears to diminish. Adolescent girls generally express less confidence in their abilities to change the world around them, accompanied by a sense of intimidation and passiveness. Indeed sex differences in depression, with female predominance, first appear at adolescence. Before then, boys are more vulnerable than girls to both medical and psychiatric illnesses.

One theory to account for this change in vulnerability to depressive illness in girls is the major hormonal changes in the reproductive neuroendocrine axis at puberty. Others have speculated that the increase in testosterone in males and the attendant aggressiveness, often directed at girls, contribute to girls' change in behavior. A large proportion of self-esteem in girls tends to be based on a sense of fulfillment in relationships, whereas self-esteem in boys generally is largely attributable to a sense of achievement in work, activities, and sports. Therefore, changes in relationships between the sexes during adolescence may affect girls and boys differently and have different consequences for their mental health. The need in boys for dominance in relationships, precipitated by surges in testosterone at puberty, may contribute to, and be a prerequisite for, a sense of self-esteem and self-worth. In contrast, passivity in girls relative to this dominance in boys may be required to maintain the relationship, which is girls' major source of self-esteem. Thus, changes in the reproductive neuroendocrine axis in girls and boys at puberty may set the stage for alterations in the power balance of relationships, which may affect the person's sense of self, self-esteem, and mental health. Interestingly, in a study of hormone replacement given to adolescent boys and girls with delayed puberty, testosterone precipitated aggression in boys while estrogen provoked aggression in girls. This study suggests that estrogen per se is unlikely to be the cause of the increased depression and loss of self-esteem observed in adolescent girls.

MENSTRUAL CYCLES

Menstrual Physiology Menstrual cyclicity results directly from ovarian cyclicity. Ovarian cyclicity starts each cycle with the development of a group or cohort of follicles, one of which becomes dominant. The follicles are composed of an oocyte surrounded by granulosa cells, which, in turn, are surrounded by theca cells.

As shown at the top of Fig. 28.2-1, follicular development is initiated by the hypothalamic release of GnRH at a pulse frequency of about once every 90 minutes. GnRH stimulates the release of the pituitary gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In turn, LH stimulates ovarian theca cells to synthesize and secrete androgens; FSH induces granulosa cell development, including the enzyme aromatase, which converts the thecally produced androgens to estrogens. In the presence of a constant GnRH pulse frequency of one pulse each 90 minutes, the secretion of LH and FSH will be regulated primarily by estradiol feedback at the level of the pituitary. Rising estradiol concentrations suppress FSH, thereby limiting the number of follicles that will develop mature oocytes.

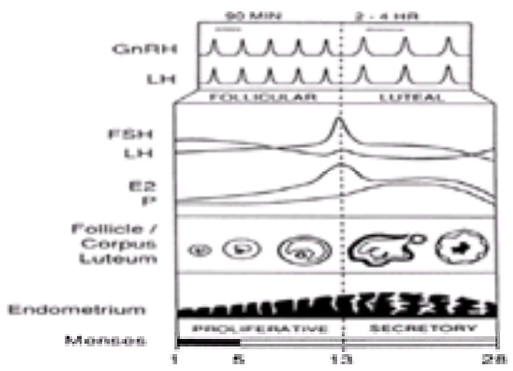

FIGURE 28.2-1 Schematization of the human menstrual cycle.

As illustrated in the middle panel of Figure 28.2-1, when estradiol concentrations exceed a critical threshold and remain elevated for at least 36 hours, which is the pattern one fully mature follicle produces, an LH surge is triggered, and ovulation ensues approximately 36 hours later. Thereafter, granulosa cells transform into progesterone-secreting luteal cells, and the ovulated follicle then is referred to as the corpus luteum.

The levels of LH, FSH, estradiol, and progesterone throughout the menstrual cycle and corresponding follicular events are schematized in the middle panels of Figure 28.2-1. The target tissues for ovarian steroids include the endometrium, whose developmental sequence is illustrated along the bottom right panel, and the hypothalamic GnRH pulse generator, whose frequency, as indicated in the top right panel, is slowed dramatically by the combination of estrogen and progesterone secreted during the postovulatory or luteal phase of the menstrual cycle. This inhibition of GnRH is followed by decreased secretion of LH and FSH, so that new follicular development is prevented until the corpus luteum regresses. As progesterone concentrations decline, GnRH pulsatility increases, and gonadotropin, especially FSH, secretion rises. The phases of the menstrual cycle can be termed follicular and luteal in reference to ovarian events or proliferative and secretory in reference to endometrial events.

It is generally assumed that regular menstrual cyclicity at intervals of 25 to 40 days signals ovarian cyclicity and ovulation, but as illustrated in Figure 28.2-2, that assumption is erroneous. A normal luteal phase has a length of more than 11 days and midluteal concentrations of progesterone secretion that exceed 10 ng/mL (30 nmol/L). The woman whose hormonal levels across a menstrual cycle are depicted in the bottom two panels of Figure 28.2-2 had a 39-day cycle. However, this cycle had a luteal phase whose adequacy with a length of 16 days and a peak progesterone concentration of 19.1 ng/mL cannot be doubted. In contrast, the woman whose hormonal concentrations are shown in the top two panels had an overall cycle length of 25 days. Although her estradiol levels rose to almost 300 pg/mL, the elevation in estradiol and LH was not followed by a rise in progesterone secretion. Thus, she had bleeding when her estradiol concentration fell, but the cycle was anovulatory.

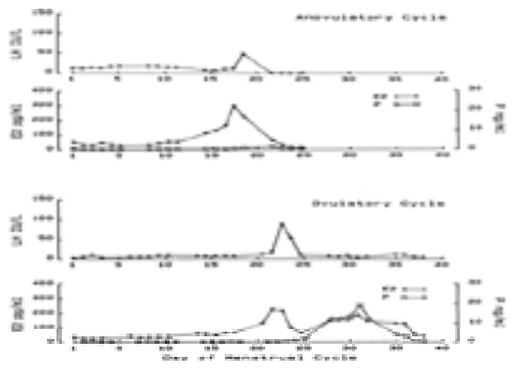

FIGURE 28.2-2 Daily concentrations of luteinizing hormone (LH), estradiol (E_2), and progesterone (P) obtained in two women from the onset of one episode of menstrual bleeding to the next. (By Tammy L. Daniels from original data.)

As these examples demonstrate, menses and menstrual cycle interval cannot be used to determine if a woman is or is not ovulatory or if the luteal phase was normal. The clinician who is linking a psychological state to a reproductive event must know how to determine the presence or absence of gonadal activity. Ovarian activity can be estimated by determining weekly estradiol and progesterone concentrations from the onset of one episode of menstrual bleeding to the next. Testicular activity can be estimated from one or two random determinations of testosterone. These assessments may not detect subtle compromise of gonadal function that may impair fertility, however, and further consultation with an appropriate specialist may be needed. Menstrual cycles can be expected to become more regular with advancing gynecological age (time since first menses) and, in the absence of pathology, generally remain regular until 5 to 10 years before menopause. During the perimenopausal years, ovarian function is characterized by higher estradiol and lower progesterone secretion. Ovarian function does not gradually decline but rather becomes erratic and unpredictable, with the potential for exposing the brain and soma to large fluctuations in hormone concentrations.

Premenstrual Syndrome Premenstrual syndrome (PMS), termed *premenstrual dysphoric disorder* in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), is a somatopsychic illness triggered by the expected excursions in sex steroids that accompany an ovulatory menstrual cycle. These somatic changes disturb psychological functioning in predisposed women. In contrast, functional hypothalamic anovulation arises in the psyche and affects the soma. In PMS, menstrual cycles are hormonally normal and the soma is preserved at the expense of the psyche. However, in a species that from an evolutionary perspective is accustomed to periodic pregnancy and lactation, there may be unappreciated physical and emotional consequences of incessant ovulation with attendant hormonal periodicity on the CNS that may place women with predisposing inherent vulnerabilities at high risk for mood disorders.

Functional Hypothalamic Anovulation Functional hypothalamic anovulation or amenorrhea (FHA) is a consequence of a nonorganic reduction in GnRH secretion that results in reduced pituitary secretion of gonadotropins and subsequent anovulation. Previously referred to as idiopathic or psychogenic amenorrhea in the psychiatric literature, FHA is a diagnosis of exclusion. That implies that the ovaries are capable of responding to appropriate gonadotropin input of either endogenous or exogenous origin; that there are no structural abnormalities of the thyroid, adrenal, pituitary, or brain; that the use of drugs, including antipsychotic medications, does not account for the suppression of GnRH; and that the patient is not pregnant. Neuroimaging may be needed to establish that there are no significant anatomical lesions of the brain or pituitary. Two major questions concerning the pathogenesis of FHA remain unresolved. First, the peripheral and central signals that disrupt GnRH pulsatility are poorly understood. Second, how do behavioral, cognitive, and personality variables activate the neural systems to disrupt GnRH secretion. Physicians and patients alike wonder what lifestyle variables provoke or contribute to this type of ovulatory dysfunction and what pharmacological and nonpharmacological treatment interventions should be considered.

The concept that psychogenic stress can induce reproductive dysfunction in women was formally introduced in 1946. The best biochemical evidence in support of the concept that stress impairs GnRH release in women with functional hypothalamic amenorrhea is the consistent demonstration that the activity of the hypothalamic-pituitary-adrenal axis is increased. Further, a prospective study found that young American women who developed transient amenorrhea while studying in Israel had higher urinary cortisol concentrations upon arrival than those whose menses remained regular.

There appears to be a dose-response relationship between the type, severity, and number of stresses on one hand and the proportion of women who develop anovulation on the other hand. Biological and psychological predispositions may confer resistance or sensitivity to various stressors. Exercise, low weight and weight loss, affective and eating disorders, various personality characteristics such as perfectionism and unrealistic expectations, drug use, and a variety of external and intrapersonal stresses have been linked to the development of anovulation. Most women with FHA, when carefully evaluated, display more than one of these traits or behaviors. Recent evidence suggests synergism between metabolic stressors, such as excessive exercise and nutritional restriction, that suppress the hypothalamic-pituitary-thyroidal axis and psychosocial challenges that activate the hypothalamic-pituitary-adrenal axis.

Recovery is possible if women with FHA develop response patterns to ongoing psychosocial demands that are less likely to activate the central and metabolic processes that disrupt pulsatile GnRH release. The current standard of practice other than observation is to offer pharmacological interventions such as oral contraceptives or hormonal replacement if fertility is not desired and pharmacological ovulation induction if fertility is sought. However, pharmacological intervention alone does not lead to spontaneous recovery and cannot be expected to ameliorate stress-induced alterations in central neurotransmission and hypothalamic function or to reverse ongoing metabolic derangements secondary to exercise or weight loss. For instance, bone accretion does not proceed apace, even if exogenous hormone replacement is given in supraphysiological doses, in the face of metabolic compromise. Although women with FHA frequently do not meet DSM-IV criteria for eating disorders or depressive disorders, all of these states are characterized by increased cortisol secretion, which alone can alter thyroid hormone secretion and action and induce metabolic adjustments. Thus, it is not surprising to find that women with amenorrhea due to decreased GnRH drive, regardless of cause, have lower bone mineral density. Further, pharmacological intervention alone may mask recognition of psychological dysfunction and forestall the development of more-effective response patterns. Also, ovulation induction may place low-weight women with functional hypothalamic amenorrhea who conceive at risk for premature labor and intrauterine growth retardation. If the parenting skills of women with the disorder are impaired by ongoing stress, their children may be at risk for poor psychosocial development. Clearly, treatment strategies need to consider that stress and mild psychological dysfunction can play an important role in the genesis of this form of anovulation. If an eating disorder is recognized, specialized psychiatric treatment is indicated.

Psychobiological characteristics can predispose a woman to chronic activation of central neural processes in response to commonplace events. Global hypothalamic dysfunction, including inhibition of GnRH pulsatility, can result. While identifying the neuromodulators that mediate the development and maintenance of the disruption of GnRH is of academic interest, clinicians must make sure that all other possible causes of anovulation and amenorrhea have been excluded before recommending psychological, psychiatric, or behavioral interventions.

FERTILITY AND INFERTILITY

Gametogenesis *Gametogenesis*, the production of oocytes and sperm, occurs as a result of puberty. Gametogenesis is the minimum physiological requirement for fertility. In women, the ovary must have oocytes that respond appropriately to gonadotropin input with the maturation of an oocyte that is ovulated. In men, the testes must be able to manufacture normal sperm capable of penetrating the layer of granulosa cells surrounding the oocyte and then fusing with the outer oocyte cell wall, the zona pellucida. The fallopian tube also must be capable of oocyte capture, and the density of sperm in the fallopian tube must be such that there is juxtaposition of sperm and oocyte. Thereafter, the tube must be capable of timely transfer of the fertilized oocyte or zygote to the primed endometrium of the uterus. Implantation must occur, and normal fetal development must ensue for the pregnancy to continue. In the absence of medical intervention, the customary manner in which ovulated oocytes are fertilized is via coitus or sexual intercourse.

Human Sexual Response It has been said that the most important sexual organ is the brain. This truism is meant to emphasize the essential role of desire and comfort in mediating sexual awareness and expression. Brain centers mediate libido in a general way. Other brain centers influence the selection of sexual partners and the circumstances under which sexual longings are expressed. Hormones such as estrogens and androgens made by the ovaries and testes bind in certain brain centers and increase sexual interest. Whether and how this sexual interest gets expressed as behavior depends upon a number of factors, including general health and well-being, the availability of a partner, a sense of what is appropriate, and prioritization of this interest above other interests and obligations. One of the major aims of social and cultural institutions is to channel or direct sexual interest in a manner that minimizes negative outcomes such as sexually transmitted diseases while ensuring that children will be born and prosper. Sexual interest can be inhibited by any number of negative emotions, including anger, fear, worry, and dislike,

and by a marked decline in health or hormones. Just like other personality factors, sexual interest or libido has a spectrum, with some people having more and others less. *Sexuality* is the term used to refer to a person's gender identity, feelings, sexual orientation, and attitudes, and it is distinct from the expression of sexuality and sexual behavior.

The human sexual response has been described as a cycle with four stages: excitement, plateau, orgasm, and resolution. The sexual response cycle is not simply a mechanical chain of events, however; it involves specific biological responses to psychological and sensory inputs. Thus the transition from one stage of the human sexual response to another is not automatic even if it is stereotypical. The human sexual response also depends on important biological events. First, there must be vasocongestion, a process in which an increased amount of blood concentrates in the tissues of the genitals and female breasts. Second, muscle tone must increase. For these two processes to take place, the nervous system must function appropriately and there can be no significant peripheral nerve impairments. If these biological processes cannot take place because of injury or illness, a person may have sexual feelings, but these feelings may not lead to a classical sexual response, such as vaginal lubrication or full penile erection.

Vaginal lubrication in women and penile erection in men are the most noticeable signs of the excitement phase. In women, this phase also involves internal vaginal expansion and nipple erection. In the plateau phase, the outer portion of the vagina swells, and the external aspects of the female genitalia, the labia, thicken and change to a darker color because of vasocongestion. In men, the testes increase in size and are pulled up against the body. A rash called a “sex flush” may develop on the upper torso. In both sexes, orgasm involves a series of muscular contractions that then diminish in intensity and rapidity. In women, there are muscular contractions of the outer portion of the vagina, the uterus, and the anal sphincter. In men, orgasm begins with contractions in the prostate and seminal vesicles, which cause ejaculation. During the resolution phase, the changes reverse to an unaroused state. Men, but not women, have a refractory period after orgasm in which ejaculation and orgasm cannot occur. In women, the orgasmic response is the same, regardless of whether there is manual stimulation of the clitoris or penile insertion, although the tempo of the sexual response may vary depending on the type of stimulation.

Aging may be associated with changes in sexuality. While sexual interest declines to some degree with aging, older men and women who live together are more sexually active than those who are not in a relationship. Because women tend to live longer than men, many elderly women will be without partners and will have limited opportunities for sexual expression, even if sexual drive is present. In men, significant changes in erections and ejaculation occur with aging. Usually it takes more stimulation to achieve an erection as a male ages. The plateau phase of sexual excitement is longer and may not end in ejaculation. When ejaculation occurs, the force of expulsion of semen and the intensity of ejaculation are lower. After ejaculation, the erection resolves more quickly and the refractory period increases. Many of these changes start to occur when men are in their 20s, and age-associated changes should be anticipated and viewed as normal.

Sexual Dysfunction in Women Sexual dysfunction can be due to psychological, hormonal, anatomical, and medication-related causes. These causes are not mutually exclusive. Psychological causes include inhibited sexual desire, which can be generalized or specific to one partner. If loss of libido is specific to one partner, then the prognosis for recovery is good. If libido always has been low and is generalized, then it is unlikely to change. Loss of interest in a given partner is difficult to restore, unless it is a temporary response to an identifiable event or issue that can be addressed in some mutually satisfactory way. Events such as childbirth that alter self-image and self-identity in both men and women may affect relationships libido, and the human sexual response in a variety of ways. As relationships are by their nature ever changing, it is to be expected that the sexual relationship will change with time; however, that change need not be for the worse. The intimacy inherent in sexual relationships requires continual renewal, so sexual relationships by nature may be vulnerable to the vicissitudes of life and aging. Decreased libido generally leads to less sexual arousal and unsatisfactory sexual contact for one or both partners. If neither partner views the sexual relationship as essential, then these developments may not threaten the stability of the overall relationship, but if there is a mismatch in outlook, alterations in libido and sexual expression may threaten the foundation of the relationship.

Hormonal changes can affect both libido and the reproductive tract. Loss of estrogen with menopause or from surgical removal of the ovaries can lead to loss of vaginal lubrication. Intercourse may be painful, or more typically, there may be less sexual sensation and decreased arousal. This may or may not decrease overall satisfaction within the relationship.

Anatomical reasons for sexual dysfunction include congenital malformations of the reproductive tract and results of surgery or childbirth. When extensive surgery is performed that involves the external female genitalia, sexual dysfunction may be due to loss of sensation from unavoidable injury to nerves, from pain at the surgical site, from loss of hormones if the ovaries were removed, from an altered sexual self-image, from fear or hesitation in the partner, or from any combination of these factors.

Organic conditions such as endometriosis, ovarian cysts, and pelvic infections can cause painful intercourse and sexual dysfunction. Diabetes can lead to nerve injury and sexual dysfunction due to reduced sensation. Other neurological conditions and alcohol use disorders can impair sexual responsivity.

Vaginismus refers to a condition in which the muscles around the outer third of the vagina have involuntary spasms in response to attempts at vaginal penetration. While this condition is generally thought to be psychological, women with vaginismus typically enjoy foreplay and can become sexually aroused and have orgasms. The male partner may develop erectile dysfunction in response, particularly if he becomes impatient or feels guilty.

Anorgasmia, or *orgasmic dysfunction*, refers to the inability to achieve an orgasm. This is not always viewed as a problem by women who report it. Anorgasmia is thought to be the most common sexual dysfunction, but it must be viewed in the context of each partner's desires and expectations. Therapy is generally not successful when the primary motivation for seeking medical intervention is to satisfy the male partner. The male partner may feel sympathetic, but he also may feel threatened, since many partners assume responsibility for the other's sexual satisfaction. A mismatch in libido or expectations can be more distressing than an identified problem.

Dyspareunia, or painful intercourse, can result from vaginal atrophy due to inadequate estrogen exposure, from endometriosis, from pelvic infections, from other anatomical conditions, or from lack of sexual lubrication.

Medications that may interfere with sexual responsivity or sexual interest include antidepressants, oral contraceptives, levonorgestrel implants (Norplant), medroxyprogesterone (Depo-provera), and GnRH-agonists. Contraceptive agents and GnRH-agonists likely act by altering hormone concentrations. In general, progestins diminish libido and sexual responsivity while estrogens increase both. Antidepressants decrease sexual drive and responsivity by acting upon important brain centers. Selective serotonin reuptake inhibitors (SSRIs) commonly lessen sexual interest. For SSRIs with shorter half-lives such as sertraline (Zoloft) and paroxetine (Paxil), it may be possible to reverse the effects on sexuality without interfering with the antidepressant effect by taking weekend drug holidays. Some antihypertensives also are associated with diminished sexual drive or satisfaction. If a close temporal link exists between the start of medication treatment and decreased sexual drive or responsiveness, it may be worth considering another medication, if a good alternative exists.

Appropriate treatment depends upon an accurate diagnosis. Organic or anatomical causes must be considered and may require medical or surgical remedies. The use of dilators may be helpful for women with vaginismus. Behavioral therapies such as sensate focus exercises, desensitization strategies for anxieties, relaxation training, assertiveness training, and directed masturbation have been successful, alone or in combination. Depending on the circumstances, couples counseling and interpersonal therapy may be recommended. The success of treatment depends upon the diagnosis.

Infertility *Infertility* is estimated to affect 10 to 20 percent of all couples. With the advent of sophisticated techniques for both diagnosing and treating the causes of infertility, many couples who in a previous era might have remained childless or adopted a child to build a family now can have biological children. Common causes of infertility include endometriosis, impaired spermatogenesis, damage to fallopian tubes or the vas deferens from infections or sterilization procedures, and ovulatory dysfunction or anovulation. The basic infertility evaluation can involve a semen analysis, hysterosalpingogram, hormonal studies, endometrial biopsy, and diagnostic laparoscopy to define possible contributing or causal factors (Table 28.2-1). Ovulation and ovulatory adequacy can be monitored by obtaining serial blood samples, performing an endometrial biopsy, or both. In contrast, spermatogenesis is difficult to assess because the process takes 70 to 90 days to complete and the morphological features of sperm that can be assessed by a standard semen analysis do not correlate well with function (i.e., ability to fertilize a human oocyte). Diagnostic uncertainty and a seemingly endless array of treatment approaches can easily provoke tension, indecision, and disagreement in the couple with infertility.

Possible Cause	Test	Comments
Anovulation	Basal body temperature chart	Patient must do each morning
	Endometrial biopsy	Office procedure in late luteal phase
	Serum progesterone	Single or multiple blood tests
	Urinary ovulation detection kit	Home use at midcycle to time intercourse
	Ultrasound	Visualize ovarian follicles and their rupture
Anatomical disorder	Hysterosalpingography	X-ray in proliferative phase to define intrauterine contours and tubal patency
	Diagnostic laparoscopy	View external surfaces of internal structures
	Hysteroscopy	Visualize endometrial cavity
Abnormal spermatogenesis	Semen analysis	Normal value >20 million per mL, 2 mL volume, 60% motility
	Postcoital test	Midcycle timing to look at sperm–cervical mucus interaction
Immunologic disorder	Antisperm antibodies	Aids semen test
Aspermia	Testicular biopsy	Determine eligibility for intracytoplasmic sperm injection
	Semen analysis for fructose	Determine if vas deferens are patent

Modified from Berkowitz GS, Lieg EW, Kennedy RH, Reiss GM, Herbert WNP: Lancet 1:1406, 1983; Ory SJ: Obstetrics and Gynecology for Office and Clinic, Philadelphia & Toronto, Saunders, 1978.

Table 28.2-1 Tests in the Infertility Workup

The sense that the window of opportunity is narrow can engender panic; the age of a woman correlates well with fecundity, and treatment success declines sharply after age 37 years, even when ovulation occurs regularly. Although fertility also declines with age in men, the decline is gradual until age 50 years, and fertility may persist beyond age 60. The offspring of older mothers have an increased risk of chromosomal trisomies, particularly trisomy 21. Recently, an increase in autosomal dominant conditions has been reported in the offspring of older fathers. Of the identifiable causes of infertility, about 40 percent are thought to be due to male factors, 40 percent to female factors, and 20 percent to both. Anovulation is the most common cause of infertility is women. About 20 percent of men with suboptimal semen parameters have microdeletions of the long arm of the Y chromosome in a region thought to play a critical role in spermatogenesis. About 10 to 20 percent of infertile couples have unexplained infertility, which means that there is no identifiable cause.

The degree to which psychogenic or lifestyle factors play a role in infertility is controversial. Couples should not be told their infertility is related to stress unless there is documented evidence of sperm dysfunction, ovulatory dysfunction, or sexual dysfunction. However, because lifestyle variables such as tobacco exposure, alcohol consumption, drug use, excessive exercise, weight loss or gain, and psychogenic stress can compromise reproduction, it is worth reviewing lifestyle factors with the couple and informing them of the potential adverse consequences of these factors in a supportive manner. Psychogenic variables can interfere with coital frequency and reduce the likelihood of conception, and they can suppress the central hypothalamic-pituitary drive to the gonad and compromise the quality and quantity of gametes produced.

Standard interventions were once limited to restorative surgery and gonadal stimulation, but they now include a variety of assisted reproductive techniques, including in vitro fertilization with embryo transfer (IVF-ET) and intracytoplasmic sperm injection (ICSI). In assisted reproductive technique procedures, the ovaries generally are hyperstimulated to produce at least three or four mature follicles from which the occytes can be retrieved surgically. Sperm and oocytes then are mixed and supported in vitro to promote fertilization. If fertilization occurs, the fertilized ovum or zygote is transferred to the recipient's uterus. The chance of implantation if three or more zygotes are transferred is generally around 30 percent but can be lower if fewer embryos are available or if the woman is over age 38. About 25 percent of implantations (as evidenced by a transiently elevated serum b-hCG concentration) are not sustained. The likelihood of a successful full-term pregnancy increases dramatically if fetal cardiac activity is observed about 2 weeks after missed menses (i.e., 4 weeks after the gamete or embryo transfer). The main indication for assisted reproductive procedures is failure to conceive with conventional interventions. In some instances, the reproductive impairment is so severe that conventional interventions are unlikely to offer success and an assisted reproductive procedure is recommended primarily. ICSI is used when there is failed fertilization during a previous IVF procedure or when too few sperm exist for conventional IVF.

Gamete intrafallopian transfer (GIFT) is a form of assisted reproduction with similar rates of success in which three to four oocytes are mixed with sperm and placed into the fallopian tube during a laparoscopy. Fertilization occurs in the tube and thus is not observed. GIFT is indicated in the absence of tubal disease or severe male factor, that is, conditions such as unexplained infertility or endometriosis unresponsive to superovulation alone. When it is not possible to correct underlying causes, substitutions are possible. Thus, not only are donor sperm available, so too are donor oocytes and surrogate mothers who will gestate the embryo of another couple. Embryos can be cryopreserved indefinitely and potentially transferred to a biologically unrelated recipient or to the woman herself years after menopause.

Treatments for infertility are expensive and consume much time and energy. A sense of psychological and physical invasion is common. Infertile men and women may feel angry, damaged, or guilty. Recent studies hinting at a link between ovarian cancer and infertility or infertility treatments further increase anxiety and psychological turmoil. The potential for husband and wife to respond differently to the experience of infertility and its treatments, particularly any of the assisted reproductive technologies, can overwhelm customary adaptation patterns and lead to psychological decompensation. Even successful infertility treatment poses challenges. Assisted reproductive technologies carry a 25 to 30 percent chance of twins and an almost 1 percent chance of triplets. If quadruplets or more result, the couple must grapple with the option of selective reduction. A multiple pregnancy increases fetal and maternal risks such as congenital abnormalities and preterm labor. Further, multiple gestation complicates postpartum adjustment and carries a lifelong parenting challenge.

Whether or not it is treated, infertility can produce a variety of psychological reactions. Responses depend on personality attributes, including adaptability, cultural expectations, support systems, knowledge about reproductive processes, and the attitudes of the involved clinicians. Infertility can damage self-image and impair sense of health and integrity. Some persons feel they are being made to suffer for past wrongs; others blame the medical profession for being inadequate or inattentive. A sense of panic, helplessness, and loss of control may compromise self-esteem. Women and men alike generally are overwhelmed by the complexity, cost, invasiveness, and uncertainty associated with medical intervention or adoption. Almost all patients who undergo infertility treatment (Table 28.2-1) experience a loss of privacy as they cope with physicians, nurses, insurance carriers, psychologists, hospitals, and laboratory personnel. The sense of intimacy that reinforces marriage and mutuality may be challenged when sex and procreation are separated by technology (Table 28.2-2). Ultimately, infertility presents the specter of a psychological death. Thus, it is not surprising that patients with infertility report as much anguish and distress as patients newly diagnosed with acquired immune deficiency syndrome (AIDS).

Method	Comments
Ovulation induction or augmentation (multiple agents, particularly clomiphene or highly purified gonadotropins)	Stimulates multifollicular development and ovulation; may produce multiple births; used in anovulation, luteal phase deficiency, unexplained infertility and assisted reproduction
Infection of spermatogenesis	Used in men with idiopathic hypothalamic hypogonadism of functional or organic nature
Artificial insemination	Donor sperm is injected into the uterine cavity or the fallopian tubes; the sperm of the husband may be used if healthy
Gamete intrafallopian transfer (GIFT)	Transfer of collected oocytes and sperm into the fallopian tubes; zygote may also be transferred (ZIFT); used for infertility from endometriosis and unexplained infertility
Intracytoplasmic sperm injection (ICSI)	Injection in vitro of sperm head or sperm DNA to cause fertilization and production of embryos for transfer to receptive endometrium; may be used even if sperm are barely viable; genetic cause of male infertility may be transmitted to offspring
Gamete donors	Donation of sperm or oocytes to another couple. Donation can include oocytes only, oocyte cytoplasm only to restore reproductive competence to aged oocytes, or donor sperm alone, or any combination
Surrogate mother	Surrogate mother receives donated embryo and carries the baby to term; a highly controversial technique with unresolved legal ramifications

Data in part from Berkowitz GS, Lieg EW, Kennedy RH, Reiss GM, Herbert WNP: Lancet 1:1406, 1983; Seidel RS, Soules MR: Obstetrics and Gynecology for Office and Clinic, Philadelphia & Toronto, Saunders, 1978.

Table 28.2-2 Assisted Reproduction Techniques

Ideally, psychological support services should be available for all individuals and couples undergoing active evaluation and intervention for infertility. Unlike the traditional medical model in which diagnostic testing precedes and directs the course of treatment, in infertility, empiric therapy may precede more invasive diagnostic testing. Cause and effect can be difficult to identify, and magical or superstitious thought processes are common in patients and practitioners alike. Infertility can threaten marital adjustment, particularly if the partners react differently to the challenges. Although fertility is an attribute of a couple, blame may be prematurely or wrongly assigned to one person in the dyad. In addition to individual or couples counseling, groups such as Resolve can offer support and information. When donor sperm, oocytes, or embryos or surrogate motherhood are being considered, a thorough psychological evaluation is recommended in advance of treatment, to ensure that all parties agree to the treatment plan and understand the potential implications and ramifications.

Reproductive technologies have made it possible to separate biological and social parenthood. A single woman may choose parenthood. The use of donor insemination or other fertility therapies in single women is controversial. Most women who seek such services have considered the consequences of single parenthood and feel that they will be able to rise to the challenges. Nonetheless, psychological evaluation should be made available to ensure that important topics and consequences have been considered. No long-term follow-up on the mental health and development of children born to single mothers has been done.

Dysfunctional attitudes and disharmony constantly threaten the infertile person. Prophylactic evaluation is preferred in all treatment settings, but specialized services may not always be immediately available. Stress can compromise gametogenesis and libido; infertility treatment alone can be stressful enough to activate the central mechanisms that compromise reproductive function. Psychological support is intended to lessen the likelihood of this effect and reverse it if it is already occurring.

Mood and cognition may be altered by pharmacological agents used to treat disorders of ovulation or to hyperstimulate the ovaries. The agents include clomiphene citrate (Clomid) and other antiestrogens, GnRH-agonists, human gonadotropins, hCG, progesterone, and bromocriptine (Parlodel). Danazol (Danocrine), a synthetic androgen, may be used to arrest the growth of endometriosis as a surgical or medical adjunct to later infertility therapy. Treatment of infertility itself is anxiety provoking because of the uncertainty and sense of expectation. However, most of the agents do alter estradiol and progesterone levels, and the resultant hormonal fluctuations may trigger mood lability in sensitive individuals. Agents such as clomiphene, danazol, and bromocriptine may also have direct effects on the brain. If the use of those agents is indicated, psychological support should be offered in preference to anxiolytics and antidepressants. A further concern for women with infertility has been introduced recently. Research has suggested that infertility treatments or infertility itself may confer an excess risk for ovarian cancer. The data, however, are far from conclusive. The uncertainty of this link only serves to exacerbate anxiety and guilt. Infertility is a far more devastating disorder than most lay persons and physicians realize.

Pregnancy Loss Unlike infertility, which can continue indefinitely, pregnancy loss is a defined event with an end. Acute reactions to an isolated miscarriage or perinatal loss such as blame, guilt, anger, and denial gradually lead to acceptance and resolution. A single miscarriage does not predict poor future reproductive performance. *Recurrent pregnancy loss*, defined as three or more losses before 28 weeks of gestation, carries a less unfavorable prognosis and resembles infertility in its chronicity and sense of lost potential. Although it might be assumed that grief and emotional turmoil would be related to gestational age, this assumption is not supported by observations. Women who miscarry have more than twice the relative risk of a major depression, compared with community women. More than half of women with a history of major depression suffered a recurrence following miscarriage. Because of the significant risk of depression, acute intervention is recommended for all women and couples who experience a miscarriage or perinatal loss; services should be extended beyond the acute event when indicated.

Pseudocyesis Pseudocyesis is the development of the classic symptoms of pregnancy—amenorrhea, nausea, breast enlargement and pigmentation, abdominal distention, and labor pains—in a nonpregnant woman. Pseudocyesis demonstrates the ability of the psyche to dominate the soma, probably via central input at the level of the hypothalamus. Predisposing psychological processes are thought to include a pathological wish for and fear of pregnancy; ambivalence or conflict regarding gender, sexuality, or childbearing; and a grief reaction to lost potential following a miscarriage, tubal ligation, or hysterectomy. The patient may have a true somatic delusion that is not subject to reality testing, but often a negative pregnancy test result or pelvic ultrasound scan leads to resolution. Psychotherapy is recommended during or after a presentation of pseudocyesis to evaluate and treat the underlying psychological dysfunction. A related event, couvade, occurs in some cultures; the father of the child undergoes a simulated labor, as though he were giving birth.

Fertility Control

Elective Abortion Elective abortion is distinct from spontaneous abortion (i.e., miscarriage) (Table 28.2-3). Elective abortion is the planned termination of a pregnancy. About 1.5 million abortions are performed in the United States each year—346 abortions for every 1000 live births. In Western nations, most women who obtain abortions are young, unmarried, and primiparous; in underdeveloped nations, abortion is most common among married women with two or more children.

Spontaneous	Spontaneous expulsion of the products of conception before viability (500 grams or about 24 weeks from last menses)
Habitual	Three or more spontaneous abortions
Missed	Expelling of products of conception; usually caused by the presence of a blighted ovum and lack of fetal development
Threatened	Uterine bleeding or cramping and positive pregnancy test; must be distinguished from an ectopic (usually tubal) pregnancy
Incomplete	Spontaneous passage of a portion of the products of conception and retention of placental fragments that result in ongoing bleeding
Elective	Induced by medical or surgical techniques before fetal viability; techniques include dilation, evacuation, and curettage; suction curettage; injection into the amniotic sac of saline or prostaglandins; hysterotomy; prostaglandins with antiprogestins (RU-486) or methotrexate; medical indications include the detection of fetal abnormalities by ultrasound or amniocentesis

Table 28.2-3 Types of Abortion

Fifty percent of abortions are performed under 8 weeks of gestation, 26 percent between 9 and 10 weeks, and 13 percent between 11 and 12 weeks. The remainder occur after 13 weeks, with 1 percent occurring after 21 weeks. Table 28.2-4 summarizes the most common abortion techniques. In contrast to what was previously thought, recent studies show no significant untoward psychological effects of elective abortion on the mental health of women. In fact, in one study comparing the outcomes of women who sought treatment in a clinic because they thought they were pregnant, women who did turn out to be pregnant and chose to abort were reported later to be doing better emotionally and in pursuing personal, educational, and work endeavors than either those who were not pregnant or those who chose to continue the pregnancy. Another study suggested untoward consequences on the mental health and well-being of women who were denied the option to abort and thus were required to unwillingly carry the pregnancy to term and then raise an unwanted child. That study suggested untoward consequences on the mental health and well-being of the child as well. However, termination of a wanted pregnancy because of an abnormal karyotype or fetal anomalies can be traumatic and supportive intervention is recommended.

Type	Benefits	Risks
Cervical dilation and evacuation of uterine contents by curettage or vacuum aspiration	Most commonly performed procedure for termination of pregnancy; can be done before 24 weeks gestation	All care Uterine perforation Adhesions Hemorrhage Infection Incomplete removal of fetus and placenta
Menstrual aspiration (minisuction)	Can be done within 1 to 3 weeks of missed period	Implanted/ectopic pregnancy was removed Uterine perforation (rare) Failure to recognize ectopic pregnancy
Medical: induction (cervical dilation with laminaria followed by high dose of IV oxytocin)	Can be used for second-trimester abortion	Water intoxication Uterine rupture Infection
Intrauterine: hyperosmotic solutions (saline)	Can be used for second-trimester abortions	Hypernatremic crisis Heart failure Peritonitis Hemorrhage Water intoxication Intrauterine necrosis
Prostaglandin (oral, intravaginal, cervical, or intramuscular)	Noninvasive procedure Can be used in conjunction with antiprogestins (RU 486) or methotrexate	Expulsion of live fetus Missed ectopic Hemorrhage Incomplete abortion
Antiprogestins (RU-486)	Nonsurgical First trimester only	Incomplete abortion Hemorrhage
Methotrexate	Nonsurgical First trimester only	Teratogenesis Hemorrhage Incomplete results

Table 28.2-4 Abortion Techniques

Techniques for inducing abortion (Table 28.2-4) have been known for at least 5000 years. In view of the risks of childbearing and the requirements of child rearing, induced abortion was viewed historically as a means of modulating the maternal and societal risks of unrestrained childbearing. Induced abortion affords women a measure of autonomy over a unique and psychologically powerful bodily function, but it arouses personal and public ambivalence and inspires controversy.

Historically, the concept of therapeutic abortion before *quickening*, generally defined as the time at which the mother perceives fetal movements, was well accepted. In

the United States, legislative regulations regarding induced abortion were introduced in the early 1800s, but their intent was to protect women from sepsis and other complications associated with the procedures. Induced abortion, whether by surgical or chemical means, now entails minimal medical risk and is clearly safer than carrying the pregnancy to term.

Current legislative attention has shifted from safeguarding maternal health to the ethics of abortion and the right of women to exercise control over their bodily functions. Traditionally, ethical deliberations regarding abortion were reserved for religions. Because of the diversity of religious perspectives on the role of women and on procreation, consensus is neither likely or necessarily desirable. Nonetheless, the current legislative debate centers on who has the authority to regulate induced abortion and to what degree. The 1992 Supreme Court ruling in *Planned Parenthood of Southeastern Pennsylvania v. Casey* upheld the basic right of women to elect pregnancy termination before fetal viability but also upheld the right of the state to regulate and restrict abortion and to define viability. Further, in some states (e.g., Pennsylvania), women who are pregnant lost the right to select whether they wish to receive advanced life support in life-threatening situations. The Freedom of Choice Act put before the U.S. Congress recognized the right of states to regulate the strictly medical aspects of abortion to safeguard maternal health. It restricts the freedom of a women to terminate a pregnancy after, but not before, fetal viability. This legislative effort represented a compromise between those who argue against any medical mediation of the process and those who would grant women complete autonomy. Application of this law would hinge on the interpretation of the phrase “fetal viability,” a concept that is not easily defined. Making the option of induced abortion contingent on fetal viability reveals continuing ambivalence about allowing women the autonomy to make decisions about physiological processes that directly shape their lives. It is difficult to appreciate how a legislative body can entrust the life of a child to the mother and simultaneously limit the mother's autonomy in making reproductive decisions. Current legislative efforts have focused on restricting the techniques used to perform late-term abortions by criminalizing physicians. This debate regarding abortion is far from resolution and is likely to intensify as medical advances such as RU-486, the antiprogestin that can chemically induce abortion in the early first trimester, increase therapeutic options.

Medical abortion soon will be available in the United States. In countries where this form of elective termination is currently available, acceptance is high but not universal. The medical risks of either surgical or medical abortion are few, but both procedures require physician input. Medical abortion, however, requires less physician input, although it does require careful monitoring to ensure that the abortion occurs in a timely fashion. Rarely, hemorrhage occurs that requires surgical intervention or a transfusion. Medical abortion can potentially increase a woman's autonomy of her reproductive capacity.

Contraception Methods of contraception fall into four main categories: barrier methods, hormonal agents, intrauterine devices, and natural family-planning methods that require abstinence around the time of ovulation (Table 28.2-5). The perfect contraceptive would be completely reversible, free of adverse effects, and completely efficacious. Since no perfect contraceptive is now available, people must select a method that best meets their needs. requently, the responsibility for choosing and using a contraceptive falls primarily on the woman. This can lead to resentment, lack of compliance, and marital disharmony. For those in a stable relationship, contraceptive counseling can include both partners.

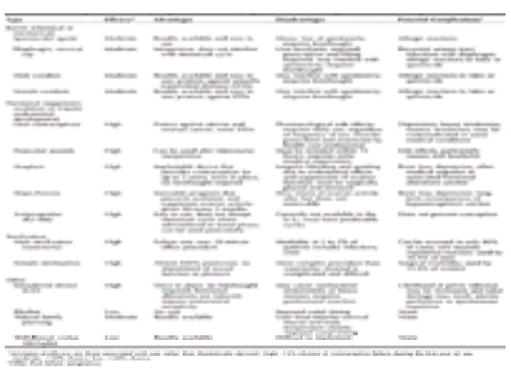

Table 28.2-5 Current Methods of Contraception

The assessment of the risks and benefits of a given contraceptive strategy should not be limited to a consideration of the biological risks alone but must take into account the mind-set of each party, particularly with regard to gender issues and cultural perspectives. If significant discord exists within a couple, counseling may be indicated. Counseling also can be considered for the person or couple who feel guilty about the idea of interfering with natural bodily functions for this purpose.

Clinicians must be mindful of the difference between actual and risk perception. Concerns of current and later bodily harm from use of contraception are common, and the risks of childbearing and child rearing frequently are underestimated. The mortality associated with childbearing is estimated to be 10 per 100,000 live births at ages 20 to 24, 44 per 100,000 between 35 and 39 years of age, and 71 per 100,000 after age 40. However, comparable mortality in nonsmoking women on oral contraceptives is 1.2 per 100,000 live births, 3.9 per 100,000 live births, and 6.6 per 100,000 live births, respectively. The potential risks of child rearing are difficult to quantitate, but they include role strain and stress, interrupted education or career advancement, depression, loss of independence, and compromise of the psychosexual relationship with the partner. This misperception of risk is particularly prevalent among adolescents, who may be uninformed and have unrealistic ideas about the rewards of pregnancy and the risks of sexually transmitted diseases. A teenager's aptitude for listening and making decisions may be limited by ambivalence and confusion. In short, despite the availability and relative affordability of contraceptive means, their use is constrained by the discrepancy between actual and imagined risk. Because coitus is not always anticipated there is a need for postcoital or so-called emergency contraceptives. Available methods include insertion of an intrauterine device (IUD), high doses of levonorgestrel, high doses of estrogen-progestin combinations, and antiprogestins. The use of levonorgestrel 0.75 mg taken twice 12 hours apart within 72 hours of intercourse was more effective (>99%) and associated with less severe adverse effects than the use of combined oral contraceptives. In the United States, only combined oral contraceptives (Preven) are explicitly marketed for use as postcoital contraception.

The mental and physical health risks of contraceptive use are significantly lower than those associated with pregnancy, parturition, and parenthood. However, contraception often gives an unwarranted illusion of control over a bodily process. No method is perfect, and unintended pregnancy can occur despite responsible use. Also, if a couple or person intends to have children, childbearing should not be postponed indefinitely in the hope that the perfect time will arrive. It can be difficult to conceive on demand.

Sterilization Sterilization can be accomplished by several methods of tubal ligation, by hysterectomy with or without oophorectomy in women, and by vasectomy in men. Hysterectomy for sterilization alone is associated with more morbidity and mortality than any method of tubal ligation; vasectomy is safer than any of the present methods of tubal ligation. Most studies do not support the contention that tubal ligation carries an increased incidence of gynecological sequelae, but failure rates are high in the first year following tubal ligation. In general, it is safest to perform a tubal ligation by laparoscopy at least several weeks following delivery. Tubal ligations immediately after delivery are done because of convenience or because of a woman's unwillingness or inability to return for a later tubal ligation.

It is difficult to determine how often reversal of a tubal ligation or vasectomy is sought or performed, and it is even more difficult to estimate the frequency of regret that the sterilization was performed. No formula can predict who will seek reversal, but factors such as remarriage, young age at time of sterilization, death of a child, and performing the sterilization during the postpartum period seem to play roles. Regret is high when sterilization is undertaken as a way to stabilize a marriage. The success of reversal depends on a variety of factors, including the method of sterilization, the ages of the partners, and the elapsed time since the sterilization procedure. Clinicians need to make couples and individuals aware of these considerations but should not use them as reasons to deny the planned procedure. Again, when a couple is involved, the mutuality of the decision should be discussed to avoid later resentment. Voluntary sterilization, especially vasectomy, has become the most popular form of birth control in couples married for more than 10 years.

SEXUALLY TRANSMITTED DISEASES

A *sexually transmitted disease* (STD) is a contagious disease acquired as a result of a physical sexual interaction. STDs always have been a reality, but from the 1950s through 1970s the infections were considered treatable and not life-threatening. AIDS, which is caused by infection with human immunodeficiency virus (HIV), is currently incurable, life threatening, and transmissible from mother to fetus. The specter of AIDS has captured the popular imagination. Although it was initially found in male homosexuals and intravenous drug abusers, HIV knows no boundaries. Sexual monogamy or abstinence has been advocated to ensure emotional health and a stable family arrangement for the potential outcome of sexual intercourse, children, but mutual sexual monogamy or abstinence also prevents STDs,

particularly AIDS.

Another sequela of STDs such as gonorrhea and chlamydia is pelvic inflammatory disease (PID). Untreated PID can develop into bilateral tuboovarian abscesses and necessitate hysterectomy and bilateral salpingo-oophorectomy. Early antibiotic treatment is advocated to prevent development of the abscesses and to reduce the likelihood of infertility, chronic pelvic pain, and ectopic pregnancy from tubal damage. These infections also can lead to obstruction of the vas deferens and chronic prostatitis in men and subsequent male infertility.

Another STD that can have serious consequences is venereal warts, or human papilloma virus (HPV). Genital infections with certain subtypes of HPV can lead to premalignant changes of the penis, vulva, vagina, and cervix and are thought to cause cervical cancer. Venereal warts can be removed chemically or surgically but are difficult to eradicate completely. Women who contract HPV are encouraged to have regular gynecological examinations and Papanicolaou smears to detect premalignant lesions.

Sexual monogamy and abstinence will prevent most STDs and are advocated as public health measures. However, libidinal impulses can be difficult to control and restrict. Therefore, measures such as condom use are recommended as an alternative public health measure. The ideal can be defined, but clinicians and policymakers need to remember that it cannot always be attained. Adolescents, in particular, need to know the potential consequences of sexual activity with regard to STDs and pregnancy. Admonishing teens to remain chaste is unlikely to be completely effective and may be counterproductive. To make responsible decisions, people need to understand the risks. Clinicians need to remember that the risks of sexual intercourse may be forgotten or seem minimal in comparison to the need for affection, contact, release, or escape. Persons who have low self-esteem or are stressed may view sex as a means of bolstering their self-image or escaping their stresses. The reinforcing properties of sex ensure that the problem of STDs will endure.

PELVIC PAIN

Pelvic pain can have many causes, including endometriosis, pelvic adhesions, ovarian or adnexal masses, hernias, and bowel or rectal disease. Pelvic pain can also be secondary to psychogenic causes, such as guilt, fertility or infertility fears, and the emotional disturbances associated with ongoing or past incest or sexual abuse. Pelvic pain should not be attributed to psychogenic causes unless a thorough evaluation has excluded organic causes. In most instances, the evaluation should include a diagnostic laparoscopy. Likewise, dyspareunia or pain with intercourse should not be assumed to have a psychogenic origin unless all anatomical causes have been excluded.

REPRODUCTION

Pregnancy, parturition (childbirth or delivery), and the postpartum period involve a series of tightly orchestrated hormonal events that create the potential for unique psychological states. As pregnancy advances, estrogen and progesterone concentrations rise, and a host of placentally elaborated polypeptide hormones induce metabolic adaptations. The effect of those hormonal excursions upon CNS activity and rhythms remains to be investigated; however, in the absence of predisposing psychological conditions or complications of pregnancy, most women adjust to the changing hormonal milieu without overt physical or psychological difficulty. Parturition is an intense biological event that is also tolerated by most, but it eventuates in the abrupt withdrawal of estrogens, progesterone, and other placental hormones. Parturition also triggers the neuroendocrine cascade that permits lactation. The metabolic demands of lactation, the need to deliver infant care across the usual circadian rest-activity cycle, and the hypoestrogenism that accompanies lactational amenorrhea present unique physiological challenges. Menses (and ovulation) generally resume in 6 to 12 weeks if the mother declines to nurse or when lactational frequency declines (usually after 4 to 6 months) if she does nurse.

Pregnancy Although pregnancy has dramatic emotional and psychological consequences, it generally protects women against the onset of mental illness unless there are underlying conditions. Teenage pregnancy appears to be a different story. For instance, pregnancy and motherhood protect against suicide, except in teenage mothers, who, despite their young age and negative personal or family histories of psychiatric illness, have an increased risk. Most likely that increased risk is attributable to the added stress felt by a young girl who is not yet equipped or ready to cope with the loss of social approval, the loss of control that pregnancy engenders, the demands of caring for a child, and the loss of future career or social options.

Pregnancy has not always been associated with low rates of suicide, however. Before the availability of contraception and legal abortion, pregnancy was often a cause of suicide, particularly if the pregnant woman was unwed and lacked social supports. In the past, punitive attitudes and adverse societal sanctions not only did not prevent unintended pregnancies, but were associated with increased maternal mortality from suicide and the complications of illegal abortions performed by unsafe techniques in unsterile settings.

Psychological Adaptation The stages of psychological adaptation to an intended pregnancy are not well understood. Both men and women who desire a pregnancy initially tend to feel empowered when it is achieved. However, as the pregnancy progresses and the realities of how life will be altered emerge, ambivalence develops. This is a normal psychological response to a major life transition. In general, most people adjust to the multiple bodily and psychological changes and develop effective coping strategies or attitudes. For instance, a husband may compliment his wife on her ever-changing physique as a means of reassuring them both that the child and parenthood are welcome, that the dyadic relationship is intact, and that he is sharing in the process. A woman may rejoice in her increasing girth and wear clothing that displays it, or she may wish to deemphasize the changes until they are dramatic. Medical advice and role models are helpful, but each woman must develop her own strategies to cope with the hormonal, metabolic, and psychological demands of pregnancy.

During the early stages of pregnancy, concerns tend to focus on bodily adjustment—how to cope with morning sickness, breast tenderness, changes in physique, sexuality, diet, and exercise. Depending on body habitus, increased abdominal size, breast size, or both may be apparent as early as 1 or 2 weeks after a missed menses or may not be apparent until 10 to 12 weeks later. Throughout pregnancy, the pregnant woman must adapt to changes in both physical and psychological boundaries. As the pregnancy advances, concerns shift to finances, the baby's room and material needs, employment issues, and capacity for parenthood. The extent to which the urge to prepare for the baby is biologically driven is not known, but in animals the preparatory efforts (nesting) appear to be hormonally initiated. In humans, this preparatory process does not seem to depend exclusively on hormones, as men also participate. Each partner may focus on a special concern, particularly if the marriage is based on discrete, stereotypic gender roles. However, throughout the pregnancy, each must share concerns and acknowledge ambivalence, to facilitate adjustment and mutuality. If this does not occur, the psychological and physical demands of pregnancy can lead to isolation and negative attitudes. Although parenting can be satisfying and deeply rewarding, it is a big responsibility; anticipatory anxiety is normal and focuses energies on important psychological tasks. The potential parents who have fantasies about the unlimited joys of parenting may not adjust well to the mundane, tedious realities associated with caring for babies and children. If the parents have other children, they must also develop strategies for coping with sibling adjustment.

The first pregnancy heralds a new life stage for both parents, but attention generally has focused on the developmental issues of the expectant mother. Pregnancy is seen as a maturational event that allows consolidation of gender identity and provides an opportunity to nurture the next generation. The psychological energy required to deal with issues of identification and differentiation in conjunction with profound metabolic and hormonal changes may lead to emotional lability, introspection, anxiety, or a desire for increased contact with one's parents. The age, life stage, and circumstances of the pregnant woman undoubtedly affect adjustment, but pregnancy is universally associated with concerns about adequacy during gestation and delivery and as a caregiver. In consolidating her identity, the woman must negotiate issues of autonomy, dependence, and sexuality. Past adjustment and current support play critical roles in determining the outcome of this pivotal developmental event. Although men do not have to confront the physical demands of pregnancy in themselves, the psychological adjustments required of men involve the same issues (i.e., consolidation of gender identity, attachment, autonomy, sexuality, and generativity).

Being able to anticipate facilitates adjustment. By definition, the first-time parent does not know fully what is required. The situation is made worse if the expectant mother or father has no guarantee of maternity or paternity leave. Allowing employers to make this decision on an individual basis is inappropriate and leaves too much room for employer self-interest. Standardized guidelines that guarantee a reasonable amount of financial and job security must be developed and applied uniformly. The needs of normal infants are predictable and do not vary by race, parental age, or socioeconomic status. Both parents need time and energy to initiate the psychological process of becoming a family. Obviously, the success of any economy depends on its human potential; strategies are needed that balance the short-term needs of business with the short- and long-term needs of children and parents. Working fathers have always been a reality; working mothers are now a reality and are likely to remain so. It is hypocritical and counterproductive to extol the virtues of parenthood but not develop reasonable provisions that allow working mothers and fathers to balance their commitments. As pregnancy can arouse primitive jealousies, working women who are pregnant may find that they are penalized in subtle ways for “neglecting” their job or other external responsibilities. Employment policies that protect pregnant women from undue pressure can help ameliorate that situation.

Psychological Tasks Associated With Assisted Reproduction Options and outcomes related to advanced reproductive technologies have introduced novel

psychological tasks that must be negotiated during and after pregnancy in addition to the more universal themes. The following situations are likely to be associated with enhanced anxiety and novel concerns: multiple gestation (Will the babies survive, and how can we parent so many at once?); surrogacy (Can I [or she] give up this baby?); donor oocytes or sperm (Who is the “real” mother or father?); selective fetal reduction (Did the “best” child survive?); single motherhood with donor sperm (Can I truly provide all that is needed? Who is the father?); in vitro fertilization or gamete intrafallopian transfer (Will the child be normal? How should I parent this special child? Who should know how this child was conceived?). These issues also arise in adoption and in single parenthood unrelated to assisted reproduction, but the elective decision to use reproductive technologies may make parents feel an enhanced sense of responsibility or predispose them to unrealistic fantasies about the child. The expectant parents in these situations may warrant prophylactic psychological intervention or, at the very least, especially attentive obstetricians and pediatricians.

Parturition Fears regarding pain and bodily harm during delivery are universal and to some extent, warranted. Preparation for childbirth affords a sense of familiarity and can ease anxieties, which facilitates delivery. Continuous emotional support during labor reduces the rate of cesarean section and forceps deliveries, the need for anesthesia, the use of oxytocin, and the duration of labor. A technically difficult delivery, however, does not appear to influence the decision to bear additional children.

Men's responses to pregnancy and labor have not been well studied, but the recent trend toward inclusion of fathers in the birth processes eases their anxieties and elicits a fuller sense of participation. If fathers are to be full partners in parenting, they must be given opportunities to participate and express themselves during pregnancy and parturition. Fathers do not parent the same way as mothers, and new mothers often need to be encouraged to respect these differences and view them positively.

Postpartum The postpartum period entails multiple physiological and psychological adjustments. Estrogen and progesterone concentrations decline precipitously, adrenal secretion of cortisol is altered, loss of placental hormones changes metabolism profoundly, and many new psychological challenges exist. Delivery itself also entails a metabolic challenge, especially if a cesarean section was performed. Maternal sleep deprivation is a common, if not universal, consequence of the infant's lack of circadian rest-activity cycle. Many of these factors can trigger postpartum depression and psychosis in biologically predisposed women. Recognizing postpartum depression, which occurs in as many as 10 percent of women, is a major problem, because screening and detection often fall to the obstetrician, who may only see the patient once at the postpartum checkup. It is critical for the obstetrician to ask about postpartum adjustment in a nonjudgmental manner and to indicate that the patient should call or return for help if she becomes overwhelmed. Optimally, the obstetrician should have an established referral process for new mothers who develop distressing psychological symptoms.

Lactation Lactation occurs because of a complex psychoneuroendocrine cascade that is triggered by the abrupt decline in estrogen and progesterone concentrations at parturition. Lactation becomes established because of the neurological stimulation transmitted by suckling. The composition and amount of breast milk changes as the infant grows. In general, babies should be fed as needed rather than by schedule. Breast-feeding has many benefits. The composition of breast milk supports timely neuronal development, confers passive immunity, and reduces food allergies. Psychological benefits accrue to both mother and infant. Every effort should be made by health professionals to convey these benefits. The workplace should include a place where women so interested can express breast milk.

Use of Psychotropic Medications In many instances the risk of psychiatric illness (e.g., depression or psychosis) is much worse for the brain and the interaction of mother and child than the potential adverse effects of psychotropic medication. If a woman becomes pregnant, however, medications should be evaluated immediately. The hormonal effects of pregnancy may change the course of her illness. However, it is not necessary to induce unwarranted guilt or to have the woman consider aborting if she does become pregnant while on psychotropic medications.

Definitive answers to the question of which psychotropic medications are safest during pregnancy and lactation are unlikely. While ethical considerations limit performing randomized, prospective interventional trials, observational data can and should be collected in registries. In patients with worsening psychiatric illness during pregnancy, outpatient psychotherapy, hospitalization, and milieu therapy should be attempted before routine use of psychotropic medication. Before a planned pregnancy, withdrawal of psychotropic medications should be attempted under close supervision. The importance of close rapport between the treating physician and the pregnant or breastfeeding patient cannot be overstated and will obviate or decrease reliance on psychotropic medication in many cases. The Food and Drug Administration (FDA) rates drugs in five categories of safety for use in pregnancy (Table 28.2-6).

Category	Definition	Drug Examples
A	No fetal risks in controlled human studies	Iron
B	No fetal risk in animal studies but no controlled human studies or fetal risk in animals but no risk in well-controlled human studies	Acetaminophen
C	Adverse fetal effects in animals and no human data available	Aspirin, haloperidol, chlorpromazine
D	Human fetal risk seen (may be used in life-threatening situation)	Lithium, tetracycline, ethanol
X	Proved fetal risk in humans (no indication for use, even in life-threatening situations)	Valproic acid, thalidomide

Table 28.2-6 FDA Rating of Drug Safety in Pregnancy

Antipsychotics No conclusive evidence indicates that antipsychotics are teratogenic, but they should not be used in the first trimester unless the patient presents a danger to herself, her unborn child, or others or hospitalization does not adequately control her psychosis. Use of these agents in the second and third trimesters is unlikely to cause fetal malformation, and there is no evidence of long-term sequelae in humans. The pediatrician should be alert to the possibility of behavioral disturbance in the neonate. In view of the potential for hypotension with aliphatic phenothiazines and thioridazine (Mellaril) and the possible increased risk of fetal malformation with chlorpromazine (Thorazine), use of high-potency agents appears preferable as first-line management; low-potency agents should be used only if unacceptable adverse effects occur with the use of other agents. Monitoring of uteroplacental sufficiency is indicated if severe hypotension occurs.

ANTIPSYCHOTICS IN LACTATION. The milk-to-plasma ratio of chlorpromazine is 0.3 to 1 and the ratio for perphenazine (Trilafon) is 1 to 1. The use of phenothiazines in lactating women has not been associated with serious consequences, and breast-feeding by mothers taking phenothiazines is not contraindicated.

Antiparkinsonism Agents Antiparkinsonian agents have not been adequately tested in pregnancy. In general, pregnant patients should not be routinely treated with antiparkinsonian drugs. The agents should be administered only to treat intolerable adverse effects associated with the use of antipsychotics.

Antidepressants Surprisingly little information exists on the use of tricyclic and other antidepressants in pregnancy, especially considering the frequency of major depression in women of reproductive age. Depression in the first trimester should be treated if possible by supportive measures. Cases of suicidality, incapacitating vegetative signs, or psychosis, warrant hospitalization. Use of antidepressants including SSRIs is warranted for vegetative signs accompanying a major depressive episode that do not resolve with supportive intervention. The available data show no statistical increase in the rate of congenital malformation in fetuses exposed to tricyclic drugs, but there are isolated case reports of limb deformities. Animal studies suggest possible teratogenic potential, but the studies are inconclusive. Amitriptyline (Elavil) and trimipramine (Surmontil) have been associated with adverse pregnancy outcomes in rats and rabbits. Trazodone (Desyrel) and amoxapine (Ascendin) have also been associated with poor fetal outcome in lower mammals. In general, therefore, while teratogenicity has not been proved, it is advisable to avoid using tricyclic drugs in the first trimester.

There has been concern about the effects of the use of tricyclic drugs in the second and third trimesters upon the neurological development of the fetus, particularly with respect to neurotransmitter systems. In addition, these agents may interfere with normal labor. Isolated case reports have documented a withdrawal syndrome in neonates, including cyanosis, difficulty breathing, and feeding difficulties after desipramine (Norpramin), urinary retention following nortriptyline (Pamelor), and dystonic movements and seizures after imipramine (Tofranil). These findings have led some authors to recommend a prelabor withdrawal period for patients on tricyclic drugs. However, no evidence indicates that intrauterine withdrawal is safer than extrauterine withdrawal. Since fetal hyperactivity and seizures are possible, extrauterine withdrawal may be safer. Like phenothiazines, tricyclic drugs can cause hypotension. A recent study by Irena Nulman found that the neurodevelopment of

children exposed to tricyclic drugs and fluoxetine (Prozac) during pregnancy and followed from birth until 86 months did not differ from that of the control group. Although another study reported more perinatal complications in women exposed to fluoxetine during pregnancy, the methods used to define the complications were not rigorous.

Whether intrauterine withdrawal is safer than extrauterine withdrawal is unclear, and the clinician should be guided by the mother's therapeutic response rather than assuming a benefit from withdrawing antidepressants prior to labor. If antidepressants are used in the third trimester, the pediatrician should be warned to anticipate the possibility of withdrawal symptoms in the infant, and any marked change in maternal blood pressure is an indication for obstetrical surveillance of uteroplacental sufficiency. Postpartum major depressive disorder should be treated first with supportive therapy, and transdermal estradiol, antidepressants, or both should also be offered to women who do not respond quickly. Estrogen therapy alone is usually not sufficient to treat major depressive disorder.

MONOAMINE OXIDASE (MAO) INHIBITORS The use of MAO inhibitors (MAOIs) is contraindicated in pregnancy for several reasons. First, studies found growth retardation in animals receiving doses in excess of the maximum human recommended dose. Second, pregnancy-induced hypertension is a common complication of pregnancy that often has an insidious onset; further exacerbation of that condition by use of MAOIs may lead to placental hypoperfusion and have serious fetal consequences. Third, if premature labor occurs, tocolysis with beta-mimetics may be obstetrically indicated but not possible because of potential interaction with the MAOI. Fourth, anesthetic management in labor may be complicated by the relative contraindication of opioids in patients taking MAOIs. When pregnancy occurs while the woman is taking MAOIs, the drug should be discontinued.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS A recent study showed that women taking fluoxetine during pregnancy do not have an increased risk of spontaneous pregnancy loss or major fetal anomalies, but women who take fluoxetine in the third trimester are at increased risk for perinatal anomalies. These investigators recommended that fluoxetine be discontinued if possible before the last trimester. However, other investigators found that the neurodevelopment of preschool children exposed in utero to tricyclic drugs or fluoxetine was unaffected. Specifically, they found no significant differences in temperament, mood, arousability, activity level, distractibility, global intelligence quotient (I.Q.), or language development in children exposed to SSRIs in fetal life.

ANTIDEPRESSANTS IN LACTATION. The use of antidepressants in the puerperium is a particularly important problem because of the clear increase in episodes of mood disorders during that time. The incidence of postpartum affective disturbance is reported to be between 10 and 15 percent. Factors predisposing to depression at that time include the rapid change in hormonal milieu which includes the abrupt withdrawal of estrogen and progesterone, decreasing serum cortisol concentration, changes in thyroid function, and the psychological and circadian stress of a newborn infant. Psychosis develops in a small percentage (0.1 percent) of new mothers. The evaluation of postpartum affective disorder should include thyroid function studies since these conditions are often associated. The treatment of postpartum depression should include immediate involvement in supportive psychotherapy. Often, the therapist can help the mother adapt to the stress of reorganizing the home to include the new baby and allay fears of the responsibilities of maternity and feelings of loss of her previous identity as a member of the workforce. However, in view of the lack of formal financial protection available to women in the workplace, concerns regarding employment and money may be well justified. Pharmacological intervention should be instituted early in the treatment. Alterations of sleep patterns are prominent symptoms resulting from both the affective disorder and the frequent awakenings by the newborn child.

The long-term effects on neurotransmitter development of antidepressants passed to the infant through the breast milk are unknown. Katherine Wisner and colleagues recently reviewed the literature and reported that amitriptyline, nortriptyline, desipramine, clomipramine (Anafranil), dothiepin, and sertraline were not found in quantifiable amounts in nurslings. Adverse effects were reported in some infants whose mothers were treated with doxepin (Adapin, Sinequan) and fluoxetine. While it is prudent for women to avoid antidepressant use during lactation, if the depression is severe, the alternative of a trial of an antidepressant should be presented in such a way that the new mother understands that her ability for effective interaction and bonding with the child may be enhanced by the increased emotional availability that may ensue. In almost all cases, patients who are not psychotic can decide for themselves whether to take antidepressants with or without discontinuation of breast-feeding or try supportive psychotherapy without pharmacological intervention. Transdermal estradiol may be used with antidepressants for women with postpartum depression without interfering significantly with lactation. Recurrence rates of postpartum depression are lower in women with a previous history of postpartum depression if antidepressant therapy is initiated within 12 hours after delivery.

Lithium and Antimanic Agents Lithium (Eskalith) is a suspected teratogen, and its use in the first trimester should be avoided. Its use was linked to development of Epstein's cardiac anomaly, although more-recent data suggest that this risk is lower than previously thought. Lithium crosses the placenta freely, and maternal and fetal plasma concentrations are similar. Reversible goiter from transplacental lithium poisoning can occur. Neonates exposed to lithium in utero have exhibited a variety of neurological toxic effects including muscle flaccidity, inhibition of normal neonatal reflexes, lethargy, and cyanosis and toxic cardiovascular effects, including atrial flutter, tricuspid regurgitation, and congestive heart failure.

Because of the consequences, lithium is best avoided throughout the first trimester if possible. When psychotic decompensation and destructive mania cannot be managed with antipsychotics alone, careful monitoring of lithium concentrations is required because of the dramatic shifts in fluid volume during pregnancy. A higher glomerular filtration rate, coupled with the increased plasma volume, often leads to a requirement for higher dosages in the gravid woman to achieve comparable serum lithium concentrations. However, dehydration often occurs during labor, especially in the hospital setting where oral intake may be restricted to guard the airway, and lithium toxicity may occur at this time. Moreover, a rapid loss of fluid volume after delivery may precipitate toxic effects. Similarly, because the newborn is subject to considerable volume fluctuations, especially with respiratory or gastrointestinal infection, toxic effects in the newborn are not uncommon. Despite these potential adverse events, however, a follow-up study of 60 babies exposed to lithium in utero failed to find more long-term sequelae in those infants without congenital malformations than in unexposed siblings, on the basis of maternal reports.

When lithium is used in the second and third trimesters, the clinician should monitor lithium concentrations at least every 2 weeks, perform an ultrasound on the fetus to exclude goiter before permitting a vaginal delivery, maintain adequate hydration during labor, decrease lithium to 50 percent of the usual dosage 2 weeks before the estimated date of confinement, and consider early delivery if decreasing the lithium dosage appears to adversely affect the maternal psychiatric condition or with evidence of pregnancy-induced hypertension.

CARBAMAZEPINE AND CLONAZEPAM Carbamazepine (Tegretol) and clonazepam (Klonopin) have not proved safer than lithium; however, in view of the high suspicion of lithium as a teratogen, the use of clonazepam instead of lithium is indicated in the first trimester if mania cannot be controlled with reasonable dosages of an antipsychotic. Anticonvulsives such as valproic acid (Depakene) and carbamazepine are used as mood stabilizers; their use has been associated with a 1 to 5 percent incidence of spina bifida or other neural tube defects. The risk is thought to be higher with valproic acid.

LITHIUM AND ANTIMANIC AGENTS IN LACTATION. The mean concentration of lithium in breast milk is roughly half the maternal serum concentration, with a range from 25 to 77 percent. During the first several months of life, the infant's kidney function is not fully developed, and the lithium excretion is slower than that of an older child. Lithium concentrations in the serum of breast-feeding infants are estimated to be a tenth to a half of those in maternal serum. Several reports of lithium toxicity in breast-feeding infants exist including cyanosis, T-wave abnormalities, and decreased muscle tone. Toxicity is especially likely during dehydration, such as during infection. Because of the toxicity, lithium is contraindicated while breast-feeding, because infants have greatly reduced renal clearance of lithium. Because of rapid metabolism, carbamazepine or valproate may be safer than lithium in the postpartum patient who cannot be adequately controlled on neuroleptics but who insists upon breast-feeding, providing the infant is carefully monitored.

Benzodiazepines Diazepam (Valium) crosses the placenta throughout gestation. Its use has been associated with cleft lip and palate. Whether diazepam is a teratogen in humans remains controversial. The likelihood is that diazepam is not teratogenic. Nonetheless, since its use is unlikely to be a medical necessity, it should be avoided in the first trimester. During the second and third trimesters, occasional use of benzodiazepines for discrete episodes of anxiety, indicated medical procedures, and severe insomnia is not likely to affect pregnancy outcome adversely.

BENZODIAZEPINES IN LACTATION. Diazepam and chlordiazepoxide (Librium) are excreted in breast milk. Therefore, nursing mothers should not use benzodiazepines.

Parenthood Parenthood is a major role that requires marked psychological adaptation. By necessity, a highly dependent human being becomes the focus of one's time and energy. Establishing an effective balance between the equally important roles of autonomy and dependence within each of the parents and between the spouses requires major shifts and reorganization.

In many cultures, additional family members live within or nearby the new family to provide support and share the time-consuming and energy-demanding burdens of the infant. Such extended families may contribute to additional role strain in the parents, but in toto they help stabilize the family unit. Increasingly in this country,

parents are being required to live up to the multiple roles of parent, spouse, friend, lover, and colleague in isolation. It often proves to be too much. Multiple competing responsibilities can precipitate child abuse, marital disruption, or mental illness. The old adage that it takes more than two people to raise a child seems well supported by experiences with parenthood. With all the stressors of parenthood, the situation of single parenthood (whether by choice or not) further accentuates these role demands. Often, single parents must seek substitute care in the form of baby sitters, live-in help, if affordable, and day care from schools or religious institutions. Since such resources are only minimally available and often very expensive, the role strain of parenthood without nearby family support systems may precipitate a state of crisis.

Even in modern society, women still have the primary responsibility for child rearing, so parenthood places particularly strong demands on the mother. Working and career-oriented mothers may be financially able to obtain other support systems to ease the demands of parenthood, but further role strain can be precipitated by demands and roles at work. Often women have multiple authoritarian demands at work but not enough power to carry out assignments. Psychological demand is further increased by the many responsibilities at home. Certainly men experience conflicts between family and work, but often their ability to use power in the workplace is balanced by their ability to receive nurturance at home, with relatively fewer demands and responsibilities and more ultimate power than women. The psychological strain on both men and women, particularly if it involves change and is not in keeping with their biological predispositions, exacerbates the customary demands of parenthood.

REPRODUCTIVE SENESCENCE

Menopause Menopause, the cessation of ovulation, is due to the depletion of responsive ovarian oocytes and generally occurs between ages 47 and 53 years. The hypoestrogenism that ensues can lead to hot flashes, sleep disturbances, vaginal atrophy and dryness, and cognitive and affective disturbances and predispose to osteoporosis, dementia, and cardiovascular disease. Menopause is generally heralded by 5 to 10 years of erratic ovarian function revealed by irregular uterine bleeding. Prior to the 1800s, menopause tended to occur just before death. Previous negative associations may reflect the nearly coincident timing of menopause and death at the turn of the last century; today's women, however, must adjust to the challenge of life after the loss of endogenous reproductive capacity.

Surgical menopause occurs when the ovaries are removed. That removal is often done in women older than age 35 years who need a hysterectomy to help protect them from future ovarian carcinoma. Prophylactic oophorectomy is a controversial procedure, and the symptoms that follow surgical castration before the age of natural menopause generally are more pronounced than those that follow natural menopause. In natural menopause, the ovaries remain intact and continue to secrete androgens, including testosterone and androstenedione which can be converted to estrone, a weak estrogen. Surgical menopause results in an abrupt and complete loss of the ovarian secretion of androgens, estrogens, and progesterone, often well before the age of menopause. Estrogen replacement therapy generally is indicated when bilateral oophorectomy is performed prior to natural menopause, but compliance may be compromised by ambivalence or a sense of premature loss if the decision to undergo oophorectomy was made without full consideration of all the risks and benefits. Androgen therapy is more controversial, in part because a tested, safe, physiological replacement product is not commercially available. The adrenal hormone dehydroepiandrosterone (DHEA) is an androgen currently being promoted as a dietary supplement to restore a sense of well-being, but few data are available on its long-term safety and effects.

Hormone Replacement Therapy The pros and cons of hormone replacement therapy have not been fully clarified; thus the question of whether to initiate or continue this therapy can pose a medical, financial, and philosophical challenge. Most studies show that estrogen replacement is associated with increased longevity, primarily because estrogen use confers cardioprotection. Estrogens also retard bone loss, retard urogenital atrophy, are mood stabilizing and neuroprotective, and retard the development of clinically apparent osteoporosis. Although women at midlife tend to gain weight, several studies have demonstrated that women who use hormone replacement therapy gain less weight and the weight gained is preferentially deposited in a gynecoid (hips and thighs) rather than android (abdominal) pattern. More-recent evidence suggests that ongoing estrogen use reduces the risk of Alzheimer's disease and other dementias by roughly 50 percent. Current evidence does not reveal a strong association between estrogen use and breast cancer. Although definitive studies have not been completed, evidence suggests that it is reasonable to permit women who have survived breast cancer to use hormone replacement therapy. Hypoestrogenism can impair sexual enjoyment and libido and cause hot flashes, night sweats, and profound fatigue. Those sequelae can generally be ameliorated or reversed with estrogen use. Progestin use is generally recommended for women with a uterus to guard against the development of endometrial hyperplasia and carcinoma; whether or to what degree progestin use compromises the beneficial effects of estrogen use needs clarification. The adverse effects that most limit progestin use are depression and bloating. Women who previously suffered from depression or PMS are most prone to mood disturbances with progestin use. To avoid or minimize the effects of progestin exposure, it is prudent to prescribe the smallest amount of progestin necessary to protect the endometrium from hyperplasia. In Europe, a progestin-containing IUD is used, which has the advantage that the progestin dose to the brain is minimized. In general, hormone replacement therapy enhances psychological functioning and promotes overall health. Recent data support the notion that antidepressant and antidementia agents are more efficacious in women when they are taking hormone replacement therapy. Since hormone replacement may last well over 30 years, it is worth titrating and individualizing route, dosage, type, and regimen with the goal of maximizing benefit and minimizing adverse effects.

The recent introduction of a wide range of estrogen and progestin products, including so-called designer estrogens or selective estrogen receptor modulators (SERMs) has expanded options. There is even less information about the long-term risks and benefits of partial estrogen agonists or SERMs than about more conventional estrogen preparations. Direct-to-consumer marketing of hormone preparations means that patients have many more questions, concerns, and ambivalence. To induce compliance, physicians must be able to explain what is and is not known. The same holds for phytoestrogens derived from soy and flax seed.

Both men and women age and experience an age-related decline in reproductive capacity, but only women experience complete gonadal cessation. Loss of reproductive capacity may present a psychological challenge to those who are not reconciled to the loss of fertility. However, even with gonadal failure, the availability of donor oocytes and sperm means that pregnancy can be initiated in a menopausal woman with an intact uterus who elects to pursue that option. Some women find these multiple options overwhelming. Menopause is not only a marker of life stage; it also presents biological and psychological challenges unique to women.

Psychophysiological Adaptation Depression at menopause was previously attributable to the empty-nest syndrome. In fact many women report an enhanced sense of well-being and enjoy the opportunity to pursue postponed goals. Recent acknowledgment that women's roles may encompass more than child rearing has helped facilitate this attitude. Thus, psychological factors may enhance well-being in older women.

In contrast, biological factors appear to predispose women to major mental illness at the time of menopause. A peak in the onset of bipolar illness in women around the time of menopause has been observed. One study reported induction of rapid mood cycling at the time of menopause in women. Yet another study found an increased number of affective episodes in women coinciding with the mean age of menopause at about 50 years.

Aging Further investigations are required to distinguish the psychological and biological effects of aging and menopause. Aging is associated with declined resiliency and circadian rhythmicity in both men and women. Desynchronized or reduced biological rhythms may compromise sleep, cognition, and mood. The brain is a target organ for gonadal steroids. Only women experience complete gonadal cessation. The loss of ovarian estrogen and progesterone exposure can precipitate hot flashes, decline in libido, sleep disturbances, affective complaints, and decreased memory, despite stable or improved life circumstances. However, both men and women experience a gradual decline in adrenal and gonadal androgen production. Androgens help maintain libido, muscle mass, strength, and energy. Androgen therapy has been advocated as a way to retard the aging process, but a tested, safe androgen replacement preparation is not commercially available for women. Many other chemotherapeutic agents have been advocated to reduce the burdens of aging. These include antioxidants such as vitamin E, phytoestrogen, and vitamin C, aspirin; alcohol; folate; vitamin D; calcium; herbal supplementals such as Ginko Biloba; and hormones such as DHEA, growth hormone, and melatonin. Menopausal women often expect that physicians who offer hormonal products at menopause to increase long-term health will also know whether other chemotherapeutic strategies have merit.

SUGGESTED CROSS-REFERENCES

Many of the reproductive transitions that may occur across a woman's life cycle are discussed elsewhere, including Section 27.5 on other conditions not attributable to a mental disorder, Section 13.4 on postpartum psychotic disorders, Section 28.3 on premenstrual dysphoric disorder, and Section 25.6 on endocrine and metabolic disorders. Chapter 19 on normal human sexuality and sexual disorders discusses important concepts regarding gender and sexuality. Chapter 20 discusses eating disorders, conditions in which ovarian cyclicity is often disrupted. Interactions between psyche and soma are discussed in Chapter 8 on clinical manifestations of psychiatric disorders, Section 25.9 on stress and psychiatry, and Section 1.11 on psychoneuroendocrinology. CHAPTER 28. SPECIAL AREAS OF INTEREST

28.3 PREMENSTRUAL DYSPHORIC DISORDER

KIMBERLY A. YONKERS, M.D., AND LORI L. DAVIS, M.D.

A number of mood, behavioral, and somatic symptoms are reported by women during the late luteal phase of the menstrual cycle. For decades these signs and symptoms have been called *premenstrual syndrome*, a variably defined constellation of symptoms occurring during the premenstrual phase of the cycle. A subset of symptoms comprises *premenstrual dysphoric disorder*, which is found in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). Premenstrual dysphoric disorder emphasizes mood symptoms and specifies that symptoms must lead to some degree of functional impairment, thus distinguishing it from milder premenstrual symptoms. Premenstrual dysphoric disorder is unique in that it is the only diagnostic category requiring prospective symptom confirmation. Despite skepticism about its existence, the verification process used to confirm this disorder is extremely rigorous and exceeds what is required for other diagnoses.

DEFINITION

The disorder is classified in DSM-IV as a mood disorder not otherwise specified. The clinical criteria for the disorder appear in an appendix. The initial five symptoms under Criteria A are listed according to the frequency with which they were endorsed by more than 600 premenstrual sufferers in five academic centers. At least one of the initial four psychological symptoms is required to confirm the diagnosis, thereby emphasizing the affective nature of the illness. Changes occurring in DSM-IV include the addition of the symptom, “a subjective sense of being overwhelmed or out of control,” and the stipulation of a symptom-free postmenstrual week. Although it is possible that a woman with premenstrual syndrome may have severe physical symptoms only, the diagnosis premenstrual dysphoric disorder can only be made if there are mood or other affective symptoms. A woman must experience symptoms during the luteal phase for the majority of menstrual cycles during the previous year. Finally, she must prospectively confirm symptoms with daily ratings over the course of two consecutive menstrual cycles.

HISTORY

Vivid descriptions and social stigma associated with menstrual-related mood and behavioral changes date back to Hippocrates, the Talmud, the Bible, and ancient African tribal culture. The feared contamination and dreaded power of the menstruating woman led to the custom of secluding a woman during her menstrual cycle in many of these ancient cultures. For centuries the mythical stigma associated with the menstruating woman has had an insidious influence on the development of a critical description and analysis of menstrualrelated disturbances even to the present day.

In 1873 Sir Henry Maudsley is credited with initiating a prospective view of the link between mental and somatic disturbance and the ovarian cycle. However, it was not until 1931 that Robert Frank published the first description of “premenstrual tension” and postulated a hormonal pathogenesis. In 1952 Katherina Dalton introduced the term *premenstrual syndrome*. Over the ensuing years, the condition was variably defined by different investigators. In an attempt to consolidate the definitions a consensus conference was held at the National Institute of Mental Health (NIMH) in 1983. This conference led to provisional research criteria for late luteal phase dysphoric disorder in the revised third edition of DSM (DSM-III-R). The criteria were included in an appendix because of controversy in the scientific as well as the public sectors. Proponents of its inclusion as a disorder maintained that it was a clinically significant condition that necessitated diagnostic criteria for clinical and research purposes; opponents feared the potential stigmatization and labeling of women. The DSM-IV task force recognized the need to re-evaluate this question and in 1988 appointed a DSM-IV Work Group to study these proposed diagnostic criteria. For more than 5 years this group of experts debated and reviewed the scientific data and concluded that evidence supported a link between late luteal phase dysphoric disorder and mood disorders. The rather cumbersome title of late luteal phase dysphoric disorder was replaced with *premenstrual dysphoric disorder* in DSM-IV. However, political groups continuing to fear the stigmatization of women persuaded the Board of Trustees to retain the criteria in an appendix.

COMPARATIVE NOSOLOGY

In the *Federal Register* premenstrual syndrome is defined as “a recurrent symptom complex which begins during the week prior to menstruation and disappears soon after the onset of the menstrual flow. This symptom complex consists predominantly of edema, lower abdominal pain (including cramps), breast tenderness, headache, abdominal bloating, fatigue, and feelings of depression, irritability, tension, and anxiety.” The 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) includes a category for premenstrual tension, but no definition is associated with this diagnosis.

Other disorders that fall under the category of premenstrual syndrome yet remain distinct from premenstrual dysphoric disorder include various forms of premenstrual exacerbation of other psychiatric illness and severe physical premenstrual symptoms. The condition should be distinguished from dysmenorrhea, which is painful menstruation; genetic data show that the two conditions do not covary among twins.

EPIDEMIOLOGY

Two sources of data suggest that the prevalence rate for premenstrual dysphoric disorder is between 2 and 10 percent in the United States. First, retrospective community studies find rates for mild symptoms varying between 30 to 80 percent, while 2 to 10 percent of women experience severe or disabling symptoms. Second, smaller prospective community studies find rates of 3.4 and 4 percent.

Using retrospective reports, Epidemiological Catchment Area study (ECA) data show an equivalent rate between African-American women and white women. A study of 120 Nigerian women finds work impairment in 7.5 percent of women. Similarly, a Swedish study finds premenstrual complaints in 73 percent of women, although only 2 percent suffered from work absenteeism. Retrospective reports suggest an average age of onset in the middle to late 20s. This is distinct from the average age a woman seeks treatment, which is in the middle to late 30s.

Like patients suffering from other mood disorders, women with premenstrual dysphoric disorder tend to have a strong family history of major depressive disorder among first-degree relatives. One study found a history of major depressive disorder in one or more first-degree relatives among 65 percent of patients.

ETIOLOGY

The causes of premenstrual syndrome and premenstrual dysphoric disorder are unknown. A number of theories have been proposed but investigations have primarily included populations that experienced premenstrual syndrome and not premenstrual dysphoric disorder. It is possible that there are overlapping etiological factors between some forms of these two conditions.

The oldest theories postulate either an absolute or relative deficit of progesterone. Numerous older investigations have attempted to establish a difference in progesterone concentrations among symptomatic women versus controls and the results have been generally unsuccessful. Problems with these studies include the fact that progesterone is secreted in a pulsatile fashion and then metabolized in a matter of minutes. Thus, very frequent sampling or integrated plasma progesterone measures are required to more clearly define differences in the concentrations of this hormone. Similar problems beset studies attempting to find differences between estradiol concentrations or the progesterone-estradiol ratio in symptomatic versus control women. To date, it has not been clearly shown that either progesterone

concentrations or the ratio between progesterone and estradiol is aberrant or deficient in women suffering from either premenstrual syndrome or premenstrual dysphoric disorder. Similarly, several studies have failed to find differences in androgen concentrations between women who have premenstrual dysphoric disorder and controls, although one group finds higher free testosterone concentrations in the former set of women.

The timing of symptom onset, that is, during the middle to late luteal phase of the cycle certainly suggests a role for gonadal hormones. However, some work sheds doubt on pathophysiological attribution limited to ovarian hormones. In one study a progesterone antagonist administered during the midluteal phase of the cycle to women with premenstrual dysphoric disorder truncated the luteal phase, yet women continued to experience premenstrual symptoms. Further, casting doubt on the role of ovarian hormones are several studies that have shown that symptoms of premenstrual dysphoria improve in some women who have had a hysterectomy but no ovariectomy. An earlier study showed that sequential addition of estrogen and then progestin administered to postmenopausal women can provoke premenstrual-like symptoms. However, several subsequent reports attempting to replicate this found that when progesterone is administered in a double-blind placebo-controlled fashion, premenstrual symptoms are no more likely to occur with progesterone than placebo. On the other hand, in support of a pathophysiological role for ovarian hormones is work showing remission in women who are either (1) spontaneously anovulatory, (2) anovulatory due to suppression ovulation, or (3) anovulatory due to natural or surgical menopause.

Endogenous Opioid Peptides Some investigators suggest that premenstrual dysphoric disorder is triggered by a decline in endogenous opioid peptides such as b-endorphin and enkephalin. This is particularly intriguing since the symptoms of premenstrual dysphoric disorder are in some ways similar to opioid withdrawal. In addition, progesterone regulates the catabolism of enkephalin. Earlier work found that b-endorphin concentrations fluctuate during the menstrual cycle with peaks at ovulation and troughs during the luteal phase of the menstrual cycle. However, not all groups have replicated these findings and it is unclear how relevant peripheral b-endorphin concentrations are to processes occurring in the central nervous system (CNS). Using a different approach, several research groups have evaluated the pulsatile secretion of luteinizing hormone (LH), which reflects the secretion of gonadotropin-releasing hormone (GnRH) and is regulated by endogenous opioid peptides. Theoretically, if there was an abnormality in the level or rate of central endogenous opioid secretion, this may also be evident in the pulsatile secretion of LH. Several studies have found differences between premenstrual dysphoric disorder and control women in LH pulse frequency, but the cycle phase showing changes has differed among groups.

Neuroendocrine Markers Some researchers find higher rates of thyroid dysfunction in women with premenstrual syndrome or premenstrual dysphoric disorder. These inconsistence are perhaps explained by a report showing that women with the latter condition have greater variability in thyroid-stimulating hormone (TSH), triiodothryronine (T_3), uptake thyroxine (T_4), and the prolactin response to thyrotropin-releasing hormone. Transient alterations in hypothalamic-pituitary-adrenal axis function are also found in these patients. The luteal-phase response to corticotropin-releasing hormone is exaggerated in women with premenstrual symptoms versus controls. However, 24-hour urinary free cortisol excretion is not different between groups or cycle phase, suggesting that this change in responsiveness of the hypothalamic pituitary adrenal axis is brief and transient. This may explain why women with premenstrual dysphoric disorder continue to have normal menstrual cycles compared to patients with sustained hypercortisolism. Finally, in support of hypothalamic-pituitary-adrenal overactivity is the finding from a study that 62 percent of women with premenstrual dysphoric disorder failed to suppress cortisol after receiving dexamethasone (Decadron).

Catecholamines Some, but not all, studies find increased concentrations of the noradrenergic metabolite 3-methoxy-4 hydroxy phenyl-ethylene glycol in patients with premenstrual dysphoric disorder. Similarly, there is one report of a lowered homovanillic acid to 5-hydroxyindoleacetic acid ratio in women with this disorder. Early a- and b-adrenergic receptor binding studies largely conducted on women who retrospectively reported premenstrual syndrome find differences in either the number or affinity of these receptors in women with premenstrual syndrome versus controls. Several recent well-controlled studies on women who meet criteria for premenstrual dysphoric disorder find no differences between symptomatic women and controls in either a_2- or b-receptor binding.

Indolamines A large amount of work has investigated potential changes of serotonergic functioning in women with premenstrual dysphoric disorder. Whole blood concentrations of serotonin are lower in women with severe premenstrual syndrome compared to controls. However, because serotonin does not cross the blood-brain barrier this may not indicate CNS pathology. A number of groups find that luteal-phase platelet serotonin uptake is decreased in women with either premenstrual syndrome or premenstrual dysphoric disorder as compared with controls.

Administration of the challenge agent tryptophan produces a blunted growth hormone and cortisol response during both phases of the menstrual cycle in premenstrual dysphoric disorder women as compared with controls. The prolactin response to various challenge agents has been blunted only during the premenstrual phase, in the follicular phase, or not at all, depending on the agent used.

GABA Women with premenstrual dysphoric disorder have lower plasma concentrations of g-aminobatyric acid (GABA) during the luteal phase of the cycle than controls. However, women who had a previous history of major depressive disorder and a current diagnosis of premenstrual dysphoric disorder have lowered plasma GABA concentrations during both phases of the cycle, which illustrates that the state-trait differences in biology may also be related to other past illnesses.

Chronobiological Factors A chronobiological hypothesis of mood disorders has been explored in the context of melatonin, a hypothesized marker for the circadian oscillators. The offset of melatonin secretion and the integrated melatonin concentration are lower in women with premenstrual dysphoric disorder, which suggests an underlying chronobiological abnormality in these patients.

Other Biological Factors Several studies show that erythrocyte magnesium concentrations, a sensitive indicator of body stores of magnesium, are lower in premenstrual syndrome patients than controls. In addition, studies of zinc and copper concentrations during the luteal phase in these patients have been shown to be lower and higher, respectively, as compared to normal controls.

Psychological Factors Early psychoanalytic formulations of premenstrual distress proclaimed that premenstrual depression was the result of a woman's grief over her failure to conceive. Also included in these interpretations was a woman's repressed hostility towards and envy of the more favored males, with the monthly menstrual cycle serving as a brutal reminder of her femininity. These theories hold no validity because the symptoms of premenstrual dysphoric disorder begin to ameliorate with the onset of menses, contrary to the analytic theory.

Personality Factors Women with premenstrual dysphoric disorder have significantly higher scores for all three dimensions—Harm Avoidance, Reward Dependence, and Novelty Seeking—on the Tridimensional Personality Questionnaire (TPQ) compared to normative TPQ data. However, the Harm Avoidance scores are significantly lower in patients with premenstrual dysphoric disorder than those with major depressive disorder. A study evaluating the comorbidity of DSM personality disorders with premenstrual dysphoric disorder found that less than 10 percent of these women met the diagnostic criteria for a personality disorder on Structured Clinical Interview for DSM-III-R Axis II Personality Disorders (SCID-II).

Cognitive Style and Processing Some studies support a mild, phase-independent memory impairment and difficulty in learning new material in women with premenstrual dysphoric disorder as compared to controls. Enhanced performance on tests of frontal lobe function has been demonstrated in the follicular compared to the luteal phase in women with or without this disorder. Mood changes have not consistently accounted for these differences. Mood disorders are associated with a number of changes in cognitive processing, including selective attention to dysphoric stimuli. Paradigms evaluating whether women with premenstrual syndrome or premenstrual dysphoric disorder preferentially recall negative events or negative words are mixed.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of premenstrual dysphoric disorder is dependent upon certain core features: (1) a specific symptom constellation as outlined in DSM-IV, (2) the timing of symptom onset during the luteal phase of the cycle, (3) the absence of another underlying psychiatric or contributing general medical disorder, and (4) the severity of the disorder and its association with functional impairment. The symptoms of this disorder are primarily affective, with depressed mood constituting the most common symptom followed by anxiety or tension, mood swings, and anger or irritability; at least one of these four symptoms is required for the diagnosis. A minimum of five symptoms must be present and the other potential complaints, which are listed in Table 28.3-1, are somatic symptoms such as breast pain and bloating.

Table 28.3-1 DSM-IV Research Criteria for Premenstrual Dysphoric Disorder

DSM-IV does not stipulate at which point during the luteal phase symptoms must commence but it does include a criterion that the postmenstrual week be symptomfree. This was included to ensure that the constellation of symptoms experienced is not merely an exacerbation of an underlying disorder. DSM-IV criteria stipulate that luteal phase symptoms be prospectively confirmed during two consecutive cycles. This requirement arose from research showing that retrospective reports correlate poorly with the results of prospective ratings in many women. In one study of 82 women who sought treatment for clinically significant premenstrual symptoms, 14 percent did not show premenstrual mood changes, 56 percent had follicular phase symptoms, and only 30 percent of women demonstrated symptoms isolated to the luteal phase of the cycle. However, some data suggest that women with severe symptomatology are more likely to confirm prospective ratings. According to prospective ratings, the time of greatest well-being is just prior to ovulation, when estradiol is peaking. The most symptomatic interval is the few days immediately preceding menses, when both estradiol and progesterone are declining. There is variability in the duration of symptomatology, with some women experiencing a few days of premenstrual changes and other women having difficulty immediately after ovulation.

DIFFERENTIAL DIAGNOSIS

Countless symptoms have been associated with premenstrual syndrome, which increases the chances that another general medical disorder may be the problem. However, the symptom constellation for premenstrual dysphoric disorder is far more specific. The most significant disorders to rule out in the differential diagnosis are mild mood disorders, such as dysthymic disorder, or chronic anxiety disorders, such as generalized anxiety disorder. It may be that women who have exacerbation of chronic mild depression or generalized anxiety constitute one of the largest groups of women with premenstrual problems. Technically, these women may be considered to have premenstrual syndrome or premenstrual exacerbation of another disorder, but they do not have premenstrual dysphoric disorder. Daily ratings can be helpful in these cases but some women may report no dysphoric symptoms on a daily rating form and admit to chronic mild depression during a clinical interview. It is also important to rule out substance-related disorders. Substance use is not included in most daily rating forms and therefore requires independent assessment. In retrospective reports, women with intermittent depression or dysphoria, such as found in recurrent brief depressive disorder, may associate symptom expression only to the luteal phase of the cycle. A number of women experience dysphoria with the onset of menses. Retrospectively patients may attribute this to premenstrual syndrome, but daily ratings will show menstrual rather than premenstrual dysphoria.

Clinical studies commonly exclude women with a number of endocrine disorders such as Cushing's disease, hypothyroidism or hyperthyroidism, and endometriosis. It is unlikely that these disorders cause a syndrome with the symptoms of premenstrual dysphoric disorder, which has a time-limited symptom pattern. Nonetheless, these are conditions that may co-occur with premenstrual dysphoric disorder and could contribute to a woman's discomfort.

COURSE AND PROGNOSIS

A number of studies find that women with premenstrual dysphoric disorder commonly present for treatment at about age 36. Many women report that their symptoms began a decade earlier and have gradually worsened over time. This has been confirmed by several longitudinal studies but not others. Some work suggests that low parity and less frequent use of oral contraceptives are associated with more severe symptoms. Another study finds that a history of severe premenstrual syndrome in one's mother is a risk factor for severe premenstrual syndrome. Women with premenstrual dysphoric disorder are more likely than women without premenstrual difficulties to have had major depressive disorder. They are also at higher risk of eventually developing major depressive disorder, especially if they have symptoms that endure through the entire 2 weeks of the luteal phase. Thus, a consideration in the clinical course of premenstrual dysphoric disorder is not only the severity and cyclical recurrence of premenstrual symptoms, but the higher risk for other mood disorders.

If the age of onset is accurate, the cumulative time that symptoms are extant in women with premenstrual dysphoric disorder can be computed. For example, if symptoms begin at age 26 and continue monthly for approximately 7 to 10 days with every menstrual cycle until the average age of menopause (age 51), a woman with the disorder will experience approximately 1400 to 2800 symptomatic days (3 to 8 years).

TREATMENT

Substantial work has focused on the treatment of premenstrual syndrome. Difficulties with this body of literature include: (1) variable definitions, (2) a failure to stipulate that women keep prospective ratings prior to study entry, (3) a failure to exclude women with ongoing psychiatric illness, and (4) generally brief study periods, such as one cycle. Treatments that have been shown effective for premenstrual syndrome may not be palliative for premenstrual dysphoric disorder. For example, a treatment tested on women suffering from premenstrual bloating and breast pain may not be effective for the mood symptoms of premenstrual dysphoric disorder. Thus, one needs to be cautious when evaluating the literature on premenstrual syndrome and its applicability to women with premenstrual dysphoric disorder. Most treatment trials illustrate a high nonspecific (placebo) response rate, especially in studies where women had milder illness. Nonspecific response rates are somewhat lower with well-characterized premenstrual dysphoric disorder populations but remain substantial. Data suggest an average duration for nonspecific response of between one and three cycles.

Hormone Agonists and Antagonists The most widely studied hormone is progesterone, although a number of trials have employed synthetic progestins. To date there are 11 placebo-controlled randomized clinical trials using natural progesterone in dosages of about 200 to 400 mg per day during the luteal phase. In addition, there are four trials using dydrogesterone (the optical isomer of progesterone) and the synthetic progestin medroxyprogesterone (Provera). The results have been mostly negative, but most trials, including two large-scale studies of over 100 women with premenstrual dysphoric disorder show no greater benefit with a progestogen than placebo. However, milder symptoms and physical symptoms may improve more with progesterone or progestin treatment.

Estrogen has been evaluated in three randomized clinical trials and results are predominantly positive. Studies used daily ratings but none included clinical criteria for premenstrual dysphoric disorder. In one study of 68 women, a single-blind placebo run-in period identified a nonspecific response in 94 percent of women during the first two cycles.

Oral Contraceptives Most work evaluating the use of oral contraceptives for premenstrual symptoms used retrospective survey designs, with two exceptions. In the first, researchers compared a triphasic oral contraceptive with a monophasic one in 32 women. The triphasic preparation was superior to the monophasic one, but there was no placebo condition. The second study included 45 women and compared a triphasic oral contraceptive to placebo; this research group found that the oral contraceptive was superior for breast pain, tenderness, and bloating but not mood or irritability.

Danazol Danazol (Danocrine) is a synthetic partial androgen agonist that can induce anovulation. It has been used in dosages ranging between 100 mg a day and 400 mg a day. Although five out of the six danazol trials employed daily ratings, none stipulated criteria as rigorous as for premenstrual dysphoric disorder. Danazol was effective in the majority of these trials although the symptoms responding include breast pain and lethargy, and less often, mood symptoms. Unfortunately, the adverse affects associated with this medication, including the potential for hirsutism, limit its usefulness.

Gonadotropin-Releasing Hormone Agonists Like danazol, GnRH agonists induce an anovulatory state by downregulating pituitary gonadotrophs, thereby inducing a medical ovariectomy. Three of four double-blind placebo-controlled trials found that this class of medication is helpful for depressive symptoms occurring premenstrually. There are substantial risks associated with this treatment. It can only be continued for 6 months before progestin and estrogen are added again to

approximate a menstrual cycle. If hormone add-back therapy is not instituted, a woman runs a risk of bone loss and of increased lipid levels, with the subsequent risk of coronary artery disease and cerebral vascular disease.

Diuretics Several diuretics including spironolactone (Aldactone), ammonium chloride, and metaxalone (Skelaxin) have been used for the treatment of premenstrual syndrome. Spironolactone has been used most frequently, perhaps because of its other putative features, including its antiandrogenic properties as well as its capacity to treat mood swings. Only one clinical trial used daily ratings as entrance criteria and this study included women who met the criteria for premenstrual dysphoric disorder. Although the results from previous trials were mixed, this last study found that spironolactone (Aldactone) was helpful for somatic symptoms. This agent may be particularly beneficial when used in conjunction with psychiatric medications in premenstrual dysphoric disorder patients who have mood symptoms as well as the physical symptoms of headache and bloating.

Other Pharmacological Treatments Bromocriptine (Parlodel) is a dopamine agonist that binds to postsynaptic receptors and inhibits prolactin secretion. It has been used in randomized clinical trials, none of which stipulated criteria for premenstrual dysphoric disorder. The results are mixed, with the positive trials showing that bromocriptine is effective for breast pain. Medications whose use is supported by a single trial include naltrexone (ReVia), clonidine (Catapres), calcium (Tums), and doxycycline (Vibramycin). Again, the patients studied in this trial did not necessarily meet the criteria for premenstrual dysphoric disorder.

Mefenamic acid (Ponstel) and naproxen (Anaprox) have been used for the treatment of premenstrual syndrome. These agents appear to be helpful for pain associated with premenstrual symptoms.

Atenolol (Tenormin) blocks b-adrenergic receptors and suppresses melatonin; it has been evaluated in two randomized clinical trials. The first showed benefit for premenstrual irritability while the second found that atenolol was equal to placebo. Atenolol may be helpful as an adjunct treatment for women with premenstrual dysphoric disorder who have a partial response to another treatment.

Psychiatric Agents Given that premenstrual dysphoric disorder is characterized by affective symptoms such as low mood, mood swings, anxiety, and tension, a number of research groups have evaluated the efficacy of psychiatric drugs in this condition.

Lithium Given the periodic expression of the illness and the prominence of symptoms such as mood swings, several authors evaluated lithium (Eskalith) in the treatment of severe premenstrual syndrome. Unfortunately, placebo-controlled trials failed to find that it was superior to placebo.

Alprazolam Five placebo-controlled randomized controlled trials have used alprazolam (Xanax) to treat premenstrual dysphoric disorder. The dosages employed range between 0.75 mg a day to 4 mg a day during the luteal phase of the cycle over the course of two to four cycles. Four studies found alprazolam to be more effective than placebo. One study included women with premenstrual dysphoric disorder and premenstrual worsening of a mood disorder; alprazolam was not effective in this latter group. All studies showed a small effect size, which suggests that alprazolam may be more effective for women who have milder symptoms or as an adjunct to other treatments. Its benefit is that it can be given during the late luteal phase of the cycle, tapered when menstruation begins, and has an immediate onset of action.

Other Anxiolytic Agents One small preliminary study showed benefit for the serotonin (5-hydroxytryptamine [5-HT] subtype 1A) (5-HT $_{1A}$) partial agonist buspirone (BuSpar), when it was administered during the luteal phase of the cycle. The authors of this study believe that if this agent is given throughout the study it efficacy may be improved even further.

Antidepressant Agents Antidepressant drugs that have been evaluated in placebo-controlled randomized controlled trials include the clomipramine (Anafranil), fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), sertraline (Zoloft), the serotonin agonist fenfluramine, the dual reuptake inhibitor venlafaxine (Effexor), bupropion (Wellbutrin), and maprotilin (Ludiomil). Nefazadone (Serzone) has only been evaluated in an open study and results from the venlafaxine multicenter trial are not yet available. The only placebo-controlled study on fluvoxamine failed to find superiority over placebo, but the methodology used in that study was problematic. The prototypical selective serotonin reuptake inhibitor (SSRI), fluoxetine, has been used in 6 small studies and one large multicenter study; the latter included over 200 women and compared a 20-mg-a-day and a 60-mg-a-day dosage to placebo. Self-ratings improved within the first cycle but attrition (11 percent) was high in the 60-mg-a-day group. In this trial treatment was administered throughout the cycle although the authors state that they continued a subgroup after the study on luteal phase treatment and that treatment response was maintained. A recent placebo-controlled study shows that fluoxetine is more effective than bupropion for premenstrual dysphoric disorder.

Paroxetine was shown to be effective for premenstrual dysphoric disorder in a small placebo-controlled study and one open trial. The placebo-controlled study is notable because paroxetine was compared to the noradrenergic antidepressant agent maprotiline. Although both agents were superior to placebo, paroxetine was significantly more effective. Similar findings were noted in a placebo-controlled study that compared bupropion to fluoxetine—fluoxetine was found to be more effective than bupropion even though bupropion was slightly more effective than placebo.

Sertraline has been evaluated in several small studies and a large multicenter study of more than 220 women. This trial, which was over three cycles, employed a flexible dosing pattern ranging between 50 mg a day and 150 mg a day. Sertraline was found to be more effective than placebo for nearly all symptoms but particularly for mood symptoms. In this multicenter trial, medication was prescribed continuously. Recent advances have been made in minimizing medication exposure to women with premenstrual dysphoric disorder who by definition are symptomatic during only the luteal phase of the cycle. The serotonergic tricyclic antidepressant agent clomipramine was effective in luteal-phase dosing. Sertraline also appears to be effective when administered only during the premenstrual phase of the cycle.

Dietary Modifications, Vitamin Supplements, Exercise, and Sleep Some researchers have suggested that pyridoxine (vitamin B_6) may be helpful for symptoms of premenstrual syndrome because it serves as a cofactor in a number synthetic reactions including those involved in the conversion of the amino acid tryptophan to serotonin. Of the seven randomized controlled trials using vitamin B_6, only one used daily ratings. The results are mixed with most showing vitamin B_6 equivalent to placebo. Similarly, studies using supplements such as evening primrose oil and optivite did not use rigorous entrance criteria and the results are variable.

Numerous uncontrolled reports, as well as the popular media, recommend dietary changes including elimination of refined sugar, salt, alcohol, and caffeine; unfortunately, these recommendations are not supported by data. In a double-blind, crossover study a specially formulated carbohydrate-rich beverage improved ratings of depression, anger, concentration, and memory compared to the isocaloric (placebo) beverage. The carbohydrate beverage may work by increasing the serum ratio of tryptophan to other large neutral amino acids. Studies of varying degree of scientific rigor show the positive effects of regular, moderate exercise on mood states and menstrual cycle symptoms. Most studies have been done on menstruating women who have PM premenstrual syndrome but not premenstrual dysphoric disorder. Sleep deprivation is palliative in major depressive disorder. Research shows that both early and late luteal phase sleep deprivation diminish symptoms in premenstrual dysphoric disorder.

Cognitive Psychotherapy, Education, and Support A number of cognitive-behavioral or relaxation therapies may be beneficial to the patient with premenstrual dysphoric disorders; however, further prospective placebo-controlled trials are needed. In one study both cognitive behavioral therapy and the comparison condition (called *information-focused therapy*, aimed at relaxation training, education, and nutrition) ameliorated the symptoms of anxiety, depression, physical changes, and negative thoughts in women with premenstrual dysphoric disorder. Another study found no difference in response to behavioral therapy or progesterone treatment in patients with prospectively diagnosed premenstrual dysphoric disorder. A third study found dydrogesterone treatment equivalent but not as longlasting as cognitive-behavioral therapy.

SUGGESTED CROSS-REFERENCES

Postpartum psychiatric disorders are discussed in Section 13.4, normal sexuality in Section 19.1, and chronobiology in Section 1.13. Monoamine neurotransmitters are discussed in Section 1.14 and amino acid neurotransmitters in Section 1.5. The biochemical aspects of mood disorders are discussed in Section 14.4. Chapter 31 presents in-depth discussions of many biological therapies.

Textbook of Psychiatry

28.4 GENETIC COUNSELING

KATE A. BERG, PH.D., AND DARRELL G. KIRCH, M.D.

New discoveries regarding the genetic basis of medical disorders have been appearing at an accelerating rate, creating broad public awareness that there are genetic determinants in a wide range of diseases. For the mental disorders, extensive family studies of heritability and recent reports of specific genetic linkage for Alzheimer's disease, schizophrenia, and bipolar disorder increasingly are leading patients and family members to request genetic counseling, directly or indirectly. Often their questions are posed to a psychiatrist. The following review of the terminology (Table 28.4-1) and key concepts in genetic counseling provides the psychiatric clinician with an approach to these questions regarding the inheritance of mental disorders.

Consultand	Person seeking genetic counseling
Genotype	Alleles at a specific locus
Informant	Person who gives information to make pedigree
Multifactorial	Traits resulting from the effect of multiple genes and environmental factors
Phenotype	Observed result of genotype and environmental factors
Polygenic	Trait produced by the action of many genes of small effect
Proband	Affected person through whom pedigree is investigated
Recurrence risk	Probability that a genetic disorder in one family member will occur in another member of the same or future generations

Table 28.4-1 Definitions of Terms

The first step in genetic counseling is to establish a diagnosis using a criteria-based system. Recurrence risk data are currently based on empirical information and may not be accurate regarding individual cases. However, when the data are used, they should be expressed in a manner that the consultand can comprehend, with minimum bias on the part of the physician toward a particular interpretation. Part of the adjustment to the information may lie in following up the family as new developments unfold. Persons who came to the session with unrealistically high estimates of risk may actually be relieved to learn that their risk was smaller than expected. When members of the family who are at high risk are discovered, intervention may even assist in altering the long-term course of the illness. The psychiatrist can help put the information in the context of the person's life and the family's needs.

Genes are not necessarily destiny. Even when the genetic contribution to a mental disorder is well defined and identifiable, the data suggest that modification of the phenotype occurs through as yet unidentified environmental factors. Undertaking the arduous scientific task of separating genetic and environmental components eventually should result not only in more effective treatment, but also in the possibility of prevention of some forms of mental illness.

HISTORY

Attitudes toward giving medical information on genetics have changed dramatically since the early part of the century. Early attempts at genetic counseling were largely prescriptive and often were implemented in the context of the eugenics movement; the current consensus is that genetic counseling should be nondirective. In the 1970s and early 1980s the primary focus of genetic counseling was the simple provision of medical facts. Successful counseling was frequently measured by the ability of the consultand to remember recurrence risk information accurately or to take a particular line of action in response to the information.

During the 1990s the emphasis has shifted to the impact that the genetic information may have on the individual and the family. Outcome is less likely to be measured by the accurate recitation of facts and is more likely to center on individual adjustment and decision making.

GENETIC FACTORS IN MENTAL DISORDERS

The evidence for a genetic contribution to the major mental disorders was initially derived from family analyses, including studies of twins and adoptees. The findings of these studies are summarized in Table 28.4-2, which shows that the recurrence risk for these disorders increases as the degree of genetic relatedness increases. The recent use of molecular genetic techniques to study families with multiple affected members has yielded a number of reports of linkage to possible chromosomal locations in different families with schizophrenia and bipolar disorder. The fact that more than one genetic locus has been identified for each of these disorders indicates that they are likely to be heterogeneous illnesses involving multiple susceptibility genes interacting with various environmental factors. Turning to substance abuse, family studies have long indicated that some forms of alcohol dependence have a genetic component, but molecular studies have failed to conclusively prove gene linkage.

	Schizophrenia[a]	Bipolar Disorder[b]	Depressive Disorder[c]	Panic Disorder[d]	Compulsive Disorder[e]
Lifetime prevalence[f]	0.8–1.9	0.4–1.1	1.7–4.7	1.4–1.5	1.9–3.0
Risk to first-degree relative		4.0–9.0	1.9–10.4	15.0–24.7	25
Both parents affected	46				
One parent affected	13				
Full sibling	9				
Risk to niece or nephew	4				
Concordance for monozygotic twins	48	67	34

Table 28.4-2 Recurrence Risk of Familial Clustering for Psychiatric Disorders (in Percentage)

Conclusive evidence does exist for a genetic contribution to other disorders listed in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). The gene responsible for Huntington's disease, an autosomal dominant disorder, and its accompanying dementia, has been localized to chromosome 4, and predictive testing is now possible for those at risk. Alzheimer's disease appears to be genetically heterogeneous. Relatively rare familial early-onset forms of Alzheimer's disease have been linked to either chromosome 14 or 21. More-recent studies have shown an association between some late-onset cases of Alzheimer's

disease and a specific allele of apolipoprotein E (ApoE) on chromosome 19. The potential clinical role of ApoE genetic screening is currently under close scrutiny.

BASIC STEPS IN GENETIC COUNSELING

The key steps in genetic counseling are outlined in Table 28.4-3. Genetic counseling is undertaken to establish a diagnosis, define the appropriate questions, provide information concerning the recurrence risk in an understandable form, give a framework for decision making concerning possible courses of action, and help the consultand make the best possible adjustment to the situation.

▸ Establish diagnosis and obtain accurate family history and pedigree
▸ Address issues and concerns raised by the consultand and by information gained through the genetic counseling session
▸ Assist with decision making and adjustment to information
▸ Provide adequate follow-up

Table 28.4-3 Steps in Genetic Counseling

In general, genetic counseling for psychiatric disorders is sought by the patients themselves, their families, their prospective spouses, and prospective adoptive parents. Geneticists and genetic counselors tend to refer consultands with questions about psychiatric disorders to psychiatrists because the factors influencing susceptibility to those disorders are complex, and there is a recognition that the presence of severe psychiatric disorders usually has serious consequences for the functioning of both the affected individual and the family. The psychiatrist may then be called upon to provide genetic information in addition to addressing the therapeutic issues that may arise. Levels of involvement by the psychiatrist may range from diagnosis and the provision of recurrence risk data to treating the primary psychiatric disorder.

As genetic knowledge expands and clinical use of genetic screening to assess individual vulnerability increases, psychiatrists may also find themselves increasingly called upon to provide assessment and treatment to consultands with nonpsychiatric disorders who are referred by other physicians or genetic counselors. Such individuals may require considerable psychological support in coping with the genetic information they have learned and in making major decisions relating to that information.

Step 1: Establishing Diagnosis and Obtaining Family History The diagnosis of the proband must be rigorously established according to recognized criteria, such as DSM-IV, before counseling takes place. Medical records should be acquired, and releases obtained to call or write treating physicians and other therapists. Since other conditions can mimic mental disorders, a thorough medical history and information about substance abuse are important. The realities of different situations will create great variability in the amount of reliable clinical information that is available.

When an accurate diagnosis has been established, the family history should be taken from the informant in the form of a pedigree using the symbols shown in Figure 28.4-1. It is customary to work up through the pedigree starting with the information given by the consultand and following the guidelines in Table 28.4-4.

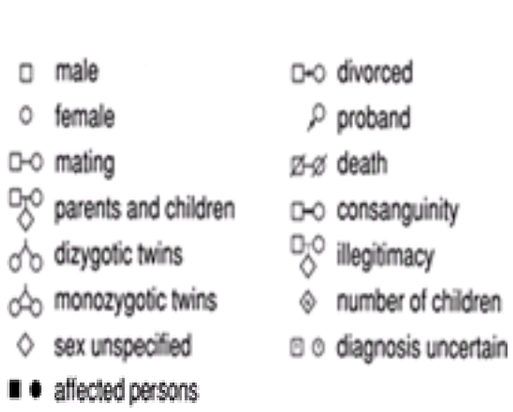

FIGURE 28.4-1 Symbols used in pedigree construction.

The informant should be asked the following questions about each person entered into the pedigree: What is the person's relationship to the informant (e.g., sibling, parent)? Is the person's relationship to the informant biological? Does the person have birth defects or a chronic disease? What is the ethnic background of the family? The following should also be determined: Marital status Maiden and married names of female relatives Occupation or educational status Address and telephone number (with assurance of confidentiality) The questions are relatively unintrusive and can, if necessary, be followed with more-sensitive questions (e.g., issues of paternity and consanguinity) if anything in the information given suggests that those topics should be pursued.

Table 28.4-4 Relevant Questions to Ask When Taking a Pedigree

If a relative is reported to be affected, the most satisfactory method of establishing the diagnosis is by direct interview or an examination of medical records. If that is not possible, as is often the case, an alternative may be to use the Family History–Research Diagnostic Criteria or similar instruments that attempt to establish a diagnosis through criteria-based questions.

Step 2: Provision of Information To provide information to the consultand, the psychiatrist should be familiar with the genetic concepts of complex disease and should determine (1) what information the consultand wants; (2) what is pertinent, but is not being asked; (3) at what pace and technical level the information should be given; and (4) what effect the information will have on the relationships within the consultand's family, since genetic information frequently has implications for the entire family.

Discussions of the genetic aspects of psychiatric disorders and the provision of recurrence risk information are complicated, not only because of diagnostic uncertainties, apparent etiologic heterogeneity, and comorbidity, but also because these disorders do not appear to involve straightforward mendelian genetics and presumably also have significant environmental components. In general, the multifactorial models used to describe complex inheritance of disorders like schizophrenia and bipolar disease are often highly technical and difficult for a layperson to conceptualize. Both the source and the magnitude of risk related to

recurrence data used in counseling need to be put in this perspective. It should be explicitly stated that the data apply to populations, not to individual persons, and thus are estimates at best.

In case A (Fig. 28.4-2) the unaffected husband (not the wife with a bipolar disorder) asked about the recurrence risk. The unaffected spouse of a person with bipolar disorder is often more concerned about the recurrence risk than is the affected person. The husband here might have been worried about the risk to his offspring, or he might actually be hoping to use information from genetic counseling to make decisions about his marriage to a person with a chronic illness or to deal with personal concerns about guilt and blame. Even for a disease whose genetic component is well understood, denial and a lack of understanding of true risk in carriers are common. In psychiatric disorders, dealing with the issue of risk in the context of other concerns may be exceptionally challenging.

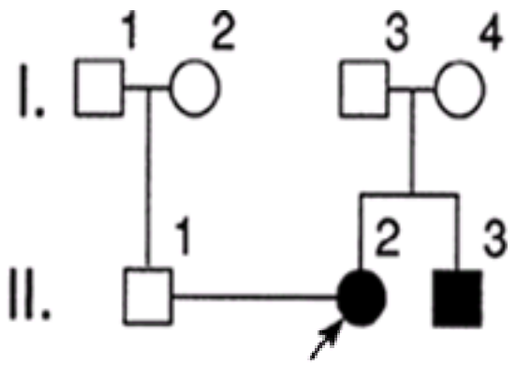

FIGURE 28.4-2 Case A. A couple in their mid-30s sought advice from the wife's psychiatrist on whether to have children. The wife (II-2), with a 10-year history of bipolar disorder and with bipolar disorder diagnosed in her brother (II-3), had had her symptoms controlled by the use of lithium carbonate. Previous attempts to function well without lithium had been unsuccessful. The couple expressed concerns about the effect of lithium on the pregnancy. In addition, the husband (II-1) wanted to know whether bipolar disorder is hereditary. (The recurrence risk of bipolar disorder is estimated to be up to 9 percent. Also, lithium has possible teratogenic effects, and the wife was entering the age range associated with increased chromosomal anomalies.)

The couple did not ask the physician about maternal age–related risk of chromosomal abnormalities in the fetus. It is standard practice to inform women who are 35 or older about the increased age-related risk of chromosomal anomalies and to discuss the availability of prenatal diagnosis. Although such discussion may fall outside the purview of psychiatric practice, this relevant clinical information should not be overlooked, even if it is handled by referral to a genetics clinic or to an obstetrician who specializes in prenatal diagnosis.

In case B (Fig. 28.4-3) the consultands were prospective adoptive parents. Their long history of infertility made them ready to look for mitigating information about recurrence risk. They also had had no direct experience with schizophrenia and had initially believed the recurrence risk to be even higher than it actually is for the offspring of either one or two affected parents.

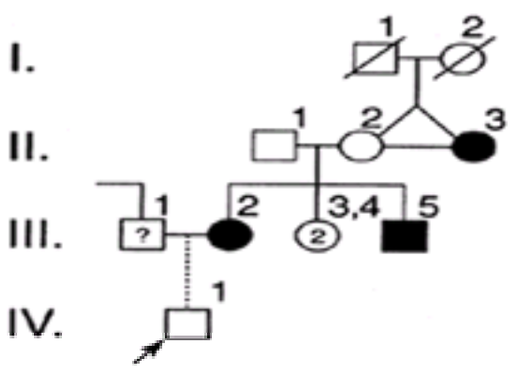

FIGURE 28.4-3 Case B. A childless couple in their late 30s, with a long history of infertility, were contemplating adoption of a newborn baby (IV-1). The baby was being placed for adoption because his mother (III-2) suffered from schizophrenia and was unable to care for him. The social worker in the case had comprehensive medical records for the biological mother and her family, including a brother (III-5) and a maternal aunt (II-3) with schizophrenia, but only hearsay reports (from the mother) that the putative father (III-1) also had schizophrenia. The adopting couple was concerned that the baby might be at increased risk for schizophrenia later in life. (The recurrence risk in the offspring of one affected parent is approximately 13 percent; for two affected parents the risk increases to 46 percent compared with a lifetime prevalence of 1 percent in the general population.)

Step 3: Decision Making and Adjustment to Information Most geneticists who perform genetic counseling take a nondirective approach to decision making. Such an approach should not be confused, however, with a lack of participation in comparing the risks and benefits of one course of action with those of others.

Each individual will view the same statistical risk from a different personal perspective. To aid the consultand, the data about statistical risk should be phrased in different ways. In case B, the risk could be described as “about 13 percent” or “one chance in eight of having schizophrenia,” and then also noted to be “an 87 percent chance of not developing schizophrenia.” The counseling clinician must take care to avoid offering personal judgments regarding the risk. Recent studies of genetic counseling and reproductive planning indicate that consultands are less focused on the absolute magnitude of the risk than on their personal desire to have children and their subjective interpretation of whether the risk is high or low.

After presenting the risk information, help in decision making can be given by exploring the consultand's feelings and reaction to the information; discussing any special cultural, ethnic, or religious factors that may be important; and using examples of options chosen by other families in similar situations. Inevitably physicians are asked what they would do in the same situation. Psychiatrists must avoid the temptation to say what they would do; answering the questions personally does not help patients think through the solution to a problem only they can answer.

Most geneticists gauge the effectiveness of counseling by their ability to help consultands meet certain goals. Primary among those goals are a diminution in any anxiety and guilt the consultands had experienced, an increase in their ability to understand the options available, and the formulation of effective plans to cope with the situation.

Step 4: Adequate Follow-Up An essential first follow-up step is a letter to the patient that recounts salient clinical issues, documents what the patient asked, recapitulates pedigree information the patient gave in narrative form, and outlines the plans, decisions, and any outstanding issues that remained unresolved at the end of the session. The letter is important not only to confirm what transpired during genetic counseling, but also for its use if the patient decides to seek a second opinion or further genetic counseling in the future. With written permission from the patient, a summary letter that includes the pedigree should also be sent to other physicians involved.

During the counseling session, the history of the patient may indicate other medical or psychiatric problems that need to be pursued, either with the consultand or with other family members. These situations are handled relatively simply through appropriate referral.

ETHICAL, LEGAL, AND SOCIAL CONSIDERATIONS

While psychiatrists always have dealt with the special considerations involved in receiving and communicating sensitive information, the new issues being raised by

advancing genetic knowledge are presenting major challenges. For example, an ethical and legal dilemma may arise when the physician receives information about untreated relatives that suggests that they are in need of medical intervention or at high risk for suicide. The consultand may not want other members of the family to know genetic information is being sought and may refuse permission for them to be contacted. This problem sometimes is compounded by situations such as that illustrated in case C (Fig. 28.4-4). Here, any information given to the consultand is also valid for the consultand's identical twin. While calling for careful attention to confidentiality, such a situation also clearly presents a need to encourage family discussion.

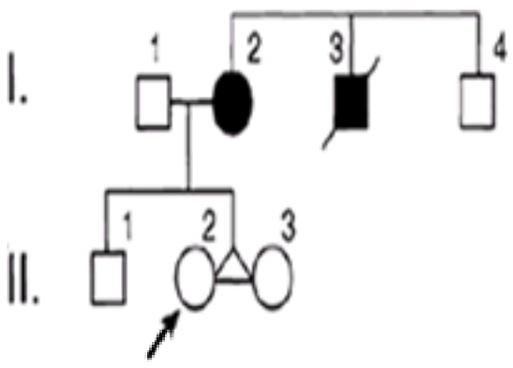

FIGURE 28.4-4 Case C. The consultand is interested in learning more about her own risk for Alzheimer's disease, a disease that affects her mother and maternal uncle. Her identical twin sister, however, vehemently denies that genetic factors could play a role in her relatives' illness. The dilemma for the physician is that when recurrence risk information is given to the consultand who is genetically identical to her sister, that information may also be conveyed to someone who has clearly expressed her wish not to know it.

As vulnerability genes for mental disorders are identified, policies and procedures for the appropriate protection of this information in relation to the decisions of insurers, employers, and similar entities are being developed by the medical profession, legislators, and others. As this occurs, psychiatrists who work with affected individuals and their families should take care always to adhere to the most rigorous ethical and legal standards of confidentiality regarding genetic information.

SUGGESTED CROSS-REFERENCES

The basic concepts of population genetics are reviewed in Section 1.17, and studies of genetic linkage of the psychiatric disorders are presented in Section 1.18. The genetics of specific disorders are discussed as follows: schizophrenia in Section 12.5, mood disorders in Section 14.3, and dementias in Chapter 10.

28.5 DEATH, DYING, AND BEREAVEMENT

SIDNEY ZISOOK, M.D., AND NANCY S. DOWNS, M.D.

Death is a universal and unavoidable phenomenon. It arouses strong feelings of dread and fear in dying patients as well as in their families and health care providers. In clinical practice death is not the special province of any single discipline or the specialty of any one branch of medicine; rather, it is the universal reminder of life and its meanings. Most physicians, mental health workers, and clergy are involved in terminal-care situations and increasingly people die in hospitals or hospice settings. This brings the medical community to the forefront of decisions on when and how life should end. Similarly, the role of physicians in regard to their patients' suicidal impulses is becoming more complex. Rather than uniformly being on the side of preserving life and preventing suicide, physicians now are being urged in certain circumstances and in the name of compassion and dignity to help some patients carry out their suicidal wishes.

Once a patient dies, medical responsibility for the patient and their family is not over. Each person who dies leaves several loved ones, family, and friends behind. Grief is the general response to death. It is restorative for many, but the bereaved also are at elevated risk for general medical morbidity, mortality, and the onset or exacerbation of a number of mental disorders. Preventing or attenuating these adverse reactions is the task of the health care system.

DEATH AND DYING

History *Thanatology*, the study of death-related behaviors, thoughts, and feelings, is a relative newcomer in medical education curricula. In the early 1960s a few university texts on thanatology appeared, and professional journals such as *Omega* began publishing articles on death, dying, and bereavement. Largely due to Elizabeth Kubler-Ross's work on death and dying at the University of Chicago and to the hospice movement, death education grew through the 1970s. Eventually, popular interest in contemporary issues such as the right to die, organ transplantation, and euthanasia began to permeate the medical milieu; the study of death and dying was finally incorporated into most medical school programs by the 1980s.

Definitions The terms “death” and “dying” are not synonymous and have no unequivocal definitions. However, because medical, legal, and moral issues cluster around when and how death takes place, definitions are necessary. *Death* may be considered the absolute cessation of vital functions, while *dying* is the process of losing these functions. Dying may also be seen as a developmental concomitant of living, a part of the birth-to-death continuum. Living may entail numerous mini-deaths: the end of growth and its potential, health-compromising illnesses, multiple losses, decreasing vitality, growing dependency with aging, and finally dying. Dying and the person's awareness of it imbues humans with values, passions, wishes, and the impetus to make the most of time.

Advances in technology have changed the focus of death definitions. Since the late 1960s the definition of death has shifted from a focus on respiratory and circulatory function to a focus on brain activity. Brain functioning and the resuscitation potential of mechanically maintained patients are a current focus. Heart transplants in the 1960s caused “brain death” to gain in prominence. Viable, intact donor organs are needed for transplants, but because organs lose viability with prolonged use of artificial respirators physicians must be able to pinpoint when brain death occurs in such patients.

Uniform Determination of Death Act Responding to that need, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research published its definition of death in 1981. Working with the American Bar Association, the American Medical Association, and the National Conference of Commissioners on Uniform State Laws, the Commission established that one who has sustained either (1) irretrievable cessation of circulatory and respiratory functions, or (2) irretrievable cessation of all functions of the entire brain, including the brainstem, is dead. Determination of death must be in accordance with accepted medical standards. The provisions of this act are now law in several states, yet problems remain. For example, the concept of brain death may be criticized as extreme biomedical reductionism. Most people would agree the central issue is not whether a particular organ is functional, but whether the person is alive—a complex and subjective decision. Distinctions of this sort will inevitably evolve from the more difficult philosophical concept of what is meant by life and what death entails.

Personal Meanings of Death Avery Weissman distills different attitudes about death and its meaning into four categories: (1) Death is an illusion and an extension of life, a prologue to another form of life; death means transition, not extinction. (2) Death is an inevitable and inexorable fact of life, a confrontation with finitude; it is an endpoint in the “contract” between the living and life's parameters. (3) Death is an explanation and expiation of life, a final judgment on the life process; it offers retribution or reward, a release from mortality's constraints. (4) Death is an exigency and a defeat of life, a tragedy, negating life's values, signifying failure and futility. Each of these theories about death is in fact a belief about life. Is death a journey to another existence, a locked system with no exit, a chance for retribution and reward, or a futile exercise?

Vital Statistics Although everyone dies of something, the way one lives is often a prescription for how one dies. Most of the 10 leading causes of death can be linked to modern lifestyles. Controlling tobacco and alcohol, avoiding obesity, reducing stress and environmental carcinogens, limiting sale of firearms, and driving safely would substantially decrease age-adjusted death rates.

Table 28.5-1 shows the 1993 age-adjusted death rates for the 10 leading causes of death. In the United States over 2.2 million people die yearly, with a crude death rate of almost 900 deaths per 100,000. The two leading causes of death, heart disease and cancer, account for more than 50 percent of all deaths. Since 1980 deaths from cardiovascular and cerebrovascular diseases and accidents and homicide have declined, whereas deaths from diabetes, chronic lung disease, and human immunodeficiency virus (HIV) infection are on the rise.

Rank	Cause of Death	Age-Adjusted Death Rate per 100,000 Population	Change 1980–1995 (%)	Male/Female Ratio	Black/White Ratio
1	Diseases of the heart	138.2	−31.8	1.82	.79
2	Malignant neoplasms, including neoplasms of the lymphatic and hematopoietic tissues	129.8	2.2	1.2	.85
3	Accidents and adverse effects	29.2	−31.0	2.1	1.1
	Motor vehicle accidents	15.7	−35.4	2.3	1.0
	All other accidents and adverse effects	13.5	−102.7	2.2	1.2
4	Cerebrovascular diseases	26.7	−34.6	.68	.9
5	Chronic obstructive pulmonary diseases	21.2	33.3	1.2	.3
6	Human immunodeficiency virus (HIV) infection	16.2		5.4	.83
7	Diabetes mellitus	13.2	30.7	.81	1.4
8	Pneumonia and influenza	13.0	1.0	.88	.7
9	Suicide	11.0	3.3	4.9	.3
10	Homicide and legal intervention	8.8	18.3	4.9	7.0

Table 28.5-1 1995 Age-Adjusted Death Rates for the 10 Leading Causes of Death; Percentage Changes in Age-Adjusted Death Rates From 1980–1995 Sex- and Age-Specific Ratios for the United States

For the first time since 1980, the average life expectancy at birth declined (from 75.8 years to 75.5 years). The decline in life expectancy is thought to reflect increases in death rates for (1) chronic disease during influenza outbreaks, (2) pneumonia and influenza, and (3) infection and unintentional injuries. Race-specific ratios were greatest for homocide and suicide. Whites were 10 times more likely to die from suicide, but 7 times less likely to die from suicide than were African-Americans.

Sex-specific ratios were greatest for HIV infection, suicide, and homicide.

Unnatural causes of death are prevalent among the young. Between ages 14 to 24, the leading cause of death is accidents, mostly vehicular. Many fatal accidents, suicides, and homicides are alcohol related. Suicides, the third leading cause in this age group (particularly among white males), have doubled since 1950. Each year half a million suicides are attempted (using firearms, poison, or drug overdose) by American youths. Untreated depression puts this group at serious risk.

The high suicide rate in the elderly is seen predominantly in white males. The married elderly who maintain good health and are connected with extended families are at lowest risk.

The United States leads other civilized countries in homicides, the second leading cause of death in the 15- to 24-year age group and the leading cause among blacks aged 25 to 34 years. “Motiveless” murders or drug-related “gang” murders are now claiming statistical significance in the homicide category, but they are still overshadowed by the more traditional cases where victim and perpetrator know or are related to one another.

Stages of Death and Dying Kubler-Ross publicized and legitimized the study of death while promulgating more humane and sensitive treatment of the terminally ill. Her extensive interviews with 400 dying patients reveal that patients know without being told that they are dying; that they need to talk about it; and that they need to maintain hope, even if there is no hope of cure. Kubler-Ross's work reminds clinicians that fatal illness is not a sudden event, that dying patients retain their humanity, and that practitioners can provide support to patients by assuring them that they will maintain their relationship with them during the dying process.

Kubler-Ross postulates five stages that many dying patients pass through from the time they first become aware of their fatal prognosis to their actual death:

1. *Denial*. “No, not me!” is the dying patient's common initial response. If it does not interfere with treatment, denial can mitigate the initial overwhelming anxiety.
2. *Anger*. “Why me?” Indignation may surface when denial subsides. Patients are irritable, demanding, and critical; anger may be directed at themselves, caretakers, family and friends, or God.
3. *Bargaining*. “Yes me, but . . .” This stage entails promises to buy additional time. Patients may promise to donate their organs to research or they may reaffirm an earlier faith in God.
4. *Depression*. “Yes, me.” The patient comes to a full realization of what is going to happen and to whom. With the impending loss of life, a pervasive despondency may set in.
5. *Acceptance*. The patient begins to accept the inevitable. This stage need not constitute defeat or total surrender. “Yes, me, and I'm ready.”

These five stages are not all encompassing or prescriptive. Not everyone will reach these stages; perhaps only a few will reach acceptance. A patient may demonstrate aspects of all five stages in one interview or may fluctuate between stages. Moreover, patients may exhibit other coping methods—such as terror, humor, or compassion—to offset each stage.

Other researchers emphasize unique ways patients cope with dying. One posits a dynamic tension between acceptance and denial. In this model there is a clustering of intellectual and affective states, set against the backdrop of one's personality and philosophy. Between the constant ebb and flow of emotions lies an interplay of hope and disbelief. Acceptance and denial play a game of tug of war, with armies of emotions such as anguish, terror, acquiescence, surrender, rage, envy, disinterest, pretense, taunting, daring, and yearning for the deceased loved one.

Another model stresses coping styles and psychosocial issues brought into play in the intervals between the earliest phases of dying and death itself. The *prediagnostic stage* involves postponement and denial. During the *established-disease stage*, patients typically need to redefine themselves in terms of work, family, religion, economics, self-esteem, incapacity, and vulnerability. Illusions of survival and fears of extinction may fluctuate with varying degrees of denial or acceptance. The *decline and deterioration stage* is characterized by dependency. More medications and assistance, less autonomy and fewer options signal decline. Family, friends, and caregivers also experience emotional burdens as they face their own inadequacies and mortality. Thanatologists agree on the importance of a form of hope that does not avoid the truths of diagnosis, survival, or terminality. Hope for recovery can transform into hope for courage to confront death with peace of mind.

Near-Death Experiences Belief in an afterlife is common in spite of the absence of empirical validation. Afterlife phenomena have been reported throughout history. Apparition (ghost) experiences were investigated in early scientific inquiries; out-of-body experiences, messages from beyond the grave, and reincarnation memories are other “proofs” cited for life after death. One psychiatrist published data from 1000 cases of children who remember previous lives.

Recent informal evidence for an afterlife comes from the large number of Americans—up to 40 percent according to one estimate—who believe in near-death experiences. Gallup polls cited eight million such claims in the United States. The manner of near-death (illness, accident, or attempted suicide), the demographics (age, education, race, sex), and religious beliefs were not significantly related to frequency of a near-death report.

Near-death descriptions are often strikingly similar, involving an out-of-body experience of viewing one's body and overhearing conversations; feelings of peace and quiet; hearing a distant noise; entering a dark tunnel, leaving the body behind; meeting dead loved ones; witnessing beings of light; returning to life to complete unfinished business; and a deep sadness upon leaving this new dimension. This experience is usually described as peaceful and loving; it feels real to participants, who distinguish it from dreams or hallucinations. These experiences provoke sweeping lifestyle changes, such as fewer material concerns, heightened sense of purpose, belief in God, joy of life, compassion, less fear of death, enhanced approach to life and intense feelings of love. Although near-death experiences do not readily lend themselves to scientific investigation and thus are not “legitimized,” the popular press has made them common knowledge and patients may want to discuss them with clinicians.

Cultural and Religious Beliefs Death is universally regarded as an important event for the individual and the social unit. Every culture and religion provides ways for its members to think about death and respond to it. Rituals, elaborately organized beliefs, and viewing death as sacred are elements common to most cultural and religious responses to death and dying. A society's death beliefs and mourning practices reveal much about the structure, function, and substance of the social unit. American ways of dealing with death and dying are probably as heterogeneous as America; however, the scientific literature on American subcultural practices regarding death is scanty. Several investigators note that in the United States, death is probably one of the most intensely experienced of all human crises, yet it is rarely discussed openly—this reveals our culture's extreme anxiety about death.

Physicians must understand the sociocultural and religious context of the dying patient. Health care issues surrounding dying and death such as autopsy approval, routine lifesaving procedures, abortion, euthanasia, and suicide are embedded within a cultural context. This context influences the patient and the family as well as the physician. When patient and physician have cultural differences, the possibilities for poor communication, misunderstanding, incongruent expectations, and noncompliance are increased.

Death Beliefs All societies attempt to control death by symbolically and ritualistically assigning an order and meaning to life. Belief in an afterlife, communion with ancestors, and connection with the spirit realm are common in many cultures and religions. Several investigators note that symbolism and ritual serve the important function of sustaining the social group after its impermanent personnel (the individual) has left the group. Cultural or religious beliefs and practices provide a kind of immortality for the social group that is comprised of mortal members.

Mainstream religious groups in traditionally Protestant America have tended to view death with equanimity. Christianity is based on the alleged triumph of its leader over the death experience. In the invitation to participate in Christ's triumph over the grave, Christianity offers believers the hope of an eternal destiny through salvation. Belief in a future world is fundamental; death is the prelude to a more glorious future where the body is transformed and the soul lives on forever.

Catholics believe in life after death. However, before entering heaven the soul must be purified and the “mystery of love” perfected in purgatory. This is done by praying to God that purgatory will be brief and that God will expedite the soul's journey to heaven.

Like Christians, Muslims believe in life after death as another stage in God's plan. Thus, the death of a loved one is seen as a temporary separation and is accepted as part of God's will.

Judaism espouses less defined notions of immortality. Although Jewish literature and teachings speak of heaven as a reward for living in accordance with God's laws, the Old Testament contains no explicit reference to a hereafter. Hope of an afterlife is not at the center of modern Jewish life and thought; instead, Judaism emphasizes a belief in the timelessness of the human spirit. Individuals live on through their children, the survival of their memory, and the continuance of their

personality as a force among the living.

Buddhism views death as a normal process, a reality that is both inevitable and unpredictable. Instead of seeing death as an end or defeat, Buddhists liken death to changing clothes that are old and worn out. They consider the actual experience of dying as extremely significant because the state of mind at the time of death can influence the quality of the next rebirth.

Mourning Practices Religious and cultural views also strongly influence mourning practices and rituals. These practices provide a setting in which to verify death, say goodbye, and honor the deceased. Of all the expressions of grief associated with death, the most common universal expression is crying or wailing. Compared to other cultures, American's grief reactions are marked by emotional restraint.

The Church of Jesus Christ of Latter-Day Saints (Mormons) provides a strong supportive community within the church, and the belief in afterlife is so strong that bereaved survivors may be discouraged from active mourning.

Roman Catholic ritual begins with the wake, a 2-day vigil before the funeral. At this time members of the community, friends, and family come to pay their respects. The funeral is incorporated into the Mass. The casket is covered with a white pall, which symbolizes the white robe of baptism. The priest is also dressed in white—symbolic of the joy of faith, which overcomes the sadness and pain of death. A lighted candle representing the new life of Christ is placed next to the casket. A month later and then annually a special Mass is celebrated for the deceased.

Jewish Americans often observe specific rituals of grief and mourning, including rapid burials, laws against cremation, and prohibitions against autopsy. *Shiva*, a traditional 7-day period of full mourning after burial, provides a time for family and friends to mourn together. Next, a 1-month period of partial mourning ensues, and work and life gradually resume. Specific memorial prayers are repeated for 1 year, then the mourning period is terminated with a ceremonial unveiling of the tombstone.

Protestant mourning practices are varied, in part because of the numerous denominations. Usually the body is prepared by the undertaker, first viewed by the family, and then the public. The funeral is frequently held in the chapel of the funeral home on the afternoon of the third day after death. Prayers are said and scriptures are read that emphasize the Christian hope for resurrection and the sustaining power of God. A funeral sermon is preached that may refer to the deceased, followed by the procession to the cemetery and a brief committal service. Some communities serve a supper for friends and neighbors. An alternative to the traditional service is a memorial service in which the casket is not present.

Black Americans, traditionally more fervent than their white compatriots, frequently observe elaborate rituals to honor the dead and are likely to turn to religious leaders as well as family for support and comfort. Although blacks are more likely to die young than whites, blacks demonstrate less fear of dying. In general, blacks are more open towards dying and mourning, and receive more comfort from grieving.

Asian-Americans also value emotional expression during the mourning period. Generally an emotionally reserved cultural group, Asian-Americans are expected and encouraged to vent uninhibited emotion during the immediate postbereavement period. Further, grief is considered a lifelong process that is not expected to end or be resolved within any circumscribed period of time.

Wealthy Mexican-Americans display attitudes similar to those of wealthy whites, engaging in similar levels of denial and avoidance; in lower socioeconomic groups, acquiescence to one's own death is more common. Mexican-Americans mourn within their community and retain extended-family ties that provide a community context.

Native-American culture is comprised of many different tribes and tribal subcultures; thus, it is important to view grief and bereavement within the context of a given tribe. Viewing life and death as a continuous circle, most Native Americans see death as an integral part of the continuity of life. During the stress of bereavement, they rely on the support of family and tribe, often viewing life after death as a reunion with deceased ancestors. To cope with the death of a loved one, Native-Americans have developed a wide array of ceremonies and rituals. These tend to be social as well as personal events, and are important for the proper mourning of the deceased and for the restoration of balance and harmony. Aspects of normal grief and bereavement in Native-American cultures may be misinterpreted as pathological by outsiders. For example, the mourning practice of cutting the flesh may be misinterpreted as the self-mutilating behavior of a patient with borderline personality disorder. Several Native-American tribal cultures describe a phenomenon of ghost illness or ghost sickness that incorporates auditory and visual hallucinations and multiple somatic symptoms. Indeed, because Native-American cultures are so spirit centered, hallucinations, dreams, and visions, common throughout life, are often observed in periods of grief and bereavement.

African-, Asian-, Hispanic-, and Native-Americans are a handful of the varied racial and cultural subpopulations that define North American society. Clinicians who work with patients on the personal issues of death and dying must take into account the broader sociocultural context of individuals and their families.

Life Cycle Considerations The clinical diversity of death-related attitudes and behaviors between children and adults have their roots in age-dependent differences in the cause of death and in developmental factors. As opposed to adults, who usually die from chronic illness, children are apt to die from sudden, unexpected causes. Almost half of the children who die between 1 and 14 years of age and nearly 75 percent of those who die in late adolescence and early adulthood die from accidents, homicides, and suicides. With their characteristics of violence, suddenness, and mutilation, these unnatural causes of death are special stressors for the survivors. The bereaved parents and siblings of dead young children and teenagers often feel victimized and traumatized by their loss; their grief reactions resemble posttraumatic stress disorder. Devastating family disruptions can occur and the surviving siblings risk having their emotional needs delayed or unmet.

Children's attitudes toward death mirror their attitudes toward life. They share with adolescents, adults, and the elderly similar fears, anxieties, beliefs, and attitudes about dying. None welcome it without ambivalence, and all temper their acceptance with healthy doses of denial and avoidance. Even so, some universal concepts are relatively specific to age groups.

Children What we know about children's attitudes towards death come from surveying healthy children, relying on adult memories of childhood, or exploring fantasies and beliefs children express during bereavement. Systematic studies of dying children have been few because children generally experience sudden, violent deaths rather than lingering illnesses. Most late-childhood and adolescent deaths are unnatural, (accident, homicide, suicide); natural causes are generally malignancies or congenital abnormalities.

Dying children often are aware of their condition and want to discuss it. Research suggests that terminal and preterminal children 3 years of age and older are aware that they are dying without being told. They often have more sophisticated views about dying than their healthy counterparts, probably because of their own failing health, separations from parents, subjection to painful procedures, and deaths of hospital friends. Attendant fears and anxieties may be unexpressed or channeled in maladaptive directions.

Often unable to meet dying children's needs or to face their own feelings, parents and caretakers may tend to avoid afflicted children, even though human contact and communication are crucial. Perplexed parents may go to extremes—overindulging their dying children, withdrawing from them, or insisting that nothing is wrong. In such instances the child receives little help with the anxieties and fears of separation and abandonment or in developing the requisite hope and courage. Eventually sensing that they are dying, such children become more terrified than those who receive guidance and support from empathic, honest family members.

The affective and cognitive development of children colors their understanding of death and their subsequent fears about dying. For example, at the preschool, preoperational stage of cognitive development, death is seen as a temporary absence, incomplete and reversible, like departure or sleep. Separation from the primary caretaker(s) is the main fear of a preschooler. This fear surfaces as an increase in nightmares, more aggressive play, or concern about the deaths of others rather than in direct discourse. Regression to more infantile behaviors signals increasing dependence on parents. Such children may assume responsibility for their death, feeling guilty for dying. Hospitalizations, separations from parents, and being subjected to painful procedures may reinforce their guilt and their belief that they are being punished. They may be unable to relate the treatment to the illness, and may instead view treatment as punishment. Dying preschoolers need reassurance from their parents that they are loved, that they have done nothing wrong, that they are not responsible for their illness, and that they will not be abandoned.

School-aged children manifest concrete-operational thinking and recognize death as a final reality. However, they view death as something that happens to old people, not to them. Between the ages of 6 and 12 years children have active fantasy lives of violence and aggression, often dominated by themes of death and killing. Games of cops and robbers or cowboys and Indians involve causal mayhem in which the “dead” are routinely resuscitated. Death may be personified as a

skeleton or bogeyman that takes people away. Dying school-aged children ask questions about their illness if encouraged to do so; however, if they receive cues that the subject is taboo, they may withdraw and participate less fully in their own care. They need help to cope with their peers and the demands of school. Teachers should be informed and updated about the child's condition. Classmates may need education and assistance to help them understand and respond to what is happening to their friend.

Adolescents Capable of formal cognitive operations, adolescents understand that death is inevitable and final. Their major fears parallel those of all teenagers: loss of control, being imperfect, and being different. Concerns about body image, hair loss, or loss of bodily control may generate great resistance to continuing treatment. Alternating emotions of despair, rage, grief, bitterness, numbness, terror, and joy are common. An adolescent's cognitive capacity to understand death may not translate into an understanding that their own personal death is possible. The potential for withdrawal or isolation is great because teenagers may equate parental support with loss of independence or may deny their fear of abandonment by actually repulsing friendly gestures. Teenagers must be part of the decision-making process surrounding their death. Many are capable of great courage, grace, and dignity in facing death.

Adults Unlike children and teenagers, older adults often readily accept that their time has come. Elderly patients may talk or joke openly about dying, and sometimes welcome it. In their 70s or beyond, they no longer harbor illusions of indestructibility; most have already had several close calls, their parents have died, and they have gone to funerals for friends and relatives. Although they may not be happy to die, they can be reconciled to it.

According to Erik Erikson, the eighth and final stage in the life cycle brings either a sense of integrity or despair. As elderly adults enter the last phase of their lives, they reflect on their time and how it has been lived. When one has taken care of things and is relatively successful and adapted to the triumphs and disappointments of life, one can look back with satisfaction and only a few regrets; one experiences a sense of integrity about oneself, feeling that one has lived totally and well and that one's life has been meaningful. Integrity of the self allows an individual to accept inevitable disease and death without fear of succumbing helplessly. However, if a person looks back on life as a series of missed opportunities or as filled with personal misfortunes, the sense is of bitter despair, a preoccupation with what might have been if only this or that had happened; then death is viewed with fear because it symbolizes emptiness and failure.

Caring Caring for a dying patient is highly individual. Caretakers need to deal with death honestly, tolerate wide ranges of affects, connect with a suffering patient and bereaved loved ones, and resolve routine issues as they arise. Although each therapeutic relationship between a patient and health provider is unique because of the patient's and health provider's gender, constitution, life experience, age, stage of life, resources, faith, culture, and other considerations, there are major themes confronted by all health providers caring for dying patients.

Breaking the News After diagnosis and prognosis have been made, physicians need to tell the patient and families. Formerly, doctors subscribed to a conspiracy of silence, believing that the less patients knew, the better their chance for recovery; it was believed that news of impending death brought despair, so the truth was withheld. The current policy is honesty and openness; the question is not whether to tell the patient, but when and how.

The American Hospital Association in 1973 drafted the “Patients' Bill of Rights,” declaring that patients have a “right to obtain complete current information regarding diagnosis, treatment and prognosis in terms the patient can be reasonably expected to understand.” Full disclosure is mandated whether the patient requests it or not.

In breaking the news of impending death to the patient, diplomacy dictates the following guidelines: (1) The health team physician should participate. (2) The spouse or partner should be present if possible. (3) Relatives need comfort, as does the patient. (4) Use simple words, even with educated patients. (5) Show compassion and emotional support, avoiding bluntness or abruptness. (6) Guessing how long a patient has to live may be inaccurate and inadvisable. (7) Encourage and answer questions, signaling one's availability for honest communication. (8) Truth is not the enemy of hope. (9) Communicate a willingness to see the patient through until death occurs. (10) Explain the situation and introduce the next step. A gentle, sensible approach helps to modulate the patient's own denial and acceptance. The physician must choose how much information to give and when, on the basis of the patient's needs and capacities.

Fears Knowing that one's death is imminent can precipitate a number of fears. Suddenly, every bodily change is interpreted as ominous, and can provoke terror. Dying patients commonly express fears of disfigurement; loss of autonomy; being a burden; being physically repulsive; disappointing family, friends, and colleagues; and facing the unknown. One group of terminally ill cancer patients surveyed reported that their greatest fears were of abandonment, pain, and shortness of breath. Effective management programs must address patient concerns. Patients need to know that they will not be abandoned and that relief from severe pain is available. Patients benefit greatly from the reassurance that their providers will not allow them to live or die in pain.

Goals of Treatment Facing an illness that cannot be cured, patients enter a phase where comfort becomes the primary goal. As illness advances and physical debilitation progresses, the incidence of pain, depression, and delirium increases. As these complications are the antithesis of comfort, they must be carefully assessed and controlled as best as possible. For palliative care to be effective, suffering must be minimized so that the quality of the remaining life can be maximized. In her landmark publication, *On Death and Dying*, Kubler-Ross described the unfinished tasks of the dying: reconciliations, resolution of conflicts, and the pursuit of specific remaining goals. Kubler-Ross sees the clinician's major task as helping patients reach these targets.

The Institute of Medicine has defined a *good death* as one that is free from avoidable distress and suffering for patients, families and caregivers; in general accord with patients' and families' wishes; and reasonably consistent with cultural, clinical, and ethical standards. With such goals in mind, three principles have been described in the psychosocial management of dying patients: safe conduct, dignified dying, and appropriate death. *Safe conduct*—defined as acceptance, clarity, candor, compassion, and accessibility—is imperative in caring for terminal patients. The difference between having a healthy dependency and being a sick victim is the ability to trust and be trusted, so patients must feel that caretakers will be there and will treat them with respect and dignity. Safe conduct can help the patient achieve a *dignified dying*, which involves the patient being regarded as responsible and capable of clear perceptions, honest relationships, and purposeful behavior, consistent with the current level of ability. The physician helps the patient relinquish autonomy as needed, prescribes required medication, and encourages the patient to resolve any remaining conflicts. The third goal for the physician is to help the patient die an *appropriate death*, one that the person might choose if he or she had the choice. Suffering is at a low ebb, conflict is minimal, and behavior has been maintained on as high a level as is compatible with physical status. The patient both expects and accepts death, and is willing, albeit ruefully, to die.

Seven Cs of Care Ned Cassen suggests seven essential features in the management of the dying patient: (1) *Concern:* Empathy, compassion, and involvement are essential; concern is ranked as the quality most appreciated by patients. (2) *Competence:* Skill and knowledge can be as reassuring as warmth and concern. In particular, health care providers must adeptly manage the complications of terminal illness—pain, nausea, shortness of breath, and hopelessness. Patients benefit immeasurably from the reassurance that their providers will not allow them to live or die in pain. (3) *Communication:* Allow patients to speak their minds and get to know them. (4) *Children:* If children want to visit the dying, it is generally advisable; children bring consolation to dying patients. (5) *Cohesion:* Family cohesion reassures both the patient and family. The clinician who gets to know the family maximizes patient support and is prepared to help the family through bereavement. (6) *Cheerfulness:* A gentle, appropriate sense of humor can be palliative; a somber or anxious demeanor should be avoided. (7) *Consistency:* Continuing, persistent attention is highly valued by patients who often fear that they are a burden and will be abandoned; consistent physician involvement mitigates these fears.

Assisting the Family Family members may need help on how to best aid and relate to their dying loved one. The task of coping with major changes in roles and relationships associated with the terminal stage of illness is compounded by a lack of preparation on how to behave in the presence of someone who is dying. Fatal illness destroys future hopes and plans, educational ambitions, established marital and parent-child adjustments, financial stability, and lifestyle. Extended illness puts excessive pressure on existing social support systems within and around the family, depleting financial and social resources as well as causing interpersonal family relationships to become estranged. One researcher has offered the following suggestions to health professionals on how to assist the family: train family members to participate in treatment; encourage them to provide emotional support and to anticipate the special needs of the patient; allow unlimited visiting so that the whole family, including children, can spend time with the patient; and provide special hospital space for patient-family meetings as well as for family members to live when the patient's death is imminent. Many of these suggestions are incorporated in hospice care of the dying and their families.

Professional Supportive Programs Supportive interventions may enhance health and contribute to survivorship in some life-threatening illnesses. Several studies have shown that group therapy interventions enhance effective coping and increase well-being in cancer and acquired immune deficiency syndrome (AIDS) patients. One important study on the effects of group intervention for women with metastatic breast cancer found that women who receive supportive group therapy and self-hypnosis for pain alleviation have higher 10-year survival rates than those who do not.

Self-Help and Mutual Support Self-help programs provide a supportive milieu for patients to share their expertise and experience. After World War II the American Cancer Society began volunteer programs in which patients visited patients to offer practical help and support. The Society later sponsored volunteer programs for women with disfiguring surgical procedures (Reach to Recovery), for families dealing with childhood cancer (Candlelighters), and for other special interest groups.

Recently, volunteer support programs for serious medical problems, as well as for families who have survived potentially fatal illnesses, have proliferated. Such programs offer patients contact with others who have experienced similar fears and obstacles and who have found a way to face death courageously. Groups buffer the impact of illness and enhance coping by providing a sense of belonging, emotional support, access to information, social contact, and self-esteem. Reinforcement to maintain effort and face painful procedures is also offered. Most groups work in proximity to professional medical services as an adjunct to traditional care, and physicians are well advised to refer patients and family members to such programs.

Hospice The founding of St. Christopher's Hospice in England by Cicely Saunders in 1967 launched the modern hospice movement. Several factors in the 1960s propelled the development of hospices, including concerns about inadequately trained physicians, inept terminal care, gross inequities in health care, and neglect of the elderly. Life expectancy had increased and heart disease and cancer were becoming more common. Saunders emphasized symptom control, care of patient and family as a unit, an interdisciplinary approach, the use of volunteers, a continuum of care including home care, continuity of care among several settings, and follow-up with family members after a patient's death. By 1974 the first hospice in the United States, Connecticut Hospice, opened. As of 1998, there are about 3000 hospices in the United States. In 1997, they cared for more than 450,00 persons (about one fifth of Americans who died).

Round-the-clock pain control with opioids is an essential component of hospice management. In 1983 Medicare began reimbursing hospice care. Medicare hospice guidelines emphasize home care, with benefits for a broad spectrum of physician, nursing, psychosocial, and spiritual services at home, or if necessary, in the hospital or nursing home. To be eligible the patient must be physician-certified as having 6 months or less to live. By electing hospice care, patients indicate that they agree to receive palliative rather than curative care and waive their right to alternative medical treatments. Many hospice programs are hospital-based, sometimes in separate units and sometimes in the form of hospice beds interspersed throughout the facility. Other program models include free-standing hospices and programs, hospital affiliations, nursing home or extended-care facilities, and home care programs only.

Hospice families generally express satisfaction with their personal involvement in care. Savings with hospice are variable, but home care programs generally cost less than conventional care, particularly in the final months of life. Hospice patients are less likely to receive diagnostic studies or intensive therapy such as surgery, chemotherapy, or medication, and are more likely to die at home. However, research studies have failed to show that the quality of life for terminally ill patients served in the hospice setting is significantly different from the quality of life for patients served in conventional settings. This may be because most traditional programs incorporate modalities offered by hospice programs. Hospice care is a proven, viable alternative for patients who elect a palliative approach to terminal care. In addition, hospice goals—dignified, comfortable death for the terminally ill and care for patient and family together—have been increasingly adopted into mainstream medicine.

Alternatives to Mainstream Medicine Even many well-educated patients, once they are told they are terminally ill, do anything within their means to outrun the prognosis. They may seek alternative treatments, ranging from innocuous programs aimed at enhancing one's general health to more aggressive, harmful, or fraudulent treatments. The majority of unorthodox practitioners are physicians. Although most patients combine unorthodox with traditional treatment, a substantial number favor unorthodox approaches as the disease progresses.

Presently unproven methods to cure cancer emphasize a holistic approach, involving purification of the body, detoxification through internal cleansing, and attention to nutritional and emotional well-being. Despite their widespread appeal, none of these alternatives has been demonstrated to cure cancer, prolong life, or diminish suffering; yet all have strong followings bolstered by anecdotal accounts of their efficacy. The popular *metabolic therapy* attributes cancer to toxins and waste material accumulating in the body; treatment is based on reversing this process by diet, vitamins, minerals, enzymes, and colonic irrigations. *Nutritional approaches*, such as macrobiotic diets or megavitamins to enhance the body's capacity to destroy malignancy, also lack firm scientific support. In 1987 the National Research Council recommended minimizing carcinogenic substances and fat in the diet, and increasing whole-grain, fruit, and vegetable consumption as preventive guidelines. *Psychological approaches* cite maladaptive personality and coping styles as being cancer-causing; treatment consists of shaping a positive attitude. *Spiritual and mystical approaches* aim at harmony between the patient and nature; cancer may be seen as an external evil to be exorcised rather than treated. Finally, *immunotherapies* have gained popularity in recent years; cancer is attributed to a defective immune system and restoration of immunocompetency is seen as the cure. Substantive evidence of efficacy is lacking in all these approaches.

Society's present emphasis on health consciousness, mind-body relationships, and individual responsibility is reflected in the current holistic alternative treatments. Staff working with terminally ill patients, especially those with cancer, must be informed of these approaches and be prepared to discuss them with patients. They must assess the patient's wish for these therapies, especially because they reflect emotional needs unmet by conventional treatment. Until cancer and other progressive chronic illnesses are successfully treated, alternative cures will continue to surface.

Aggressive attempts also are made to forestall or overcome death. *Cryonic suspension* attempts to maintain patients in an indefinite hypothermic state until medical science develops means to resuscitate the body and cure the terminal illness. Several bodies are already cryonically suspended, awaiting the future, despite scientific skepticism about the procedure or its ultimate desirability. Others look to genetic engineering or cloning as potential antidotes to mortality. These approaches tend to see death as the enemy rather than as an integral part of life.

PHYSICIAN AID IN DYING

Until recently traditional medicine did not entertain the notion of allowing patients to choose when to die. Three major forces have coalesced to force the medical community to alter its position. First, more patients die in medical institutions, often from chronic conditions such as cancer, AIDS, or neurodegenerative processes. It is estimated that over 60 percent of all deaths occur in hospitals, with another 20 percent occurring in nursing homes. Of those dying at home, a growing minority do so with hospice care. Increasingly, health care providers have a significant and ongoing role in the way people live out their last days to weeks of life. Second, advances in modern medical technology can prolong an individual's biological processes such as respiration well beyond the point at which they have any reasonable hope for achieving an autonomous, meaningful existence. This capacity has created countless medical, legal, and ethical dilemmas that now face patients, their families, and society at large. Third, the trends toward increasing patient involvement in care, patient rights, and consumerism in medicine have forced the medical community to listen to patients' wishes and to offer them choices rather than to dictate solutions.

The current debate surrounding patient autonomy regarding life and death decisions was fueled by 3 pivotal court cases with variable outcomes. The most celebrated court case involved Karen Ann Quinlan, whose adoptive parents petitioned the court to disconnect her respirator after she had lapsed into a long, irreversible coma. The New Jersey Supreme Court, after much debate, ruled that a ventilator (presumed to be keeping her alive) could be turned off. To the surprise of all parties, the patient lived another 10 years without the respirator and died of pneumonia in 1985.

In a second landmark case, a nonvegetative patient, Elizabeth Bouvia, asked to be allowed to die. Suffering from cerebral palsy, with just enough muscular control to generate her electrically powered wheelchair and to chew and swallow if fed by someone else, she wanted to be admitted to a hospital and allowed to starve to death. The hospital force-fed her, which brought the issue to court. Although the judge thought that Bouvia was competent and sincere, he ruled in favor of the hospital, refusing to sanction passive euthanasia in a nondying patient, despite the patient's wishes and her chronic suffering. Ultimately, a California Court of Appeals ordered physicians to remove the nasogastric tube from Bouvia, rejecting the hospital's contention that removing the patient's tube would make it party to a suicide. Thus, the court did not require that a patient be comatose or terminally ill to refuse life-saving treatment.

In a third pivotal case the United States Supreme Court ruled in 1988 on an appeal regarding Nancy Cruzan. Cruzan had been in a persistent vegetative state since an accident in 1983, and her parents sought permission to withdraw her feeding tube and let her die. Citing the lack of evidence about what her wishes would have been, the Missouri Supreme Court denied the Cruzans' request, a decision that the United States Supreme Court upheld by a five-to-four vote. Although it affirmed the right of competent persons to refuse life-sustaining treatment, the court's decision retained the broad powers in individual states to rule on such matters without federal intervention. When originally proposed 30 years ago, advance directives were short statements by patients wishing to avoid “heroic measures.” Such directives have evolved into three types of advance directives: (1) living wills, (2) durable powers of attorney, and (3) value histories.

Advance Directives As the movement for the protection of health care consumers gains credibility and as patients begin to realize that they have rights, more individuals are leaving *advanced directives*. Such documents enable competent persons to state the type of medical care that they wish to receive should they become unable to participate in treatment decisions. A *living will* allows patients to express in writing whether they elect to receive or expressly refuse such procedures as cardiopulmonary resuscitation, artificial respiration, parental nutrition, and hydration. These documents may also have provisions regarding pain medications, even those that may shorten life. Living wills are legally enforceable in most states and are generally endorsed by the medical and legal professions. Table 28.5-2 provides an example of a living will. Another type of advanced directive, a *durable power of attorney*, designates someone to make medical decisions in the event that the person becomes incompetent or otherwise unable to make decisions. The third type of advanced directive, values histories, allows patients to

indicate their values and what gives their lives meaning, some for such as the so-called *Medical Directive* are a combination of all the types.

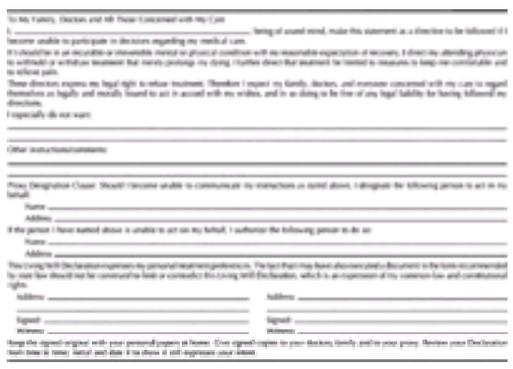

Table 28.5-2 Advanced Directive

The Uniform Rights of the Terminally Ill Act, drafted by the National Conference of Commissioners on Uniform State Laws was approved and recommended for enactment in all states at its annual conference in 1985. The act authorizes an adult to control the decisions regarding the administration of life-sustaining treatment by executing a declaration instructing a physician to withhold or to withdraw life-sustaining treatment if the person is in a terminal condition and is unable to participate in medical treatment decisions. In the early 1990s the Self-Determination Act became law in the United States and required that all health care facilities provide each patient admitted with written information about the right to refuse treatment, ask about advance directives, and keep written records of whether the patient has a directive or has designated a health care proxy. When such clarity is not present, common sense should prevail and the patient's next of kin should be asked to provide substitutive judgment about what the patient would want.

Euthanasia From the Greek term for good death, *euthanasia* means compassionately allowing, hastening, or causing the death of another. Generally someone resorts to euthanasia to relieve suffering, maintain dignity, and shorten the course of dying when death is inevitable. Euthanasia can be *voluntary* if the patient has requested it, *nonvoluntary* if the decision is made without the patient's consent, or *involuntary* if the decision is made against the patient's wishes. Euthanasia can be *passive*, simply withholding heroic lifesaving measures, or *active*, deliberately taking a person's life. Although the moral, ethical, medical, and legal issues involved in each form of euthanasia have not been fully worked out, most clinicians have little problem with passive, voluntary euthanasia if the patient's death is thought to be inevitable, close at hand, and accompanied by relentless suffering. However, few agree that involuntary, active euthanasia is acceptable under any circumstances. The ethics of other combinations of activity and consent are controversial.

Arguments for and against euthanasia have been articulated by well-intentioned, thoughtful individuals on both sides of the debate. Proponents of euthanasia argue that quality of life and patient dignity are more important than the number of hours or days a patient lives. Two of the strongest arguments revolve around patient autonomy and dignified dying. Respect for each patient's autonomy has become a guiding principle in medicine. One of the most dramatic ways patients may exercise their right to self-determination is by asking for life-sustaining treatment to be withdrawn. If the patient is mentally competent, physicians are honor bound to respect such wishes. Proponents of active, voluntary euthanasia argue that the same rights should be extended to patients who are not on life-sustaining treatment but who also choose to have their physicians help them die. The second argument rests on the knowledge that some deaths—especially from cancer, AIDS, or progressive neurological lesions—may be slow and miserable. Not all pain can be relieved, and often symptoms, such as dyspnea, nausea, and weakness are even more difficult to control. Furthermore, dying may bring great indignities and extended suffering. Thus, euthanasia may provide a dignified and peaceful alternative for some hopelessly miserable patients.

Opponents of euthanasia also provide strong ethical and medical justification for their position. First, active euthanasia, even if the patient voluntarily requests it, is a form of killing, and outside of war, self-defense, or perhaps capital punishment, killing should never be sanctioned. Second, euthanasia is almost never necessary because most suffering can be relieved with skillful and compassionate care. The fact that some physicians are poorly educated in pain control or other palliative care measures should be addressed by education rather than by legalizing euthanasia. Third, many patients who request aid in dying may have unrecognized or untreated depression, a difficult diagnosis to make in the context of chronic and painful medical illness. Core symptoms of major depressive disorder include the wish to die, compromised ability to think clearly, a sense of hopelessness about the future, a tendency to embellish pain and misery, and a view of the world that embraces pessimism and negativity. Yet, many terminally ill patients see primary care physicians who may be ill-equipped to diagnose depression in the elderly or other complex situations. Even well-trained psychiatrists have difficulty diagnosing depression in severely ill patients. Studies indicate that the will to live of many patients with life-threatening illnesses improves substantially after treatment of depression. Fourth, legalizing voluntary euthanasia will put us on a moral slippery slope, inexorably leading to involuntary euthanasia or to euthanasia for children with birth defects or adults with mental illness. Thus, once active euthanasia is tolerated or legalized, increasingly liberal interpretations of the guidelines will occur. As barriers are broken the line of acceptable cases will be redrawn and there will be little justification for limiting the practice to the terminally ill or to persons who are cognitively intact enough to request it. Why not extend one's “help” to persons in the earliest stages of HIV infection, nonterminal accident victims who envision a life of disability and dependence, patients suffering from chronic treatment-refractory depression, or illnesses such as Alzheimer's disease? Fifth, euthanasia would be a particular threat to the economically and socially vulnerable; and the poor, mentally ill, or disabled may be coerced to request it. In the present era of managed care, with its emphasis on cost containment and the economics of care, this argument is particularly disturbing. Patients may request euthanasia in order to not be a burden; overwrought family members might pressure vulnerable patients to request it, and cost-conscious doctors may see it as a solution to capitated care. Finally, euthanasia violates the time-honored mission of physicians to be unambiguously committed to preserving life. Legalizing euthanasia could lead to further distrust of doctors, and could keep otherwise needy patients from seeking care or consulting with physicians. Although many physicians would agree that patients have a right to die, and competent, rational patients may have a right to choose when to die, that does not translate into physicians having the right or obligation to kill.

Most medical, religious, and legal groups in the United States are more impressed with the arguments against euthanasia than for it and oppose legalization of euthanasia. Both the American Psychiatric Association and the American Medical Association condemn active euthanasia as illegal and contrary to medical ethics; however, few persons have been convicted of euthanasia.

The World Medical Association issued the following declaration on euthanasia in October 1987: “Euthanasia, that is, the act of deliberately ending the life of a patient, even at his own request or at the request of his close relatives, is unethical. This does not prevent the physician from respecting the will of a patient to allow the natural process of death to follow its course in the terminal phase of sickness.”

The New York State Committee on Bioethical Issues also opposes euthanasia. The committee stated the following:

> Physicians are obligated to relieve pain and suffering and to promote the dignity and autonomy of dying patients in their care. This obligation includes providing effective palliative treatment even though it may occasionally hasten death. However, physicians should not perform active euthanasia or participate in assisted suicide. Support, comfort, respect for patient autonomy, good communication, and adequate pain control may dramatically decrease the demand for euthanasia and assisted suicide. In certain carefully defined circumstances, it is humane to recognize that death is certain and suffering is great. However, the societal risks of involving physicians in medical interventions to cause patients' death is too great to condone active euthanasia or physician-assisted suicide.

Both proponents and opponents of euthanasia are closely watching the experience in the Netherlands, where euthanasia is officially a crime but its practice has been accepted for over 20 years, protected by a body of case law and strong public support. In 1984 the Royal Dutch Medical Association set out criteria for performing euthanasia or physician-assisted suicide: (1) the request for euthanasia must come only from the patient who must be entirely free, voluntary, and a mentally competent adult; (2) the patient's request must be considered, durable, persistent, and documented; (3) the patient must be experiencing intolerable (but not necessarily physical) suffering, with no prospect of improvement; (4) other alternatives must have been considered and found wanting; (5) the euthanasia must be performed by a physician; and (6) the physician must consult with an independent colleague who has experience in the field.

In 1990 the Dutch government appointed a commission, headed by Professor Jan Remelink, the Attorney General of the Dutch Supreme Court, to oversee a careful, nationwide study of the practice. From physician interviews and questionnaires, the commission reported that of the roughly 130,000 deaths in the Netherlands in

1990, 38 percent involved a medical decision concerning the end of life. Most of these were to allow someone with a terminal illness to die without heroics or to treat unbearable pain with medications in such doses that the patient's life may have been shortened. However, 2300 deaths, or 2 percent of the total, were the result of euthanasia. The most frequent reasons for requesting euthanasia included loss of dignity (57 percent), pain (46 percent), unworthy dying (46 percent), being dependent on others (33 percent), and tiredness of life (23 percent). Another 400 deaths (0.3 percent) were assisted suicides. In 1000 of the deaths (0.8 percent) the patient was not consulted when euthanasia was performed despite the clarity of the Dutch guidelines regarding this requirement. In response to these involuntary cases, in 1993 the national government and medical association released a statement condemning involuntary euthanasia, and reporting procedures were clarified by law. Still, only a minority of the physician-assisted deaths are reported as such on death certificates.

A study of Dutch nursing home physicians who administer euthanasia found that about 1 out of every 8 requests for euthanasia in nursing homes is granted. The most frequent reasons for euthanasia requests were fear of deterioration of condition (25 percent), fear of suffocation (15 percent), unbearable suffering (14 percent), and pain (11 percent). The period of time from the first discussion of the subject and the actual administration varied from more than a year (3 percent) to less than a day (7 percent). In 15 percent of the cases no consultation with another physician was requested, and in 15 percent of the cases it was someone other than the patient (e.g., child of patient, or physician) who first broached the subject. All guidelines were met only 41 percent of the time.

Both proponents and opponents of euthanasia point to the Dutch experiment to support their position. Those who favor some form of physician-assisted dying in the United States are reassured by the small fraction of total deaths accounted for by euthanasia or assisted suicide. Furthermore, it was performed in fewer than a third of those who requested it, even less so in nursing homes, indicating the reluctance of many doctors to honor such requests. And, euthanasia was usually performed on those who were terminally ill. On the other hand, those who oppose euthanasia or assisted suicide point to the abuses. In almost 1000 cases, or nearly 1 percent of all deaths, patients were euthanized without their request or consent. Accurate reporting remains a problem, and in nursing homes the topic of euthanasia may be first broached by physicians themselves who often carry it out almost immediately after initial discussion and often do not consult other physicians. The importance of waiting before carrying out euthanasia is underscored by the finding that 85 percent of the patients that initially request aid in dying in the Netherlands withdrew their requests once their symptoms were controlled. Furthermore, many argue that in the United States, which, unlike the Netherlands, does not have universal health insurance, and where large segments of the population are uninsured, these abuses are even more likely.

A recent survey of doctors and death in Australia found that medical decisions to end life are involved in about 30 percent of deaths in that country. Potentially life-prolonging treatment is withheld or withdrawn in 25 percent of deaths; in 24 percent of Australian deaths, a decision to use high doses of opioids to relieve pain may have hastened death without an explicit intent to do so; in another 7 percent of deaths, a decision to use high-dose opiods for pain relief was made with some intention to hasten death; and in 4 percent of deaths a decision was made to administer drugs that would end a patient's life without a specific request from the patient. Despite the controversy stirred by this survey, Australia's Northern Territory became the only country in the world where euthanasia and physician-assisted suicide are legal and practiced. Enacted in July 1996, Australia's Rights of the Terminally Ill Act mandates that the patient must be at least 18 years old and mentally and physically competent to make the request. At least three doctors must concur, including a specialist confirming that the patient is terminally ill and a psychiatrist who certifies that the patient does not suffer from a treatable depression. In addition, after all paperwork has been completed, there must be a waiting period of at least 9 days before the procedure can be administered. Since July 1996 four people died under the Act. However, by the end of the following year the Australian Parliament overturned the law.

Physician-Assisted Suicide In the United States most of the debate centers on physician-assisted suicide rather than euthanasia. Some have argued that physician-assisted suicide is a humane alternative to active euthanasia in that the patient maintains more autonomy, remains the actual agent of death, and may be less likely to be coerced. Others believe that the distinctions are capricious in that the intent in both cases is to bring about a patient's death. Indeed, it may be difficult to justify providing a lethal dose of medication to a terminally ill patient (physician-assisted suicide) while ignoring the desperate pleas of another patient who may be even more ill and distressed but who cannot complete the act because of problems with swallowing, dexterity, or strength.

There are several degrees to which a physician may assist in ending the life of a suicidal patient. Physician-assisted suicide may involve providing information on ways of committing suicide, supplying a prescription for a lethal dose of medication or a means of inhaling a lethal amount of carbon monoxide, or perhaps even providing a suicide device that the patient can operate.

Founded by Derek Humphry in 1965, the Hemlock Society is concerned with active euthanasia and assisted suicide. It boasts a national membership and broad recognition. The success of Humphry's book *Final Exi*, a how-to guide to suicide and a bestseller in 1991, attests to its popularity. The society supports physician-assisted suicide and active, voluntary euthanasia for the terminally ill but it does not encourage suicide in the absence of terminal illness. The Hemlock Society has led state initiatives to permit physicians to help terminally ill patients die in Washington in 1991 and again in California in 1992. The so-called death-with-dignity initiative did not pass, but in each case it received almost 50 percent of the popular vote. Since then, the Hemlock Society's efforts influenced the 1994 passage of a ballot initiative to legalize physician-assisted suicide in Oregon and in making public and medical opinions more accepting of physician-assisted suicide.

In 1991 the *New England Journal of Medicine* published the case of Diane, a woman with acute leukemia who elected not to undergo the recommended course of treatment, which had a 25 percent chance of success. This publication fueled the debate about the physician's role in assisted suicide. When Diane initially raised the possibility of taking her own life, her physician referred her to the Hemlock Society for information. When she subsequently requested enough barbiturates to kill herself, her physician gave her the prescription she eventually used to end her life. Despite her past history of depression and intermittent complaints of low energy, anger, trouble sleeping, and sadness, her physician felt that giving her the means to kill herself was appropriate, humane, and compassionate care. Others argued that the case highlights the potential pitfalls of legalizing physician-assisted suicide and the need for a comprehensive evaluation of occult depression in all patients who seriously consider suicide.

The controversy is further heightened by the publicity and court proceedings surrounding the activities of retired pathologist, Jack Kevorkian, who in 1989 provided his suicide machine to a 54-year-old woman with a diagnosis of probable Alzheimer's disease. After the woman killed herself with his device, Kevorkian was charged with first-degree murder. The charges were later dismissed because Michigan had no law against physician-assisted suicide. Since that case, Kevorkian has assisted in over 100 additional suicides, often for persons he had met only a few times and frequently for persons who did not have a terminal illness. Kevorkian's license to practice has been revoked and more murder charges have been leveled against him. The most recent charges against Dr. Kevorkian stem from a televised depiction of his first publicized procedure of clear-cut active euthanasia. He was convicted of manslaughter in 1999 and sentenced to prison. That an unliscenced physician could so readily move from assisted suicide to active euthanasia provides additional fuel to the slippery slope argument. His attorneys and followers applaud his courage in easing pain and suffering; his detractors counter that he has become a serial mercy killer. Several opponents of Kevorkian's methods charge that without safeguards, consultations, and thorough psychiatric evaluations, patients may seek suicide not because of terminal illness or intractable pain but because of untreated depressive disorders. They argue that suicide rarely occurs in the absence of psychiatric illness. Finding more effective treatments for pain and depression rather that inventing more sophisticated devices to help desperate patients kill themselves defines compassionate and effective physician care.

Despite the abhorrence that many physicians and medical ethicists express toward physician-assisted suicide, poll after poll shows that as many as two thirds of Americans favor the legalization of physician-assisted suicide in certain circumstances. There is even evidence that the formerly uniform opposition to physician-assisted suicide within the medical community has eroded. While one recent survey of hospice physicians and nurses found overwhelming opposition to assisted suicide, another 1992 survey reported that 21 percent of geriatric internists would consider assisting in the suicides of competent, nondepressed dementia patients. In a 1996 poll of Oregon psychiatrists' attitudes toward physician-assisted suicide, two thirds endorsed the view that a physician should be permitted, under some circumstances, to write a prescription for a medication whose sole purpose would be to allow patients to end their lives. The poll revealed that psychiatrists' moral beliefs influence how they might evaluate patients requesting assisted suicide and that their confidence in accurately assessing whether depression is impairing the judgment of a patient requesting assisted suicide was low. A 1997 poll of 118 physicians in San Francisco working with AIDS patients found that 53 percent of the physicians anonymously indicated that they had intentionally prescribed a deadly dose of narcotics to patients who wanted to die. A national survey published in 1998 polled over 1900 physicians and found that 18 percent had received requests for assistance with suicide and 11 percent had received requests for lethal injections. Furthermore, 3 percent of the physicians reported they had written at least one prescription to be used to hasten death, and 5 percent said they had administered at least one lethal injection. Finally, a 1998 telephone poll of oncologists found that 16 percent had participated in euthanasia or physician-assisted suicide. That poll also found that in only one third of cases do oncologists adhere to all of the main safeguards generally endorsed by proponents of euthanasia and physician-assisted suicide: Only 61 percent of patients both initiated and repeated their requests for aid in dying, and physicians sought consultation in 40 percent of cases (Table 28.5-3). About one quarter of the oncologists who performed euthanasia or assisted a patient with suicide regretted their participation. Consistent with their positions on active euthanasia, the American Medical Association, the American Psychiatric Association, and the American Bar Association continue to oppose physician-assisted suicide.

	Percentage adhering to safeguard
Patient request	
Patient initiated request	79
Patient repeated request	63
Patient initiated and repeated request	61
Patient distress	
Pain	84
Poor physical functioning	87
Pain or poor physical functioning	97
Second opinion	
Discussed with another physician	40
Evaluated by psychiatrist	5
Adhered to all 3 safeguards	34

Table 28.5-3 Adherence to Proposed Safeguards in the Practice of Euthanasia and Physician-Assisted Suicide Among Oncologists in the United States

Several court decisions are currently in various stages of review. In rejecting a constitutional right to physician-assisted suicide in 1997, the U.S. Supreme Court preserved the distinction between the withdrawal of life-sustaining treatments and assisted suicide or active euthanasia. At the same time, however, the Supreme Court may have blurred the distinction by endorsing terminal sedation. In 1994, Oregon narrowly passed a ballot initiative legalizing physician-assisted suicide (Table 28.5-4). A federal court judge subsequently struck down Oregon's Death with Dignity Law, in part because the law did not require evaluation by a mental health professional. That decision was later overturned by the Ninth Circuit Court of Appeals in February 1997, opening the way for the legalization of physician-assisted suicide in Oregon. Almost simultaneously, the Second Circuit Court of Appeals held that the New York law that bans assisted suicide is unconstitutional as applied to physicians and their dying patients. After an initiative to repeal the Oregon law was rejected by 60 percent of Oregon voters in November 1997 the law was enacted. Within a few months a 30-year-old grandmother in Portland, Oregon, became the first person disclosed to have died under this new suicide law. Shortly thereafter, Attorney General Janet Reno issued a statement that federal law does not authorize the prosecution of physicians who comply with the state law. More court's decisions may well shape the future direction of these important and hotly debated issues as the twenty-first century draws near.

- Oregon residents whose physicians determine they have less than six months to live are eligible to ask for suicide medication.
- A second doctor must determine if the patient is mentally competent to make the decision and is not suffering from mental illness such as depression.
- The law does not compel doctors to comply with patient requests for suicide medication.
- Doctors who agree to provide medication must receive a request in writing from the patient, signed by two witnesses. The written request must be made 48 hours before the doctor delivers the prescription. A second oral request is made just before the doctor writes the prescription.
- Pharmacists who are opposed to suicide may refuse to fill the prescriptions.
- The law does not specify which medication may be used. Supporters of the law say an overdose of barbiturates combined with antinausea medication would probably be used.

Table 28.5-4 Oregon's Assisted Suicide Law

To help guide clinicians facing requests for physician-assisted suicide, the vice president of the AMA's Institute for Ethics has proposed the following 8-step clinical protocol:

1. An evaluation of the patient for depression or other psychiatric conditions which could cause disordered thought;
2. An evaluation of the patient's “decision-making competence”;
3. A discussion with the patient about his or her goals for care;
4. Evaluation and response to the patient's “physical, mental, social, and spiritual suffering”;
5. Discussion with the patient about the full range of treatment and care options;
6. The consultation by the attending physician with other professional colleagues;
7. Assurance that care plans chosen by the patient are being followed, including removal of unwanted treatment and the provision of adequate pain and symptom relief; and
8. A discussion with the patient explaining why physician-assisted suicide is to be avoided and why it is not compatible with the principled nature of the care protocol.

Advances in technology bring more complex medical, legal, moral, and ethical controversies regarding life, death, euthanasia, and physician-assisted suicide. Some forms of euthanasia have found a place in modern medicine, and expansions in the boundaries of patient's rights and their ability to choose the way they live and die are inevitable. Both patients and physicians need to be better educated about depression, pain management, palliative care, and quality of life. Medical schools and residency training programs need to treat death, dying, and palliative care with the care and attention they deserve. Open debate and an honest exchange of viewpoints are needed. Society must ensure that economics, ageism, and racism do not get in the way of adequate and humane management of patients with a chronic terminal illness. Finally, national health care policy must provide adequate insurance, home care, and hospice services to all appropriate patients. If these mandates are followed, the argument for physician aid in dying will lose much of its impact.

BEREAVEMENT AND GRIEF

Definitions The terms bereavement and grief are not consistently applied. In 1982 the Institute of Medicine appointed a Committee on Health Consequences of the Stress of Bereavement, composed of multidisciplinary clinicians and researchers, to study bereavement factors and their impact on general and mental health. The definitions agreed upon by that committee include:

Bereavement—the fact of loss through death.
Bereavement reaction—any psychological, physiological, or behavioral response to bereavement.
Bereavement process—an umbrella term that refers to the emergence of bereavement reactions over time.
Grief—the feelings and associated behaviors, such as crying, accompanying the awareness of irrevocable loss (not necessarily, but including, loss through death).
Grieving process—the changing affective state over time.
Mourning—the social expressions of grief, including funerals, visitations, and rituals.

Normal Bereavement Reactions Sigmund Freud and other early psychoanalytic writers called the painful relinquishing of ties to the deceased the work of grief. Thus, grief was viewed as a restorative reaction to separation. Grieving is completed when the bereaved is free to invest emotional energy in new directions.

Influenced by attachment theory, recent theorists emphasize that the work of grief involves a series of attachment behaviors rather than simply separation. Attachment theory posits a human instinct to form strong, persistent affectional bonds. A natural response to the loss of an attachment bond is separation anxiety, which generates intense but predictable behavior geared to recoup or revive the lost relationship. Thus, the crying of a baby when its mother or father leaves is viewed as an attempt to retrieve the lost parent. In bereavement, these attempts fail to achieve their goal and attachment bonds must ultimately be realigned. The first response to loss, protest, is followed by a longer period of searching behavior. As hope to reestablish the attachment bond diminishes, searching behaviors give way to despair and detachment before bereaved persons eventually reorganize themselves around the recognition that the lost person will not return. While the bereaved ultimately learn to accept the reality of the death, they also find psychological and symbolic ways of keeping the memory of the deceased person very much alive. Grief work allows survivors to redefine their relationship to the deceased and to form new but enduring ties.

Grief and mourning may be best understood as attempts to solve the separation versus attachment dilemma. On the one hand, reality demands the bereaved person accept the loss in order to achieve a healthy adaptation to continued life in the real world—a life that is now missing a key person in a palpable way. On the other hand, psychological needs dictate a counterbalancing demand to maintain ties to the lost relationship, which although now technically illusory, are nevertheless quite real to the survivor. This dilemma requires working through for the survivor to regain emotional homeostasis, balancing the separation and attachment valences. The former demand—accepting the loss—is likely to generate intense anguish while the latter demand—maintaining the relationship—usually provides comfort. The typical course of bereavement includes some fluctuations between anguish and comfort, mediated by the shifting needs and capacities of the mourner.

Other Forms of Grief Much of the course, phenomenology, assessment, complications, and treatment of bereavement can be applied to other losses as well. Indeed, a growing body of literature on the psychological effects of divorce attests to the similarity between the grief associated with divorce and the grief associated with bereavement. Epidemiological studies suggest that divorce may be a greater risk factor for depression than widowhood. The loss of a pet may engender profound grief reactions in some persons. In medical settings the loss of youth, health, cognitive abilities, sensory acuity, body parts, relationships, roles, abilities, and potentials can and do trigger grief responses that often warrant clinical attention. A young woman facing a mastectomy, a middle-aged man about to retire, an old woman losing her eyesight—are all likely to grieve. In none of these instances does a set guideline prescribe what is considered normal or accepted grief. Rather, people cope with and respond to these losses in a variety of ways. An important component of understanding human behavior involves identifying the potential for persons to experience grief reactions to a multitude of everyday life events and appreciating the variability in the ways that those reactions are expressed.

Mourning From earliest history, every culture records its own beliefs, customs, and behaviors related to bereavement. Specific patterns include rituals for mourning (e.g., wakes or sitting shiva), for disposing of the body, for invocation of religious ceremonies, and for periodic official remembrances. The funeral is the prevailing public display of bereavement in contemporary North America. The funeral and burial service acknowledge the real and final nature of the death, countering denial; they also garner support for the bereaved, encourage tributes to the dead, unite families, and facilitate community expressions of sorrow. The burial is usually in a cemetery, which may serve as an ongoing serene focus for memories and tributes. If cremation replaces burial, ceremonies associated with dissemination of the ashes perform similar functions. Visits, prayers, and other ceremonies allow for continuing support, coming to terms with reality, remembering, emotional expression, and concluding unfinished business with the deceased. Several cultural and religious rituals provide purpose and meaning, protect the survivors from isolation and vulnerability, and set limits on grieving. Subsequent holidays, birthdays, and anniversaries serve to remind the living of the dead, and may elicit grief as real and fresh as the original experience; over time, these anniversary grievings become attenuated, but often remain in some form.

Phenomenology of Grief Bereavement reactions involve alterations in feeling states, coping strategies, interpersonal relationships, biopsychosocial functioning, self-esteem, and world view that may last indefinitely. Manifestations of grief reflect the individual's personality, previous life experiences, past psychological history, the significance of the loss, the nature of the bereaved's relationship with the deceased, the existing social network, intercurrent life events, health, and other resources. Despite individual variations in the bereavement process, investigators have proposed grieving process models, which include at least three partially overlapping phases or states: (1) initial shock, disbelief, and denial; (2) an intermediate period of acute discomfort and social withdrawal; and (3) a culminating period of restitution and reorganization. Like Kubler-Ross's stages of dying, the stages of grief do not prescribe a correct course of grief; rather, they are general guidelines that describe an overlapping and fluid process that varies with the survivors (Table 28.5-5).

Shock and denial (minutes, days, weeks)
Disbelief and numbness
Searching behaviors: pining, yearning, protest
Acute anguish (weeks, months)
Waves of somatic distress
Withdrawal
Preoccupation
Anger
Guilt
Lost patterns of conduct
Restless and agitated
Aimless and amotivational
Identification with the bereaved
Resolution (months, years)
Have grieved
Return to work
Resume old roles
Acquire new roles
Reexperience pleasure
Seek companionship and love of others

Table 28.5-5 Phases of Grief

In the *shock and denial* phase, disbelief and numbness predominate. The funeral, gathering of friends, and other mourning rites help survivors to accept the loss in a supportive environment. As numbness turns to intense feelings of separation, various searching behaviors (such as pining, yearning, and protest) take over.

The second phase, *acute anguish*, predominates once the searching proves fruitless. Erich Lindemann, in the first study of bereavement, described six components of acute grief: (1) Intense somatic distress, occurring in waves and lasting from 20 minutes to 1 hour, is manifested by a tight throat, choking and sighing, an empty feeling in the abdomen, weakness, tenseness, and mental pain. Because visits may provoke these somatic disturbances, withdrawal from friends, relatives, or others is common. (2) Thoughts of the deceased preoccupy the survivor. (3) Filled with guilt, survivors may accuse themselves of having mistreated or neglected the dead. (4) Irritation and anger are directed inward, or toward the deceased, friends, relatives, doctors, the world, or God. (5) Restlessness, agitation, aimlessness, and lack of motivation are accompanied by abandonment of usual habit patterns. (6) Identification phenomena, the adoption of traits and behaviors of the deceased (especially those of the final illness), which is often considered pathological, may occur. Acute anguish lasts weeks or months, gradually giving way to a return of well-being and the ability to go on.

In *restitution* (or *reorganization*), the bereaved recognizes the extent of the loss and that grieving has been accomplished. Attention shifts to life apart from the deceased. The hallmark of restitution is that survivors recognize that they can return to work, resume old roles, acquire new ones as necessary, experience pleasure, and seek companionship and love.

Duration of Grief Most societies mandate modes of bereavement and time periods for grieving. In contemporary America the bereaved is expected to return to work or school in a few weeks, to establish equilibrium within a few months, and be capable of pursuing new relationships within 6 months to a year. Ample evidence suggests that the bereavement process does not end within a prescribed interval; certain aspects persist indefinitely for many otherwise high-functioning, normal persons.

Perhaps the most lasting manifestation of grief, especially after spousal bereavement, is loneliness. Often present for years after the death of a spouse, for some loneliness may be a daily reminder of the loss. Other common manifestations of protracted grief occur intermittently. For example, a man who has lost his wife may experience elements of acute grief every time he hears her name or sees her picture on the nightstand. Usually these reactions become increasingly short-lived over time, dissipating within minutes, and may become tinged with positive and pleasant affects. Such bittersweet memories may last a lifetime. Thus, most grief does not fully resolve or permanently disappear; rather, grief becomes circumscribed and submerged only to reemerge in response to certain triggers.

Anticipatory Grief Grief may begin before the actual death. In *anticipatory grief*, grief reactions are brought on by the slow dying process of a loved one through injury, illness, or high-risk activity. Although anticipatory grief may soften the blow of the eventual death, it may also lead to premature separation and withdrawal while not necessarily mitigating later bereavement. At times the intensification of intimacy during this period may heighten the actual sense of loss even though it prepares the survivor in other ways.

Anniversary Reactions When the trigger for an acute grief reaction is a special occasion such as a holiday or birthday, the rekindled grief is called an *anniversary reaction*. It is not unusual for anniversary reactions to occur each year on the same day the person died, or in some cases, when the bereaved individual becomes the same age the deceased was at the time of death. Although these anniversary reactions tend to become relatively mild and brief over time, they can be experienced as the reliving of one's original grief and may prevail for hours or days.

Multidimensional Assessment of Bereavement and Grief Mourning phenomena are not sufficient to describe the full impact of losing a loved one to death. A multidimensional approach addresses seven features: (1) emotional and cognitive responses, (2) coping strategies, (3) continuing relationship with the deceased, (4)

changes in functioning, (5) alterations in existing relationships, (6) forming relationships, and (7) changes in identity. Assessing these features lends itself to rational management and treatment strategies.

The emotional and cognitive responses of shock, anguish, loss, anger, guilt, regret, anxiety, fear, intrusive images, depersonalization, feeling overwhelmed, loneliness, unhappiness, and depression may also be intermingled with positive feelings such as relief, joy, peace, or happiness, which emerge after the loss of a special person. To mitigate the anguish of acute grief, coping strategies help “dose” the pain a mourner can bear at any point. Strategies include suppression, intellectualization, rationalization, humor, avoidance, exposure, activity, involvement with others, passive distraction (e.g., immersion in television), or indulgence in food, alcohol, tobacco, or sex. Many persons say that their belief in God helps them cope and find meaning in death.

One powerful means of mitigation is the continuing relationship with the deceased. Faced with the dilemma of balancing reality's demands to accept life without their lost loved one and equally powerful inner forces dictating they maintain their attachments by retrieving what has been lost, the bereaved gradually learn to realign their attachment bonds. Survivors experience the transformation of a relationship that had heretofore operated on several levels of actual, symbolic, internalized, and imagined relatedness to one in which the actual (living and breathing) relationship has been lost—but other forms of the relationship remain and new ones may develop. Thus, it is not unusual for bereaved individuals to maintain continuing contact by dreaming of their deceased loved ones, looking for them in crowds, sensing their presence, feeling them watching out for or protecting them, reliving conversation or “speaking” with them, and even having auditory or visual hallucinations. In addition, symbolic representations (also known as linkage objects), such as the clothing, writings, favorite possessions or rings may be kept indefinitely, and living legacies such as identification phenomena, carrying out the deceased's mission, memorial donations, or seeing them live on in others through genetic endowments become other means of perpetuating the relationship. Periodically visiting the grave or lighting candles also keeps memories alive. Ultimately, memories become the most powerful means of continuing the relationship with the deceased. Bereaved individuals may get great comfort from hearing that the relationship has not been totally severed but that it is perfectly acceptable, and even normal for the relationship to endure indefinitely.

A fourth dimension of grief and bereavement, changes in functioning, involves an assessment of the ways general medical health, psychological health, social networks, and occupational functioning are affected. Grief may take its toll on any of these indices of biopsychosocial functioning. Even in the absence of severe medical or psychiatric complications, a diminished sense of well-being and vague somatic complaints are common. Sleeplessness is an enduring symptom of bereavement, lasting for over a year in a substantial percentage of bereaved individuals. Social inhibition or isolation occasionally occurs. Disability or impaired work performance and satisfaction are not uncommon. The challenges of taking on new roles or meeting new demands may appear overwhelming. For example, widows may need to learn for the first time how to service the car or maintain financial records and widowers may be challenged by cooking, shopping, housecleaning, or child-rearing tasks.

Bereavement may entail changes in ongoing relationships. Complex changes occur within the family. For example, when a spouse dies and there are grown children there may be conflicts in the expectations of the children and surviving parent over issues of emotional support, finances, decision-making, and future directions. Survivors may have to contend with the grief of their own parents, children, in-laws, and siblings and their efforts to enlist support for themselves. There is an opportunity for achieving greater intimacy, repairing old wounds and sharing grief; conversely, it may be a time of exacerbation, conflict, and disruption. Friends may be a major source of support for the bereaved, especially when empathy and sympathy are freely given and when they are accepting of the enormous fluctuations in the feelings, moods, and needs of the survivor. Friends can share the pain and allow its free expression. On the other hand, there are times when friends may feel threatened or overwhelmed by the intensity of the survivor's neediness and suffering.

A related dimension is the development of a new relationship, often a major concern yet a source of embarrassment and awkwardness. A bereaved spouse who attempts to begin a new romance may be challenged by continued devotion to the spouse, societal sanctions, fears of recurring loss, and perceived disloyalty of the children. Despite these challenges, many bereaved spouses, especially widowers, do remarry, often within a year of two of their bereavement and frequently are surprised at how well their new marriage works out. Remarriage has been found to be associated with well-being and a positive adaptation to bereavement. The strongest predictor for the remarriage of widows is age, with younger women being more likely than older widows to find a new mate. For widowers, income and education are most strongly associated with remarriage.

Finally, the multidimensional approach includes changes in identity. During initial grief, feelings of being overwhelmed and helpless may cause the bereaved to regress. Later, survivors may be surprised by their capacity to tolerate grief, carry on, and even find new approaches to life. Often there is an evolving sense of strength, autonomy, and independence. Having mastered acute grief, survivors experiences existential growth and may become more compassionate, patient, and balanced. In time, some survivors may transform their tragedies into new careers, relationships, and personal evolvement.

Bereavement Since bereavement often evokes depressive symptoms, the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) V code (no mental illness) of bereavement attempts to distinguish normal grief reactions from major depressive disorder (Table 28.5-6) According to DSM-IV, if the symptoms of a major depressive episode begin within 2 months of the loss of a loved one and do not persist beyond the 2 months, they are generally considered to result from bereavement unless they are associated with marked functional impairment or include morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation. DSM-IV recommends the following:

Bereavement	Major Depressive Disorder
Symptoms may meet syndromal criteria for major depressive episode, but survivor rarely has morbid feelings of guilt and worthlessness, suicidal ideation, or psychomotor retardation	Any symptoms as defined by DSM-IV
Dysphoria often triggered by thoughts or reminders of the deceased	Dysphoria often autonomous and independent of thoughts or reminders of the deceased
Onset is within the first 2 months of bereavement	Onset at any time
Duration of depressive symptoms is less than 2 months	Depression often becomes chronic, intermittent, or episodic
Functional impairment is transient and mild	Clinically significant distress or impairment
No family or past personal history of major depressive disorder	Family or past personal history of major depressive disorder

Table 28.5-6 Differentiating the Depressive Symptoms Associated with Bereavement from Major Depressive Disorder

> This category can be used when the focus of clinical attention is a reaction to the death of a loved one. As part of their reaction to the loss, some grieving individuals present with symptoms characteristic of a major depressive episode (for example, feelings of sadness and associated symptoms, such as insomnia, poor appetite and weight loss). The bereaved individual typically regards the depressed mood as normal, although the person may seek professional help for relief of associated symptoms such as insomnia or anorexia. The duration and expression of normal bereavement vary considerably among different cultural groups. The diagnosis of major depressive disorder is generally not given unless the symptoms are still present two months after the loss. However, the presence of certain symptoms that are not characteristic of a normal grief reaction may be helpful in differentiating bereavement from a major depressive episode. Those include (1) guilt about things other than actions taken or not taken by the survivor at the time of the death; (2) thoughts of death other than the survivor feeling that he or she would be better off dead or should have died with the deceased person; (3) morbid preoccupation with worthlessness; (4) marked psychomotor retardation; (5) prolonged and marked functional impairment; and (6) hallucinatory experiences other than thinking that he or she hears the voice of, or transiently sees the image of, the deceased person.

The depressive syndromes associated with bereavement are common; in many cases they are self-limited, require no active treatment, and are not associated with prolonged psychosocial impairment or reduction in life quality. However, clinicians must recognize that depressive syndromes, even in the context of bereavement, deserve careful attention and clinical evaluation. The DSM-IV designation of bereavement should not lull the clinician into a false sense of security or therapeutic nihilism. Research has shown that at least one third of persons who manifest a depressive syndrome within a few months of their loss continue to be depressed a full year later; further, their depressions often are associated with suicidal ideation, medical morbidity, and psychosocial disability. Thus, depressive syndromes, even if they can be understood in the context of bereavement, may herald a disabling and potentially life-threatening illness. When a depressive syndrome occurs early in the course of bereavement, the clinician should assess the severity, associated symptoms, persistence, pervasiveness, and the patient's past history when deciding whether to treat the syndrome. In general, the more severe the depressive symptomatology and the more the bereaved individual has a positive family or past personal history of major depressive disorder, the more likely it is that the early depressive syndromes of bereavement will persist. Effective treatment of depressive

syndromes facilitates the work of grief. The outworn notion that medications or psychotherapy impede the process of grief is unsubstantiated and may serve to prolong suffering and disability. Clearly, more research work needs to be done in this area.

Complicated Bereavement Several correlations between known risk factors and specific bereavement complications have been identified. These include multiple, sudden, or unexpected deaths, including suicide, murder, catastrophic circumstances, and stigmatized deaths (e.g., abortion, AIDS); preexisting personality in the bereaved marked by insecurity, low self-esteem, dependence, and characteristic difficulties coping with stress; a relationship with the deceased marked by ambivalence or undue dependency; loss of a child; poor health, depression, or prior substance abuse; multiple concurrent life stresses or other crises; and perceived lack of social support. Gender and age are controversial risk factors.

Complicated bereavement is described by a confusing array of terms: *abnormal, atypical, distorted, morbid*, or *unresolved*. Most concepts surrounding it can be viewed as either complicated processes of grieving, or as high-risk medical or psychiatric illnesses.

Complicated Processes Three patterns of complicated, dysfunctional grief syndromes have been identified: chronic, hypertrophic, and delayed grief. *Chronic grief*, the most common, is an unremitting grief that is often highlighted by bitterness and idealization of the dead. Chronic grief may be most likely to occur when the relationship between the bereaved and the deceased had been extremely close, ambivalent, or dependent, or when social supports are lacking and friends and relatives are not available to share the sorrow over the extended period of time needed for these mourners. In *hypertrophic grief*, seen most often after a sudden and unexpected death, bereavement reactions are extraordinarily intense. Customary coping strategies are ineffective in mitigating anxiety and withdrawal is frequent. When one family member is experiencing a hypertrophic grief reaction, disruption of family stability can occur. Hypertrophic grief frequently takes on a long-term course, but it may become attenuated over time. *Delayed grief* refers to absent or inhibited grief when one normally expects to find overt signs and symptoms of acute mourning. This pattern is marked by prolonged denial; anger and guilt may complicate its course. Although family members, friends, and clinicians are often alarmed when a bereaved person shows minimal overt symptoms of grief after losing a loved one, empirical evidence fails to support a relationship between inhibited grief and other negative outcomes.

Some investigators have used the *unresolved grief* to refer to arrests in the normal process of grief. Using operational criteria to define the arrests, one group of investigators found unresolved grief to be common, existing in 10 to 25 percent of the various populations studied; it is associated with depressive symptoms and syndromes, persistent somatic preoccupations and distress, pathological identification phenomena, and chronic mourning.

The more sudden, unexpected, and unnatural the death, the more likely the bereavement process is to overlap with traumatic stress reactions. Indeed, in the most traumatic situations, such as when an individual survives combat, natural disasters, or physical attacks while others succumb, both grief and posttraumatic stress disorders may co-occur. In other situations there may be more of a mingling of symptoms of grief and traumatic stress, resulting in what some have called *traumatic grief*. In such situations the grief tends to be both chronic and hypertrophic. Themes of violence, victimization, and volition (i.e., the choice of death over life, as in the case of suicide) are intermixed with other aspects of grief, and traumatic distress marked by fear, horror, vulnerability, and disintegration of cognitive assumptions may ensue. Disbelief, despair, anxiety symptoms, preoccupation with the deceased and the circumstances of the death, withdrawal, hyperarousal, and dysphoria are more intense as well as more prolonged than under nontraumatic circumstances, and there may be an increased risk for other complications. Deaths that are sudden and unanticipated but not necessarily unnatural are associated with grief reactions that involve greater levels of disbelief, anxiety, self-reproach, feelings of abandonment, and even suicidal ideation than grief following anticipated deaths. At least two groups of investigators recently have proposed operational criteria for complicated or traumatic grief. One of the groups also has found a strong association between traumatic grief and both physical and psychological morbidity, including substantial comorbidity with major depressive disorder with a fairly robust response to treatment with antidepressant medications.

High-Risk Medical or Psychiatric Illnesses Bereavement reactions also can be considered to be complicated if the medical or psychiatric outcomes are adverse. Medical complications include exacerbations of existing diseases and vulnerability to new ones; fear for one's health and more trips to the doctor; and an increased mortality rate, especially in men. Although early retrospective studies suggested that morbidity and mortality rates after bereavement were extremely high, more recent carefully controlled prospective studies reveal that such risks are not uniformly distributed. The highest relative mortality risk is found immediately after bereavement, particularly from ischemic heart disease. The greatest effect of bereavement on mortality is for men under age 65. Although greatest during the first year, the increased risk of mortality continues for many years unless the man remarries. Higher mortality rates in bereaved men than in bereaved women are due to increases in the relative risk of eath by suicide, accident, cardiovascular disease, and some infectious diseases. Evidence for increased mortality for women in the first year after bereavement is equivocal, but some evidence suggests increased mortality in the second year; in widows, the relative risk of death from cirrhosis and perhaps suicide increases. In both sexes bereavement appears to exacerbate health-compromising behaviors, such as alcohol consumption, smoking, and the use of over-the-counter medications.

Psychiatric complications of bereavement include increased risk for major depressive disorder, prolonged anxiety, panic, and a posttraumatic stress-like syndrome; increased consumption of alcohol and drugs; increased cigarette-smoking; and increased risk of suicide. The best studied of the potential pathological outcomes of bereavement is depression. Grief and depression are not synonymous, although symptoms and behaviors may overlap. Sleep disturbances and dysphoria are common to both, but not all bereaved persons manifest a full depressive syndrome. Studies show that about one third of all widows or widowers manifest a full depressive syndrome 1 month after the death of a spouse, approximately one fourth do so at 7 months, and approximately 15 percent at 1 and 2 years. Fifty percent will meet criteria for major depressive disorder during the first year; 10 percent may meet criteria for the entire year. Interestingly, antidepressant medications may ameliorate depression without necessarily affecting other aspects of grief.

The relationship between grief and depression is complex. One can grieve without being depressed, but loss may well precipitate depressive episodes in vulnerable individuals. Not only are bereaved persons at high risk for major depressive episodes, but they also appear to be at risk for lingering subsyndromal depressive symptoms. Such symptoms, even in the absence of full depressive disorders, may be associated with prolonged personal suffering, role dysfunction, and disability.

Until recently bereavement was excluded as a possible criterion for the diagnosis of posttraumatic stress disorder. However, DSM-IV allows the possibility for sudden and unexpected deaths of loved ones to precipitate posttraumatic stress disorder in vulnerable individuals. Indeed, a recent epidemiological study in Detroit found that news of a sudden and unanticipated death of a loved one accounted for 31 percent of all the posttraumatic stress disorders in that community. Others have found that even expected death following chronic illness can sometimes lead to posttraumatic stress disorder.

Because of their psychosocial, emotional, and cognitive immaturity, bereaved children may be especially vulnerable to psychopathology. Enduring psychological symptoms of anxiety, somatic conditions, and depression have been observed in community and patient samples of children who have lost a parent or a sibling, and some studies report a relation between childhood bereavement and later mental illness, especially depressive disorders.

Biological Perspectives Developments in bereavement biology have occurred on three major fronts: endocrinological responses, immunological changes, and sleep studies. Endocrinological studies suggest adrenocortical activation in response to bereavement, related to separation distress. Results of bereavement studies using the dexamethasone suppression test to measure adrenocortical responses have been equivocal, although one such study suggested a relationship between nonsuppression and separation anxiety. Similarly, the sudden loss of a partner, which evokes separation reactions, has been associated with increases in adrenal function and cortical secretion as well as elevated serotonin levels in the hypothalamus of squirrels and rhesus monkeys.

A variety of life stress events, including bereavement, have been found to alter humoral and cell-mediated immunity in humans and animals. Spousal bereavement has been associated with inhibited lymphocyte stimulation responses to several mitogens during the first several weeks after the death, and with impaired natural killer cell activity in bereaved widows with dysphoria. At least one monkey study also has demonstrated inhibited lymphocyte stimulation to various mitogens in infant monkeys after separation.

Sleep disturbances are among the most frequent and persistent bereavement-associated symptoms. Even if bereavement has not disrupted sleep per se, sleep electroencephalographic changes consistent with depression, such as decreased rapid-eye movement (REM) latency and deep sleep and increased total REM sleep, have been found in bereaved, depressed widows. Circadian rhythms and sleep pattern disturbances in infant monkeys also have been noted in response to separation.

Separation studies in primates may shed light on human grief and bereavement as well as on the pathogenesis of depression. Separation of infant monkeys from their mothers is highly traumatic, eliciting responses akin to protest followed by despair. The despair response can be attenuated if substitute caretakers are available. Further, short-term separations of this kind may have long-term effects and may predispose the infant monkeys to severe behavioral reactions to future separations. The protest-despair response is similar regardless of the cause of the separation. Developmental, neurochemical, and pharmacological variables can alter the

response. For example, if monkeys had been raised by their mothers in the first several months of life prior to life in peer groups, the response to later peer separation is less intense. Monkeys with lower concentrations of norepinephrine in cerebrospinal fluid responded to separation with more huddling and self-directed behaviors than those with higher concentrations. Imipramine (Tofranil) reverses peer separation reactions and prevents future reactions when the drug is maintained. Drugs that lower norepinephrine concentrations increase separation response severity whereas serotonin-blocking drugs have no effect, suggesting that the separation response is sensitive to catecholamine depletion.

LIFE CYCLE PERSPECTIVES

Bereavement During Childhood and Adolescence About 4 percent of North American children lose one or both parents by age 15; sibling death is the second most commonly experienced bereavement. Grief reactions are colored by development levels and concepts of death, and may not resemble adult reactions. Children may display minimal grief at the time of death and experience the full effect of the loss later. Indifference, anger, or misbehavior may be displayed rather than sadness; behaviors may be erratic and labile. Even older children frequently feel abandoned or rejected when a parent dies, and may show hostility toward the deceased or the surviving parent, now perceived as one who might also “abandon” them. They may feel responsible for the parent's death because of their own past misbehavior or because they said or wished that the parent would die at some time. Psychological tasks particularly relevant to bereaved children and adolescents have to do with their capacity to accept the tragedy of death, their capacity to tolerate the anguish that ordinarily accompanies grief, and, in the case of parental bereavement, their developmental need for the deceased parent in order to complete the goals of healthy maturation.

Children under the age of 2 may show loss of speech or diffuse distress. Children under the age of 5 may respond by developing eating, sleeping, bowel, and bladder dysfunctions. Strong feelings of sadness, fear, and anxiety can occur, but these feelings are not persistent and tend to alternate between longer-lasting “normal” states. School-aged children may become phobic or hypochondriacal, withdrawn, or pseudomature, and school performance and peer relations often suffer. Like adults, adolescents run the gamut of bereavement reactions, ranging from behavioral problems, somatic symptoms, erratic moods, to stoicism. Adolescent boys losing a parent may become deliquent; girls may turn to a sexual partner for comfort and reassurance. Behavioral disturbances and depressions are common at all ages. Although the surviving parent may underestimate their child's dysphoria, interviews of children and adolescents themselves reveal rates of depressive episodes that are at least as high as those of bereaved adults. Although several investigators suggest that bereaved children and adolescents have long-term vulnerability to a variety of physical and mental illness, the link between childhood bereavement and subsequent depressive disorders is strongest.

Bereaved children must be treated according to their levels of emotional and cognitive maturity. They need to be told that the death is real and irreversible and that they are blameless. Fairy tales and insincere theological explanations add to children's confusion and may reinforce notions that they have done something wrong. Feelings and concerns should be expressed, and questions should be invited and answered with simplicity, candor, and clarity. Children, like adults, need rituals to commemorate their loved ones; attending the funeral and participating in mourning may be beneficial first steps.

Bereavement During Adulthood There is no consensus on which type of loss is associated with the most severe reactions. Although the death of a spouse is often ranked as the most stressful life event, some have argued that losing a child is even more profound. The death of parents and siblings in adult life has not been systematically studied but is generally considered relatively mild compared to the loss of a spouse or child. The impact of therapeutic and spontaneous abortion generally has been underestimated—prenatal bonding may be intense but social support, mourning rituals, and other aspects of socially sanctioned grief have not been established for this loss. Thus, the bereaved parents may not have the opportunity to vent and share their misery. Grief appears most intense for the mother who suffers a late perinatal losses (stillbirths or neonatal deaths rather than miscarriages), and often is re-experienced during subsequent pregnancies. *Sudden infant death syndrome* is particularly problematic because the death is sudden and unexpected; parents may experience extra guilt or blame each other, often resulting in subsequent marital difficulties.

The surviving family members, friends, or lovers of individuals who have died from AIDS are uniquely challenged. AIDS carries with it the stigmata of the illness itself and of the gay community in general, caretakers' fear of contracting the illness; also, it is most prevalent in people who are in the prime of life. Asymptomatic infection may provide infected persons and those close to them time to adapt to the diagnosis. But when an HIV-positive person begins to manifest symptoms of opportunistic infection or associated cancer, the illness again becomes a threat and coping with its emotional reality is arduous and complex. Often caretakers as well as HIV-positive patients wish for death, which can evoke feelings of guilt. For bereaved lovers, their own HIV status, multiple losses, and other concurrent stressors may complicate recovery. Gay men who have lost lovers to AIDS may be more depressed, consider suicide more often, and be more vulnerable to illicit drug use than other bereaved individuals.

Despite stereotypes and popular mythology, the elderly do not have any more difficulty coping with the deaths of loved ones than their younger counterparts do. Indeed, their grief is often described as less intense and prolonged, and less likely to be associated with increased drinking, health concerns, depression, or anxiety. Yet seniors face more losses than individuals at other phases of the life cycle, and intense loneliness may be a lasting memorial to those who have died. Most studies of late-age bereavement have been done on community samples, thus bypassing the most frail senior citizens who live in nursing homes, tertiary care centers or those who are too physically or cognitively impaired to complete questionnaires. It stands to reason that for highly impaired seniors who lose a spouse they depended on for daily functions or who was their sole source of companionship, bereavement reactions may be profound.

Caring for the Bereaved Most bereaved individuals do fine without treatment. The support, reassurance, and information they require is usually provided by family and friends and sometimes by clergy, so that other professional help is unnecessary. When such support is not available, mutual support groups may help fill the gap. It is easy to underestimate the power most persons have to cope with distress and master adversity. However, there are times when formal intervention may facilitate the grieving process, prevent future problems, or treat ongoing complications. Various interventions are available. These include self-help approaches, such as the Widowed to Widowed model, They Help Each Other Spiritually (THEOS), or Compassionate Friends; group interactions, both mutual support types and professionally run groups; a variety of supportive, psychodynamic, short-term and grief-specific interventions; and medication. The specific indications for any one type are not always clear, and no one form of intervention has been proven more beneficial than others.

In general, for bereaved persons with moderate distress who are experiencing grief-process difficulties, a mutual-support group is often all that is necessary. It is efficient, cost-effective, and clinically effective. Such groups provide members with personal contact, information, an opportunity to share coping techniques, a sense of universality and belonging, increased self-worth, reinforcement for positive change, and an opportunity to help others. Several studies have confirmed the benefits of such mutual support or self-help programs.

Although natural, restorative healing processes help most people get through their grief without professional assistance, sometimes more formal psychotherapeutic interventions are warranted. This is particularly true for high-risk individuals, such as people who have a history of mental illness; who have lost someone to suicide or homicide and who are experiencing traumatic grief; who have experienced multiple simultaneous losses or adverse life events; who are bereaved as the result of an accident in which the survivor may have been at fault; or persons whose poor health, lack of social supports, or life stresses have overwhelmed their capacity to cope. Most advocated psychotherapeutic approaches are relatively brief and time-limited and have been shown to be beneficial. Certain common features can be identified: First, most therapies include an educational component, helping the bereaved know what to expect, offering perspective on their pain, and normalizing their confusing array of feelings and behaviors. Second, therapies encourage the expression of the full range of bereavement emotions and affects. Evocative techniques, such as role playing, writing letters to the deceased, looking at pictures, or even visiting the burial site can be effective. Third, most therapies attempt to help the bereaved come to peace with their new relationship to the deceased. This usually involves systematic exploration of all aspects of the relationship, both in the past over time and as it has developed since the death. Fourth, most therapies attend to the bereaved person's new identity, focusing on an integrated self-concept and a stable world view. The roles of the psychotherapist in the bereaved person's evolving identity are numerous. Therapists must recognize early regression for what it is, and they must be able to maintain a conviction about the bereaved person's adaptive capacities. Contained in such a conviction are both the belief and knowledge that the bereaved person can survive and will feel better. As survivors venture out to try something new, they may find themselves stymied by old conflicts that can be examined in a psychotherapeutic fashion. The therapist plays a powerful role in supporting the bereaved person's attempts to try out new behaviors, explore new relationships, expand attitudes, and grow through the experience.

When grief is complicated by a major depressive episode, psychotherapeutic techniques to treat major depressive disorder, such as interpersonal or cognitive-behavioral therapy, should be considered. An integrative approach that combines elements of psychoeducation, support, grief-specific interventions, and aspects of interpersonal and cognitive-behavioral therapy as appropriate for the person at any given time, are recommended. If the depression is mild, this may be all that is necessary. In more moderate to severe depressions, or when psychotherapy has not worked, psychopharmacological intervention should be considered. Medications are particularly indicated when there is a past history of severe depression, suicidal ideation, psychomotor retardation, morbid feelings of worthlessness or guilt, or when psychosocial impairment is substantial. When making the decision whether or how to treat a major depressive disorder associated with bereavement, time since death is only one of many considerations; equally important are such factors as past and family history of depression, severity of depressive symptoms, suicidality, general medical health, and functional impairment. Treatment does not impede the grieving process; rather, effective treatment facilitates adaptive

processes and prevents the distortion and coping interference brought on by depression.

Similarly, when grief is complicated by posttraumatic stress disorder, both conditions need to be addressed. In general, treatment of the traumatic distress takes precedence over the grief. Treating anxiety or sleeplessness pharmacologically is controversial. Prescriptions and over-the-counter preparations used by bereaved persons reflect their efforts to relieve suffering and limit dysfunction. However, no controlled studies have established the efficacy and safety of antianxiety or hypnotic agents, nor is there evidence to support claims that medication will suppress the bereavement process or interfere with an adaptive outcome. When grief-related symptoms of anxiety are expressed so continuously that they interfere with cognitive and other functions of living in a substantial way, anxiolytic medications and psychotherapeutic interventions should be considered. For persons who develop persistent sleep disorders, interventions with hypnotic agents can be both humane and beneficial. It is rare for the judicious use of anxiolytic or hypnotic agents in bereaved persons to lead to problems of drug abuse. However, when confronted with a bereaved person who complains of anxiety or poor sleep, the clinician should ascertain whether these symptoms are part of an occult depressive episode before treating the symptom.

SUGGESTED CROSS-REFERENCES

Related themes of loss are discussed in Chapter 26 on divorce and other relationational problems. Attachment theory is discussed in Section 44.1 on reactive attachment disorders of infancy or early childhood. Section 25.9 covers bereavement and loss within the broader context of stress theory. Dealing with potentially fatal or terminal-phase-illness is covered in Section 25.4 on cardiovascular disorders, Section 25.11 on psycho-oncology, and Section 2.8 on the neuropsychiatric aspects of AIDS. Uncomplicated bereavement is discussed in the differential diagnosis of major depression in Chapter 14.6 and again in Chapter 45 on childhood depression and suicide.

28.6 CHRONIC PAIN AND THE PLACEBO EFFECT

JAMES C. EDMONDSON, M.D., PH.D.

Pain is an intrusive, unpleasant, sensory, and emotional experience. In most people's minds, pain is a reliable indicator of injury, and everyone has had experience with acute pain. The details of diagnosis and management of acute tissue injuries have been thoroughly studied for centuries by the spectrum of medical and surgical specialists. In most cases, acute pain stops when the tissues heal. However, when pain persists, its connection to actual tissue injury frequently becomes more tenuous, and psychological factors may begin to predominate.

In clinical practice chronic pain has two divergent sources, one resembling the acute pain experience and the other of more obscure origin. The first group contains patients with medical conditions that cause chronic tissue injury. Ongoing pathology may continuously trigger the acute pain experience, but because the tissues do not heal, the pain remains a daily annoyance for an extended time. Many patients with such conditions (Table 28.6-1) accept their plight and maximize their coping abilities; others may become devastated by their suffering and lose their jobs, family, and social supports. In the United States at least 30 million patients suffer from medical conditions associated with chronic pain.

Arthritis	Muscle strain
Osteoarthritis	Persistent overexertion
Rheumatoid arthritis	Inflammatory bowel disease
Cancer	Crohn's disease
Any histological type	Ulcerative colitis
Neuropathy	HIV
Diffuse	Sickle cell anemia
Focal	Endometriosis
Multifocal	Movement disorders
Brain injury	Parkinson's disease
Traumatic brain injury	Generalized dystonia
Thalamic stroke	Focal dystonia
Limb amputation	Huntington's disease
Phantom limb pain	Multiple sclerosis

Table 28.6-1 Medical Conditions Associated With Chronic Pain

In the second group of patients the acute pain experience persists beyond a reasonable time expected for tissue healing after an acute injury, thereby becoming chronic. These patients persistently perceive pain, with its associated affective distress, in the absence of demonstrable tissue pathology. This perplexing group of patients, by some estimates numbering another 40 million Americans, is not readily classified as to etiology or personality type.

Unlike the well-established body of knowledge for illnesses based on tissue pathology, classification and treatment of patients with chronic pain in the absence of obvious tissue pathology is a relatively young field. Because the condition defies medical logic, many such patients encounter a negative bias from caregivers, who may not acknowledge the patients' distress or who may suggest derisively that “it's all in your head.” Pain without injury, like the placebo effect, is discomforting for professionals taught to trust their senses. Nevertheless, caregivers must appreciate that their own smug confidence in appearances may prevent them from fully comprehending the cognitive and emotional limits of the pain experience. In fact, chronic pain without injury—like the placebo effect (healing without medication)—transcends evidence-based medicine and enters the realms of philosophy and politics. Although it is poorly addressed in traditional medical education, every practitioner will frequently encounter patients with chronic pain. In this chapter, the psychosocial and neuroscientific aspects of chronic pain are discussed.

History Aristotle considered pain to be an emotional experience distinct from the five primary senses, because it did not reflect a specific external stimulus. This view predominated until the seventeenth century when Rene Descartes distinguished the body from the mind and assigned a separate role to each in the perception of pain. Descartes likened the nerves to wires that took a tiny bit of a noxious stimulus and transmitted it faithfully to the brain, where the mind then examined, assessed, and reacted to it. The Cartesian dualistic view, which is highly intuitive, remains the view held by most people. However, Descartes' theory could not explain two paradoxical observations: severe tissue injury could occur without pain and pain could occur without injury. The first of these conundrums was addressed in the gate control theory of pain, introduced in 1965 by Patrick Wall and Ronald Melzack. The gate control theory took into account not only ascending signals, but also descending projections that determined which pain signals ascended to consciousness. In this theory, tissue injury without pain occurred because descending signals “closed the gate” to the perception of pain. Although the gate control theory explained injury without pain, it could not explain the perception of pain without injury. For example, amputees appeared to experience complex patterns of pain in portions of the limb distal to the site of amputation (i.e., in the complete absence of any peripheral tissue). This and other observations focused attention on the brain's internal representation of pain and how the brain attends to or ignores pain signals.

Sensory Experience Sensory systems create an internal representation of the external world. Projections of visual, sonic, and tactile input are organized into maps in subcortical nuclei and in patches of the cortex. Specifically, visual images are arranged visuotopically, sounds are represented tonotopically, and tactile sensations are faithfully displayed according to the body plan. For example, the somatotopic configuration of tactile sensations in the postcentral gyrus is called a homunculus (from the Latin for “little man”). The cortical representational code for olfactory and gustatory input, however, has not yet been deciphered. Relevant features are extracted from these primary sensory representations by secondary sensory areas and are compared with memories. Thus, at any one time a potentially huge volume of data about various sensory experiences can contribute to conscious perception. However, people can rarely attend to more than one or a few details at a time. People consciously perceive a meager image of the world and operate within a narrow range of available experience. How the brain determines which data reach consciousness and which are ignored is not well understood; yet the boundary zone between conscious and unconscious attention holds many clues to the experience of pain without injury.

A window into the activation of different brain regions during specific sensory operations is being opened by the techniques of functional neuroimaging. These methods permit identification in real time of the brain regions that are active during mental proceedings. They add the dimension of time to high-resolution neuroimaging. These powerful new techniques promise to help define the neuroanatomical pathways for learning and memory during the experience and recollection of pain. However, examination of brain activity, only some of which is conscious, may yield conclusions that run counter to common intuition. For example, patients with low back pain without an obvious pathological cause will likely be studied in the future by functional neuroimaging. If disabling low back pain is found to originate entirely from memory stores within the brain, without activation of pain fibers from the periphery, then the person experiencing the pain must indeed grapple with the counterintuitive notion that “it is all in the head.” The coming era promises to enthrall the theoreticians of pain and to raise profound questions about the reliability of conscious perception.

Clinical Aspects In current clinical practice, a myriad of pharmacological, exercise-based, cognitive, behavioral, and interventional treatments is available for chronic pain. The premises for these run the gamut from the conviction that nearly all pain faithfully represents some tissue damage to the notion that 95 percent of chronic pain results from psychological factors. Where the truth lies on this spectrum certainly differs for each patient. The placebo effect, frequently considered a nuisance to be explained away, in fact, likely underlies the success of many currently used treatments for chronic pain. Despite the prominent role of psychological factors in the

maintenance and remission of chronic pain, efforts to define a pain-prone personality or to devise a test battery that consistently predicts outcome have been largely disappointing. The most effective approach is a detailed, highly individualized assessment of physical, psychological, and supportive factors, and the steady application of a multifaceted treatment plan agreed upon by both the patient and the team of caregivers.

STIMULI THAT ELICIT ACUTE PAIN

Acute pain may be caused by a variety of stimuli. Tissue damage leads to the release of cellular components that bind to and activate nerve endings. Extremes of tactile pressure, heat, cold, or in fact any sensory input, if intense enough, may cause pain. Tissues heal themselves once the painful stimulus is removed, and the acute pain resolves simultaneously. Numerous medical conditions may cause persistent tissue damage and are thus associated with chronic pain (Table 28.6-1). Patients with these conditions deserve an exhaustive medical evaluation and prompt treatment of their conditions. Many of these conditions have a genetic contribution, a factor for which there are virtually no diagnostic tests at this time. Therefore, the statement that a person's complaints of pain are not supported by an objective assessment of disease or disability must be interpreted in light of the limitations of current diagnostic methods.

The pain receptors of different tissues respond to specific stimuli. Skin receptors respond to pricking, cutting, crushing, burning, and freezing. The visceral structures instead respond to mucosal engorgement or inflammation, smooth muscle spasm, or traction on the mesenteric attachment. Skeletal muscle pain receptors respond to ischemia, injuries to the connective tissue sheath, necrosis, hemorrhage, and injection of irritating solutions. Prolonged contraction of skeletal muscle causes an aching pain. Joints do not respond to pricking, cutting, or cautery but do respond to inflammation and hypertonic saline. Arterial pain receptors respond to piercing and inflammation.

NEUROBIOLOGY OF SOMATIC PAIN PERCEPTION

Skin and Peripheral Nervous System

Anatomy and Physiology External stimuli elicit nerve impulses at the peripheral nerve endings. The cell bodies of sensory fibers are located in the dorsal root ganglia. Despite the expectation that specific endings (i.e., free nerve endings, Meissner corpuscles, Pacinian corpuscles, and Ruffini endings) are associated uniquely with specific modalities of somatosensory perception (i.e., touch, pain, temperature, vibration, and pressure), studies have failed to confirm a clear correlation between histological morphology and function. For example, the cornea, which has only free nerve endings, can perceive all somatosensory modalities.

Cutaneous stimuli are classified as thermal, mechanical, and chemical. Individual nociceptive nerve endings may respond to any combination of sensitivities; most commonly they respond to all three classes. Thermal nociceptors are triggered by skin temperatures in excess of 45°C (113°F), a level of heating that elicits subjective pain. Mechanical nociceptors respond to as little as 10 micronewtons of force, which is too little force to elicit pain. Chemical nociceptors respond to bradykinin, serotonin, histamine, substance P, protons, and adenosine triphosphate (ATP), among other endogenous molecules.

Pain is transmitted from the skin to the spinal cord with a high degree of spatial resolution by both very fine, unmyelinated, slowly conducting C fibers and thinly myelinated A-delta fibers. Nonnociceptive (nonpainful) stimuli are transmitted by large, thickly myelinated, rapidly conducting A-beta fibers. Table 28.6-2 lists the fiber sizes and nerve conduction velocities of the three types of fibers. The cell bodies of the sensory neurons form the dorsal root ganglia. The diversity of dorsal root ganglion cell types, as defined immunocytochemically according to neurotransmitters and receptors, significantly exceeds the three defined sizes of nerve fibers.

Fiber Type	Fiber Diameter (μm)	Nerve Conduction Velocity (m/s)	Nociception
A-beta	6–20	30–80	No
A-delta	1–5	12–30	Yes
C	0.4–1	0.5–2	Yes

Table 28.6-2 Three Types of Sensory Nerve Fibers

Two classes of C fibers are distinguished by biochemical and anatomical characteristics. Whereas both fiber classes require nerve growth factor (NGF) during development, receptors for NGF persist into adulthood on only about half of the fibers. These NGF-responsive fibers contain substance P and calcitonin gene–related peptide (CGRP) and terminate in Rexed's lamina I and the outer part of lamina II of the dorsal horn of the spinal cord. Fibers that lose NGF responsivity acquire sensitivity to glial-derived neurotrophic factor (GDNF), do not contain substance P or CGRP, and project to the inner part of lamina II of the dorsal horn.

Chemistry Tissue damage causes the release of proteolytic enzymes, which liberate agonists for peripheral nociceptors, including histamine, prostaglandins, serotonin, bradykinin, substance P, protons, potassium ions, and ATP. These substances elicit pain and cause local vasodilation when injected into the skin. Substance P and CGRP are released into the skin from C-fiber terminals on stimulation of nociceptors, where they produce neurogenic inflammation: the dilation of cutaneous vessels and the release of histamine.

THERMAL SENSITIVITY Capsaicin, a product of *Capsicum* peppers, elicits the subjective sensation of heat. It has been used to identify a receptor, VR1, which contains a nonselective cation channel with high permeability for calcium ions. Sudden increases in temperature activate the VR1 ion channel. VR1 appears to be one member of a family of heat-sensitive ion channels, which are segregated in distinct neuronal populations.

MECHANICAL SENSITIVITY Little is known about the molecules that respond to mechanical stimuli in humans. In the nematode *Caenorhabditis elegans*, The *mec* gene family encodes mechanoreceptors, which have structural homology to sodium channels. Whether such a mechanism for transforming movement into electrical activity exists in humans is not known.

CHEMICAL SENSITIVITY The chemical responsivity of nociceptors is determined by the presence of specific receptor molecules (e.g., receptors for serotonin, histamine, bradykinin). Evidence for ATP as a nociceptive stimulus has appeared, including the identification of an ATP receptor, P2X3, which is highly abundant only in GDNF-responsive, non-peptide-containing C fibers.

Exposure to chemicals or infectious agents activates the immune system and triggers the release of cytokines that stimulate subdiaphragmatic vagal afferents. Activation of these fibers causes generalized heightened sensitivity to pain, which is experienced as “hurting all over.”

Spinal Cord

Anatomy and Physiology

INPUT In the spinal cord, pain fibers enter in the dorsolateral quadrant in a superficial layer called the dorsal root entry zone. Pain fibers tend to enter in the lateral part of the dorsal root entry zone, and many of the tiniest fibers ascend in Lissauer's tract. Most A-delta and C afferent pain fibers cross Lissauer's tract and enter the gray matter of the dorsal horn. Most A-delta fibers terminate in the most superficial layer of gray matter, Rexed's lamina I, and the remainder terminate in the middle layers of the dorsal horn, in lamina V. C fibers, as discussed above, terminate in laminae I and II. Lamina II is also called the substantia gelatinosa (Fig. 28.6-1). A smaller number of fibers decussate and terminate in the contralateral dorsal horn. Functional sensory units consisting of overlapping patches of skin are called dermatomes, and their corresponding sensory nerves with peripheral and central extensions emanate from the dorsal root ganglion and project to the corresponding

spinal segments, of which there are 31. Many fiber termini activate local somatic and autonomic reflexes entirely within the spinal cord.

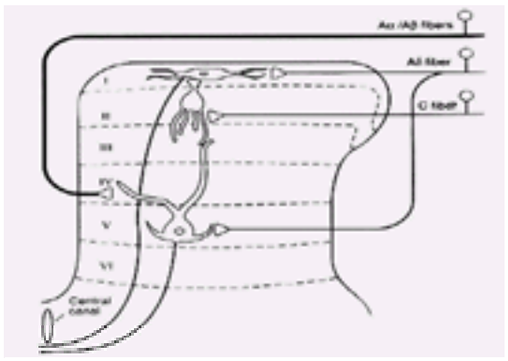

FIGURE 28.6-1 Termination of sensory afferent fibers in the dorsolateral quadrant of the spinal cord. The Roman numerals to the left denote the laminae of Rexed. A-delta (Ad) fibers project to both lamina I and lamina V, where they synapse on projection neurons. C fibers project to lamina II (shown) and lamina I (not shown). A-alpha and A-beta (Aa/Ab) mechanoreceptor fibers, which do not conduct pain impulses, terminate in lamina IV. (Reprinted with permission from Jessell TM, Kelly DD: Pain and analgesia. In *Principles of Neural Science*, ed 3, ER Kandel, JH Schwartz, TM Jessell, editors. Appleton & Lange, New York, 1991.)

LAMINAE I AND II Experimental ablation of substance P–containing, NGF-responsive pain fibers in lamina I does not affect responsiveness to painful mechanical or thermal stimuli, but it does abolish hypersensitivity to chemical stimuli produced by capsaicin. This suggests that lamina I may mediate hyperalgesic responses to inflammation. Disabling of processing by GDNF-responsive fibers in the inner part of lamina II by targeted knockout of the g isoform of protein kinase C in mice does not affect responsiveness to acute thermal or mechanical nociceptive stimuli; however, it does significantly reduce painful responses induced by nerve injury. These data suggest a model for the establishment of chronic pain states, in which NGF-responsive, peptidergic fibers mediate pain in inflammatory conditions, and GDNF-responsive, nonpeptidergic fibers mediate neuropathic pain.

DORSAL HORN CELL TYPES In lamina I, at least three histologically and functionally distinct neuronal cell types have been defined, each of which projects to a specific thalamic nucleus and thus activates a specific region of cerebral cortex. Nociceptive-specific cells respond to one or more types of nociceptors, a second cell type responds to innocuous cooling, and other cells respond to heat, pinch, and cooling (HPC cells). The ascending tracts projecting from these neurons maintain a strict somatotopic organization up to the thalamus.

CENTRAL PROJECTIONS The primary pain afferents synapse in the dorsal horn, and the secondary pain fibers decussate in the anterior commisure and ascend in the anterolateral fasciculus. The lateral fibers of this fasciculus form the spinothalamic tract, which rapidly transmits sensory-discriminitive aspects of pain to a lateral thalamic relay nucleus, from which a precise localization of nociceptive impulses is relayed to the mid/anterior insular cortex. Medial fibers of the anterolateral fasciculus contain the spinoreticulothalamic, or paleospinothalamic tract, which transmits impulses in a slower and less well localized fashion to the reticular core of the medulla and midbrain, which relay them to the medial and intralaminar nuclei of the thalamus. The medial thalamic area then projects to the anterior cingulate cortex. Other medial fibers of the anterolateral fasciculus project directly to the hypothalamus as the spinohypothalamic tract. The medial fibers with their diffuse projections and activation of the frontal lobes and limbic system are proposed to mediate the affective-motivational aspects of pain, or the unpleasant feelings associated with pain.

Painful thermal, electrical, and other stimuli travel in the medial and lateral ascending spinothalamic tracts. A parallel, lateral ascending pathway activated by nonpainful cold stimuli inhibits central processing of painful stimuli. Contact with a surface at temperatures above 15°C activates both systems and normally does not elicit pain because the inhibitory pathway suppresses the nociceptive pathway. If the inhibitory pathway is inactivated by peripheral nerve block of A-delta fibers, then stimuli up to 24°C are perceived as painful because of the unopposed action of the C fiber–activated nociceptive pathway.

Surgical sectioning of the ascending pain pathways may result in ablation of pain and thermal sense in the opposite side of the body. This effect is usually temporary, as auxiliary pathways are recruited over months to years to transmit nociceptive impulses. Therefore, partial cordotomy, or tractotomy, is generally an unsatisfactory approach to the treatment of chronic pain, because it is a permanent lesion that gives only temporary relief of pain.

Chemistry

NEUROTRANSMITTERS AND RECEPTORS C fiber terminals contain substance P, CGRP, glutamate, brain-derived neurotrophic factor (BDNF), and ATP, whose release is modified by presynaptic receptors for aminobutyric acid (GABA), μ opioids, adenosine, glutamate (N-methyl-D-aspartate [NMDA] and GluR5), and ATP (P2X family). Postsynaptic dendrites contain neurokinin-1 (NK-1), metabotropic glutamate, d-amino-3-hydroxy-5-methyl-4-isoxazole proprionate (AMPA) glutamate, NMDA glutamate, trkB, μ-opioid, and GABA receptors. C fiber inputs initiate long-term changes in synaptic excitability by promoting phosphorylation of the NMDA glutamate receptor. The resulting increase in response to any subsequent glutamatergic input underlies the phenomenon of central sensitization.

SUBSTANCE P AND OTHER NEUROKININS The neuropeptides substance P, neurokinin A, and neurokinin B bind most strongly to neurokinin receptors NK-1, NK-2, and NK-3, respectively. To discriminate the function of each neurokinin and each of the neurokinin receptors, targeted gene deletion (knockout) experiments have been done in mice. Two strains of mice were created in which the gene for preprotachykinin A, the precursor of substance P and neurokinin A, was deleted. These knockout mice displayed significantly reduced behavioral responses to moderately, but not mildly or intensely, painful stimuli. This reduction applied variously to thermal, mechanical, and chemical stimuli, but differences in the genetic backgrounds of the mice contributed to inconsistencies in their response in a variety of painful tests. These knockout mice required smaller dosages of opioids to achieve analgesia in the presence of moderately to intensely painful stimuli.

Early-generation NK-1 receptor inhibitors were inconsistently effective against pain, which implicated the NK-2 and NK-3 receptors in the mediation of substance P's effects. Several novel NK receptor antagonists were developed as adjuncts to opioids; however, available clinical trial data failed to demonstrate an analgesic action of NK-1 receptor antagonists. These studies indicated that substance P is not the sole pain substance; rather it appeared to be responsible for neurogenic inflammation in the periphery and may have modulated the overall sensitivity to pain. For example, the spinal cord action of substance P has greater intensity and domain in chronic inflammation than in acute pain.

Intense noxious stimulation sensitizes the central nervous system (CNS) and temporarily increases spinal reflexes, a phenomenon called wind-up. Wind-up is inhibited by antagonists of the NMDA and NK-1 receptors and is completely abolished in knockout mice that lack a functional NK-1 receptor. NK-1 receptor knockout mice can perceive acute pain of all intensities, but they are significantly impaired in their ability to suppress nociception after stress. The fight-or-flight response to stress involves temporary analgesia, probably mediated by descending pathways originating in the brainstem. This analgesia is adaptive in that it allows the animal to escape or defend itself without the distraction of pain. The stress-induced analgesic response is significantly reduced in NK-1 knockout mice.

INTERACTION OF NEUROKININS WITH GLUTAMATE Glutamate, acting through presynaptic NMDA receptors potentiates release of substance P, and substance P promotes the action of glutamate on postsynaptic NMDA receptors, the net effect of which is the enhancement of synaptic efficacy. Blockers of glutamate receptors of the NMDA and non-NMDA classes reduce pain-induced behaviors in laboratory animals. The NMDA glutamate receptor antagonist dizocylpine (i.e., MK-801) also reduces stress-induced analgesia.

SUBSTANCE P AND DEPRESSION Unexpectedly, a substance P receptor antagonist has shown promise as an antidepressant drug. The success of this agent has provided the first evidence of substance P receptor involvement in the regulation of mood. In this role, drugs of this class could become an important adjunctive treatment for chronic pain.

DESCENDING TRACT NEUROTRANSMITTERS In addition to substance P receptors, the dorsal horn contains binding sites for opioids, norepinephrine, and serotonin. The receptors, including serotonin (5-hydroxytryptamine [5-HT] type 2 [$5HT_2$]) receptors, are activated by descending fibers from the brainstem that reduce the sensitivity of the ascending pain system. Well-known examples of the potential descending influence of these corticospinal pathways include athletes or soldiers

with significant musculoskeletal injuries who nevertheless persist in their duties until the termination of the engagement, at which point they finally complain of pain.

Certain glutamatergic synapses in the dorsal horn are normally inactive ("silent") except in the presence of intense stimulation. Descending serotonergic input from the brainstem raphe nuclei activates 5-HT_1 receptors to transform these silent glutamatergic synapses into functional ones. In the early postnatal period, this stabilizes the serotonergic synapses and establishes the influence of the descending fibers. In the adult, recruitment of AMPA glutamate receptors may facilitate responses of pain pathways to nonpain input, which may promote chronic pain. This is only one of the effects of descending serotonergic input.

PROSTAGLANDINS Prostaglandins mediate pain perception at several points in the pain pathway. Aspirin, acetaminophen, and the nonsteroidal anti-inflammatory drugs all relieve pain by inhibiting cyclooxygenase-2, the synthesic enzyme for prostaglandins. In the spinal cord, prostaglandin E_2 increases the peak current through certain sodium channels, which contributes to the sensitization of nociceptors in inflammatory states. These particular sodium channels are found only on pain fibers.

NOVEL POTENTIAL THERAPEUTIC TARGETS A dorsal root ganglion acid-sensing ion channel (DRASIC) is unique to dorsal root ganglion neurons. DRASIC, the capsaicin receptor (VH1), and the specific sodium channel sensitized in inflammatory states are all unique to nociceptive neurons. Therefore, they each present a novel target for therapeutic intervention. At present, no agents acting at these sites are available for clinical use.

Plasticity of Peripheral Fibers and Spinal Cord

SENSITIZATION The terminal arborization and receptor densities of nociceptive fibers appear to be under tonic control by NGF. NGF appears to regulate the amplification of cutaneous stimuli both acutely and chronically. Acutely, increased concentration of NGF in the skin causes hypersensitivity to painful thermal stimuli, partially by triggering the release of histamine and serotonin from mast cells, and partially by direct action on nerve fibers. Conversely, blockade of NGF action prevents the sensitization of nociceptors to painful stimuli. In humans, administration of NGF produces prolonged muscle pain. Chronically, NGF regulates the densities of receptors for capsaicin, GABA, and bradykinin. NGF overexpression skews the population of A-delta fibers toward an increased percentage of nociceptors. NGF also controls the concentrations of substance P and CGRP, and the net effect of NGF is to increase excitability in the dorsal horn. Less is known about the role of GDNF in the maintenance of nonpeptidergic fibers. One role of GDNF analogous to that of NGF is to prevent the loss of nerve terminals resulting from nerve injury. As NGF can prevent the downregulation of substance P and CGRP caused by nerve section, so can GDNF maintain the levels of characteristic molecules of nonpeptidergic fibers after nerve injury.

Drugs that act on several cellular pathways have been tested in an effort to abort the persistence of established hypersensitivity. No approach has been fully successful in reversing the cascade of sensitization, at clinically tolerated doses. In contrast, in the case of postsurgical pain, techniques are under study to avoid triggering the sensitization responses to pain. For example, regional anesthesia (i.e., either spinal, epidural, or peripheral nerve blocks) is begun prior to the surgery and continued until tissue damage has begun to heal. Reliable clinical trials demonstrating the benefit of such "preemptive anesthesia" are difficult to carry out, but recent data show that rigorous regional anesthesia in the perioperative period reduces postoperative pain for weeks to months. These results bear on the use of anesthesia for painful experiences in newborns, such as circumcision. For example, newborns experience months of greater sensitivity in the heel pad that was lanced for blood samples than in the unlanced heel.

In one model of chronic pain, NGF increases the release of substance P in the spinal cord and triggers the sensitization of the spinal cord to painful stimuli (central sensitization) that characterizes states of persistent pain. Central sensitization is a heterosynaptic facilitation of dorsal horn neurons that results in the aberrant perception of pain during nonpainful stimulation. Overactivation of substance P–containing nerve termini resulting from NGF upregulation is thought to increase the simultaneous activation of pre- and postsynaptic elements in the dorsal horn and to allow "learning" of the pain response. Synapses thus stabilized will chronically lower the pain threshold (i.e., exaggerate the significance of painful stimuli).

Less can be said about modulation of GDNF in neuropathic pain states, other than the theoretical advantage of increasing peripheral concentrations of GDNF to limit loss of nociceptor synapses in lamina II. Many neurotrophic factors support the survival and function of A-delta and C fibers. As subsets of nociceptors are more fully characterized and new neurotrophic interactions are discovered, additional novel therapeutic targets may emerge.

NEUROPATHIC PAIN AND ALLODYNIA One proposed mechanism of neuropathic pain is that nerve damage reduces the number of nociceptive terminals in the spinal cord and permits the termini of innocuous mechanoreceptors to occupy the synapses normally reserved for pain responses. This results in the perception of pain in response to normal touch, a characteristic feature of chronic neuropathic states. Provision of NGF, GDNF, or both after nerve injury in mice maintains nociceptive termini in the spinal cord and prevents synaptic remodeling. The fact that nociceptors display receptors for a number of other known neurotrophic factors suggests that other trophic interactions will emerge to reveal further complexities of nociceptor synaptic plasticity.

Thalamus The spinothalamic tract fibers terminate on the ventrobasal, posterior, and intralaminar nuclei and the nucleus submedius. Each thalamic nucleus projects fibers to a distinct region of the cortex and contributes a distinct aspect of pain perception. As discussed above, two lateral thalamic relay nuclei—the ventral medial nucleus, posterior part and the ventral posterior inferior nucleus—receive nociceptive fibers from nocioceptive-specific and cooling-specific cells via the medial and lateral spinothalamic tracts and project to the middle and anterior insular cortex and the postcentral gyrus (Brodmann's area 3a). The medial thalamus—specifically the medial dorsal nucleus, ventral caudal portion—receives fibers from HPC cells via the inhibitory lateral spinothalamic tract and projects to the anterior cingulate cortex (area 24c). Whereas pain fibers are neatly segregated in the spinal cord, the response of a particular neuron becomes less predictable at the thalamic, limbic, and cortical levels. Thalamocortical projections mediating tactile and proprioceptive stimuli and the discriminative aspects of pain terminate in the somatosensory cortex. Fibers mediating the emotional aspects of pain probably terminate in the amygdala, hypothalamus, and limbic structures, including the anterior cingulate cortex.

Anecdotal evidence of one neurosurgeon collected during procedures to ablate tremors or anginal pain by cauterizing small regions of the thalamus showed that, in rare cases a small electrical stimulus immediately precipitated a classic panic attack. Cessation of the stimulus promptly terminated the attack. These observations of a psychological experience (usually viewed as a reaction to external danger) originating entirely within the brain resembled the phenomenon of pain sensations in the absence of tissue injury. A compelling body of evidence now supports a model in which people are aware only of the brain's representation of sensations, and that indistinguishable representations can rise to consciousness in response either to external or to internal stimuli.

Cerebral Cortex Nociceptive input rises to conscious perception in the cerebral cortex. Functional neuroimaging studies using functional magnetic resonance imaging (fMRI), positron emission tomography (PET) scanning, and electroencephalographic localization techniques have opened a new window on the higher processing of painful stimuli.

Thermal Pain Perception Behaviorally, cold environmental stimuli inhibit the perception of pain at the CNS level. Peripheral cold stimulation reduces the pain caused by electrical nerve stimulation, and cold ambient temperatures reduce pain behavior.

ANATOMY OF THERMAL RESPONSIVENESS Four brain regions of importance to thermal perception are the pericentral or primary somatosensory cortex (S1), the lateral opercular or secondary somatosensory cortex (S2), the mid/anterior insula, and the anterior cingulate cortex. S1 and S2 are differentially activated by cool (20°C) and warm (40°C) stimuli as follows. Cool stimuli activate only the mid/anterior insula and S2, while warm stimuli activate the insula, S1 and (more weakly) S2. The insula is activated by both innocuous and noxious stimuli, whereas the anterior cingulate is activated only by noxious stimuli. All four areas are activated by painfully hot (47°C) and painfully cold (5°C) stimuli, though cold activates S1 less intensely than does heat. The insula is activated by all thermal and painful stimuli, and it is proposed to maintain a general sense of the body's physiological condition. The anterior cingulate is activated only by thermal stimuli in the painful range. Digital subtraction of the activation patterns elicited by cool or warm stimuli from those elicited by cold or hot stimuli isolate only the anterior cingulate cortex as pain specific. This part of the anterior cingulate cortex is distinct from that activated by attention tasks, which indicates that the complex anterior cingulate cortex has a pain-responsive region that has been proposed to mediate the emotional and motivational aspects of pain. Separate studies have identified other cells in the anterior cingulate cortex that fire in anticipation of a painful stimulus. The patterns of activation of the anterior cingulate cortex, insula, and S1 and S2 in response to hot stimuli vary during the menstrual cycle. Activation in women in the midfollicular stage resembled that of men, but differed from that of women in the midluteal phase, although pain ratings did not vary across the phases.

THERMAL ILLUSION The pain-specific region of the anterior cingulate cortex is activated in a thermal grill illusion, in which a row of alternating warm and cool bars elicits pain. The warm (40°C) or the cool (20°C) bars in isolation are not painful, and neither stimulus alone activates the anterior cingulate pain locus. Interposing 1-cm–wide bars so that skin contacts an alternating pattern of warm and cold elicits pain and activates the anterior cingulate pain locus. The pattern of activation of the somatosensory cortices by the thermal grill is characteristic of cold pain. Cool bars alone activate both the medial nociceptive spinothalamic pathway and the

lateral inhibitory pathway. The inhibitory pathway normally predominates and suppresses the activity of the anterior cingulate pain region, and the cool bars are not perceived as painful. In the thermal grill illusion, the alternation of warm and cool bars reduces the lateral inhibitory activity by half, but does not affect the medial tract neurons. This inactivates the inhibitory signals and allows the medial pathway to activate the anterior cingulate region, which leads to the perception of pain.

Central Pain Syndromes Chronic pain can be caused by injury to the CNS itself (e.g., strokes, trauma, multiple sclerosis, and other structural lesions). Patients complain of deep aching or burning pain in the part of the body that projects to the injured region of the CNS. In addition, the affected body part has reduced pain sensitivity and thermal discrimination, and there may be allodynia, or “different pain,” in which an innocuous stimulus is perceived as painful.

The thermal grill illusion offers an explanation of the burning, ice-like pain and cold allodynia described by patients with central pain. Central pain syndromes are associated with damage to the lateral, inhibitory spinothalamic tract and the lateral thalamus and are not correlated with injury to the medial thalamus. In fact, one patient with lesion-induced central pain was unable to experience additional pain during the thermal grill illusion, suggesting that her lateral spinothalamic tract was fully inhibited by her injury and, therefore, not subject to further modification by the thermal grill. These data are consistent with a model in which inactivation of the inhibitory mechanism by a structural lesion aberrantly unmasks cold-stimulated pain perception associated with activation of the anterior cingulate cortex pain region.

Reciprocal Connections As in all sensory systems, there is an extensive projection from the higher to lower centers that modulates pain perception. The number of descending corticothalamic fibers is about ten times the number of ascending thalamocortical fibers. The cortex and hypothalamus project descending fibers to the periaqueductal gray matter of the midbrain, the ventromedial medulla, and to the posterior horn of the spinal gray matter. Other descending pathways originate in the locus ceruleus, dorsal raphe nucleus, and nucleus reticularis gigantocellularis.

Plasticity of Thalamocortical Loops The corticothalamic loop for nociception is not characterized, but data from other sensory systems provide a model for plasticity in a corticothalamic system. In the corticothalamic loop for vision, if the corticothalamic fibers are inactivated by treatment of the cortex with local anesthetics or NMDA receptor antagonists, the receptive fields of their corresponding thalamic neurons expand greatly, suggesting that corticothalamic fibers normally exert an inhibitory influence on expansion of the synaptic domain of thalamic neurons. In a complementary observation, if the cortical cells are electrically stimulated, they promote the sharpening of thalamic receptive fields and suppress responses of neighboring thalamic neurons. In this manner, descending corticothalamic fibers help to amplify specific thalamic inputs while simultaneously generating a surrounding field of suppression of thalamic activity. Conversely, synchronized firing of ascending thalamocortical cells increases the chance that their corresponding cortical cells will fire. It appears that thalamic maps are constantly remodeled by experience, as are cortical maps.

PHANTOM LIMB PAIN Phantom limb pain consists of the painful sensations consciously localized distal to the site of amputation. The absence of input from the amputated region leads in one of several ways to reorganization of sensory maps in the brain. Examples in which peripheral input molds cortical synaptic connectivity have been described in the somatosensory, visual, auditory, and olfactory systems. For example, in the somatosensory cortex of the adult, the homunculus redistributes itself over the remaining healthy cortex if part of the somatosensory cortex is damaged (e.g., by stroke).

Amputation deprives the CNS of sensory input from the distal limb, which would normally have been localized in sensory maps in the lower brainstem, thalamus, and cortex. Clinical experience suggests that reorganization may occur in any combination of the sensory maps. In some cases, input to thalamic neurons previously representing the hand may be reorganized so that they are stimulated by touching the arm stump, yet they may continue to signal touching of the hand in their connections to the cortex. Thus, upon contact of the arm stump, the subject is conscious of contact to the missing hand. Phantom limb pain presumably involves similar discrepancies between reorganization and respecification in pain pathways.

HYPNOSIS At the functional level, even in the absence of anatomical changes, alterations in mood, attention, or expectation can markedly influence the conscious perception of pain. For example, hypnosis is a state of heightened suggestibility attainable by a certain proportion of the population. Under a state of hypnosis, gross distortions of perception of any of the sensory modalities can be achieved on an instantaneous time scale. The anatomy of the sensory systems does not change, yet the same specific stimuli may be perceived with diametrically opposed emotional value before and after induction of the hypnotic state. For example, an onion may be savored as if it were a luscious chocolate truffle under hypnosis, and rejected as abhorrently pungent by the same subject only seconds later, when the hypnotic suggestion is reversed. How hypnosis redirects the flow of information in the cortex has not been determined, but it presumably involves sensory and association areas of the brain as well as the anterior cingulate gyrus. The unconscious changes in mental processing triggered by hypnosis are thought to be similar to those that underlie the effectiveness of placebo therapy for the treatment of chronic pain. Other techniques, such as biofeedback, attempt instead to establish conscious control over attention and allow purposeful diversion of psychic energy from pain pathways.

HEMISPHERIC LATERALIZATION OF PAIN PROCESSINC Recent functional neuroimaging studies found that painful and nonpainful somatosensory information was processed mostly in the right hemisphere. Although there was a homuncular representation in the primary somatosensory cortex of both hemispheres, painful and nonpainful thermal stimuli significantly activated the right thalamus, right dorsolateral prefrontal cortex, and right inferior parietal cortex, regardless of whether the stimuli were applied to the right or the left forearm. The dorsal prefrontal cortex is known to be densely connected with the posterior parietal cortex and is active during tasks requiring spatial working memory. In right-handed people, damage to the right posterior parietal cortex produces deficits in spatial attention and body awareness, which are not seen with the corresponding left cortical lesions. It is not known whether the same regions of the right hemisphere will turn out to be active during the experience of chronic pain.

ORGANIC CAUSES OF CHRONIC PAIN

Ongoing damage to any bodily tissues or to pain fibers at any point of the neural axis may elicit chronic pain. The mechanism is basically the same as that for acute pain, except that the injured tissues do not heal, and therefore the painful sensation continues without resolution. Analysis of the cause of pain and identification of appropriate treatment strategies are relatively straightforward in these cases, though many tens of millions of people in the United States with such conditions cannot achieve satisfactory pain relief with current analgesics. This major debilitating situation is due both to the limitations of current drugs and to prejudice on the part of caregivers, who often ration out an amount of analgesic quite inadequate for the person's subjective pain.

Physician prejudices play a large role in their habits of prescribing analgesic drugs. Many State Medical Boards have set up means of tracking prescriptions of controlled substances, and the threat of disciplinary action for overprescription worries many physicians. In 1997, in response to complaints that physicians were in fact undermedicating pain and causing needless patient suffering, the Federation of State Medical Boards published guidelines aimed at easing physicians' fears of the consequences of overly liberal use of controlled substances. Under these guidelines, physicians would not be punished if they were to take a proper medication history, outline a treatment plan, obtain informed consent from their patients, monitor the use of the drugs, and keep detailed records. As the population ages and more individuals develop conditions with chronic pain, physicians and patient advocate groups increasingly will seek clarification of the limits of governmental regulation of prescription of controlled analgesic drugs.

Any patient with chronic pain deserves a thorough evaluation seeking organic causes of pain, and if the first such evaluation does not yield positive findings, repeat evaluations should be performed at appropriate intervals. Establishment of a definite diagnosis guides the therapeutic approach, but equally important, it reassures the patient and family members that the suffering has a specific cause. Patients with chronic pain and their families must learn what will aggravate and what will mitigate the pain associated with a specific condition. Moreover, if no specific cause for the pain is uncovered despite a thorough investigation, the caregivers must be quite confident of this fact prior to discussing methods for accepting and coping with chronic pain. A careful, thorough medical evaluation should convince patients that the caregiver is dedicated to understanding their condition and suffering. A strong rapport between patient and provider is itself often a powerful analgesic.

Pain Due to Chronic Tissue Injury Many conditions with chronic tissue injury cause pain: musculoskeletal disorders, rheumatoid arthritis, cancer, acquired immune deficiency syndrome (AIDS), irritable bowel syndrome, peptic ulcer disease, inflammatory bowel disease, angina head trauma and movement disorders.

Other medical conditions causing chronic pain include sickle cell disease and endometriosis.

Pain Due to Neuropathy Stump pain is a common complaint after amputation of a limb. Stump pain is distinct from pain in a phantom limb, which presumably involves central projections of fibers severed in the amputation. Stump pain appears to result from the formation of painful neuromas at the severed ends of peripheral nerves.

CHRONIC PAIN WITHOUT EVIDENT ORGANIC CAUSE

Patients with certain types of chronic pain (e.g., chronic low back pain, angina pectoris, trigeminal neuralgia, migraine headache, tension-type headache, temporomandibular joint syndrome, postencephalitic myalgia syndrome, or fibromyalgia) should have a thorough neurological or orthopaedic evaluation, or both. However, in most cases, it will not be possible to ascribe the pain clearly to a specific lesion. It is possible that current diagnostic tools are insufficiently sensitive to detect certain subtle tissue injuries that could generate chronic pain. In fact, hypochondriacal patients who hold this conviction may spend a great deal of time pursuing a medical diagnosis while denying the possibility that the pain could be largely maintained by psychological conflicts.

After a thorough medical, neurological, and orthopaedic evaluation has failed to establish a physical reason for chronic pain, psychological factors must be considered. Chronic pain often appears at the location of a previous injury beyond a reasonable period of time for wound healing. The simplest explanation for this is that the memory of the painful injury retains its grip on the patient's attention, even after the painful stimuli cease.

PLACEBO EFFECT

The localization of pain without tissue pathology to the memory circuits of the CNS raises many of the same issues as an analgesic response to an inactive treatment—a placebo. In both cases, a subconscious mental operation either introduces or suppresses the experience of pain. In other words, the conscious brain accepts spurious input as real, based on unconscious motivations. This remarkable notion runs counter to the tenets of evidence-based medicine and tries the limits of common sense. It is instructive to examine the placebo effect in detail to evaluate the evidence for and against the ability of the brain to reconsider its own sensory input.

A placebo is an inactive treatment disguised as an active treatment. The success of the ruse depends on the health care setting, professional staff, complicated paraphernalia, and appearance of the medication. Whether a placebo response is elicited depends on the force of the provider's persuasion that a particular therapy will work and the readiness of the patient to ignore perceptable evidence that the intervention is a sham. Many psychological factors are thought to contribute to these tendencies, often in an ideosyncratic manner. Only some of these factors, however, have been confirmed experimentally. Ultimately, response to a painful stimulus is a synthesis of the physical sensation with internal memories, drives, and associations. The neuroanatomical terrain on which various sensations and recollections compete for conscious attention is being gradually and carefully mapped by functional neuroimaging.

The idea that conscious perception may have little or nothing to do with pathophysiology and that inactive remedies can take on a life of their own entirely within the brain is a discomforting thought. Yet, the placebo effect exerts a surprising and powerful impact not only on medical care, but more widely, in economics and politics.

Examples of the Placebo Effect The power of the placebo effect is tightly linked to the patient's perception of the caregiver. For example, in the eyes of many, the most impressive specialty is surgery. The surgeon is imbued with an aura of mystery and omnipotence. Surgical treatments are rarely tested against a placebo, and placebo-controlled trials that have been completed are generally compromised by manipulation of the assignments to active or placebo treatments for various reasons. Thus, in the absence of objective data, specific operations come into vogue on the basis of the well-meaning, but often subjective, convictions of influential surgeons.

For example, in the 1950s ligation of the internal mammary artery was commonly performed to treat angina pectoris, on the assumption that blood that would otherwise pass through the internal mammary artery would instead prevent ischemic heart injury by causing the coronary arteries to form extra blood vessels. Many patients whose internal mammary arteries were ligated experienced a reduction in angina after surgery. However, pathological examination of heart muscle failed to find any new vessels, which threw the premise of the procedure into question. The technique was finally subjected to a placebo-controlled trial. Some patients received a sham operation consisting of exposure of the artery without ligation; in the remainder, the vessel was ligated as usual. Unexpectedly, both groups had a comparable rate of success, as measured by reduced pain, increased walking distance, fewer medications, and some normalization of the electrocardiogram. Not only did these results indicate that placebo was as effective as the procedure, but more impressively, the benefits persisted in both groups for at least a 6-month period of observation. This was surprising, because the placebo effect was often considered to be temporary at best.

Other examples of therapies introduced widely, then later withdrawn because controlled studies failed to prove a specific action, include glomectomy for asthma, evamisole for herpes simplex, photodynamic inactivation for herpes simplex, organic solvents for herpes simplex, and gastric freezing for duodenal ulcers. Studies of these therapies, involving over 7000 patients, consistently showed good responses in 30 percent and excellent responses in 40 percent of the patients. In fact, clinical experience in general has confirmed that nonspecific but beneficial effects are commonly seen in the initial period after introduction of a therapy.

Another example of the power of an impressive machine and the influence of a white coat was the use of ultrasound therapy to reduce pain and jaw tightness following wisdom tooth extraction, a treatment initially reported to be as effective as steroids. To discriminate the effects of the ultrasound waves themselves from the remainder of the treatment experience, a study was designed so that the intensity of the ultrasound was set at different levels, including zero, without the knowledge of the patients or therapists. At no ultrasound output, there was actually a better outcome than when normal intensities were used. To rule out the possibility that the benefit was actually due to the massaging effect of the ultrasound probe, patients were taught to massage themselves with an inactive probe with the same movements used by the professionals. This produced no benefit. The only aspect of the ultrasound treatment associated with a good outcome was the presence of an expert-appearing therapist apparently administering invisible sound rays from a complex machine. The good outcome included not only pain reduction, but also increased jaw opening and reduction in swelling, two measures not usually considered purely psychological in origin.

These surgical and radiological examples were particularly dramatic, but similar examples too numerous to count have also been reported for pharmaceutical treatments. All new medications are subjected to placebo-controlled trials, in which some fraction of the subjects take a pharmacologically inactive pill identical in appearance to the active medicine. The percentage of patients taking placebo who nonetheless improve by the trial criteria generally hovers around 30 to 40 percent, but may range from nearly zero to almost 100 percent. A small number of novel treatments involve surgical implantation of genetically engineered cells, which the U.S. Food and Drug Administration (FDA) considers akin to drugs. The FDA is requiring sham operations, including drilling holes into the skull, prior to approval of the therapies. These unusual cases raise controversy, as patients may be subjected to the risks of anesthesia without receiving the active treatment.

Popular Perceptions of the Placebo Effect For centuries placebos were associated with quackery. In the absence of specific therapies, however, the power of persuasion was often the best treatment that could be offered. Nevertheless, more-astute observers recognized a fine line between benevolent and neutral or even malicious uses of placebos. With the discovery of effective, specific therapies, the ethics of dispensing a placebo became even more complicated, and the bias against understanding and using placebos strengthened. Presently, in the evaluation of new drugs, for example, the patient is asked to give “informed consent” to the possibility of being randomized to the placebo arm of a study. In practice, this smacks of coercion, as few patients are sophisticated enough to understand fully the comparisons being made. Moreover, the more thoroughly subjects are informed about the premises of the study, the lower the likelihood of a truly blinded comparison.

Today, deliberate deception in the form of prescribing a placebo is considered unethical outside institutionally sanctioned clinical trials. Within clinical trials comparison with placebo may be considered an irksome bureaucratic requirement for which investigators must hide their enthusiasm for their new agent. A considerable fraction of the $200 million to $500 million cost of bringing a drug from initial synthesis to market is spent on the comparison with placebos, mostly in phase III clinical trials. Yet, the existence of a fraction of patients who respond to placebo is generally deemed of no intellectual interest and an impediment to the discovery of the true mechanism of action of the drug. Despite this impatience with the placebo effect, the factors that determine the magnitude of the placebo effect are a key part of the art of medicine: the use of the provider-patient rapport to maximize compliance with and benefit from a prescribed therapy. In the case of established therapies that were not compared with placebo prior to their wide acceptance, it is often not considered ethical subsequently to assign patients to the placebo arm of a controlled trial. Thus, in the case of well-established treatments for certain emotionally charged ailments, the lack of an objective comparison with placebo has opened the door to unscrupulous manipulation by politically powerful groups.

To the medically unsophisticated, recognition of the placebo effect is counterintuitive and unsettling. A person who responds to a placebo may feel foolish and may become angry at the provider of the placebo.

Seven Myths Regarding the Placebo Effect Seven myths have arisen in traditional medicine to explain away the placebo effect.

MYTH ONE The first myth is that patients who respond to placebo were not actually sick in the first place but rather displayed symptoms of purely mental origin that happened to resemble a known organic condition. This notion, which basically supposes a hysterical origin for symptoms, is dangerous and cruel. It is contrary to true cases of conversion disorder, in which symptoms do not exactly mimic organic conditions but conform to the patient's own concepts of disease. It is too great a leap to

suppose that all placebo responders initially had a conversion disorder.

MYTH TWO The second myth is that the placebo is the equivalent of no treatment at all. This myth ignores the effect of the setting of drug administration. Further countering this myth is the fact that people can distinguish whether caregivers are actively giving them something or doing nothing for their illness.

MYTH THREE The third myth is that a fixed fraction of patients respond to placebos, usually about one third. In the literature, the placebo response rate varies from close to zero to almost 100 percent. The placebo response rate in clinical practice, where the patient knows the provider, is even higher than that in the detached, anonymous setting of clinical studies. Other factors that determine the placebo response have been identified, including the appearance of the dose of medication. The most effective formulation is a capsule with colored beads, followed in descending order of influence by colored tablets, then by white tablets with corners, and finally by round white tablets. Placebo response is increased if the pills are taken from a bottle with a commercial label rather than one with a typed label. In one example of the crossover experimental design, subjects who encountered active medicine first were more likely to respond to the placebo than those who encountered the placebo first. In fact, several studies have found that the sequence in which the pills are given can convert placebo nonresponders to responders.

MYTH FOUR The fourth myth is that people who respond to placebo are characteristic in certain psychological ways, variously described as suggestible, hypnotizable, neurotic, extroverted, introverted, acquiescent, desiring to please, lacking in sophistication, and accepting of authority. As with efforts to define a pain-prone personality, most studies have failed to find a placebo response–prone personality, and in those that reported a correlation, it was variously positive or negative.

MYTH FIVE The fifth myth is that pain is a multidimensional experience, and placebos affect only part of the pain. This supposes a simple Cartesian dualism of body and mind. While some experimental protocols have shown that opioids and benzodiazepines independently affect either the intensity or the unpleasantness of pain, respectively, clinical experience has shown that placebos may affect one, the other, or both dimensions. The exact effects depend on factors such as suggestion, expectation, and instruction.

MYTH SIX The sixth myth is that the placebo response is produced by endogenous opioids. With the description of endorphins and enkephalins (the endogenous ligands for the opioid receptors in the brain and spinal cord), a theory was soon proposed that the placebo effect was mediated by these molecules. This proposal captured the imagination of both scientists and the general population and gave some respectability to the distasteful business of placebos. Despite its popularity, however, there is no evidence to support this concept. Careful studies of the effect of the opioid receptor antagonist naloxone (Narcan) on the placebo response have shown either positive, neutral, or negative results. Actually, the endorphins and enkephalins are weak ligands for opioid receptors. However, this fact, does not change the idea that the opioid receptors are somehow involved. Indeed, the recent discovery of a potent endogenous ligand for the μ-opioid receptor, called endomorphin, would appear to throw a life preserver to the theory. Opioid receptors are likely to play some role in the placebo response, but it is quite unclear how critical their exact role is.

MYTH SEVEN The seventh myth is that statistical analysis can discriminate the pure therapeutic action from the placebo response. Since patients respond to many cues during treatment, including the actions of the drug itself, it is not possible to identify and correct for the placebo effect with certainty. An active treatment exerts physical and psychological effects that cannot be exactly duplicated by the placebo. Efforts to use a placebo whose adverse effects mimic those of the active drug are never as clean as desired, and this approach may simply muddle the conclusions by introducing additional variables. For some nonpharmacological treatments, such as acupuncture, an active placebo cannot be defined. It is nearly impossible not to tip the subject off to some expected effect of a new drug under evaluation, if only through the wording of the instructions to subjects or the subtle reactions of the person administering the therapy. For example, in 22 studies of analgesics covering a range of potencies from aspirin to morphine, the larger the therapeutic effect, the larger the placebo response. Whereas one would expect higher ratios of drug responders to placebo responders with stronger analgesics, in fact, over the entire spectrum of analgesic potencies, 55 to 60 percent more patients responded to the active drug than responded to the corresponding placebo.

The placebo response appears to be inextricably linked to the perception of pain. It has defied all attempts to wish or reason it away. On the contrary, the placebo effect is a powerful phenomenon, whose harnessing distinguishes master healers from technicians. Rational, evidence-based medicine has erected a barrier to the acceptance of both the placebo effect and chronic nonorganic pain. This defensive posture fits nicely with the needs of some patients with chronic pain to go from specialist to specialist in an endless search for the physical cause of their pain and to subject themselves to an array of potentially dangerous interventions in an effort to eradicate the source of their pain. A fuller appreciation of the placebo effect by providers and patients would often lead much more directly to control, if not elimination, of the pain. It is not wise to underestimate the power of the brain to legitimize a deceptive image.

Psychological Explanations of the Placebo Effect

Affective The idea that the placebo reduces the unpleasantness of pain or decreases anxiety is not supported by experimental data. Moreover, any affective changes associated with the placebo could be a consequence rather than a cause of the reduction in pain.

Cognitive The commonest explanation is that the placebo effect results from the expectations of the subject. Subjects will readily state whether they believe that a certain therapy will work, and this attitude faithfully predicts their response to placebo. The expectation of success has variously been called belief, faith, confidence, enthusiasm, bias, meaning, credibility, transference, and anticipation. Response to placebo requires sufficient learning ability to generate an expectation. The learning of expected effects depends on culture, education, experience, and personality. In turn, the intensity of the expectation is influenced by the provider's expectation, enthusiasm, and charisma. Many reports discuss the effects of the provider-patient relationship on the placebo response. It is a tragedy that the pressures of managed care to see many patients rapidly impair the development of provider-patient rapport and very likely undermine many intangible cues that contribute to the effectiveness of active therapies.

The clinical observations of the power of anticipation were supported by neurophysiological recordings of neurons in the frontal lobe of primates. Selected frontal lobe neurons began to fire when the animal expected a favorite type of food. If the food was presented, the neurons fired more rapidly; if food the animal disliked was presented instead, the animal became angry and the neurons ceased firing.

Behavioral Conditioning In classical Pavlovian conditioning, a subject learns to associate an unrelated stimulus with the expectation of a particular physical stimulus. In classical conditioning, a sound may elicit salivation, a drop in blood sugar, immune suppression, and other physiological responses, even in the absence of an appropriate causative stimulus. In the analogy with pain relief, a powerful analgesic reduces pain and serves as the unconditioned stimulus. If a uniformed professional administers the medication with a hypodermic needle, then the patient becomes conditioned to expect that pain relief will follow the appearance of the needle-wielding person in a white coat. Therefore, if the uniformed professional injects saline with the hypodermic needle, the patient may still achieve level of analgesia identical to that achieved with the active medicine.

Cognitive and conditioned factors may overlap in people. For example, it is possible to set up a paradigm of conditioned learning with a mild anesthetic, then to manipulate the expectation of potency of the medication and subsequently observe a greatly increased conditioned response to the same anesthetic.

Attention Appropriate to the Situation Anecdotes gathered in wartime and during sporting competitions describe individuals who have suffered severe tissue damage yet report pain only after the battle. It appears that their attention is focused on a primary goal, either leaving the deadly battlefield or winning the competition, and the somatic sensations of tissue injury are temporarily ignored. This disconnection between injury and pain is not seen in all victims, however; some report high levels of pain immediately. In general, fear reduces pain, while anxiety increases sensitivity to pain. Three behavioral responses are seen for pain: first, an attempt to avoid further injury; second, seeking aid and safety; and third, recovery from injury. The third phase includes immobilization of the painful part, protection of the injured area from contact, social withdrawal, and sleep.

NEUROANATOMICAL BASIS OF ATTENTION

In animals, stereotyped reflexive behavioral patterns are elicited in response to specific stimuli. The animal selects the stimulus to which it will respond and executes only one motor program at a time. Sensory input is used continuously to guide the movements toward the goal. In people, in the case of the placebo response, the conscious perception of pain is but one of several items that can grab the attention, and under certain circumstances the brain can ignore or exaggerate conscious awareness of somatosensory pain signals. The placebo taps into this capacity and diverts attention away from the perception of pain, directing attention instead to other nonpain concerns. Instead of operating at the site of tissue injury or on the ascending pain pathways, the placebo acts on the mechanism by which conscious

attention is directed. Experimental data are emerging to localize this function within the brain.

Somatic sensations first arrive in the cortex in the somatosensory areas. Simultaneously, other cortical regions are receiving visual, auditory, olfactory, and gustatory stimuli. Features extracted from these inputs are compared with memory stores and are routed through the amygdala, where an emotional significance is assigned to the internal representation of particular external stimuli. The amygdala and hippocampus consolidate new memories according to the goals and drives of the individual, and long-term memory stores are encrypted in the cortex. Separate experiments have determined a part of the anterior cingulate gyrus that is activated during all cognitive tasks, no matter in what sequence other brain regions are activated. This region is thought to play an important role in routing each particular event around the various areas of the brain.

Two complementary techniques have been used to map the pathway of neural impulses in humans in real time. Functional neuroimaging techniques (fMRI, PET scanning, and single photon emission computed tomography [SPECT] scanning) reveal all the brain regions activated in a brief mental task, but not the order in which they are activated. Electroencephalographic recordings of event-related potentials (ERPs) reveal the sequence of activation to millisecond accuracy. In combination, the imaging and the ERP data can be used to map a cognitive pathway from one brain region to the next. Improvements in fMRI techniques continue to increase the temporal and spatial resolution of the method.

Early studies to map changes in brain activity caused by changes in attention yielded interesting results almost immediately. For example, subjects were asked to attend to a specific feature in a scene, and this revealed one cascade of activation of different brain regions. The same subjects were then asked to attend to different details in the same scene, and a novel cascade of activations was seen instantaneously. In separate recent experiments designed to trace the brain activity required for sentence comprehension, change of a single word triggered an immediate and long-lasting divergence in cognitive pathways. In this protocol, subjects read sentences that were identical except that the first word was either *before* or *after*, which confer distinct meanings in discourse. Studies revealed a divergence in the ERP responses over the left frontal hemisphere within 300 ms, depending on whether the sentence began with *before* or *after*. Although the remainder of the sentence remained unchanged, the cognitive pathways continued to diverge over the course of the sentences. This study demonstrated that discrete high-level, real-world knowledge had immediate and sustained consequences on neural processing.

It is not difficult to envision that similar immediate and sustained changes in neural processing accompany each of the subtle cues triggered by a placebo and the context in which it is administered. Conversely, numerous contextual cues could influence the rate at which a painful experience recedes from attention. For example, if a painful experience distracted an individual and prevented recognition of a certain unconscious psychological conflict, then the memory of a painful experience might remain prominent to justify ignoring the unwanted problem.

A model for the activity of the placebo in the human brain can therefore be defined: a myriad of sensory data converges on the brain, including pain signals, antipain interventions, and placebos. These are compiled with memories and expectations based on neural pathways, orchestrated by the anterior cingulate gyrus. Subtle cues and stimuli may profoundly alter the particular pathways chosen. From this hodge-podge of competing events, a network (probably involving the prefrontal cortex and the caudate nucleus) assigns priorities by which individual events will rise to consciousness. For example, if painful sensations overwhelm other priorities, then the person will experience pain. Alternatively, if compliance with the suggestions of a respected caregiver is important, then pain may be ignored.

In the case of chronic pain in the absence of ongoing tissue damage, the memory of pain associated with a particular traumatic event may achieve priority. This will be experienced by the person as pain located in a specific part of the body. Moreover, actual ongoing nonpainful somatosensory stimuli from that body part (i.e., simple pressure) may be exaggerated and perceived as painful because of the associations in the spinal cord and brain with the memory of pain.

The pervasive influence of a painful memory clinically resembles posttraumatic stress disorder, in which the recollections of an extremely traumatic, but not necessarily directly injurious, event intrude continuously into every aspect of the subject's life. For example, there is a conceptual and biochemical similarity between the changes in the brain in posttraumatic stress disorder and the changes in the brain and spinal cord following intensely painful stimuli. In both cases, short-term, intense experience is “learned,” and this memory then exerts a pervasive long-term influence on subsequent experiences, whether painful or not. In both posttraumatic stress disorder and psychologically charged acute pain, a traumatic experience outside the usual range of experience is etched indelibly into the memory. Patients with posttraumatic stress disorder experience increased arousal and vigilance, intrusive recollections of the traumatic event, flashbacks, distortions of perception, and intense psychological distress and physiological reactivity in response to stimuli that resemble the traumatic event. In an analogous syndrome, the circuits of the spinal cord and brain respond to noxious environmental stimuli by establishing persistent hyperalgesia, in which patients experience chronic pain, preoccupation with painful sensations, and pain in response to even nonnoxious peripheral stimuli. Both posttraumatic stress disorder and sensitization of the spinal cord by noxious stimuli are ancient phenomena with a high degree of evolutionary conservation.

CLINICAL APPROACH TO PATIENTS WITH CHRONIC PAIN

Pain Behavior Pain behavior is the way individuals think, feel, and act in relation to their pain status. Pain behaviors are either adaptive or pathological, as when the pain behavior is disproportionate to the objective pathology. A full picture of an individual's pain behavior includes considerations of cognitive style and level of functioning, affective status, and overt behaviors.

Cognitive Aspects A person's individual conception of the cause and significance of pain influences mood and behavior. The conception of pain is formed from experience, observation, and teaching. Whether information is gathered reluctantly, eagerly, or ambivalently depends on cognitive style, developmental history, and personality type. Data can be gathered obsessively or only in overview, which determines how detailed the information is. Patients form opinions about the etiology, pathology, treatment, and prognosis of their condition. Patients may labor under a misperception caused by poor communication with a provider or through exaggeration of the significance of one or more factors, for a variety of reasons. Inaccurate information may then engender ineffective pain behavior.

Affective Aspects All features of an experience with pain have a symbolic significance derived from the person's unique background and sensitivities. The meaning of an individual's pain can only be discovered by patiently tracing associations evoked by the pain experience. Because pain is a somatic sensation, one must understand the patient's body image and its significance to the person's sense of self and place in society. Pain may be associated with ideas of punishment, guilt, loss, threat, or sexual gratification and may thus elicit corresponding emotions. The main affective states encountered with pain are depression, anxiety, and anger. These affects may lead to guilt and shame, and they may be intense enough to disrupt customary coping strategies.

If a patient with chronic pain is depressed or anxious, these conditions should be treated on their own merits with available methods. The “chicken-and-egg” question of whether depression causes chronic pain or vice versa does not have one answer. Each patient should be evaluated with a history and mental status examination to uncover both preinjury mood disturbances and current affect. A psychotherapist must ensure that patients have a realistic understanding of their illness. If patients resist challenge of distorted notions about their pathology, the therapist should provide reassurance that emotional support will be available at all stages of treatment.

Anger and resentment toward the provider may interfere with the provider-patient relationship, particularly if these feelings are not acknowledged and accepted by the patient. Patients need room to ventilate any feelings of anger, guilt, anxiety, and shame toward caregivers and reassurance that these feelings are normal and will not cause caregivers to punish or abandon them. Although it is only human for providers to react defensively to criticism, they must make every effort to establish any basis in reality for a patient's feelings of hostility and resentment.

Behavioral Aspects The wide range of individual reactions to pain, from minimal disruption of activities to the triggering of a calamitous collapse of family and occupational support, appears after injuries of many different types. Although one cannot predict a priori where an individual patient will fall on this spectrum, behaviorally oriented psychologists have studied a person's reaction to pain as a means of communicating their subjective experience. Pain behaviors include (1) verbal complaints of pain and suffering, (2) nonlanguage sounds (i.e., moans, sighs), (3) body posturing and gesturing (i.e., limping, rubbing a painful body part or area), and (4) maintenance of functional limitations (i.e., reclining for excessive periods of time). Efforts to distill the various possible combinations of each of the behaviors into a single index of subjective pain have been unsuccessful, perhaps for obvious reasons. For example, there is no systematic heirarchical scale for any of these pain behaviors individually, much less in combination. In addition, because pain behaviors are subject to voluntary modification, they cannot serve as the basis for an objective scale upon which to base predictions of outcome.

Patients' behaviors not only reflect what they think and feel, but also are constrained by social and medical boundaries. The practical limits of physical activities and recommendations for rehabilitative exercises should be detailed by a physician or rehabilitation therapist. Clear advice regarding the permissible range of active and passive movements permits the patient to exercise with less fear of further injury. Members of the patient's social setting should also be told what the patient is expected to do and how they can expedite recovery. Family members and friends may have their own unconscious conflicts and motives that lead them to perpetuate

the patient's illness role and undermine appropriate adaptation to injury.

Pain behavior varies from culture to culture, and whether it is abnormal depends on the culture. Pain behavior becomes abnormal if it is maladaptive, either by persisting longer than expected on the basis of the severity of injury or by being exaggerated and refractory to reasonable intervention by a qualified practitioner. Abnormal pain behavior is considered to be motivated by unconscious conflicts, as distinguished from malingering, in which the sick role is consciously manipulated for secondary gain. Unconscious conflicts may be neurotic, in which pain behavior is used as an immature defense against other fears, or psychotic, in which the patient's belief in the presence of pathology is delusional.

NEUROTIC ABNORMAL PAIN BEHAVIOR The two ends of the spectrum of neurotic abnormal pain behavior are hypochondriasis and conversion disorders. Hypochondriacal reactions are characterized by an overconcern for health disproportionate to the objective pathology. Hypochondriacal patients have anxiety about being ill, yet remain convinced of the presence of disease despite reassurance to the contrary. They are preoccupied with bodily symptoms, but usually they have insight into the irrational nature of their fears. These symptoms define hypochondriasis in the American Psychiatric Association's fourth edition of *Diagnostic and Statistical Manual of Mental Disorder* (DSM-IV). Hypochondriacal patients are more comfortable discussing their symptoms than any other problems in their lives, and they may deny any psychological stresses. Hypochondriasis permits the patient to withdraw from responsibilities, to become dependent on others, to punish the self and thereby assuage guilt, and to direct hostility toward others, including caregivers, by complaining but not responding to reassurance.

Patients with conversion reactions deny preoccupations or fears about illness but complain about pain and its consequences. These symptoms define pain disorder (DSM-IV), which has also been called somatoform pain disorder, psychogenic pain disorder, idiopathic pain disorder, and atypical pain disorder. The DSM-IV diagnostic criteria for pain disorder include (1) pain in one or more anatomical sites as the predominant focus of the clinical presentation and of sufficient severity to warrant clinical attention, (2) pain that causes clinically significant distress or impairment in social, occupational, or other important areas of functioning, (3) pain whose onset, severity, exacerbation, or maintenance is strongly influenced by psychological factors, (4) the symptom or deficit is not intentionally produced or feigned (as in factitious disorder or malingering), and (5) pain not better accounted for by a mood, anxiety, or psychotic disorder and not meeting criteria for dyspareunia.

Many patients with chronic pain display features of both hypochondriasis and conversion disorder, and these symptoms may be lumped together as abnormal pain behavior. The Illness Behavior Questionnaire (IBQ) can help to categorize a patient's neurotic tendencies.

BEHAVIORAL TREATMENTS The use of devices that have little or no practical effect on the source of pain, but which suggest comfort, may trigger subtle psychological reactions in the broad category of the placebo effect. For example, lumbar supports are often worn by workers suffering from low back pain. There is scant evidence that such supports confer sufficient immobility to reduce biomechanical loading of the trunk or to limit motion during manual lifting. On the other hand, wearing the supports may remind workers to use better lifting and safety techniques. Six large studies (each with some methodological limitations) have left unclear whether lumbar supports prevent low back injury. In contrast, the likelihood of reporting of low back pain is more clearly associated with prior back injury, dissatisfaction with the job, poor interactions between the worker and the supervisor, and poor employee appraisal rating. Thus, the benefit of lumbar supports, especially in the context of education in safe techniques, more likely is due to psychological factors and redirection of attention away from the dissatisfaction with the job than to actual physical factors.

EXERCISE General recommendations for exercise in patients with chronic pain cannot be defined; a specific program of stretching, mobilization, and gradual introduction of activities must be outlined individually for each patient, depending on the details of tissue injury and functional goals. Individuals' response to encouragement is influenced by their coping style. Patients with mature defenses will follow a graded exercise program faithfully and will tolerate a certain degree of discomfort with the expectation of improvement. Patients who derive secondary gain from illness, within the dynamics of their family or work situation, may find unconscious ways to sabotage an exercise program, either by avoidance or by overexertion that causes more injury.

Multidisciplinary Pain Clinics Abnormal pain behavior is best approached in a multidisciplinary pain clinic, in which the staff discusses and coordinates a multifaceted approach to helping the patients understand and treat their pain. Given the somatic nature of the complaints, caregivers must be able to move comfortably between somatic and psychological discussions. Credence must be given to the patients' complaints, and they must be fully involved in planning their treatment program. Treatment is most successful in an ongoing relationship with a primary caregiver who anticipates the inevitability of advances and setbacks and can help patients interact as needed with the multispecialty pain clinic.

MULTIAXIAL ASSESSMENT OF PAIN

Medical assessment and treatment of injuries is an essential first approach to a patient with pain, both for purposes of rehabilitation and to determine the degree of compensable disability. A thorough medical assessment may rule out organic pathology with confidence, yet delve into the patient's experience of pain only superficially or not at all. Many medical and surgical clinicians rely on subjective estimations of the level of pain, (i.e., mild, moderate, or severe) to follow a patient's progress. This approach introduces obvious variability from patient to patient and is an inadequate basis for emotional and psychological treatment approaches in patients who exhibit no obvious organic cause for pain.

The traditional medical conception of pain promotes a view that pain is of physical or psychological origin, or some combination thereof. In practice, there may be limits to how accurately clinical assessment and diagnostic tests can predict an expected level of pain or duration of disability. The importance of psychological factors may need to be inferred from the incongruity of the patient's complaints and disability compared with a best guess of the pain and disability expected from a specific injury. The presence of significant psychological conflicts does not guide the treatment but rather indicates a need for a comprehensive psychological assessment.

Rating Scales for Assessing Chronic Pain Numerous rating scales have been constructed to organize the diagnostic criteria for psychiatric disorders and for personality characteristics. Several psychiatric rating scales have been used to define personality profiles that predict outcome after injury or surgery, including the Minnesota Multiphasic Personality Inventory-II (MMPI II), Rorschach test, Symptom Checklist–90, as well as scales specifically developed for chronic pain patients, including the Pain Apperception Test, Low Back Cognitive Distortion Scale, low back (Lb) scale derived from the MMPI-II, Back Pain Classification Scale derived from the McGill Pain Questionnaire (MPQ), and the Mensana Clinic Test for Chronic Back Pain. Establishing the validity of a particular scale has generally included comparing answers given by a defined population of patients with those given by both a normal population and a population defined by an unrelated criterion. Not every scale has been thoroughly validated in clinical trials.

One early goal for which rating scales were developed was identification of a pain-prone personality. This elusive goal was based on certain assumptions, including the hypothesis that historical factors such as familial alcoholism, child abuse, or spouse abuse predisposed a patient to develop psychogenic pain as a masked form of depression. After several unsuccessful attempts, it became clear that empirical data were inadequate to demonstrate the existence of a pain-prone personality. Moreover, none of these rating scales, administered pretreatment, consistently and accurately predicted treatment outcome. The data from published tests of these rating scales also did not support similar attempts to define a “low back personality” apart from the emotional disturbance associated with chronic limitation and disruption of activity.

None of the attempts to discern a purely psychological etiology for chronic pain permitted formulation of an overarching theory of pain. In fact, close inspection of patients with chronic pain revealed as broad a range of contributory factors as there were different personalities and circumstances. This realization stimulated the development of comprehensive descriptive assessment instruments that sought to define an operative constellation of factors, including cognitive, affective, psychosocial, behavioral, and physiological components. This approach emphasized current functioning and did not attempt to pigeonhole patients into theoretical categories of personality or behavior.

Accurate characterization of patients' idiosyncratic views of their misfortune, their unique experience of pain, and their coping resources—personal, financial, familial, and social—were combined to outline a realistic treatment plan. It turned out that patients' motivation for treatment and how this was balanced against other demands on their time and energy was particularly important. A patient's perceptions of caregivers, employers, and family members were likely to influence the strength of the therapeutic bond and thus the success of a therapeutic regimen.

Tests developed to standardize the psychosocial and behavioral dimensions of chronic pain included the Sickness Impact Profile, the IBQ, the Behavioral Assessment of Pain (BAP), the Millon Behavioral Health Inventory (MBHI), and the West Haven–Yale Multidimensional Pain Inventory (MPI), as well as additional test batteries to assess coping repertoire. These provided information about one facet of the chronic pain experience, which was best used in combination with medical, affective, and cognitive assessments.

Application of scales that relied on self-reporting of distress and disability revealed that no person was a truly objective self-observer. For example, a group of asymptomatic occupational therapy students took three pain behavior rating scales with the instruction to imagine that they had chronic pain and to represent themselves as either coping well or coping poorly. The students achieved significantly different scores depending on how they imagined themselves coping. Students portraying poor coping emerged with scores indistinguishable from those of a comparison group of patients enrolled in a multidisciplinary pain clinic at a teaching hospital, showing that one could bias one's answers to self-assessment scales to appear either healthier or more ill. In conclusion, these studies reinforced the importance of a detailed, open-ended, unstructured interview, corroborated by significant others, as the only reliable way to reveal an individual's motivations.

Minnesota Multiphasic Personality Inventory The most widely used rating scale for chronic pain is the MMPI. Studies have focused on the “neurotic triad,” the first three of the 10 standard scales, in patients with chronic pain. Scores on the hypochondriasis (Hs) scale, which measures “abnormal, psychoneurotic concern over bodily health,” and the hysteria (Hy) scale, which measures the tendency toward conversion disorder and which shares 20 of its 60 items with the Hs scale, were both elevated in some patients with chronic pain. In contrast, scores on the depression (D) scale, which measures symptomatic depression, were low in many patients with chronic pain. These scores contributed to the “conversion V,” that is, high on scale 1 (Hs), low on scale 2 (D), and high on scale 3 (Hy).

People with high scores on the Hs scale are excessively concerned about bodily processes even though there is no organic basis to their problems. They have excessive bodily concerns, numerous vague somatic symptoms, and undefined complaints such as gastric upset, fatigue, pain, and physical weakness. They are likely to be selfish, self-centered, narcissistic, pessimistic, defeatist, cynical, and dissatisfied, and their complaining, whining, demanding, and critical behavior may make others miserable. They express hostility indirectly and are not very responsive to psychological therapy.

People with high scores on scale Hy tend to deny social anxiety, to deny psychological problems, to seek excessive attention and affection, and to resist gaining insight into their own behavior. They tend to react to stress by developing physical symptoms such as headaches, chest pains, weakness, and tachycardia. They have an expectant mood and are facile in social situations.

People with high scores on scale D are characterized by the features of depression, which include a generally negative frame of mind and a tendency to report poor morale, lack of hope in the future, dissatisfaction with life, or low mood. A patient with a high score on scale D is less likely to find pain self-reinforcing than a patient with a low score on scale D.

Among the numerous supplementary measures derived from the MMPI, subtypes of patients with chronic pain were defined in a variety of settings. In one attempt, four subtypes, called P, A, I, and N, were suggested. Type P appeared the most psychopathological, in that scores on nearly all scales were elevated. Type P patients were extreme in their claims of physical illness, psychological distress and social maladaptation. Demographic correlates included poor education, high rates of unemployment, and limited household income. Type A was defined by a conversion V on the neurotic triad scales. It had no unique demographic correlates. Type I had elevated scores on all of the neurotic triad scales and on no others. Type I patients appeared to be the most physically infirm, with multiple surgeries and hospitalizations. They often did not improve in physical status with treatment, but appeared to benefit psychologically. Type N profiles were normal in that no scale scores, except perhaps scale K (which measures defensiveness and a tendency to deny problems), were often elevated. Type N patients were moderate in their claims of ill health, often were better educated and employed, and appeared to respond well to treatment.

Despite the complex schemata suggested by these scales, application of MMPI criteria to additional groups of patients with chronic pain successfully predicted response to treatment only about half of the time. The MMPI was not specifically tailored for patients with pain, and its major weakness in this application is that it lacks questions to assess the presence of actual physical abnormalities that could cause pain. Its clinical usefulness is therefore limited compared with other, more specific rating scales. The lengthy MMPI should be used cautiously as the basis for treatment decisions in patients with chronic pain.

McGill Pain Questionnaire The MPQ consists of four parts (Fig. 28.6-2). First, patients indicate the site of their pain on a drawing of a human figure. Second, patients must choose between 78 adjectives divided into 20 groups, covering sensory qualities, affective states, and specific medical conditions. Third is a series of questions about prior pain experience, pain location, and use of pain medication. Fourth, patients rate their current pain on a pain intensity index (PPI), which is a visual scale from “no pain” (0) to “excruciating” (5).

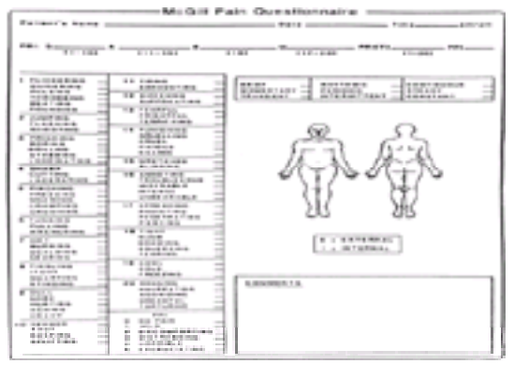

FIGURE 28.6-2 The McGill Pain Questionnaire. (Reprinted with permission from *Textbook of Pain*, ed 3, PD Wall, R Melzack, editors. Churchill Livingstone, Edinburgh, 1994.)

The MPQ has been applied in a wide range of settings in the assessment of both acute and chronic pain. The verbal pain descriptors circled are processed to generate ratings that aim to distinguish three components of the pain experience: the sensory-discriminative, the motivational-affective, and the cognitive-evaluative. However, empirical data do not support the proposed discriminations, but rather indicate that the MPQ scores are correlated only with the intensity of pain.

Emory Pain Estimate Model One of the earliest rating scales devised specifically for patients with chronic pain was the Emory Pain Estimate Model (EPEM), in which assessment was divided into “pathology” and “behavior.” The pathology score was derived from quantification of physical examination procedures (i.e., ratings of joint mobility and muscle strength) and abnormalities on radiological studies. The behavior score was a composite of activity levels, pain verbalizations, drug use, and abnormalities on certain MMPI scales. The EPEM defined four classes of patients with chronic pain. Class I, in which there were higher scores on the behavior scales and lower scores on the pathology scales, contained patients who displayed low levels of activity, high verbalizations of pain, prominent social and psychological malfunctions, and frequent misuse of medications. Class II, in which scores were low on both the behavior and pathology scales, contained patients who displayed highly dramatized pain complaints with ill-defined anatomical patterns, yet who did not have significant behavioral malfunctions. Class III, in which scores were high on both scales, contained patients with clearly demonstrable injury or illness and high-intensity illness behavior. Class IV, in which there were high scores on the pathology scale and low scores on the behavior scale, contained patients who demonstrated competent coping in the presence of a demonstrable pathological condition.

The EPEM was criticized for the arbitrary grouping of factors in both the behavior and pathology scales and for the uneven weighting of significant and incidental findings. It was more a projection of the authors' impressions than an empirically derived inventory. At the time it was devised, however, the EPEM was important in that it set out to compare medical and behavioral evaluations in the same patient. Subsequently, other, more robust, rating scales supplanted it.

Waddell Approach A comprehensive assessment of a series of patients with chronic pain was factor analyzed to determine the relative contributions to disability of physical impairment and psychosocial factors. Although the scales were not validated across several different groups of patients, conclusions were nonetheless drawn on a representative group of patients. Physical impairment was found to account for 40 percent of the variance on the disability index, while psychological distress (depression and somatic preoccupation) accounted for an additional 23 percent of the variance, and magnified illness behavior (cognitive distortion of symptoms) accounted for 8 percent of the variance. The methods in this report were not compiled into a clinically useful instrument, but the results represented one effort to discriminate the source of disability based on empirically derived criteria.

West Haven–Yale Multidimensional Pain Inventory The MPI characterized cognitive-behavioral factors, such as the impact of pain on the patients' lives, how

significant others responded to the patients' pain, and how active the patients were in common daily activities. The first of two parts assessed (1) reports of pain and suffering; (2) patients' perceptions of how pain interferes with their lives, including interference with family and marital functioning, work, and social-recreational activities; (3) dissatisfaction with their present levels of functioning in each of the areas listed in (2); (4) the support provided by spouses, family, and significant others; (5) perceived life control, incorporating the perceived ability to solve problems and feelings of personal mastery and competence; and (6) affective distress, including ratings of depressed mood, irritability, and tension. The second part consisted of ratings by patients of the frequency with which significant others respond to their expression of pain by (1) punishment (i.e., irritability, ignoring), (2) solicitousness (i.e., taking over their chores), and (3) distraction (i.e., encouraging them to work on a hobby).

Statistical analyses identified three distinct patient profiles on the MPI: (1) *Interpersonally Distressed*, patients with a common perception that significant others were not very understanding or supportive of their problems; (2) *Globally Dysfunctional*, patients who perceived the severity of their pain to be high, reported that pain interfered with much of their lives, reported a higher degree of psychological distress due to pain, and reported low levels of activity; and (3) *Adaptive Copers*, patients who reported high levels of social support, relatively low levels of pain and perceived interference, and greater activity. In two populations of patients with chronic pain, the three profiles represented 28, 43, and 29 percent of the patients, respectively.

Correlation with medical findings showed that the patients in the Globally Dysfunctional group had significantly more abnormal findings on medical assessment than the patients in either of the two other groups. Further analysis of the Globally Dysfunctional group permitted the definition of two subgroups of roughly equal size: a subgroup of Globally Dysfunctional patients with significant medical findings (a truly globally impaired group), and another subgroup with a high degree of psychological and behavioral disability but with relatively few abnormal physical findings.

The MPI was normed only on patients with chronic pain and it was validated against 10 other scaled measures of pain and cross-validation on additional groups of patients. For example, one comparison of MPI classification and abnormality on MMPI scales found that MPI Globally Dysfunctional and Interpersonally Distressed scores differed significantly from the MPI Adaptive Coper scores on MMPI scales 4 (psychopathic deviate), 6 (paranoia), 7 (psychasthenia [anxiety disorder with obsessive-compulsive features]), and 8 (schizophrenia). The Globally Dysfunctional and Adaptive Coper scores also significantly differed on MMPI scale 2 (depression). Some 79 percent of Globally Dysfunctional patients and 62 percent of Interpersonally Distressed patients displayed psychopathology as defined by significant two-point scale elevations on the MMPI, whereas only 23 percent of Adaptive Copers had significant two-point MMPI scale elevations.

A disadvantage of the MPI, found on wider use in the United States and Europe, was that the questions used to assess activity level, which were appropriate for middle-class suburban Connecticut, did not translate across socioeconomic and geographic boundaries.

Illness Behavior Questionnaire The IBQ consisted of a self-administered 62-item questionnaire developed from the Whiteley Index of hypochondriasis. Seven scales were derived. Scale 1, general hypochondriasis (GH), detected a fearful attitude toward illness, some degree of insight into the irrationality of these fears, and a high level of arousal or anxiety. Scale 2, disease conviction (DC), indicated strong affirmation of the presence of disease and resistance to reassurance by caregivers. Scale 3, psychological versus somatic focusing (P/S), defined a spectrum ranging from a tendency to blame oneself and accept the need for psychiatric help (psychological focusing) to a tendency to reject the possibility of psychological factors and instead focus on somatic problems (somatic focusing). Scale 4, affective inhibition (AI), indicated difficulty expressing personal feelings, especially negative ones, to others. Scale 5, affective disturbance (AD), indicated the presence of anxiety or depression. Scale 6, denial (D), indicated denial of current life problems and attribution of all problems to physical illness. Scale 7, irritability (I), indicated anger and awareness of interpersonal friction. Combinations of these primary scales yielded two additional second-order factors, affective state and disease affirmation, and an index of whether conversion disorder was present.

The profiles derived from the IBQ could clue the provider to the patient's pattern of resistance and could indicate where further questioning might uncover a psychological conflict at the root of neurotic abnormal pain behavior.

PHARMACOTHERAPY

Drugs appropriate for patients with chronic pain fall into three pharmacological classes: nonopioids, such as aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), and acetaminophen; opioids and other narcotics, both natural and synthetic; and adjuvants, such as antidepressants, anticonvulsants, and antihistamines.

Analgesics Analgesics are most appropriate for the treatment of pain due to tissue injury. For patients with chronic pain but no demonstrated organic pathology, in whom psychosocial factors play a significant role in the maintenance of pain, long-term use of analgesics should be limited as much as possible. Such patients should be encouraged to increase their functioning while using a minimum of analgesics.

Aspirin and Nonsteroidal Anti-Inflammatory Drugs Aspirin and NSAIDs inhibit the cyclooxygenases COX-1 and COX-2 reducing the generation of prostaglandins such as prostaglandin E_2 which stimulate cyclic adenosine monophosphate (cAMP) and contribute to the sensitization of nociceptors. Inactivation of COX-2 is responsible for aspirin's anti-inflammatory, analgesic, antipyretic, and anticancer activities. Inactivation of COX-1 contributes to aspirin's antithrombotic, bronchospastic, and ulcerogenic effects, which significantly limit the use of aspirin and the NSAIDs for chronic pain. Aspirin irreversibly acetylates and inactivates both isoforms of COX but is 10 to 100 times more potent on COX-1.

The number of people in the United States with chronic pain not adequately treated with aspirin or NSAIDs (mostly osteoarthritis) is estimated at 30 to 40 million. Since the current treatment of chronic inflammatory conditions is often inadequate because NSAID dosing is limited by adverse effects, there is great interest in the recent discovery of derivatives of aspirin that selectively inhibit COX-2 and have little activity on COX-1 (Fig. 28.6-3). Because they are less limited by gastric adverse effects, selective COX-2 inhibitors can be used at concentrations capable of inactivating a greater percentage of the body's COX-2 than can aspirin or the NSAIDs. One such preclinical agent, *o*-(acetoxyphenyl)hept-2-ynyl sulfide (APHS), permanently inhibited COX-2 100 times more selectively than did aspirin. Reversible COX-2 inhibitors are at least as efficacious as NSAIDs for treatment of arthritis pain. Soon after it was marketed, the reversible COX-2 inhibitor celecoxib (Celebrex) became the fastest-selling new drug ever, reflecting the immense pent-up demand for novel analgeic drugs. In clinical experience, celecoxib and another reversible COX-2 inhibitor available in Great Britain, meloxicam, are associated with greatly reduced, but not absent, adverse gastrointestinal effects, including bleeding, ulcers, and perforations. It remains to be seen whether these adverse effects are directly due to the novel COX-2 inhibitors or are a carry-over from previous NSAID use. A second reversible COX-2 inhibitor, rofecoxib (Vioxx), is also approved for use in the United States.

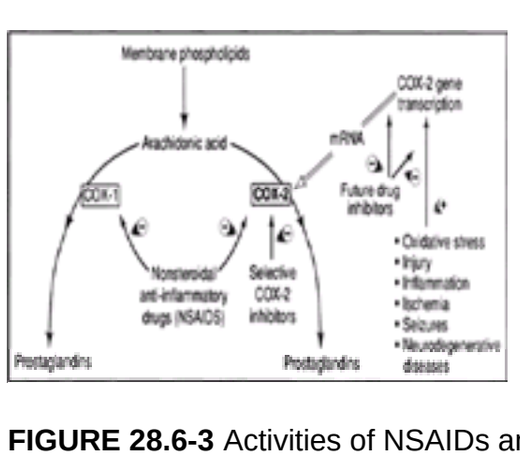

FIGURE 28.6-3 Activities of NSAIDs and COX-2 inhibitors. NSAIDs inhibit both COX-1 and COX-2, whereas selective COX-2 inhibitors only have significant inhibitory activity on COX-2. (Reprinted with permission from Pennisi E: Building a better aspirin. Science *280:* 1191, 1998.)

Clinical Guidelines for NSAIDs and Acetaminophen NSAIDs and acetaminophen are among the most widely used over-the-counter drugs (Table 28.6-3). These agents have a ceiling of therapeutic efficacy such that the pain in certain patients may be partially or not at all reduced by them. As doses reach the upper therapeutic range, each dose increment yields diminishing returns, and at higher doses, adverse effects predominate. Many patients with chronic pain control their pain with long-term use of these agents, and tolerance is not inevitable. Some patients, however, (especially those without demonstrable organic pathology) may eventually

cease to respond to these drugs and may then seek prescription analgesics.

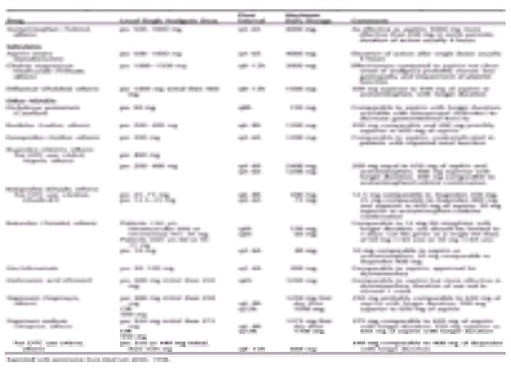

Table 28.6-3 Acetaminophen and NSAID Analgesics

ACETAMINOPHEN Unlike the NSAIDs, acetaminophen limits pain but does not reduce inflammation. There are almost no immediate adverse effects of acetaminophen, even at doses up to 1500 mg, but excessive doses taken either short- or long-term can cause potentially irreversible and even fatal hepatic injury. The threshold dose for hepatic damage is reduced in alcoholic patients, fasting patients, and those whose cytochrome P450 enzymes are induced. The maximum safe dosage for most patients is 4 g a day.

ASPIRIN The most prominent of aspirin's adverse effects are gastritis and (to a lesser degree) precipitation of asthma. Aspirin irreversibly inactivates platelet function and may prolong the bleeding time, which may be clinically relevant up to 10 days after the last dose, until bone marrow production replenishes the blood with active platelets. Long-term high dosages may cause salicylism, through a combination of CNS and peripheral effects. Many people take daily enteric-coated aspirin indefinitely as prophylaxis against heart attack and stroke.

OTHER NSAIDS Most NSAIDs are capable of higher levels of pain relief than are acetaminophen or aspirin. The NSAIDs comprise a heterogeneous group of chemical structures, and they have various specific toxicities in addition to their common gastric toxicity. Some NSAIDs are recommended for no more than 5 or 10 days of use, and these agents are unsuitable for chronic pain. Caution must be used in administering NSAIDs to patients with peptic ulcer disease, hypertension, alcohol abuse, congestive heart failure, ascites, volume depletion, and renal insufficiency and those who use diuretics. Some NSAIDs may cause drowsiness. NSAIDs cause a reversible inhibition of platelet function that ceases soon after the last dose is metabolized. Gastritis may be mitigated with concurrent administration of misoprostol (Cytotec), a prostaglandin E_1 analogue that compensates for the inhibition of prostaglandin synthesis resulting from inhibition of COX-1 by NSAIDs. Other agents used to reduce NSAID-induced gastritis include histamine type 2 (H_2) receptor antagonists, proton pump inhibitors, and antacids. Despite these countermeasures, NSAID toxicity can affect a significant percentage of elderly patients with chronic pain. Above the age of 60 years, the risk-benefit ratio tips in favor of opioids over NSAIDs.

Opioids The analgesic effect of exogenous opioids results primarily from binding to μ-receptors. Activation of k-opioid receptors may also produce analgesia, but a more significant function of k-receptors is to antagonize the actions of the μ-receptors. Both electrophysiological and behavioral studies in animals have shown that k-opioid agonists oppose the analgesic actions of μ-opioid agonists, probably at the brainstem level. μ-Opioid agonists produce euphoria and place preference, while k-opioid agonists cause dysphoria and aversion. μ-Opioid agonists are rewarding and increase release of dopamine in the mesolimbic system, whereas k-opioid agonists block the rewarding effects of μ-opioid agonists and decrease mesolimbic dopamine release. Mesolimbic dopamine activity is closely linked to reward behavior. Because morphine binds to both μ- and k-receptors, an imbalance between μ- and k-receptors may be the cellular basis for the tolerance that often develops to the effects of opioids. Clinical experience has repeatedly shown that opioid dosages must be gradually advanced to ever higher dosages to achieve the same subjective relief of pain.

μ-Opioid agonists bind to receptors in the spinal cord that act through inhibitory G proteins. Opioids inhibit neurotransmitter release at the first synapse encountered by incoming signals and inhibit sensitization of nociceptors by inflammatory stimuli. Opioids also reduce activation of the medial spinothalamic tract and increase activation of the inhibitory lateral spinothlamic tract. Thus, in sum, opioids act at the level of the spinal cord to reduce the activation of fibers that stimulate the anterior cingulate pain region and simultaneously potentiate the activation of fibers that suppress the anterior cingulate pain region.

At the supraspinal level, the principal antinociceptive pathways originate in the noradrenergic locus ceruleus and the serotonergic nucleus raphe magnus and descend into the spinal cord. Opioids activate these descending pathways. Thus, opioids act in concert on several neural tracts at both spinal and supraspinal levels, each of which independently reduces the intensity of pain perception.

Mice in which the μ-, k-, or d-opioid receptors have been experimentally deleted each display altered pain responses, though the abnormalities depend on the particular testing paradigm used. Further knockout studies targeting each of the various pharmacological subtypes of the μ-, k-, and d-receptors should permit finer dissection of the actions of each member of the opioid receptor family. Naturally occurring variations in pain sensitivity among different mouse strains have been associated with differences in the abundance of μ-receptors.

Clinical Guidelines for Opioids Naturally occurring opiates—morphine and other plant alkaloids—and the synthetic opioids are clinically the most effective analgesics across a wide range of conditions, including inflammatory and neuropathic states. Opioids are classified as full agonists, partial agonists, and mixed agonist-antagonists (Table 28.6-4). There does not appear to be a ceiling for the analgesic effects of full agonists, except that imposed by adverse effects. Injectable opioids have been used in numerous interventional treatments, including slowly releasing pumps that continuously inject tiny doses of opioids directly into the cerebrospinal fluid of the spinal cord. These have variably been shown to relieve certain types of chronic pain, but the effective dosage must be gradually increased each month. The clinical usefulness of opioids is limited by respiratory depression, constipation, development of tolerance, development of physical and psychological dependence, and perceived abuse potential, which is, however, rare above the age of 60. Recent clinical practice guidelines of the American Geriatrics Society in fact recommend use of opioids for treatment of chronic noncancer pain in patients over the age of 60, because the risk of tolerance and dependence with opioids is relatively less than the risk of gastric and renal toxicity due to chronic use of NSAIDs.

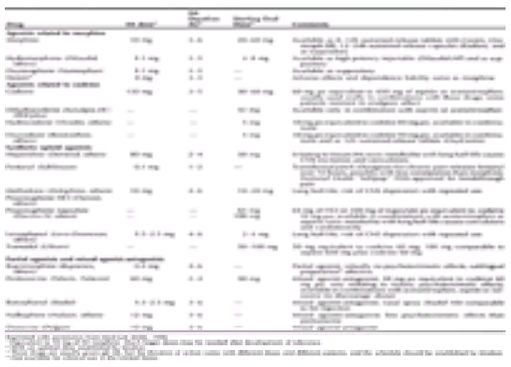

Table 28.6-4 Opioid Analgesics

TOLERANCE Tolerance to opioids develops with chronic use and is experienced first as a shorter duration of analgesia and later as a decreased effectiveness of each dose. Because tolerance to the CNS and respiratory depressive effects develops roughly simultaneously with the tolerance to the analgesic effects, the dosage

may safely be gradually escalated to achieve a constant degree of analgesia. Tolerance occurs independently for each opioid receptor, and clinically the cross-tolerance between full agonists may not be complete. The risk of tolerance may be reduced by using the lowest effective dosage of opioid in combination with nonopioids, and if tolerance develops, it may sometimes be overcome by changing to another full agonist, starting with half or less of the customary equianalgesic dosage.

DEPENDENCE Physical dependence is revealed by abrupt discontinuation of a strong opioid or by administration of an opioid antagonist. It may appear after only a few days of opioid use, but clinically relevant dependence results only from use of a morphinelike opioid for several weeks. Patients who use opioids for relief of acute pain or cancer pain rarely experience euphoria and only rarely develop dependence to the mood-altering effects of opioids.

ADVERSE EFFECTS The most common adverse effects include sedation, grogginess, dizziness, nausea, vomiting, and constipation. The most serious adverse effect is respiratory depression. Strategies include giving smaller, more frequent doses; using opioids with a shorter half-life; and augmentation with a stimulant such as dextroamphetamine (Dexedrine) or methylphenidate (Ritalin). Tolerance usually develops rapidly to the sedative and emetic effects, but constipation is persistent, and a bowel regimen should be given early in the course of treatment. Respiratory depression and apnea are more common in patients with chronic obstructive pulmonary disease, cor pulmonale, decreased respiratory reserve, or preexisting respiratory depression, even with usual doses of opioids. Tolerance to the respiratory depressive effects develops rapidly, but patients taking opioids are more sensitive to the respiratory depressant effects of general anesthetics, phenothiazines, sedative-hypnotics, tricyclic drugs, or other CNS depressants.

DOSAGE STRATEGIES The effective dosage of opioids varies widely among patients, and it is always necessary to titrate the dosage between the need for analgesia and the appearance of adverse effects. Once a strong opioid is chosen, its dosage should be increased to the point of toxicity prior to switching to another opioid. Once the adequate dosage has been determined, opioids should be given on a regular, around-the-clock schedule rather than on an as-needed basis. This schedule may reduce the overall dosage of opioids compared with that needed to treat the reemergence of pain. A supplementary dose should be available as needed between regular doses, for breakthrough pain.

Representative Opioid Drugs

MORPHINE Morphine was the first opiate to be discovered and is still the standard of efficacy for strong injectable analgesics. Oral formulations undergo extensive first-pass metabolism but are also highly effective, particularly in sustained-released preparations (MS Contin). Oral morphine is used widely for treatment of cancer pain, but fears about dose escalation necessitated by tolerance and about the development of dependence sharply limit its use for treatment of chronic, noncancer pain. Physician surveys have documented a solemn reluctance to prescribe high doses of opioids, which could cause death by respiratory suppression. This level of caution exceeds that for numerous other potentially hazardous therapies, and it shows the discomfort physicians have with pain management. When used appropriately, opioids rarely cause death. Morphine has no more liability for dependence than do equally effective dosages of any full opioid receptor agonist.

MEPERIDINE Because of the accumulation of a long-acting toxic metabolite, normeperidine, meperidine (Demerol) should be used only for the treatment of acute pain. Normeperidine may cause dysphoria, irritability, tremors, myoclonus, and seizures, especially with large repeated doses or in patients with renal insufficiency. Administration of meperidine to a patient using a monoamine oxidase inhibitor (MAOI) may cause severe encephalopathy and death.

METHADONE AND LEVORPHANOL Oral methadone (Dolophine) and sometimes levorphanol (Levo-Dromoran) are used to treat chronic cancer pain, especially in patients who are tolerant to morphine. Because of their long half-lives, 24 to 36 hours and 12 to 16 hours, respectively, significant amounts can accumulate with repeated dosing, especially in elderly or debilitated patients, which may cause CNS depression. Access to methadone is tightly regulated by state agencies because of its use as a treatment for opioid dependence.

TRAMADOL The oral opioid agonist tramadol (Ultram) also blocks the reuptake of norepinephrine and serotonin. Its effectiveness is comparable to that of combinations of aspirin or acetaminophen with codeine or propoxyphene. Tramadol may cause seizures, especially in patients concomitantly taking an antidepressant, an MAOI, or a dopamine receptor antagonist (typical antipsychotic). Tramadol is not scheduled as a controlled substance by the U.S. Drug Enforcement Agency, but opioid-type dependence has occurred.

PARTIAL AGONISTS AND MIXED AGONIST-ANTAGONISTS The partial agonist buprenorphine (Buprenex) and the mixed agonist-antagonists pentazocine (Talwin), butorphanol (Stadol), nalbuphine (Nubain), and dezocine (Dalgan) all have a therapeutic ceiling and are comparable to moderate dosages of full agonists. They can precipitate opioid withdrawal in patients physically dependent on full agonists. Their risk of dependence is less than that of full agonists but may be clinically relevant. Only pentazocine is available for oral use, in combination with acetaminophen or aspirin. Butorphanol is available in a nasal spray for treatment of acute migraine, but the development of dependence and drug abuse with this formulation is a growing problem.

Nicotinic Receptor Agonists Nicotine has antinociceptive properties, but its low activity and significant adverse effect profile make it unsuitable for this purpose in humans. Nicotinic acetylcholine receptors are assembled from various combinations of a, b, d, and g subunits. The receptor subtypes in the CNS responsible for pain relief differ from those that mediate the undesirable effects, which include those at the neuromuscular junction and in sympathetic ganglia. A nicotine analogue, epibatidine, isolated from the skin of wild frogs, is 200 times more potent an analgesic than morphine in animals, and its effects are not antagonized by opioid receptor antagonists, suggesting that it acts on a distinct neurotransmitter system. Epibatidine is not suitable for use in humans because it causes seizures and even death. Other adverse effects of epibatidine are mediated in part through non-CNS nicotinic acetylcholine receptors.

A derivative of epibatidine, ABT-594, was as effective an analgesic as morphine for both acute and chronic pain in early clinical trials and it lacked many of the undesirable effects of opioids. ABT-594 inhibits neuronal activity in the dorsal horn of the spinal cord produced by noxious stimuli, yet it has no effect on perception of innocuous pressure or thermal stimuli. Unlike opioids, which cause respiratory depression and sedation, ABT-594 has little effect on respiration and actually makes animals more alert. Both opioids and ABT-594 reduce the appetite, but ABT-594 causes fewer gastric adverse effects and has shown no withdrawal syndrome in at least one animal model of addiction. Whether the nicotine-like qualities of ABT-594 will produce addiction in humans similar to that produced by tobacco products is not yet known. Clinical trials of the safety of ABT-594 have begun in Europe. Testing of additional epibatidine-like drugs is a high priority of the pharmaceutical industry.

Cannabinoids D-9-Tetrahydrocannabinol (D-9-THC), the active ingredient of marijuana, has relieved pain inconsistently in humans. For example, marijuana smoking has long been used to treat chronic pain and nausea due to cancer. D-9-THC is available for prescription as dronabinol (Marinol). In animals, D-9-THC and other cannabinoid drugs cause significant motor impairment at analgesic doses. Cannabinoids occupy receptors also bound by endogenous cannabinoids. Endogenous cannabinoids share an analgesia-promoting brainstem circuit with opioids, which includes the rostral ventromedial medulla. Recently, inactivation of the rostral ventromedial medulla was shown to abolish the analgesic, but not the motor effects of cannabinoids. Cannabinoids and opioids modulate the rostral ventromedial medulla in pharmacologically dissociable ways to produce analgesia. Therefore, cannabinoid receptor agonist activity in the rostral ventromedial medulla could conceivably relieve pain without affecting movements, although further studies are needed to confirm this hypothesis. Based on this model, intensive drug development may eventually create a rostral ventromedial medulla–specific cannabinoid analgesic that is safe for humans.

Adjuvant Drugs The nociceptive element of chronic pain that is responsive to NSAIDs and opioids may be only a part of the entire pain experience. Neuropathic pain is generally less responsive to NSAIDs and opioids but may be effectively treated with antidepressants and anticonvulsants. The affective component of chronic pain may respond to antidepressant or anxiolytic agents. Any underlying psychiatric disorders should be treated appropriately.

Antidepressants Numerous studies have found an association between chronic pain and affective spectrum disorders such as depressive and anxiety disorders. Depression may exacerbate and distort the perception of nociceptive pain. Cognitive factors typical of depression, such as pessimism, learned helplessness, and negative automatic thoughts, may be ameliorated with antidepressant therapy. Antidepressant drugs are among the safest and most effective agents for the treatment of chronic pain. Sleep disturbances associated with chronic pain may respond to antidepressants with sedative properties, such as trazodone (Desyrel), nefazodone (Serzone), mirtazapine (Remeron), paroxetine (Paxil), or tricyclic drugs. Tricyclic antidepressants have been used extensively for treatment of constant neuropathic pain, but they have more serious adverse effects and offer no therapeutic advantage over newer antidepressants. Newer antidepressants may be more efficacious for neuropathic pain because higher dosages may be used without sedation or anticholinergic effects.

Anticonvulsants Lancinating pains typical of trigeminal neuralgia, postherpetic neuralgia, nerve trauma, or infiltration of nerves by cancer may respond to anticonvulsants, such as carbamazepine (Tegretol), phenytoin (Dilantin), clonazepam (Klonopin), and gabapentin (Neurontin).

Caffeine Caffeine is not an analgesic by itself, but in controlled trials it potentiated the analgesic effects of acetaminophen, aspirin, and ibuprofen for headache, oral surgery pain, and postpartum pain. A widely used migraine headache treatment contains a combination of butalbital (a barbiturate for sedation) and caffeine plus aspirin (Fiorinal) or acetaminophen (Fioricet, Esgic).

Antihistamines Hydroxyzine (Atarax, Vistaril) and other first-generation H_1 receptor blockers may increase the analgesic effect and reduce the nausea and vomiting of opioids in postoperative and cancer pain.

Corticosteroids In painful chronic inflammatory conditions such as arthritis or infiltration of nerves by tumor, the anti-inflammatory effects of corticosteroids may have analgesic effects. Long-term use of steroids is associated with weight gain, immunosuppression, peptic ulcer disease, skin changes, euphoria, insomnia, mood swings, personality changes, depression, psychosis, electrolyte abnormalities, loss of muscle mass, cataracts, glaucoma, and adrenocortical insufficiency (on precipitous withdrawal).

Antipsychotic Agents Chlorpromazine (Thorazine) and other low-potency dopamine receptor antagonists are effective in the acute management of migraine headache refractory to standard analgesics. This class of drugs is not commonly used for treatment of chronic pain, but it is useful for patients whose pain is part of a delusional complex.

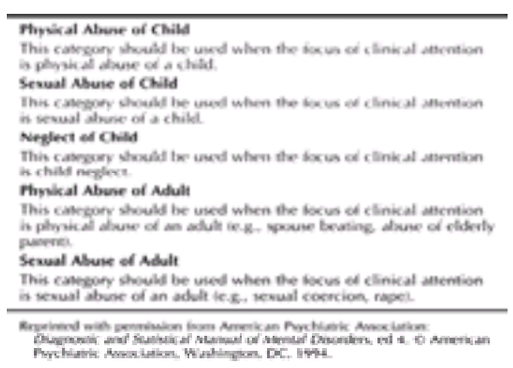
28.7 PHYSICAL AND SEXUAL ABUSE OF ADULTS

BESSEL A. VAN DER KOLK, M.D.

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) specifies five problems related to abuse or neglect: (1) physical abuse of child, (2) sexual abuse of child, (3) neglect of child, all discussed elsewhere in this textbook, and (4) physical abuse of adult and (5) sexual abuse of adult, both discussed here. (Table 28.7-1). Physical abuse of adult includes spouse or partner abuse and abuse of elderly persons. Sexual abuse of adult includes rape, sexual coercion, and sexual harassment.



Physical Abuse of Child
This category should be used when the focus of clinical attention is physical abuse of a child.
Sexual Abuse of Child
This category should be used when the focus of clinical attention is sexual abuse of a child.
Neglect of Child
This category should be used when the focus of clinical attention is child neglect.
Physical Abuse of Adult
This category should be used when the focus of clinical attention is physical abuse of an adult (e.g., spouse beating, abuse of elderly parent).
Sexual Abuse of Adult
This category should be used when the focus of clinical attention is sexual abuse of an adult (e.g., sexual coercion, rape).

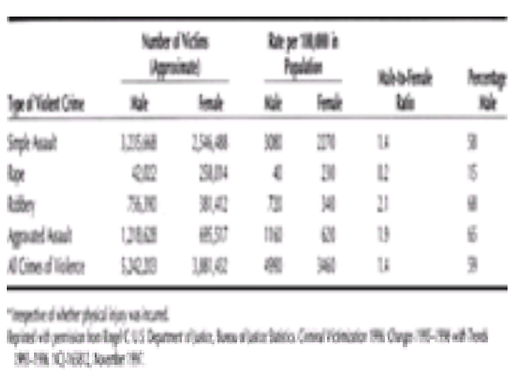
Table 28.7-1 DSM-IV Problems Related to Abuse or Neglect

Violence is probably the most important public health problem in the United States. Violent deaths, including those caused by accidents and interpersonal violence, are the third leading cause of death, after cardiovascular disease and cancer. However, when one considers the amount of expected life lost by specific causes of death, violent deaths are responsible for more years of expected life lost than any other cause of death. Accidents account for about 60 percent of violent deaths, suicides for 25 percent, and homicides for 15 percent. The morbidity resulting from violence is also considerable. This not only concerns the physical injuries and disabilities that result from interpersonal violence, but also the psychological sequelae that follow in its wake.

With an annual homicide incidence of 7.9 per 1000 citizens, the United States is considered the most violent industrialized nation in the world. One study estimated that 83 percent of Americans will fall victim to a violent crime (Table 28.7-2) at some point in their lives, and about 25 percent will become victims of three or more violent crimes. Overall, at least 15 percent of the population report having been molested, physically attacked, raped, or involved in combat. Men are physically assaulted more than women (11.1 vs. 10.3 percent), while women report higher rates of sexual assault (7.3 vs. 1.3 percent). More whites (18.4 percent) than African-Americans (11.6 percent) report having been physically assaulted, even though the death rate due to criminal assault is four to five times as high in black males and females than in whites. Teenagers and young adults are most vulnerable to becoming victims of violent crime; in 1996, about a third of all victims of violent crime were ages 12 to 19. Almost half of all victims of violence were under age 25. These different forms of violence have both short- and long-term sequelae, affecting both the physical and psychological well-being of the victim.



Type of Violent Crime	Number of Victims (Approximate)		Rate per 100,000 in Population		Male-to-Female Ratio	Percentage Male
	Male	Female	Male	Female		
Simple Assault	1,735,660	2,546,480	1080	1270	1.4	58
Rape	42,022	258,014	40	230	0.2	15
Robbery	756,390	381,432	720	340	2.1	68
Aggravated Assault	1,210,628	695,537	1160	620	1.9	65
All Crimes of Violence	3,742,203	3,881,432	4980	3460	1.4	59

Table 28.7-2 Victimization by Nonlethal Violent* Crime by Sex, 1996

High levels of violence are accompanied by high patterns of medical utilization; at least one in five women seen in emergency departments has symptoms related to abuse. In emergency rooms, patients are generally only symptomatically treated for their injuries, which are rarely recognized and treated as related to abuse. Even when recognized, medical staff are often at a loss about what to do and are unaware of resources to address the needs of traumatized individuals.

EPIDEMIOLOGY

Males account for the vast majority of both perpetrators and victims of violence. In 1997 the male rate of death by violence was 10.7/100,000; the female rate was 3.0 per 1000. The lifetime risk of becoming a victim of criminal homicide for men is 1 in 84, compared with 1 in 282 for women. The male suicide rate in 1995 for men was 19.8, for women, 4.4. Each year over a million completed or attempted robberies and between 4 and 5 million assaults are reported. These two crimes lead to over 75,000 injuries each year that are severe enough to require hospital admission. The male rate of victimization by these crimes in 1996 was 49.5 per 1000, compared with 32.3 per 1000 for women. Men sustain twice as many severe injuries as women do.

Despite the prevalence of male victimization, women are overrepresented in virtually all forms of research on victimization: research on the psychological response of male victims is virtually absent. This has a variety of causes, including the likelihood that men are more prone than women to regard the victim role as inconsistent with culturally defined self-perceptions. Research has shown that men are much less likely to report their victimization to either their families or the police and that women seek psychiatric help for the psychological effects of interpersonal victimization far more often than men do. James Gilligan has pointed out that “in forcing the victim to experience utter helplessness, victimization challenges a very basic component of male identity.” He describes how shame becomes the central psychological way in which male victims cope with the aftermath of interpersonal assault and victimization.

Domestic Violence For women (but not for men) violence perpetrated within relationships that are supposed to involve care and protection is a much more serious problem than violence perpetrated by strangers. In 1994 62 percent of the almost 3 million attacks on women were by persons whom they knew, while 63 percent of the almost 4 million assaults on males were by strangers. It is estimated that one in three Americans have witnessed an incident of domestic violence. Over a third of

the victims of domestic assault experienced serious injury, compared with a quarter of the victims of stranger assault. Domestic abuse and child abuse are closely related; in homes where spousal abuse occurs, children are abused at a rate 1500 percent higher than the national average.

Between 1993 and 1997 approximately 10,000 people over the age of 15 in the United States were killed by their domestic partners (including married, common-law, divorced, or dating partners); 70 percent of the victims were women and 30 percent were men. Approximately one half of women murdered in the United States are killed by a current or former male partner. It is estimated that about one third of emergency room visits by women are in response to partner violence. Even though in approximately half of violent couples the wives are also violent, the women virtually always are more terrified and more likely to be seriously injured. Women are more likely to be injured by their male partners than men are by their female partners. About one fifth of pregnant women are battered.

It is estimated that from 2 to 3 million women are assaulted by a male partner each year in the United States. Between a quarter and half of all women experience some form of physical violence from their partners during marriage. Victims of marital violence have a higher rate of unconsciousness and internal injuries than victims of stranger assault; in one study, over 80 percent of all assaults against spouses and ex-spouses resulted in injuries, compared with 54 percent of the victims of stranger violence.

After separation women continue to be at risk. One half of battered women who leave their relationships continue to experience violence from their estranged partners. Violence also is widespread in dating relationships. The prevalence of physical aggression is even higher among nonmarried couples than among married couples.

From 1976 through 1984 the overall numbers of women killing male partners decreased more than 25 percent. This drop was linked with the presence of domestic violence legislation and other services for abused women. This decrease was not matched by a similar decline in men killing female partners.

Rape *Rape* is defined as the perpetration of an act of sexual intercourse against the victim's will and consent, whether her will is overcome by force or fear resulting from threat of force or by drugs or intoxicants, or when mental deficiency renders her incapable of exercising rational judgment, or when she is below an arbitrary age of consent. Rape can occur between married persons and persons of the same sex. Legally, to be classified as rape, only slight penile penetration of the victim's outer vulva is required; full erection and ejaculation are not necessary. Forced acts of fellatio and anal penetration, although they frequently accompany rape, are legally considered sodomy.

In 1996, 197,000 American women were estimated to have been forcibly raped. Of these, only 16 percent were reported to the police. One of every eight adult women, or at least 12.1 million American women, will be the victim of forcible rape sometime in her lifetime. In the United States more than 6 out of 10 of all rape cases (61 percent) occur before victims reach age 18. Among U.S. adolescents aged 12 to 17, 8 percent are estimated to have been victims of serious sexual assault, 17 percent victims of serious physical assault, and 40 percent have witnessed serious violence. Twenty-nine percent of all forcible rapes occur before the age of 11. Among adult women, an estimated 32,101 pregnancies result from rape each year.

Sexual assault is also widely prevalent in domestic settings. James Kilpatrick found that only 22 percent of rapes were perpetrated by strangers. Husbands and boyfriends were responsible for 19 percent, and other relatives accounted for 38 percent.

Perpetrators Most rapists commit other violent crimes as well and use sex to dominate, hurt, and debase their victims. Sexual violence and physical violence often occur in the same individual. One survey found that almost 13 percent of the men in a large epidemiological sample had been physically aggressive toward their partners in the past year. More than 33 percent of those aggressive acts were severe, consisting of punching, beating, or threatening with a knife or gun. Gilligan has pointed out that the more hurt, humiliated, and downtrodden men feel, the more likely they are to perpetrate violence, particularly physical violence against intimates, the women and children in their life.

Men who assault female partners are more likely to have witnessed or experienced violence in childhood, to abuse alcohol, to be sexually assaultive to their wives, and to be at risk for violence against children than nonabusive males. Many jealous husbands and boyfriends are charming to everyone except their wives and girlfriends. They monitor the woman's every move and tend to prevent contact with other sources of support and protection. They are prone to interpret their behavior as betrayal and this infuriates them. When their anger explodes into violence, they lose control. In contrast with dependent men who are primarily afraid of being abandoned by their partners and try to ensure continued submission, others are sociopaths who become physiologically less aroused when their violence escalates. These sociopaths are cold and calculating con artists, relatively free of the trappings of emotional dependence, but with a high incidence of antisocial and criminal traits and sadistic behavior. They use aggression with the intent to control, subjugate, or intimidate their partners.

In these abusive relationships emotional abuse tends to continue even after physical attacks abate, eventually keeping the spouse intimidated without the use of force. Battered women often have complex relationships with their abusers. Deprived of alternative sources of care, they tend to seek refuge with the nearest available human being when frightened. When the perpetrator also is seen as the principal source of protection, victims often become protective of their batterers and form intense emotional attachments that may be hard to break, even when ample objective evidence shows that continued contact with the perpetrator constitutes a danger to the victim. Only about one third of battered women in one study were able to escape from their abusive relationships within a 2-year follow-up period. After 5 years, 65 percent of battered women had left. Battering rarely stops on its own. A combination of arrest, prosecution, fines, and counseling often works for nonsociopathic batterers.

ETIOLOGY

Age In the United States, most rape victims (61 percent) are below age 18; almost a third are below age 11. Since the mid-1980s the rate of violence among persons aged 15 to 17 has increased sharply, and, particularly among black youth in this age range has outpaced changes in violence in all other age groups. In 1996 about a third of all victims of violent crime were ages 12 to 19. Almost half of all victims of violence were under age 25. During a time span of 4 years, 94 percent of a group of men aged 20 to 29 had to go to an emergency room at least once. In 41 percent of the cases the cause was a violent encounter. Violent crime declined slightly during the 1990s.

Prior Exposure to Family Violence Witnessing domestic violence as a child is the single most important risk factor for the intergenerational transmission of family violence. A history of physical or sexual victimization in childhood is an important risk factor for later assault, regardless of the relationship to the perpetrator in these later assaults. Both victims of partner and stranger assault are nearly twice as likely to experience abuse in childhood than nonvictims. A survey of over 4000 adults found that witnessing marital aggression between parents was the single most important predictor of which adolescent girls would grow up to be victims of marital assault. Males who witnessed their fathers' violence as children were 10 times more likely to grow up to abuse their partners than boys not exposed to marital violence.

Sex Domestic abuse and sexual violence against women are enormous social problems. Most violence against women is perpetrated by an intimate partner; approximately one third of all women are assaulted by an intimate man during adulthood. Witnessing domestic violence markedly increases the sense of vulnerability in all children. However, gender differences exist in the ways that children respond to witnessing domestic violence; girls tend to become afraid of being attacked, while boys, though feeling fearful of being violated, tend to display behaviors indicating that they identify with the attackers.

Children who are traumatized by witnessing domestic violence tend to display pronounced, inappropriate attitudes about violence as a means of resolving conflict. They may come to expect it as a way of life. Witnessing the chronic helplessness of their mother and their father's alternating outbursts of affection and violence, they learn that people have no control over their impulses. As adults, they may attempt to undo the past by love, competency, and exemplary behavior. However, if this fails, their lack of experience with nonviolent resolution of differences makes them vulnerable to being unable to resolve differences by verbal communication. During periods of occupational stress or family transitions such as pregnancies and the birth of children, partners who come from violent homes may return to earlier coping mechanisms, such as self-blame, numbing (by means of emotional withdrawal or drugs and alcohol), or physical aggression.

Substance Abuse Between 5.9 and 6.9 million adult women in the United States are estimated to have a substance use disorder. Substance abuse is highly correlated with domestic assaults, both on the part of the victim and the perpetrator. Active substance use is associated with increased risk of victimization. Conversely, assault has been shown to lead to substance use. Risk of new victimization is greatest in women who already use drugs and who also have previous assault histories. Substance abuse use occurs in a context that increases the likelihood for victimization and is associated with a general propensity to affiliate with assault-prone individuals or to engage in risk-taking activities.

Socioeconomic Factors Poverty (but not race) is a strong risk factor for exposure to assaults and other traumas. For women, being with a partner is a risk factor for assault.

CLINICAL FEATURES, COURSE, AND PROGNOSIS

Victims of interpersonal assaults have many of the same reactions as victims of other types of trauma. During an assault, a victim's primary focus is on survival and self-protection. The subjective experience consists of a mixture of shock, confusion, numbness, withdrawal, and speechless terror. Some victims may put up fierce resistance, while others dissociate and offer no defense. The number of and severity of psychological symptoms is largely determined by the frequency and duration of the assault. The more prolonged the abuse, the more likely the victim is to react with numbing and dissociation. When the aggressor is someone the victim loves, trusts, and depends on (e.g., victims of intrafamilial abuse), the victim is likely to respond to assaults with increased dependence and paralysis in their decision-making processes. Unlike people who are brutalized by strangers, victims of marital violence have legal, financial, and role relationships with their assailants, which confounds their capacity to respond appropriately to the violence. They may feel particularly vulnerable, betrayed, and hopeless. They often become depressed and suicidal.

In the emergency room they display cuts, burns, bruises, sprains, black eyes, broken ribs, and lost teeth. In primary care settings they complain of chronic headaches, muscle aches, abdominal pains, recurrent vaginal infections, sleep and eating disorders, and depression.

When the perpetrator is a spouse, boyfriend, or acquaintance (Table 28.7-3), many victims are reluctant to label rape or physical assault as such. Many victims feel emotionally dependent on their assailant (generally, the greater the fear, the greater the feeling of dependence and fear of abandonment). Many victims are justifiably afraid of retribution by an assailant. Many victims are familiar with being blamed for the abuse, and they fear the stigma attached to being a victim of rape or domestic violence. Many victims have difficulty recalling all relevant aspects of violent interpersonal trauma. Indeed, the inability to recall important aspects of the event is part of the definition of posttraumatic stress disorder.

Table 28.7-3 Physician Reference Card

Like rape victims, women abused by male partners exhibit long-term reactions including fear, anxiety, fatigue, sleeping and eating disturbances, intense startle reactions, and physical complaints. They often continue to dissociate in the face of threat, appear spaced-out, and have difficulty imagining effective action. They often develop problem-focused coping, in which the goal is making the feelings go away rather than changing the objective situation. This emotion-focused coping accounts for the fact that persons who develop posttraumatic stress disorder are vulnerable to alcohol and other substance abuse. Between a quarter and a half of all patients who seek substance abuse treatment are comorbid with posttraumatic stress disorder. The relation between substance abuse and posttraumatic stress disorder is reciprocal: drug abuse leads to assault and assault leads to use. Research has shown that new assaults lead to significant role-escalating alcohol and drug use in women.

Not all victims of interpersonal assault develop posttraumatic stress disorder. Rape is a trauma that gives rise to one of the highest rates of any traumatic event, approximately 70 percent. After physical assaults approximately a quarter of victims develop posttraumatic stress disorder, and more than half of various shelter populations currently suffer from it. Once victims develop the disorder, the intense flashbacks and nightmares force them to cope with the constant recurrence of the memory of the trauma with little anticipation of relief. In contrast to the actual trauma, which is terrifying, the symptoms of posttraumatic stress disorder seem never ending. The recurrent intrusive recollections and the nightmares themselves become new triggers of panic, which leads to a variety of (usually maladaptive) avoidance maneuvers. Avoidance and numbing further alienates victims from contact with the social support essential for recovery. Thus the very attachments that can provide a powerful motivation for survival in the face of threat can be threatened by the secondary changes in the responsiveness of the victim with posttraumatic stress disorder. The disorder of attention and concentration means that they can no longer lock into their current environment with the same sense of energy and involvement; simple activities such as reading, conversing, and watching television are no longer reflex activities but demand greater effort. This further interferes with effective functioning and with the capacity to make the decisions necessary to put their life back on track. Once people develop posttraumatic stress disorder, they are most likely to suffer from depression as well. Sexual assault is associated with an increased lifetime rate of attempted suicide. A history of sexual trauma before age 16 years is a particularly strong correlate of attempted suicide.

Physical Health Consequences Approximately one third of sexual assault victims suffer some form of injury. Physicians frequently treat the injuries only symptomatically or fail to recognize the injuries as abuse. Given the high morbidity and mortality rates in domestic violence, failure to identify or intervene increases the likelihood of further physical injury or death.

Use of medical services increases sharply in the year following a rape. In one study, medical care was sought by 92 percent of crime victims during the first year following the crime and by 100 percent during the second year. There was an 18 percent increase in utilization over prerape levels during the first year, 56 percent during the second year, and during the third year service use was 31 percent above prerape levels.

Pregnancy as a Result of Rape The exact incidence of pregnancy after rape is unknown; however, an estimated 1 to 10 percent of rapes result in pregnancy. Not only is the report of rape often delayed, but reports of pregnancy are delayed even further. Many delayed reporters are adolescent victims, especially if the rape was incestuous. They conceal the pregnancy to protect the family from stress or because of fear of the abuser. Pregnancy occurs more often among incest victims than among women who have been raped by a nonfamily member, probably because the former may occur on a regular basis increasing the risk of pregnancy. About 10 to 20 percent of incest victims become pregnant.

Male Rape In some states, the definition of rape has become gender neutral: the word “person” has been substituted for the term “female”; homosexual rape is included in the definition, and the use of an object, in place of a penis, for penetration also constitutes sexual assault. Male rape is a significantly underreported crime.

Homosexual rape is much more frequent among men than among women, and it occurs regularly in closed institutions, such as prisons and maximum security hospitals. Estimates are that 0.5 to 3 percent of male inmates are sexually assaulted. No figures are available for nonincarcerated persons.

The attacks are violent, rather than sexual, and are used to express anger or power. The dynamics are identical to those involved in heterosexual rape. The crime enables the rapist to discharge aggression and to aggrandize himself. The victim is usually smaller than the rapist. He is always perceived as passive and unmanly (weaker) and is used as an object.

The rapist selecting a male victim may be heterosexual, bisexual, or homosexual. He forces his victim to have sex through entrapment (for example, by getting him drunk), through intimidation by threats with a knife or gun, or through the use of brute force. Male rape can involve one or several forced sexual acts: The most common act is anal penetration of the victim; the second most common act is forcing the victim to perform fellatio. Frequently, the rapist makes an effort to bring the victim to ejaculation by fellatio or masturbation. That condition is humiliating to the victim, and it reinforces the rapist's sense of conquest and his fantasy that the victim wanted or enjoyed the rape. The male rape victim often feels, as do the raped women, that he has been ruined. In addition, he often fears he will become

homosexual because of the attack.

Date Rape *Date rape* or *acquaintance rape* is a term applied to situations in which the rapist is known to the victim. The rape can occur with a new boyfriend, on a first date, on a ride home after a party, or when the man and woman have known each other for many months. Considerable data on this type of rape have been gathered from college populations, and many schools have set up counseling programs to deal with these assaults.

A survey of 500 students at one university found that 16 percent of the women had been raped by men they knew or were dating. Of the men interviewed, 11 percent stated they had committed rape. Those findings are reflected in studies at a number of institutions throughout the United States. In a survey including several universities, 38 percent of the male students said they would commit rape if they thought they could get away with it, and 50 percent of the male students subscribed to myths that predispose to rape tolerance—that women don't mean it when they say “no” to intercourse or that they want to be coerced into having coitus.

In addition to suffering the symptoms experienced by all rape survivors, victims of date rape berate themselves for exercising poor judgment in their choice of male friends. They are more likely to blame themselves for provoking the rapist (by saying they should have not worn a low-cut dress, for example) than are other victims. Ironically, self-blame aids the recovery of these and other rape victims. Focusing on something they could have done differently seems to restore an element of control to the victim who has been made to feel so helpless. Date rape victims are less likely than others to report the crime to authorities. Also, because victim and rapist frequently have friends in common, the woman fears being disbelieved and being ostracized by her social group if she talks about the attack.

Among very young teenagers who have had intercourse, the majority said they had done so at times involuntarily. Nearly three-quarters of women who had intercourse before age 14 said they had at some point been forced to have sex.

Statutory Rape Intercourse is unlawful between a male over 16 years of age and a female under the age of consent, which varies from 14 to 21, depending on the jurisdiction. Thus, if an 18-year-old man and a 15-year-old girl have consensual intercourse, the man may be held for statutory rape. That type of rape may vary drastically from the crimes described above in being nonassaultive and in being a sexual act, not a violent act. Nor is it a deviant act, unless the age discrepancy is sufficient for the man to be defined as a pedophile; that is, when the man is 10 years older than a young girl or the girl is 12 years old or less. Charges of statutory rape are rarely pressed by the consenting girl; they are usually brought by her parents.

Stalking *Stalking* is defined as a pattern of harassing or menacing behavior coupled with a threat to do harm. In 1990 California passed the first antistalking law and most states now prohibit stalking although some will not intervene unless an act of violence has occurred. In states with stalking laws the person can be arrested based upon a pattern of harassment and can be charged with either a misdemeanor or felony. Some stalkers continue that activity for years; others for only a few months. Stalkers may be mandated by the court to undergo counseling sessions. In all instances stalkers should be reported to law enforcement agencies as the best means of deterrent.

Sexual Harassment *Sexual harassment* refers to sexual advances, request for sexual favors, verbal or physical conduct of a sexual nature—all of which are unwelcomed by the victim. In over 95 percent of cases the perpetrator is a man, the victim, a woman. In the case of a man being harassed it is almost always by another man. A woman sexually harassing a man is an extremely rare event. The victim of harassment reacts to the experience in various ways. Some blame themselves and become depressed; others become anxious or angry. In general, harassment most commonly occurs in the workplace and many organizations have developed procedures to deal with the problem. All too often, however, the victim is unwilling to step forward and lodge a complaint because of fear of retribution, of being humiliated, of being accused of lying (which is exceedingly rare), or ultimately being fired from the job.

The types of behavior that make up sexual harassment are broad. They include abusive language, requests for sexual favors, sexual jokes, staring, ogling, and giving massages, among others.

To reduce harassment organizations may distribute material that is educational (Table 28.7-4). Employers are obligated to investigate every complaint, which most often are addressed to the Equal Employment Opportunity Commission. Appropriate organizational responses range from a written reprimand to firing the offender.

WHAT YOU SHOULD KNOW ABOUT SEXUAL HARASSMENT

WHAT IS SEXUAL HARASSMENT?

WHAT IS PROHIBITED?

The 1980 Equal Opportunity Employment Commission Guidelines for Sexual Harassment encompass:

1. Unwelcomed sexual advances.
2. Requests for sexual favors.
3. Verbal conduct of a sexual nature.
4. Physical conduct of a sexual nature.

UNDER WHAT CONDITIONS?

When such conduct has the purpose or effect of:

1. Unreasonably interfering with an individual's work performance.
2. Creating an intimidating, hostile or offensive working environment. (This can be interpreted to include the "terms, conditions or privileges of unemployment" such as the psychological and emotional work environment and subjecting female employees to anxiety and debilitation.)
3. When submission to or rejection of the conduct is made either explicitly or implicitly a term or condition of an individual's employment or
4. Is the basis for employment decisions affecting the individual.

WHO IS RESPONSIBLE?

1. The employer who is committing the act.
2. The employer, even if its agents and supervisors committed the act regardless of whether the acts were authorized or even forbidden.
3. The employer for acts committed by an employee's coworker.
4. The employer for conduct by a non-employee (such as a customer or supplier) if the employer "knows or should have known of the conduct and fails to take an immediate and appropriate action."
5. The employer, if timely corrective actions are not taken.

Table 28.7-4 Educational Material to Reduce Sexual Harassment

TREATMENT

The strongest predictors of psychological adjustment after an assault are the degree of injury, severity of life threat, a history of having received emotional support from a nonabusive adult during childhood, current social support, participation in psychotherapy, and educational background.

Early Intervention Assault victims require a multidisciplinary approach encompassing emotional, medical, and forensic care. Appropriate therapeutic action taken early may influence the prognosis for a significant proportion of assault victims. Psychological interventions must pay attention to the particular posttrauma phase of the victim.

Safety When their own resources are inadequate to deal with threat individuals need to rely on others to provide them with safety and care. After an assault victims must establish contact with their natural social support system. If this system is inadequate to ensure the safety of the patient, institutional resources must be mobilized to help the patient find a place to recover. After an assault the victim first needs to be in a place where she is physically safe and where she can rest, sleep, and eat.

Anxiety Management After the patient's safety has been ensured, variety of psychological interventions may be needed. Caregivers may need to help victims identify the problems they face and help them formulate appropriate solutions. Assault victims must learn to distinguish between the real-life threats that often persist and the haunting, irrational fears that are part of posttraumatic stress disorder. If anxiety dominates, victims need help in strengthening their coping skills. Practical anxiety-management skills training may include deep muscle relaxation, breathing control, role playing, covert modeling, thought stopping, and guided self-dialogue.

Emotional Processing To put the assault in perspective, some form of debriefing is often helpful. During this process victims are encouraged to recreate the event in words, individually or in a group. They are asked to articulate what they think happened and what led up to it—their own contributions to what happened, their thoughts and fantasies during the event, what the worst part of it was, and their reactions to it in detail, including how it has affected their perceptions of themselves and others. Such exposure therapy is thought to promote symptom reduction by allowing patients to realize that (1) remembering the trauma is not equivalent to experiencing it again; (2) the experience had a beginning, middle, and end; and (3) the event now belongs to their personal history.

In recent years a new technique, eye movement desensitization and reprocessing, a form of exposure therapy, has been shown to help desensitize patients with posttraumatic stress disorder without fully engaging them in a verbal reliving the traumatic experience. Although exposure therapy can help overcome traumatic intrusions, it needs to be applied cautiously. Some patients recalling their trauma may become flooded with both the traumatic memories and memories of previously forgotten trauma. Increased activation of traumatic memories may be associated with increased shame, guilt, anger, and alcohol and drug use. Patients with

posttraumatic stress disorder are a particularly avoidant group that presents a number of treatment obstacles, especially for exposure techniques.

Prevention Against Recurrence After gaining an understanding of their own vulnerability, victims need to devise a plan to prevent a recurrence. This may involve a geographic move or some other active measure that interrupts the assault–substance use cycle and may reduce the potential for both future victimization and substance abuse. Thus, interventions for women who experience assault should not be limited to attempts to reduce immediate and overt trauma-related symptomatology (e.g., anxiety and depression) but should also address development or exacerbation of substance use. Conversely, treatment of women with substance use disorders, particularly illegal substance abuse, should address the issues of prior victimization and how to reduce the likelihood of future victimization.

Group Treatment Group therapy, including twelve-step self-help programs, can be extremely useful in helping victims move beyond a helpless stance in which they are vulnerable to repeating the trauma, either as victim or as perpetrator. Such groups provide both human attachments and a meaningful cognitive frame for dealing with the sense of helplessness. The purpose of these groups is to help the member regain a sense of trust and belonging by making interpersonal commitments. As long as victims are dominated by feelings of shame and social isolation they are prone to regress to dealing with anxiety with anxious or dependent attachments and addictive behaviors. Groups emphasize living in the here and now and show that responsible adults are faced with a variety of choices in how to conduct their lives.

28.8 ALTERNATIVE AND COMPLEMENTARY HEALTH PRACTICES

THOMAS J. KIRESUK, PH.D. AND ALAN TRACHTENBERG, M.D., M.P.H.

OVERVIEW

The term *alternative and complementary health practices* covers a large and heterogeneous collection of health care systems and methods, including folk medicines, healing rituals, and self-care methods from cultures around the world. Recent information from the National Institutes of Health (NIH) National Center for Complementary and Alternative Medicine (NCCAM) (Table 28.8-1) states that the scope of alternative and complementary health practices includes 12 major health care systems, 26 categories of practice, over 350 methods, and 10,000 ways of using these methods. The term “alternative” has been defined in various ways. The World Health Organization defines alternative therapies as “usually lying outside of the official health sector.” David Eisenberg's definition stipulated, “neither taught widely in US medical schools nor generally available in US hospitals.” Thus, alternative therapies can be thought of as being alternative in origin (they come from somewhere else) rather than as necessarily being alternatives to standard therapies.

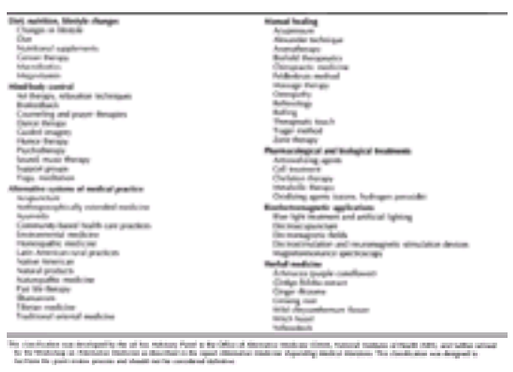

Table 28.8-1 Classification of Alternative Medical Practices From the NIH Office of Alternative Medicine

In contrast, conventional (standard, orthodox, or allopathic) medicine is the type of medicine taught in U.S. medical schools and practiced in U.S. hospitals. The term “allopathic” was coined by the inventor of homeopathy, Samuel Hahnemann (Fig. 28.8-1) to refer to the use of procedures or medications that counteract the signs and symptoms of disease. This term was used in contrast to his method, *homeopathy*, which used medications that could cause the same symptoms in a healthy person as those being treated in patients. Conventional medicine (including Western medical and surgical traditions) is based to a large extent on the results of scientific research and presumes that the body is a biological and physiological system. Disorders are believed to have causes that can be treated with medications, surgery, and complex technological methods to alleviate or cure.

FIGURE 28.8-1 Samuel Hahnemann. (Reprinted with permission from the New York Academy of Medicine, New York, NY.)

Alternative and complementary health practices typically use a holistic, health-oriented approach to the patient rather than a disease-oriented diagnostic and treatment model. The British have used the term “complementary” to denote that these therapies act by complementing, or building on, the body's own resources or defense systems. The treatment methods have not been developed through Western research methods but do have complex theoretical bases and centuries of reported experience with clinical applications. Modern medicine and psychiatry evolved out of a similar accumulation of empirically based knowledge, much of which has been, or is now being, subjected to modern research examination. For example, the origin of psychotherapy was based on nonsystematic case study reports, followed in the 1920s and 1930s by surveys of reports on improvement rates, then by studies that included control groups in their design, and from the 1950s to today, there has been exponential growth in research studies on psychological therapies with greater research rigor. It appears that alternative and complementary health practices are on a similar trajectory but, one hopes, at an accelerated rate, given the availability of contemporary research methodology and analyses.

Some treatment methods classified as alternative have been used in psychiatry for years, and psychiatrists may be surprised to see techniques such as biofeedback, guided imagery, psychotherapy, support groups, art therapy, and relaxation included as alternative medicine practices in the classification system produced by the NIH Office of Alternative Medicine. This classification difficulty points out the evolving, integrative process of medical education and practice. As research data accumulate, one might expect that other forms will find acceptance when it is merited.

The world-wide utilization rates of alternative and complementary health practices are extraordinary. The World Health Organization estimates that between 65 and 80 percent of the world's health care services are currently classified as traditional medicine. In many countries traditional medicine constitutes the major form of

treatment. According to Eisenberg's updated survey findings, Americans spent $27 billion, most of it not reimbursed by insurance, on alternative treatments in 1997. The use of these therapies increased by 25 percent during the seven-year period between surveys, and expenditures increased by 45 percent. Nearly 50 percent more people (a total of 83 million) visited alternative medicine practitioners in 1997 than in 1990. There are more professional visits for alternative and complementary health practices than for conventional primary care. Of Americans using alternative and complementary health practices, 60 percent do not tell their doctors. The authors expressed concern that as many as 15 million people take prescription drugs as well as herbs or high-dosage vitamins, perhaps placing these individuals at risk for harmful medication interactions.

Surveys suggest that U.S. consumers use alternative and complementary health practices for a wide variety of conditions and visit providers of alternative and complementary health practices more frequently than primary care medical doctors, some of whom have begun to refer to alternative therapy practitioners. Use of alternative and complementary health practices does not appear to be restricted by social class, educational level, or sex, although women and Americans with more education seem more inclined to use these practices. The Office of Alternative Medicine has identified more than 700 journals that publish research on alternative and complementary health practices topics. Many of these journals have been developed in Europe and Asia specifically for alternative and complementary health practices research. Approximately 40 percent are in languages other than English.

Patient and physician surveys are not the only indication of the increasing prevalence of alternative and complementary health practices. For instance, they are finding their way into medical school curricula (63 medical schools in a recent listing), and leaders in the health care market and legislators are debating coverage for alternative medicine. Changes in terminology from *unconventional* or *alternative* to *complementary* and *integrative* speak to the increasing collegiality between disciplines.

In 1991 Congress established the Office of Alternative Medicine (now the NCCAM) at the NIH to examine the broad range of therapeutic systems and evaluate their usefulness and safety, and provide scientific explanations for their effectiveness (if any). The NCCAM has been careful to point out that inclusion of treatments in their classification system and support of research on alternative and complementary health practices is not based on biomedical hypotheses about their mechanisms nor even necessarily a belief in their efficacy. It is driven, rather, by the public health imperative created by the fact that so many Americans are using alternative and complementary health practices in the absence of adequate data. Although many proponents of these practices are willing and even eager to submit their methods to objective scientific scrutiny, few of these proponents have adequate training or scientific resources themselves to conduct the necessary objective studies. The few proponents who do manage to perform an adequate study that suggests efficacy are simply disbelieved by those who choose to remain skeptical. The research task, therefore, has fallen to the public health community to bridge the gap between communities where alternative and complementary health practices are already culturally accepted and the orthodox biomedical community, who expect a higher quality of evidence despite continuing to use many regular medical interventions that have not yet met the modern standards of evidence-based medicine.

While the high prevalence of use of alternative and complementary health practices by the general public is well documented, the efficacy, effectiveness, safety, and validity of most of these therapies is not well established. The first task is to sort through the many claims, prevalent beliefs, and the evidence (which is often preliminary). However, many of the claims do not stand up to close scrutiny, and the rush to the marketplace by many advocates of particular treatments or methods greatly complicates the evaluation process. Certainly, popular publications and advertisements provide a flood of statements that have variable levels of formal evidence—most commonly none. In many cases alternative and complementary health practices research, while appropriately intended to elicit positive findings (if available) for closer review, often does not use standard research methods that are commonly accepted in conventional research. However, some therapies, through the process of evaluative review, do emerge as promising.

The following review lists some of the most visible alternative and complementary health practices that have some data on which to base claims or research for effectiveness in the treatment of (broadly defined) psychiatric conditions. Diagnostic systems such as the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and the ninth revision of *International Statistical Classification of Diseases* (ICD-9) may or may not be used in these reports and claims; rather, terms such as *anxiety, insomnia, sense of well-being*, and *depression*, are used.

A general observation regarding the methodology of the research on alternative medicine applies to many forms of treatment research. The research is often reported without reference to the rationale for the choice of *P* value, sample size, estimates of statistical power (the probability of detecting a difference between treatments when in fact differences exist), the basis for estimating treatment effect size, and the rationale for the choice of controls. Without these basic determinations, much research in this area is inconclusive. If statistical differences are not found when sample sizes are inadequate, one cannot conclude that a lack of efficacy has been demonstrated (rather than a type II error). There is a definite role for case studies and preliminary reports in the development of new knowledge. Problems arise primarily when inappropriate conclusions or claims are made or when previously unknown adverse effects emerge.

ACUPUNCTURE AND ACUPRESSURE

Biomedical research on acupuncture has been evaluated by a recent NIH Consensus Development Conference. The best summary of this form of treatment can be obtained from the 1997 conference report:

The practice of acupuncture to treat identifiable pathophysiological conditions in American medicine was rare until the visit of President Nixon to China in 1972. Since that time there has been an explosion of interest in the United States regarding the application of the techniques of acupuncture to American medicine. In some European countries, such as France, acupuncture is already well accepted and regarded as just another medical specialty.

Acupuncture describes a family of procedures involving stimulation of anatomical locations on or beneath the skin by a variety of techniques. The most studied mechanism of stimulation of acupuncture points employs penetration of the skin by thin, solid, metallic needles (Fig. 28.8-2), which are manipulated manually or stimulated by electrical impulses. Stimulation of these areas by moxibustion (burning small cones of dried, powdered artemesia vulgaris (moxa) leaves held above the point to be warmed or placed on the skin and removed before overheating occurs), pressure, heat, and laser is also used in acupuncture practice, but due to the paucity of studies, these techniques are more difficult to evaluate. Thus, there are a variety of approaches to diagnosis and treatment in American acupuncture that incorporate medical traditions from China, Japan, Korea, France and other countries.

FIGURE 28.8-2 Acupuncture. Once in place, the needle may be manipulated either by twirling or gentle pumping action. (Reprinted with permission from Shealy CN, editor: *The Complete Family Guide to Alternative Medicine*. Barnes & Noble, New York, 1996.)

Acupuncture has been used by millions of American patients and performed by thousands of physicians, dentists, licensed acupuncturists, and other professionals for relief or prevention of pain and for a variety of health conditions. After reviewing the existing body of knowledge, the U.S. Food and Drug Administration recently removed acupuncture needles from the category of “experimental medical devices,” and now regulates them just as it does other clinical tools such as surgical scalpels and hypodermic syringes, under good manufacturing practices and single-use standards of sterility.

Over the years, the United States Public Health Service (NIH and particularly the former ADAMHA Institutes) has funded a variety of research projects on acupuncture, including studies on the mechanisms by which acupuncture may have its effects, as well as clinical trials and other studies. There is also a considerable

body of international literature on the risks and benefits of acupuncture, and the World Health Organization lists a variety of medical conditions that may benefit from the use of acupuncture or moxibustion. Such applications include prevention and treatment of nausea and vomiting; treatment of pain and addictions to alcohol, and illicit drugs; treatment of pulmonary problems such as asthma and bronchitis; and rehabilitation from neurological damage such as that caused by stroke.

The report concludes that positive results have been obtained regarding adult postoperative and chemotherapy nausea and vomiting and postoperative dental pain. Acupuncture may be a useful adjunct treatment or an acceptable alternative or be included in a comprehensive management program for conditions such as addiction, stroke rehabilitation, headache, menstrual cramps, tennis elbow, fibromyalgia, myofascial pain, osteoarthritis, low back pain, carpal tunnel syndrome, and asthma. Plausible mechanisms of action for acupuncture include the release of endogenous opioids and other neuropeptides in the central nervous system and the periphery and changes in neuroendocrine function.

The NIH consensus report does not refer to psychiatric conditions other than addiction. A recent review of acupuncture for schizophrenia concluded that research on acupuncture or low-power laser treatment was significantly or seriously flawed. While some studies (8 papers were reviewed) suggest that the treatments may be as effective as chlorpromazine (Thorazine) in schizophrenia, no scientifically sound conclusions can be drawn. The research is an example of preliminary research with findings that appear to be worthy of further study. One study provided preliminary information (*N* = 40) that acupuncture might reduce the dosage of antipsychotic medication for patients with schizophrenia, thereby reducing adverse effects without reducing clinical effectiveness. This is a potentially important role for acupuncture, as well as other unorthodox therapies, which may be used to complement standard therapies rather than as an alternative to replace treatments already proved effective.

There is also preliminary research regarding the treatment of depression. Two random clinical trials compared electroacupuncture with amitriptyline (Elavil) in the treatment of depressed patients. Both studies (sample sizes of 47 and 241) found significant improvement resulting from the treatments, with no significant difference between the two groups. Follow-up of 148 patients for 2 to 4 years revealed no significant difference in depression recurrence rates.

Another pilot trial of the effects of acupuncture for depression was conducted on a sample of 22 women with major depressive disorder. Significantly greater improvement was found in the 11 women randomized to receive an 8-week course of acupuncture specific for major depressive disorder as compared to the 11 controls who received non-specific acupuncture for the same period.

Animal research has been reported which indicates that acupuncture and electroacupuncture are capable of accelerating the synthesis and release of serotonin and norepinephrine in the central nervous system (CNS). The authors cite the above human subject research and stated that clinical data indicates that electroacupuncture is effective in treating depressive patients and is at least as effective and has a higher therapeutic index than tricyclic amitryptyline. Given the preliminary nature of the research and a plausible mechanism of action, there is a need for replication and placebo controls for these findings.

In an open trial report on the use of acupuncture for the treatment of psychogenic impotence, 20 of 29 subjects demonstrated improvement. A common observation made by acupuncturists, administrators, and many recipients of the treatment is that acupuncture has a soothing effect, inducing relaxation and greater amenability to treatment. In substance abuse treatment, acupuncture appears to be associated with reduction in alcohol abuse. Early research findings have led to current major research funded by National Institute on Alcohol and Alcoholism (NIAAA) and National Institute on Drug Abuse (NIDA). The effect of acupuncture on cocaine and heroin use remains to be demonstrated. An NIDA-supported study of acupuncture and cocaine use found no differences among different doses of acupuncture, true and sham acupuncture, and standard treatment. Patients receiving acupuncture perceived significant improvement, which was not related to placebo responsiveness measures. Current research methods have not examined this perceived efficacy. The finding does help explain the widespread popularity of the treatment in spite of the lack of consistent data supporting specific efficacy (in conditions other than nausea, vomiting, and some types of pain). A consortium that includes several federal agencies and the Conrad Hilton Foundation has funded a nationwide multisite study of acupuncture (among other treatments) for cocaine addiction, which may produce definitive data by the end of 1999.

The use of acupuncture in the treatment of smoking is another popular application that has been tested several times without consistent demonstration of benefit. The research on this topic is inconclusive because of the wide variation in the definition of the treatment and the variation in research methods. Animal research is being conducted which may shed light on whether acupuncture can have an effect on nicotine dependence. A recent study reported a randomized, single-blind comparison of two sets of acupuncture points administered to a sample of 46 subjects twice a week for three weeks. Test acupoints included 2 body electroacupuncture, 3 ear acupuncture, and 6 ear acupressure sites. Control acupuncture included 11 body points presumed to be noneffective for smoking cessation. Statistically significant differences were found in reduction of cigarette consumption, concentrations of cotinine and thiocyanate, but no significant changes in serum peroxides and plasma fibrinogen concentrations for either group. Taste aversion and desire to smoke fell significantly in both groups but the reduction was larger for the test group. This study did not have placebo control for the two sets of acupuncture treatments, the sample was small, duration of treatment effects was not measured, and the treatment points are multiple and require replication by others. However, this research is an example of the kind of carefully done, multimeasure study that can form the basis for further research. Even though the research evidence for smoking cessation is in an early stage of development, physicians will encounter many individuals who swear by this treatment.

HERBAL MEDICINE

Herbal medicine is probably the most widely used alternative and complementary health practice. Including all individual herbal remedies and their combinations, there are literally thousands of herbal treatments. Herbal medicine relies on plants to treat illness and maintain health. It is the oldest known system of medicine, with historical origins attributed to China about 4000 BC, but certainly plants were used medicinally worldwide throughout prehistory. Ancient texts of Asian medicine are still in use, and modern Chinese medicine relies on herbs in addition to other methods such as acupuncture, massage, diet, and exercise to correct “imbalances” in the body. A Greco-Roman medical text by Dioscorides, *De materia medica*, describes the use of over 500 plants to treat disease, beginning a tradition followed in European medicine to this day.

The decline of herbal medicine in Western countries in the twentieth century was related to scientific and technological advances that led to the use of synthetic and chemically purified pharmaceuticals; nevertheless, according to some estimates, at least 25 percent of current medicines are devised from the active ingredients of plants. The examples are many: digitalis from foxglove, ephedrine from “Mormon tea,” morphine from the opium poppy, taxol from yew, and quinine from the bark of the chinchona tree. In addition, many modern medicines are congeners of compounds from plants in which their biological actions were first discovered.

About $1.5 billion a year is spent in the United States on herbs that are legally classified as dietary supplements, and the quality control standards applied by the Food and Drug Administration (FDA) are those applied to foods rather than pharmaceutical or over-the-counter (OTC) quality standards. Concerns arise only when unsupported health claims are made for food or dietary supplements. Thus there is little reliability in content and quality control for most herbal preparations sold in health food stores, pharmacies, and supermarkets. Efforts to regulate quality are being made through organizations such as the American Botanical Council and the Herb Research Foundation, but according to the Federal Trade Commission (FTC), poor manufacturing practices and false advertising still exist. One useful approach to quality control conducts spectrographic and other pharmacological analyses to determine the herbs' identity and the concentration of specific compounds that may be associated with a particular herb's clinical activity. Germany and Britain have developed useful quality standards that can generally be depended on in products imported from European countries or claiming to meet those standards in U.S. products (such claims, if false, are actionable by the FTC). The possibility of allergic reactions or toxic interaction with medications should always be kept in mind when patients are eating plant substances of uncertain purity or identity.

St. John's Wort There are many herbal products that have been used legally or illegally for their mood-altering or sedative effects. Examples include the opium poppy (opium), *Atropa belladonna* (deadly nightshade), Indian hemp (hashish), hyoscyamine (henbane), scopolomine (thorn apple), and hypericum (St. John's wort). Of these, St. John's wort has received the greatest recent research attention and is currently the subject of an NIH-funded multisite trial of its effects on depression. Prior research with St. John's wort has used a variety of methods including comparison with placebo controls, comparison with imipramine (Tofranil), large-scale postmarket reporting, and animal research. Meta-analysis of 23 randomized trials that included a total of 1757 outpatients with mainly mild or moderate depressive disorders concluded that Hypericum extracts were significantly superior to placebo and as effective as standard antidepressants. The individual research studies reported very low (in most studies, none) rates of adverse effects, fewer and milder adverse effects compared with imipramine. Criticism of the research includes concerns regarding heterogeneity of patients, interventions, dosage levels, extract preparations, and diagnostic classifications.

There has been some concern regarding longer-term effects and possible enhancement of photosensitivity. In particular, it has been suggested that the use of St. John's wort should not be combined with use of a selective serotonin reuptake inhibitor (SSRI) (e.g., paroxetine [Paxil]). This example of potential undesirable consequences resulting from combinations of herbal and standardized pharmaceuticals is emblematic of a larger concern regarding all the known and unknown side

effects of drug and herbal product combinations.

A recent review of St. John's wort included a detailed discussion of the several proposed mechanisms of action and added concerns regarding adverse effects and drug interaction effects. Generally the authors felt that there were fewer adverse effects with hypericum than with conventional antidepressants. Potential adverse effects that were listed included photodermatitis, delayed hypersensitivity, gastrointestinal tract upset, dizziness, dry mouth, sedation, restlessness, and constipation. There do not appear to be significant adverse effects on cardiac conduction with hypericum extracts. Contraindications for the use of St. John's wort included pregnancy, lactation, exposure of strong sunlight, and pheochromocytoma. The potential for monoamine oxidase inhibitor-like drug interactions cannot be excluded since appropriate drug interaction studies are not available.

A recent review concluded that hypericum is at least as safe and possibly safer than conventional antidepressant drugs.

Kudzu (*Pueraria Lobata*) A Chinese herbal medicine (labeled NPI-028 by researchers in the Research Triangle) has been used historically in the treatment of alcohol intoxication. It is still prescribed in China and Southeast Asia, and its use was documented in early historical documents (Li Shizhen 1590–1596). NPI-028 consists of six Chinese herbs, including *Pueraria lobata* and *Citrus reticulata*. This preparation has suppressed alcohol drinking by three different strains of alcohol-preferring rats. Renee Lin and coworkers reported in 1995 that puerarin, daidzin, and daidzein, extracted from kudzu and given orally, suppressed voluntary alcohol consumption by alcohol-preferring P rats. NPI-028 was effective in lowering ethanol intake at lower doses in alcohol-preferring vervet monkeys. These effects of NPI-028, which contains kudzu, are comparable to recently reported effects of two extracts from the kudzu plant. Wing-Ming Keung and Bert Vallee at Harvard Medical School showed that daidzin and daidzein were the active herbal components from *Radix pueraria* (kudzu root) that suppressed alcohol intake in Syrian golden hamsters. Daidzin differs from disulfiram in its selective and reversible inhibition of aldehyde dehydrogenase-1 (ALDH-1). Daidzin also decreases blood alcohol concentrations and shortens sleep time induced by ethanol. These findings provide a basis for the possible use of this traditional Chinese herbal medicine in the treatment of alcohol abuse.

Kava The term *kava* refers to the Pacific Island plant, *Piper methysticum* Forst (Piperaceae) and the beverage prepared from it. The preparation is used in traditional island ceremonies and has therapeutic and mood-altering characteristics. There is a considerable body of literature regarding kava, including a bibliography containing approximately 800 references, articles concerning chemical and pharmacological studies, and a review written by a native of Fiji with 153 additional references. Kava was in an apparently successful treatment to facilitating smoking cessation in which it was combined with collaborative and village empowerment group and ceremonial methods.

Kava drinking has been introduced into Aboriginal communities in North Australia. Used at much higher consumption levels than in Oceania, several effects were noted: mental and physical relaxant effects, and anecdotally reported improvement in schizophrenic and mood disorders, resembling the effects of antipsychotic agents. There are also reports of abuse, and kava is one of the herbs sometimes recommended in the drug culture for a “legal and natural” high.

A recent review of kava human-trial research indicates that kava products may be beneficial in the management of anxiety and tension of nonpsychotic origin and does not adversely affect cognitive function, mental acuity, or coordination in comparison with oxazepam. Long-term use at higher daily dosages (400 mg of kavalactones) may result in scaling of the skin on the extremities. There is a possibility that kava may potentiate the action of other centrally mediated agents and interact with alcohol. However, in a placebo-controlled, double-blind study few adverse effects were found.

Valerian In the treatment of anxiety and sleep disorders, valerian is considered one of the most effective herbal preparations. It is obtained from the dried rhizome and roots of the perennial herb *Valeriana officinalis* and has been known for its sedative properties for 2000 years. Pharmacological tests have demonstrated the activity of valerian on the CNS. Biochemical receptor assays have demonstrated interaction with the inhibitory neurotransmitter g-aminobutyric acid (GABA). Several reviews of clinical investigations support its use as a calmative and sleep-promoting agent. A clinical report of an overdose (20 times the recommended therapeutic dose) stated that the symptoms were mild and resolved within 24 hours. Another study of overdose of a sleep-inducing preparation that included valerian found no evidence for hepatotoxicity, although longer-term studies would be required to establish risk for long-term users. The advantage over synthetic psychopharmacological agents is the low incidence of adverse effects.

A recent review of valerian included animal studies that showed results consistent with other hypnotic agents such as the benzodiazepines. Human clinical studies confirmed a mild sedative effect, but did not evaluate the efficacy of valerian as a treatment for primary or secondary insomnia. The authors concluded that valerian had not been demonstrated to be superior to existing hypnotic treatments or other treatments of insomnia. As with many herbal preparations, there is insufficient information to recommend valerian in pregnancy and during lactation. Valerian may potentiate the effects of other CNS depressants and the usual precautions taken with other sedating agents also apply to valerian.

Passion Flower In Britain, passion flower is one of the most popular herbal sedatives. It is derived from the dried flowering and fruiting top of a perennial climbing vine *Passiflora incarnata* L. However, in spite of its popularity, it is a relatively unproven minor tranquilizer. Animal research has indicated prolonged sleeping time and reduced amphetamine-induced hypermotility. Synergism with kava was also noted. The FDA prohibited the use of passion flower in OTC sedative preparations because it has not been proved safe and effective; however, the German Commission E authorized its use in the treatment of nervous unrest, on the basis of the results of animal research.

A recent summary stated that hypersensitivity vasculitis and “altered consciousness” have been reported with products containing passion flower. Interactions with other psychotropic medications have not been adequately studied. Because of its potential sedative effects, the usual precautions regarding operating motor vehicles or machinery should be made. The authors of this review concluded that excessive use during pregnancy and lactation should be avoided.

Gingko Biloba Probably one of the most studied of all traditional herbal medicines is gingko biloba. The gingko tree has bilobed leaves that resemble the maidenhair fern. It is believed to be the oldest living seed plant. Gingkolic acid and related alkylphenols constitute major components of the lipid fraction of the fruit pods of *Ginkgo biloba* L. This class of substances s present in ginkgo leaves, which are widely used to prepare extracts for the treatment of peripheral or cerebral circulatory disorders, as well as vascular dementia and dementia of the Alzheimer's type. Ginkgo is widely used in European medical practice to improve cognitive function in patients diagnosed with symptoms of “cerebral insufficiency,” with over 5 million prescriptions written annually in Germany alone. Most research studies use ginkgo leaf extract EGb 761 (Tavonin).

Pharmacological studies have shown that the therapeutic effect of ginkgo is based on several active constituents with vasoactive and free radical-scavenging properties. A recent review of studies of clinical improvement of memory and other cognitive functions by ginkgo biloba came to the following conclusions:

> The extract is used to alleviate symptoms associated with cognitive deficits, eg, decreased memory performance, lack of concentration, decreased alertness, tinnitus, and dizziness. The use of ginkgo extract in either dementias of the Alzheimer or multi-infarct type or in the case of cerebral insufficiency, a symptom complex related to age-dependent impairment of cerebral circulation, is based mainly on positive results from good-quality placebo-controlled studies that enrolled approximately 1200 patients with criteria established by International Classification of Diseases (9th and 10th revisions, ICD-9 and ICD-10) or the 3rd revision of the Diagnostic and Statistical Manual (DSM-III-R) (uncomplicated dementia). Effect on cognitive symptoms was within the range of a 25% improvement. Memory, concentration, and alertness were the first symptoms to be relieved, with tinnitus and dizziness improving somewhat later. A minimum of 4 to 6 weeks were needed before a pronounced effect could be expected. The pharmacologic advantage of ginkgo appears to be a very tolerable side-effect profile, with a side-effect frequency at the placebo level.

A recent multicenter placebo-controlled, double-blind, randomized trial of the extract of *Ginkgo biloba* for dementia concluded that EGb 176 was safe and appeared capable of stabilizing and (in a substantial number of cases) improving the cognitive performance and social functioning of demented patients for 6 months to 1 year. Although modest, the changes induced by EGb 176 were objective cognitive measures and were of sufficient magnitude to be recognized by the caregivers. Egb 761 and placebo did not differ significantly in the number of patients reporting adverse events or in the incidence and severity of these events.

A recent open trial of *Gingko biloba* extract found significant improvement in antidepressant-induced sexual dysfunction predominantly caused by SSRIs, with women being more responsive to the sexually enhancing effects than men. A related placebo-controlled study found EGb 761 effective against the congestive symptoms of premenstrual syndrome, with improvement also shown in neuropsychological symptoms.

There is evidence that ginkgo can serve as an augmenting agent with conventional antidepressants. In addition, animal studies indicate that ginkolide B may have a neuroprotective effect in brain injury. The most common adverse effect is headache, which can be avoided by individualized graduated dosage. While concern has

been expressed that ginkgo may potentiate other anticoagulants or increase bleeding time, the concern has not been substantiated. Nevertheless, a recent review concluded that caution should be exercised when ginkgo is combined with anticoagulant treatment, including aspirin, where there is a risk of bleeding as in peptic ulcer disease and subdural hematoma. Safety in pregnancy and lactation has not been established.

Yohimbine Yohimbine, an indole alkaloid obtained mainly from the bark of the yohimbe tree (*Pausinystalia yohimba*), a common tree in West Africa, is an a_2-adrenergic receptor antagonist that is marketed pharmaceutically for treatment of impotence. A wide range of animal and human research studies of yohimbine have used a variety of research designs and analyses. A recent meta-analysis of randomized, placebo-controlled trials of yohimbine monotherapy for erectile dysfunction examined the evidence for therapeutic efficacy and safety. The review found that yohimbine is superior to placebo and that serious adverse reactions were infrequent and reversible. Dietary supplements or other natural products of the yohimbe tree sometimes contain significant quantities of yohimbine, but this is unusual.

An earlier review of four meta-analyses integrated data from controlled and uncontrolled clinical trials of yohimbine used alone and controlled and uncontrolled trials of yohimbine used in combination with other drugs. The results indicated a consistent tendency for yohimbine and medications containing yohimbine to enhance erectile functioning, relative to placebo.

A cautionary note was provided by a study of the effects of yohimbine on blood pressure and plasma concentrations of catechols in patients with essential hypertension. The study concluded that yohimbine increases sympathetically mediated plasma norepinephrine concentrations, which in turn produce a pressor response. The authors stated that

> [y]ohimbine should be administered with caution to patients with high blood pressure, especially in individuals with evidence for increased basal sympathetic outflow or those undergoing concurrent treatment with tricyclic antidepressants or other drugs that interfere with neuronal uptake or metabolism of norepinephrine.

Preliminary studies indicate that yohimbine may be useful in the treatment of sexual adverse effects induced by SSRIs, and two case reports concerned clomipramine (Anafranil) (six patients) and fluoxetine (Prozac) (nine patients). A study of nine women with hypoactive sexual desire showed no improvement in sexual desire. A large-scale retrospective case review of 596 patients treated with SSRIs identified 97 patients who had experienced sexual dysfunction associated with SSRIs; 45 patients opted for treatment with trials of yohimbine, amantadine (Symmetrel), or cyprohepatidine (Periactin). All three antidotes were found to be safe and relatively effective, and yohimbine was significantly more effective in reversing SSRI-induced sexual dysfunction.

There are several animal studies using a variety of animal models. For example, yohimbine was shown to enhance sexual behaviors in male rats, including those that were castrated and aging male rats. Yohimbine influence in the absence of testosterone raises interesting questions about the role of a $_2$-receptors in sexual arousal and behavior.

A memorable single-blind study concerned the effect of yohimbine on the reproductive activity of 12-year-old male captive Nile crocodiles, 18 animals divided into 3 ponds. Each pond contained 6 males and 30 females. Yohimbine capsules of 30 mg, twice a day for 1 week were administered to all six in pond 1, two in pond 2, and none in the control pond. A significant increase in the frequency of headslap sexual display was noted as well as an appearance of this daily behavior 1 hour earlier than controls. While there was no apparent increase in copulatory frequency in treated animals, probable increase in successful copulations was inferred because of the prolonged reproductive period and a significant increase in the fertility percentage of eggs in the treatment ponds. While not easily replicated, these results are compatible with findings in other animal research.

A recent review of yohimbine stressed the psychopathology that may be associated with its use. The authors indicate yohimbine is commonly used to provoke panic attacks and anxiety in studies of the pathophysiology, psychopharmacology, and treatment of anxiety disorders. They point out that tricyclic drugs, medications with central a-adrenergic blocking properties, centrally acting sympathomimnetics, monoamine oxidase inhibitors, and antimuscarinic agents potentiate the action of yohimbine. They conclude their summary with cautionary statements, which stress the potential of yohimbine to produce psychiatric symptoms, primarily anxiety or panic, especially in patients with preexisting panic disorder. Once again, however, they point out that many commercial products containing yohimbine bark actually have little or no yohimbine.

A summary of herbal remedies that affect psychiatric symptoms is given in Table 28.8-2.

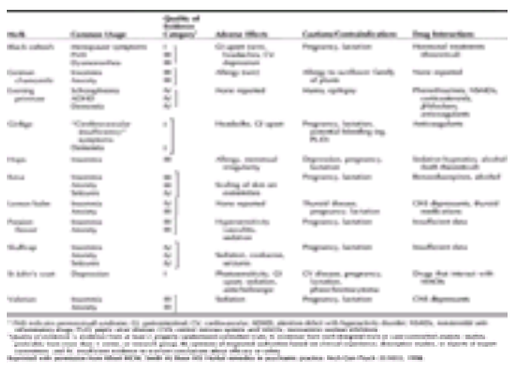

Table 28.8-2 Herbal Remedies Commonly Used to Treat Psychiatric Symptoms*

OTHER HERBAL REMEDIES

There are several other herbal preparations that have been mentioned or reviewed with regard to their psychiatric relevance. They are mentioned here briefly in order to alert the reader to their presence in the literature and because of the likelihood that increasing numbers of patients may be using them or asking about them. The summaries are derived from a review article appearing in the November 1998 *Archives of General Psychiatry*.

Capsicum Capsicum (*Capsicum annuum* L) commonly appears in the form of chili or cayenne pepper. A number of studies support its use for pain relief where it is applied in the form of capsaicin cream. Other uses, such as treatment for colic and dyspepsia, and for improvement of peripheral circulation in patients with cardiovascular conditions, have not been investigated scientifically. Capsicum is mentioned in this section because it may elevate the secretion of catecholamines and therefore should be used with caution concurrently with monoamine oxidase inhibitors.

Chaste Tree Chaste tree (*Vitex agnuscastus* L) has been used traditionally for symptoms of prementrual syndrome, mastodynia, menopause, hyperprolactinemia, and menstrual irregularity. Because an affinity for dopamine type 1 (D_1) and receptors D_2 has been reported, there is a potential for interaction with other dopaminergic drugs, such as the antipsychotics and metoclopramide (Reglan).

Evening Primrose There is little evidence to support the use of evening primrose (*Oenothera biennis* L) for psychiatric conditions such as schizophrenia, childhood hyperactivity, and dementia. Case reports indicate potential harmful effects in mania and epilepsy. Phenothiazines, nonsteroidal anti-inflammatory drugs, corticosteroids, b-adrenergic receptor antagonists, and anticoagulants may interact adversely with evening primrose.

German Chamomile This herb (*Matricaria recutita* L) has a mild hypnotic effect, and has been used in a variety of gastrointestinal, and mouth and skin irritations, pediatric colic and teething, and mild insomnia and anxiety. There have been no randomized or controlled clinical studies. Adverse reactions are rare and mainly allergic in nature.

Hops The female flowers of the plant Humulus Lupulus L have been used as mild sedative and hypnotic agents. There are no clinical studies of its effects on

insomnia or anxiety disorders. The authors caution against its use in depression, pregnancy, and during lactation. Possible potentiation effects may exist when used with sedative hypnotic agents and alcohol.

Lemon Balm No clinical studies support the use of lemon balm (*Melissa officinalis* L) for its reputed hypnotic or anxiolytic effects in humans. No adverse effects have been reported from the use of lemon balm. However, the authors note that safety in pregnancy and lactation has not been established. The herb may potentiate other CNS depressants including alcohol and may interact with thyroid medications or thyroid disease.

Siberian Ginseng Siberian ginseng (*Eleuthrococcus senticosus* [Rupr and Maxim]) is readily confused with plants of the genus Panax which include Panax ginseng CA Meyer (i.e., ginseng, Chinese ginseng, Korean ginseng) and Panax quinquefolius L (i.e., Canadian ginseng, American Ginseng). Siberian ginseng is believed to help fatigue and stress, to improve endurance, and to have immunostimulatory properties. It is mentioned here because some studies report alteration of barbiturate-induced sleeping time and therefore should be used with caution with sedative-hypnotic agents.

Panax Ginseng Panax ginseng is commonly used in the belief that it can treat stress and fatigue and improve endurance. Common adverse effects include insomnia, hypertension, diarrhea, restlessness, anxiety, and euphoria. The authors recommended caution with regard to use in patients with hypertension and diabetes and in conjunction with centrally acting medications. They also note that ginseng may potentiate the effect of monoamine oxidase inhibitors, sympathomimetics and haloperidol (Haldol).

Skullcap While the ingredients and pharmacology of Skullcap (*Scutellaria laterifolia* L) are not well documented, and the existing research may not apply to the preparations currently in use, the reviewers describe its use as a sedative and anticonvulsant. Giddiness, confusion, sedation and seizures are potential adverse effects. The authors advise avoiding skullcap use in pregnancy and lactation and caution that there may be interaction with other CNS drugs.

It should be noted that while the authors of this review provided thorough critique of extant research of herbal preparations and were consistent in their examination of claims for herbal products and potential hazards, they concluded their review with the following statements:

> However, the experience of other cultures, whether in less developed countries or in history, should not be ignored. Contemporary medical research may finally allow us to separate the traditional remedies that can effectively treat disease from those that are superstition and myth. In addition, research into the biochemical and pharmacological effects of these herbs may uncover novel treatments for psychiatric illness or yield fresh insights into basic disease mechanisms.

A summary of herbal remedies that affect psychiatric symptoms is given in Table 28.8-2.

AROMATHERAPY

Aromatherapy is the therapeutic use of aromatic plant oils. Named by the French chemist René-Maurice Gattefosse in 1928, aromatherapy is one of the fastest growing alternative therapies in the United States and Europe. The essential oils of plants are organic compounds with specific cyclic or aromatic components. Substances with strong odors were used in ancient civilization as both medicines and perfumes. Today, plant oils are inhaled using atomizers or absorbed though the skin during massage (aromatherapy massage). Plant oils are said to have many therapeutic effects—analgesic, psychological, antimicrobial—some of which have been demonstrated in various ways. For examples, oil of cloves is a commonly used dental analgesic. Aromatherapy is said to relieve stress and anxiety and alleviate gastrointestinal and musculoskeletal disorders, among others. In psychiatry, olfactory stimulation has been used to elicit feeling tones, memories, and emotions during psychotherapy. The essential oils used in aromatherapy can cause skin irritation or allergic reactions in some people. Table 28.8-3 lists some essential oils and their purported effects.

Oil	Effect
Chamomile	Tranquilizing
Eucalyptus	Antiseptic
Geranium	Astringent
Jasmine	Stimulant
Lavender	Analgesic, tranquilizing
Neroli	Sedative-hypnotic
Peppermint	Stimulant
Rosemary	Stimulant
Sandalwood	Antiseptic, stimulant

Table 28.8-3 Essential Oils in Aromatherapy and Their Purported Effects

One example of aromatherapy research that pertains to psychiatry is an open-trial, small-sample (*N* = 15) study of depressed patients conducted in Japan, which reported that the application of citrus fragrance could markedly reduce necessary doses of antidepressants. While replication, larger samples, and placebo controls would be required to substantiate this finding, the result is consistent with reports of users of aromatherapy. Previous animal research indicated that citrus fragrance could alleviate stress-induced immunosuppression, and various scents have been used in nursing homes to improve the mood of severely demented (and other) patients.

TRANSCRANIAL NEUROELECTRIC STIMULATION

The typical application of transcranial neuroelectric stimulation involves placing surface electrodes in the mastoid region. The electrodes are stimulated with low-amperage and low-frequency alternating current. No seizures are induced, and there is little (if any) resemblance between transcranial neuroelectric stimulation and electroconvulsive therapy (ECT). The method was originally used in the 1950s to treat insomnia and has been used in the treatment of depression and anxiety. Studies of the effectiveness of this method in treatment of substance abuse have not shown a consistent treatment effect, although greater comfort during detoxification has been reported. Similar methods have been called Limoge and Russian Electrosleep therapy.

A related method, rapid-rate transcranial magnetic stimulation, applies electromagnetic stimulation to the left dorsolateral prefrontal cortex of patients with drug-resistant depression. Only a small sample (*N* = 17) of patients was used in a multiple-crossover, randomized, placebo-controlled trial in which sham stimulation was applied to different cortical areas. Eleven of the 17 patients showed significant improvement on the Hamilton Rating Scale for Depression, and no adverse effects were reported. It was suggested that this method might serve as a nonconvulsive alternative to ECT.

THERAPEUTIC TOUCH

Therapeutic touch, a theory of healing with the hands, was developed by Dolores Krieger who studied Theosophists and other healing practitioners who healed by “laying on of hands.” The first major publication appeared in 1972, and since that time the method has been taught in more than 80 colleges and universities in the United States and in 67 other countries. Therapeutic touch has gained popularity in the nursing profession as well as among some physicians and less orthodox healers. Recent television and news reports describe the use of therapeutic touch during surgical procedures.

An initial stage in both therapeutic touch and many forms of massage is placing the hands at a distance ranging from less than an inch up to several inches above the body. It is believed that something unspecified (e.g., somatic information, heat, “energy,”) can be transferred and sensed by the therapist and sometimes the patient and that the healing process is thereby enhanced. Krieger reported four studies stating that increase in hemoglobin values indicate the biological effect underlying the laying-on of hands. An intriguing double-blind study also suggested that therapeutic touching speeds the healing of small, standardized skin wounds.

A review of the research in this area concluded that some evidence exists to support the practice of therapeutic touch for the treatment of pain and anxiety but that the 11 studies lacked conceptual clarity and operational definition of the treatment method and findings. A recent study in *JAMA* presents the view of skeptics of this and other alternative and complementary health practices. This study tested the assertion of some practitioners that they could sense the effects of human bodies on their hands but did not test any of the therapeutic claims made for therapeutic touch. A more recent clinical trial reported efficacy for therapeutic touch in the treatment of pain from osteoarthritis of the knee. There may be several aspects of the interaction between the therapeutic touch practitioner and patient that affect a patient's state of mind or other determinants of pain and healing.

HOMEOPATHY

Homeopathy was developed by Hahnemann 200 years ago and was introduced to the United States in the early nineteenth century. It was believed to be effective in cholera epidemics against which the standard treatments of the day (bleeding and purging) were ineffective or harmful. By 1900 there were 22 homeopathic medical schools, more than 100 hospitals, and approximately 15,000 practitioners in the United States. In the 1920s, with the introduction of modern pharmacotherapies and the standardization of conventional physician training programs using funding guidelines favoring American Medical Association (AMA)-approved institutions, homeopathic hospitals and schools (including almost all of the women's medical schools of the time) disappeared or were converted to allopathic medicine. However, the practice of homeopathy is increasing in this country and around the world. Homeopathy has been popular in Europe throughout the twentieth century, and in India it has retained enormous popularity since its introduction by the British Empire. Homeopathic medicines are sold over the counter in the United States; in 1992 sales were $200 million, and they have increased each year since then.

Hahnemann based homeopathic drug treatment on the following assumptions: disease symptoms result from the body's own efforts to throw off the illness; medical substances elicit a standard array of signs and symptoms in healthy people; the medicine whose effect in normal people closely resembles the symptoms of the illness being treated is the one most likely to initiate the curative response by helping the body complete its own curative efforts. This law of similars— *Similia similibus curantur* (“Let likes be cured by likes”)—led to the term “homeopathy” (“similar experiences”). The process begins with administering small doses of a substance to healthy volunteers to determine the agent's symptom profile. This is called a homeopathic “proving.” The patient is then given the substance whose symptom profile most closely matches the patient's symptom profile. Classical homeopathy develops individualized treatment for each patient; however, a variety of other approaches exist. Homeopathic remedies sold in the United States must meet the standards of monographs in the *Homeopathic Pharmacopoeia of the U.S*. (HPUS), which was recognized in the Food, Drug and Cosmetic Act with authority equivalent to that of the *United States Pharmacopoeia* (USP).

The HPUS is unique in several ways. First, there are over 2000 medications, including plants (e.g., aconite and hellebore), minerals (e.g., copper, gold, and iodine), and animal products (e.g. snake and jellyfish venom and tissue extracts). Second, medications are prepared as tinctures, that is, mixed with 95 percent grain alcohol, or as pills with lactose fillers. Last, medications are dispersed in infinitesimally dilute solutions, from 1:10 to 1:10 ^{1000}, far beyond the point at which any molecules of the medicine can be expected to still be found in the solution. To date, no one has been able to provide possible mechanism for homeopathy. Meta-analyses and reviews of research have come to different conclusions regarding the efficacy of homeopathy. While homeopathy is being used in the United States and the United Kingdom, little research has been published in standard peer-reviewed journals regarding its clinical application. However, a vast homeopathic medical literature exists, some of which has been published continuously (and with consistent standards) since the nineteenth century. While “classical” homeopathy is said by its proponents to be most effective in treating mental symptoms, the literature on randomized blinded trials is currently limited mainly to gastrointestinal and respiratory problems.

A case report on 12 outpatient adults who had major depressive disorder, social phobia, or panic disorder illustrates the use of homeopathy in psychiatry. Duration of treatment was 7 to 80 weeks. Response rates were 50 to 58 percent, depending on the outcome measure. While the authors concluded that homeopathy might be useful in the treatment of affective and anxiety disorders in patients with mildly to severely symptomatic conditions, the study is clearly an early case study that requires replication, larger samples, and placebo or treatment comparison controls.

> A patient with paranoid schizophrenia had been completely noncompliant with medications and had been continuously hospitalized for over 4 years. In the week following one oral administration of an individually chosen homeopathic remedy, this patient began to completely cooperate with the ingestion of antipsychotic medications that then served to clear his psychosis.

While anecdotal, this case is not isolated. An open minded physician cannot see many of these impressive changes without feeling that this is something worthy of further study.

Another intriguing randomized blinded trial conducted on postconcussive head injury suggested that moderately disabled patients could significantly improve their level of function, even years after their original injury.

The homeopathic evaluation process includes holistic consideration of all physical and psychological characteristics of the patient and does not necessarily depend on a diagnosis. As in many forms of alternative and complementary health practices, restriction to single therapeutic agents for particular diagnoses is believed to be an inappropriate way to evaluate the treatment. There are research methods to deal with this issue, but they are complex and more expensive than usual, and they require preliminary findings to justify the investment.

Bach Flower Essence Therapy A related method, Bach flower essence therapy, first described by a British homeopath named Edward Bach and named for him, involves elixirs produced by flowers floating in a bowl of water in sunlight. These elixirs are consumed, and practitioners claim that the treatment produces gentle healing and is free of adverse effects. While there are anecdotal reports of the use of these modalities for the treatment of addictive disorders and posttraumatic stress disorder, efficacy remains to be demonstrated.

MASSAGE

Massage involves manipulation of the soft tissues and surfaces of the body. It was prescribed for the treatment of disease over 5000 years ago by Chinese physicians, and Hippocrates considered it an important method of healing.

Massage may affect the body in several ways: it is said to increase blood circulation, improve the flow of lymph, soothe sore muscles, and have a tranquilizing effect on the mind. Many mothers and pet-owners have noted the calming effects of massage on children or animals.

Various massage techniques have been described: stroking, kneading, pinching, rubbing, knuckling, tapping, or applying friction. Massage is most often done with the hands and fingers, but vibrating machines and electrical stimulation are also used. The different types of massage therapy that have evolved over the years are more similar than different. These include Swedish, Oriental, Shiatsu, and Esalen massages. Most people who experience massage find it physically and mentally refreshing. A few preliminary studies have supported the perceived benefits of the treatment.

In a study of 11 patients with human immunodeficiency virus (HIV) infection, using an interrupted time trial design, massage therapy increased natural killer cell number, natural killer cell cytotoxicity, and soluble cluster of differentiation 8 (CD8) and the cytotoxic subset of CD8 cells. There was a major decrease in cortisol, significant decreases in anxiety, and increases in relaxation. The authors concluded that apparent clinical improvement is associated with massage.

A review of massage therapy for infants and children with various medical conditions showed that the treatment resulted in lower anxiety and stress hormones and improved clinical status. In a related study, 52 hospitalized depressed and adjustment-disordered children were treated with 30-minute back massage given daily for a 5-day period. Compared with subjects viewing relaxing videotapes, massaged subjects were less depressed and anxious and had lower saliva cortisol levels after the massage. Nurses rated the subjects less anxious and more cooperative on the last day of the study.

AYURVEDA

Asian Indian medicine has been traced to sacred writings dating to the second millennium BC. This system of medicine evolved through early periods of magical practices and use of a wide variety of herbal medicines. Medical treatises written during a period around the first century AD form the basis for most later writings. Current forms of this medical system demonstrate both Buddhist and Hindu contributions and are highly respected, involving considerable medical training from

recognized ayurvedic medical schools all over India.

Recent writings pertaining to psychiatry include treatises explaining achievements in the field of mental health, basic ayurvedic concepts, and their relationship to the modern scientific world. Ayurvedic concepts may be related to conditions such as anxiety, neurosis, and depressive disorders. Medical literature reviews have compared ayurvedic concepts to the works of Freud, Kurt Lewin's field theory, homeostatic imbalance as a source of mental illness, and personality types and their correspondence to types of mental disorders.

BIOENERGETICS

Bioenergetics, based on the belief that dammed-up “vital” energy produces maladaptive behavioral patterns, evolved from the work of the Austrian psychoanalyst Wilhelm Reich (1897–1957), who studied with Freud. Reich believed that energy fields were propelled by sexual impulses called ergs and that satisfactory orgasms indicated healthy bodily functioning. Modern-day practitioners look for areas of muscular tension in the body that are thought to be associated with repressed memories and emotions. Therapists try to bring these repressions to consciousness through a variety of relaxation techniques, including massage or noncontact methods resembling therapeutic touching. The research published in this area includes topics such as the effects of bioenergetics and progressive relaxation on self concept, locus of control, and social behavior of hospitalized psychiatric patients.

Related to these concepts are the use of deep breathing and focusing on attendant bodily feelings, together with facilitated fantasy development. Four types of related body psychotherapies are Gestalt therapy, Reichian therapy, Lowenian bioenergetics, and primal therapy. All share the belief that psychopathological functioning is rooted in rigidification of behavior and experience that are biologically and somatically, or physically remembered, in contrast to the reasoning of mental consciousness, or CNS memory. Several therapies use various kinds of mental and physical manipulations to “dislodge” traumatic memories of painful events stored in physical locations of the body.

BIOFEEDBACK

Biofeedback refers to a therapeutic process in which information about an individual's physiological processes such as blood pressure, heart rate, brain waves, temperature of extremities, or muscle tension is monitored electronically and “fed back” by means of sounds, lights, or electronic gauges. Using these techniques individuals can control a variety of physiological responses formerly thought to be completely nonvoluntary and thereby deal more effectively with stress reactions such as anxiety and pain. Feedback regarding status of brain waves has also been found useful—alpha waves being associated with relaxation and meditation, theta waves with focused attention. Herbert Benson has described a common “relaxation response” visible in most people as a result of alpha wave biofeedback, transcendental meditation (TM), or other reproducible meditation techniques.

Some early findings indicate that alpha or theta feedback may have significant effects on substance abuse. Several studies show positive effects on presurgical anxiety. Enough studies exist to permit meta-analyses of various forms of anxiety reduction methods, including biofeedback. In substance abuse studies, the various therapeutic components of the biofeedback process have not been separated. Number of sessions, attention effects, relationship with the therapist, and situational demand are some of the variables that could be involved in producing the treatment effects.

A review of biofeedback for mental disorders concluded that the method can help selected patients modify specific responses or response patterns, but it does not appear to be a treatment of choice for any mental disorder.

CHELATION

Chelation therapy is a conventional medical procedure used to treat accidental poisoning with heavy metals, such as lead, arsenic, and mercury. A chelating agent (ethylenediamminetetraacetic acid [EDTA]) is infused into the bloodstream and binds to the metal, which is then excreted renally. As an alternative medical practice, chelation therapy is used as a form of preventive medicine to remove lead, cadmium, and aluminum from the body. These substances are believed to be associated with hypertension, premature aging, memory loss, and the symptoms of Alzheimer's disease. Chelation therapy is popular as a treatment for atherosclerosis, but the randomized trial data do not support its efficacy for indications other than heavy metal toxicity.

An example of research on this method is a study of 83 male and 56 female patients (mean age, 63 years) who were treated with EDTA infusions with supportive multivitamin and trace mineral supplementation over approximately 60 days. Improvement was shown on the Cornell Medical Index emotional symptomatology. The research in this area, as with atherosclerosis, is inconclusive but does provide an insight into the popularity of the method and the loyalty of its users.

CHIROPRACTIC

Chiropractic is primarily concerned with the diagnosis and treatment of disorders of the musculoskeletal system, especially those of the spine. It was developed by a Canadian, Daniel David Palmer (1845–1913), who moved to the United States in 1895. He believed that spinal misalignment leading to abnormal nerve transmission is the cause of all illness (Fig. 28.8-3).

FIGURE 28.8-3 Daniel David Palmer (1845-1913), the founder of chiropractic. (Reprinted with permission from Shealy CN, editor: *The Complete Family Guide to Alternative Medicine*. Barnes & Noble, New York, 1996. Credited to British Chiropractic Association.)

Chiropractors diagnose illness by clinical examination and X-ray. Doctors of chiropractic (D.C.s) are trained in accredited chiropractic colleges and licensed in all 50 states. Procedures include the adjustment and manipulation of the articulations and adjacent tissues of the human body, particularly of the spinal column, and sometimes related therapies such as heat therapy, traction, and nutritional counseling. The latter procedures are included in the practices of the “mixers” but eschewed by the “straight” chiropractors who strictly limit their practice to spinal manipulation. Chiropractic is the largest independent alternative health profession in the Western world, and the United States is home to 52,000 of the world's approximately 56,000 chiropractors. Chiropractors are recognized by many government and insurance agencies and treat approximately 20 million patients in the United States annually.

There is little available research regarding chiropractic treatment of psychiatric illnesses. One small-sample (*N* = 21) study of patients with elevated blood pressure involved randomization to active treatment, placebo treatment, or no treatment. Active treatment was found to be related to reduced blood pressure while state anxiety was reduced in the active and placebo treatment. This is an early preliminary study that could form the basis for more-definitive studies.

EXERCISE

A recent review of exercise as a treatment for depression included reference to more than 1000 trials and a meta-analysis of 80 studies. Generally, the evidence indicated that a statistically significant treatment effect favored the exercise groups over that found for the comparison groups. This effect was found for all forms of

regular exercise, was independent of age or sex, and increased with the duration of therapy.

DANCE THERAPY

Dance therapy was formally recognized in 1942, when pioneer dance therapist Marian Chase (1896–1990) was hired at St. Elizabeth's Hospital in Washington, D.C. Although within the profession dance and movement are widely used synonymously, each term actually describes a point of view; *movement* encompasses the whole world of physical motion, whereas *dance* is a specific creative act within that world, usually involving music. The American Dance Therapy Association defines dance therapy as “the psychotherapeutic use of movement which furthers the emotional and physical integration of the individual.” Dance therapy sessions have four basic goals: the development of body awareness; the expression of feelings; the fostering of interaction and communication; and the integration of the physical, emotional, and social experiences that result in a sense of increased self-confidence and contentment.

There are several hundred references to dance therapy, many of which are descriptive and theoretical. The method has been applied to a wide range of psychiatric conditions. A meta-analysis of 23 studies with a total sample of 781 subjects, concluded that dance and movement therapy can be effective for treatment of a variety of symptoms, particularly anxiety. However, the research is characterized as having methodological problems such as inadequate control groups and lack of use of standardized measures.

EYE MOVEMENT DESENSITIZATION AND REPROCESSING

Eye movement desensitization and reprocessing is a method discovered by Francine Shapiro, who reported reduced levels of distress associated with traumatic memories if the recall of these memories could be accompanied with a certain form of rapid and rhythmic eye movements. While the nature of the research and the necessary components of the treatment are controversial it is generally conceded that the procedure is useful in the treatment of traumatic stress reactions in some patients. Criticisms generally concern the fidelity to standards of treatment; the necessity of eye movements; the use of appropriate control groups, research designs and measures; consideration of comorbidity; and consideration of other concurrent treatment. It has been suggested that as the quality of the research increases, there is less support for the efficacy of the technique beyond its imaginal exposure component. While initial reports concerning this technique have been encouraging, additional research is recommended. However, the current popularity of the method is notable.

CULTURALLY SPECIFIC THERAPIES

It is particularly difficult to summarize culturally specific therapies because of the extent and variety of these healing practices associated with religious beliefs and experiences that are applied worldwide. These “treatments” are not limited to geographic areas such as ayurveda in India or traditional Chinese medicine in China. Adding to the difficulty is the fact that they are not linked to written documents that expound their basic tenets or standards of practice. The writings that do exist are typically descriptive, often the publications of anthropologists or individuals who had personal experiences with these “treatments” or processes. Nevertheless they must be represented in this summary of alternative and complementary health practices because of their importance and prevalence, and their use worldwide to heal mental and physical illnesses that are inextricably intertwined with spiritual “illnesses.”

Shamanism A shaman is an individual who is believed to have the power to heal the sick and communicate with the spirit world, including primeval forces and spirits of the dead. The origin of the term appears to be from the Siberian and Ural-Altaic region, but individuals having this designation can be found in many parts of the world, including American aboriginal groups (first nations, Indians, and Alaskan natives). Qualifications of a medicine man (or woman) are determined by a series of initiatory trials and teaching and “certification” by qualified, recognized elders. These often include cleansing ceremonies (fasting, sweat lodge) and a “vision quest.”

Through the experience of trance-like states, the shaman conducts healing ceremonies that deal with the individual's loss and recovery of the soul. The ceremony is sometimes facilitated by rhythmic sounds, dancing, physical pain or privation, and the use of “spiritual herbs.” Through this process the shaman escorts the soul of the dying to the afterlife or to spiritually determined solutions to insoluble personal or social problems.

Research on this topic is generally descriptive and philosophical, although a few studies use clinical research methodology. One study reports on shamanistic contributions to the treatment of schizophrenia and other mental illness in Japan. Another study examined the outcomes and satisfaction of 188 patients treated by shamans in Taipei, Taiwan, with matched samples of patients treated by physicians. Five distinctive sickness types, including psychiatric problems, were involved. Both patient and experimenter reports indicated 75 percent improvement but greater dissatisfaction with shamanistic treatment, which is often difficult or uncomfortable.

Generally, the treatment research on shamanism can be characterized as early and preliminary. The difficulties in applying standard biomedical research designs to indigenous therapeutic practices are great, so studies are primarily naturalistic and observational. Even in the absence of efficacy data, however, the inclusion of nonharmful cultural rituals in the community mental health setting can be justified by concerns about cultural competence, the importance of community traditions, contributions to self-image, and the maintenance of socially positive behavior.

Peyotism or Peyote Religion, Native American Church Peyotism, or Peyote religion, is a Native American pantribal religious system that uses *Lophophora williamsi* (peyote), a substance obtained from the top of the peyote cactus. The substance contains mescaline, which is noted for its hallucinogenic and other mental effects. The use of peyote is part of a religious ritual that contains Native American and Christian components and promotes brotherly love, family care, self-support, and avoidance of alcohol. Peyote, like any drug, can be used to produce states of intoxication without accompanying religious intent. This is a major reason for the controversy surrounding the legalization of the substance for religious purposes. The Native American Church was formalized in 1918 to seek exemption from government prohibition of the use of peyote for sacramental purposes. Several states have supported the constitutional freedom of religion for this organization. The Supreme Court has established a legal precedent that has significant implications for the religious use of peyote and for sacramental use of all traditional substances other than alcohol. It has been estimated that there are more than 225,000 members of the Native American Church.

Research on this topic is generally difficult because of the multicomponent nature of the “treatment,” the self-selection of the church members, lack of explicit standardization of the treatment, and other factors such as the formation of social networks to help prevent relapse and the participation by many in dance ceremonies held several times a year in various parts of the country. “Treatment” may be a social system that has peyote as only one of its probable “active” ingredients. The range of related practices includes sweat lodges, other herbs, cultural reeducation, and sun dances, among others. Research results have been contradictory, and recommendations drawn from historical and epidemiological data have not been investigated in controlled studies. Several factors probably contribute to outcome success in this area as they do in all substance abuse research. Many health workers in the Indian Health Service of the U.S. Public Health Service have seen long-term sobriety associated with Native American Church attendance by former public inebriates.

Even with this embryonic state of scientific information, this alternative and complementary health practice has great momentum, and participants and believers have a powerful conviction of its benefits and personal evidence for its salutary effects on not only substance abuse but physical health, mental health, and spiritual wholeness as well.

PRAYER AND SPIRITUALITY

The many forms of prayer, the number and variety of participants, and the theological and cultural contexts within which prayer is conducted make this topic extraordinarily difficult to summarize. The broadest definition of spiritual healing includes many of the topics covered above, since practices or treatments have accompanying philosophical, theological, and supernatural concepts (viz., the concept of “qi” in traditional Chinese medicine, the Vedic origins of ayurvedic medicine, the “other-worldly” concepts of shamanism). There is considerable interest in defining the professionally appropriate place of prayer and spirituality in the practice of medicine, psychology, nursing, and other health professions. The pervasive interest in faith healing, the curative anecdotes of television evangelists, and the millions of hopeful individuals visiting religious shrines in search of relief give witness to the continuing interest in and prevalence of prayer and spirituality in the process of healing. Some religions specifically recommend against standard psychiatric therapies and offer their own approach as the only valid alternative for mental and spiritual health.

The authors believe that no responsible physician should recommend replacing safe and efficacious medical practices with various forms of faith healing or religious treatment. However, words in the title of this section—complementary and alternative health practices—were chosen deliberately to indicate that these forms of intervention may include personal practices that may facilitate, enhance, or impede standard interventions. When demonstrated to be safe and effective, some of

these may be appropriate for addition to the psychiatric armamentarium. However, no matter how safe or even effective, some may never be appropriately included for medical treatment or insurance reimbursement. Some of the uneasiness that surrounds this topic is related to reports of the withholding of medical treatments with known efficacy because of a religious disbelief in the physical reality of the symptoms or illness or the spiritual dangers of otherwise safe practices. On the other hand, there should be no opposition to the appropriate recognition of a patient's religious beliefs and behaviors in American medicine. This summary considers the health effects of spirituality and describes the research that deals with a component of spirituality, prayer.

Prayer The traditional research approach to topics of this kind is to select one component of a complex form of intervention and manipulate it in an effort to demonstrate its independent or interactive contribution to the healing process. In this case, the act of prayer can be considered a form of distant healing defined by Elizabeth Targ as any purely mental effort undertaken by one person with the intention of improving the physical or emotional well-being of another (intercessory prayer). In a similar manner, the act of prayer can be self-administered and studied as part of the therapeutic process (personal or group prayer). An additional classification provided by Jeffrey S. Levin lends itself to research strategies that can reduce the total complexity of the topic. The classification consists of a pair of dichotomous concepts that are based on whether healing has naturalistic or supernatural origins and whether it operates locally or nonlocally.

Several lines of research evaluate prayer and spirituality. A few are listed here to indicate the variety of approaches and reported effects. Several clinical reports and reviews advocate the use of shared prayer, silent prayer, and distant prayer in nursing care. One review concerned the use of guided imagery and prayer and reported the benefits experienced by both nurses and patients dealing with terminal medical conditions.

Surveys indicate that 92 percent of a sample of inner city homeless women reported one or more spiritual or religious practices. Some 48 percent reported that prayer was significantly related to less use of alcohol or street drugs or both and fewer perceived worries and depression.

Experimental research included a large randomized control trial that investigated the effects of directed and nondirected prayer and a control condition randomly assigned to 496 volunteers. The measures included self-esteem, anxiety, and depression. Agents (those praying) improved significantly on 10 measures. A significant positive correlation was found between the amount of prayer the agents did and their scores on the five objective tests. Agents had significantly better scores than did subjects on all objective measures. Patient improvement was related to the subject's conviction concerning whether he or she had been assigned to a control or experimental group.

Wound healing, the rate of reepithelialization of standardized full-thickness human dermal wounds surgically administered, was used as the outcome measure to compare therapeutic touch, Reiki, LeShan, and intercessory prayer. The five experiments conducted produced inconsistent results. The complexity of the design and treatments made this research difficult to interpret.

A randomized, double-blind, within-subject crossover research design was used to examine the effect of nontraditional distant prayer upon autonomic and CNS measures using multisite surface electromyographic recordings. Other measures included hand temperature, heart rate, skin conductance, blood volume, and pulse. Two of the four muscle regions that were monitored showed significant reduction in electromagnetic readings during and following the distant healing intervention, for most subjects. While some scant evidence supports the possibility of distant mental effects on humans, animals, and other biological systems, the confounding effects of hope, expectation, relaxation, investigator bias, and other participation activities need to be taken into account in future research. In human substance abuse research, for instance, it remains to be determined whether prayer has efficacy in addition to its nonspecific, personal treatment effects.

One randomized blinded trial of intercessory prayer (distant prayer by others) for patients who were identified by name and study number showed no benefit to those randomly assigned to be prayed for. However, the notion of praying for an unknown party by study number has been ridiculed by many critics. Also, several drug treatment officials have claimed that they “would pray for the control group.” This negative result does not disprove previous published work claiming evidence of benefit to cardiac care unit patients who were randomized to receive intercessory prayer or not receive it. In that study, complication rates and survival were significantly better in myocardial infarct patients who were prayed for.

Spirituality A large body of epidemiological research indicates that religious beliefs and practices are negatively correlated with substance abuse and positively correlated with health status. However, the investigation of these findings by clinical studies is just beginning.

One study combined nearly all the desirable aspects of research design and measurement: a homogeneous baseline group including careful selection and exclusion criteria; use of accepted diagnostic and outcome measures; random assignment to treatments; waiting list controls; posttreatment, 3-month, and 2-year follow-up; control for significant therapist variables; multivariate analyses; monitored treatments; and separate analysis of therapist religiousness and the religiously based cognitive-behavioral therapy. The clinically depressed patients were self-identified Christians. The religiously based cognitive therapy and the pastoral counseling patients obtained significantly improved posttreatment depression and adjustment scores, compared with those of the nonreligious cognitive therapy group and the waiting list controls. One interesting finding was the difference that was attributed to the superior performance of the nonreligious therapists (with values dissimilar to those of the patient) in the religious therapy group. Improvement in all three groups was equal at follow-up and greater than the posttreatment waiting list group effect. Generally, the findings indicated that religious subjects receiving religiously based cognitive-behavioral therapy did better at posttreatment regardless of the religiosity of the therapist conducting the therapy. Relevant to the discussion of this topic were the enduring effects of the pastoral counseling treatment that was used as one of the experimental controls.

Nocebo Effects Probable effects can be associated with prayer and interventions having spiritual components without knowing the causal components or mechanisms for these effects. If a therapy and therapeutic process are harmonic with the patient's value and religious system, there are likely to be enhanced treatment outcomes, even if these effects can be understood as placebo effects. However, if there is efficacy in such a process, there are also likely to be risks. The negative placebo outcomes associated with a medical or religious intervention are termed *nocebo effects*, results that worsen mental or physical health and intensify suffering.

No discussion of alternative and complementary health practices in mental health would be complete without a description of the nocebo effect. Just as positive expectations and a good doctor-patient relationship can have a positive effect on health outcomes (the placebo effect); it is reasonable to assume that negative expectation or a noncommunicative, distrusting, or hostile relationship can have negative effects on the patient.

A large number of case histories describe intensification of illness or production of death in various cultures, including the United States. Sudden death, hexes, curses, the consequences of taboo violations, voodoo death, and the production of aversive symptoms have been considered from various perspectives—anthropological descriptions, conditioned reflex learning, illusion of control studies, cerebral neurophysiology, and sympathetic adrenal responses leading to cardiovascular collapse. The point here is that the effects exist, and it is conceivable that negative expectations generated by any respected figure of medical authority could be associated with ill effects.

Obviously, all physicians and health practitioners should strive to obtain the most positive possible placebo effect in our clinical relationships, to add as much as possible to the specific efficacy of our therapies. The placebo effect was most of what physicians had to offer patients for most of medical history. The loss of doctor-patient relationships with optimal placebo effects has been blamed, rightly or wrongly, for much of the current popularity of alternative practitioners in the United States. Physicians should never worsen outcomes by painting an unnecessarily bleak picture for patients and their families, no matter how strong the medicolegal incentives are for doing so.

SUGGESTED CROSS-REFERENCES

Psychoneuroendocrinology is covered in Section 1.11 and the immune system and its interaction with the central nervous system is discussed in Section 1.12. Cross-cultural psychiatry is covered in Section 4.4, Chapter 25 discusses psychological factors affecting medical condition, and Section 25.9 discusses stress and psychiatry. Chronic pain and the placebo effect is covered in Section 28.6 and cults, quarks, and nonprofessional therapies are discussed in Section 28.9. Transcranial magnetic stimulation is also discussed in Section 31.3, other biological therapies which also contains an extensive table on herbal preparations.

The views expressed in this section are those of the authors, not those of the United States Public Health Service.

28.9 NONPROFESSIONAL THERAPIES, QUACKS, AND CULTS

LOUIS J. WEST, M.D.

In 1910 Robert Means Lawrence wrote:

> It is worthy of note that the most notorious quacks, often men of genius and education, though mentally ill-balanced, and morally of low standards, have been great travellers and shrewd observers of human nature. When such an one becomes ambitious to acquire wealth, he likely to prove a dangerous person in the community.

Nonprofessional modes of therapy for psychiatric disorders have multiplied rapidly in the United States and other developed countries during recent years, along with the general explosion of alternative medicine. There is now a bewildering variety of such methodologies. Quacks, who have always touted cures for physical diseases, today widely extend their claims to include mental and emotional illnesses as well. Meanwhile, there has been an alarming growth in the number of totalist cults, many of which claim to offer their followers health benefits—physical, mental, emotional, and spiritual. Physicians, other health professionals, and the public must be aware of these developments and recognize both their attractions and their dangers.

NONPROFESSIONAL THERAPIES

Some nonprofessional approaches to psychological self-improvement are essentially benign carried out by organizations engaged in procedures that may benefit some of their members, clients, followers or customers. However, many enterprises pose definite risks to those lured by their promises. All represent potential hazards if pursued as substitutes for professional care needed by a patient. A real danger exists that serious symptoms—physical, mental, or emotional—will be misunderstood, ignored, or masked during the course of nonprofessional interventions. Symptoms may even be temporarily relieved through the power of suggestion or the placebo effect but to the dangerous neglect of underlying pathology, which patients often erroneously attribute nonexistent to their nonprofessional therapists. Patients also are likely to expect professional responsibility, confidentiality, and other ethical standards or commitments that are legally not required of nonprofessionals and, in fact, usually do not obtain.

Ruthless cult leaders and venal quacks may offer psychiatric benefits in the cynical knowledge that they are perpetrating hoaxes and swindles. Even sincere nonprofessional healers tend to assume that their methods possess wide or universal applicability and to offer them to all comers with uncritical enthusiasm. Indications and contraindications for treatment are usually lacking in the formulations of such self-styled healers. Many of them assume that anyone is bound to benefit from their procedures, regardless of the sufferer's specific complaint. Unlike such persons, ethical practitioners of health-related professions realize that risk is inherent in any specific treatment. Untoward reactions inevitably occur in some patients. A qualified professional must be able to recognize latent and manifest complications of therapy and to take prompt and appropriate action if needed to help or protect the patient. When a given treatment produces dangerous side effects, fails to produce the desired therapeutic benefit, or (as may happen) fails to prevent—or even causes—exacerbation of the patient's illness, health professionals understand, but nonprofessionals often do not realize, that such treatment must be discontinued or modified. Patients seeking help from amateurs, quacks, cult leaders, gurus, faith healers, and assorted alternative practitioners are likely to believe that these nonprofessionals possess the knowledge, skills, clinical judgment, and ethical values of physicians. Disaster may result.

Contemporary quacks, while thriving, have been subject to surprisingly little scrutiny. On the current scene, with its myriad commercial health-related promoters, it is extremely difficult to differentiate the traditionally defined quack from the nonprofessional or alternative therapist, let alone the genuine professional practitioner. For example, all are now free to advertise. Many individuals, organizations, agencies, sects, and cults tout nonprofessional mental healing, psychotherapy, and self-improvement to the public. These vendors are a large and constantly changing group. Some purport to be purely spiritual, mystical, or religious. Others profess to be totally scientific, secular, and rational. Between these extremes is a spectrum of enterprises that partake, to various degrees, of both mystique and pseudoscientific rationale.

Another spectrum applicable to nonprofessional therapeutic enterprises is the specificity of goals. Some operators and organizations offer procedures that are directed precisely at highly defined problems or symptoms, such as smoking, overeating, alcohol abuse, drug addiction, and sexual inadequacies. Others strive to generally restore or maintain health, regardless of the disease or complaint in the particular case. Still others promote a general state of self-improvement, going far beyond the health orientation proper but including it. The widely accepted idea (especially popular in Western societies) that everyone needs self-improvement, better health, greater longevity, and development of untapped potential makes such approaches essentially universal in their stated applicability and seductively attractive.

MYSTIQUES

The past few years have seen a renewed and unabashed interest by some psychiatrists in parapsychology, including telepathy, psychokinesis, clairvoyance, and prescience. One prominent colleague has written positively on reincarnation, another on mediums, a third on thought transference in dreams. Experiences with hallucinogenic drugs have led others to formulate different, perhaps mystical, ways of knowing reality. Even biological scientists and astronauts have involved themselves in parapsychological experiments that would have seemed outrageously mystical 20 years ago but are now taken as a matter of course. Astrology and prophecy seem to be as much in vogue today as they were in the fifteenth century. Many citizens eagerly accept the idea that the earth is being visited regularly by benign denizens of other solar systems, ferried by spacecraft known as unidentified flying objects (UFOs). A professor of psychiatry has treated a number of people who claim to have been abducted and manipulated by these aliens; he believes and publishes their stories.

The extent to which mental illness today is recognized as bona fide disease may be reflected by the fact that faith healers of this day seem to be concentrating more of their attention on it. In the distant past the healing of mental disorders remained largely the province of various priesthoods. *Madness*, defined as demonic possession, was cast out (exorcised) through the use of interpersonal or group ceremonies that were given religious definitions. Today some of the most successful nonprofessional healing and self-improvement programs offer a combination of old-fashioned religious and modern pseudoscientific (or science fiction) formulations. The reasons for such developments probably include the power of suggestion derived from the mysteries of both science and religion and a general groundswell of antiintellectual sentiment within the New Age (actually medieval) fashion of thought.

QUACKS

Voltaire commented that the charlatan was born when the first knave met the first fool. Quacks probably deserve to be considered charlatans, but their victims (or patients) are not necessarily fools. They may be merely ignorant, or superstitious, or naive, or suggestible, or misled by sincere friends, or misguided by certain religious teachings, or frightened, or even desperate enough to try anything when other remedies have failed or when more responsible helpers can offer no hope. Such patients and their loved ones may be vulnerable to the false or exaggerated claims of the quack, whose primary motives are usually financial gain, prestige, power, or all three. The quack thrives by claiming to help people with ailments for which cures or treatments have not yet been satisfactorily developed by scientific medicine; for diseases that are particularly feared such as cancer, acquired immune deficiency syndrome (AIDS), sexually transmitted disease, tuberculosis, or epilepsy; with chronic, recurrent, or intermittent syndromes such as arthritis, multiple sclerosis, or vascular headaches; and today, for nervous and mental disorders of all kinds.

Famous quacks, both men and women, have often been striking in appearance, personality, or both. They usually attach phony degrees and titles to their names and

may display false or misleading credentials on their office walls. Testimonials by persons allegedly helped or cured are commonly used, not only by ordinary quacks but by religious faith-healers as well, to enhance their prestige and to increase the suggestibility of prospective patients. One of the most famous quacks in history was a nineteenth century Englishman named John St. John Long. While he specialized in curing (usually healthy) patients of imaginary tuberculosis, he also ventured into psychiatry. He stated, “The great power I possess in extracting fluid from the brain, has enabled me to reach the very seat of disease.” He was a handsome and dynamic man who was said to be particularly successful in treating unhappy female patients.

An important element of the continuing success of quackery, and of healing cults, especially in relationship to psychiatric disorders, is mistrust or resentment toward the established practice of medicine. Physicians have always been vulnerable to attack. Keeping mankind healthy and out of the grave is an impossible task. Health professionals are likely to be prosperous (evoking envy); they are busy, and their professional manner may be brusque; the therapy they prescribe may be unpleasant, protracted, and without guarantees of cure. Quacks have traditionally enhanced their own credibility by disparaging reputable physicians and legitimate medical practice. They play upon public ambivalence toward the medical establishment, which has led in recent times not only to the thriving of quacks, but also to the spread and acceptance of alternative medicine in all its manifestations. Quacks deliberately misrepresent themselves as possessing medical or other health-professional qualifications and skills that they do not posses. They are active in all aspects of the health field, preying on patients with both physical and mental illnesses and on patients' families as well. Even licensed health professionals may properly be termed quacks if they dishonestly or fraudulently claim to offer cures through knowledge that they lack or use techniques or medications that they tout as beneficial or curative when they have no known value (other than the placebo effect and the powerful effect of deliberate suggestion) for the condition being treated. Spiritual healing is, of course, extremely difficult to attack under laws concerned with pure foods and drugs or governing the practice of legitimate health professions, and it is not surprising that many quacks operate under this umbrella.

Despite government regulations, agencies to control fraud and misrepresentation, and widely available educational materials on health matters, quackery may have prospered in the last few years partly because of the high cost and incomprehensibility of modern biotechnical medicine; partly because so many persons lack health insurance; partly because HMOs demand rapid, high-volume, impersonal health care delivery by legitimate practitioners; partly because the growing numbers of elderly adults are vulnerable to extravagant claims of relief or cure for their chronic ills; and partly because many contemporary young persons are open to antiestablishment attitudes that leave them vulnerable to the blandishments of persuasive quacks. In their skepticism about large commercial and governmental institutions, including universities and large research organizations, numerous young people have been caught up in a wave of antiintellectualism that began in the 1960s and has not yet abated. Meanwhile the quacks are constantly at work to exploit every advantage, legally and culturally, in their untiring efforts to make money at the suffering public's expense.

CULTS

Periods of great turbulence in human history are often accompanied by the emergence of unusual numbers of cults, religious and otherwise. Some cultlike activities and the beginnings of a counterculture (beatniks and the beat generation) emerged in America in the 1940s and 1950s following World War II and the Korean War. A new set of disturbances in the American culture welled up during the 1960s with the expansion of an unpopular war in Southeast Asia, massive upheavals over civil rights, and a profound crisis in values defined by unprecedented affluence on one hand, potential thermonuclear holocaust on the other. Young people were caught up in three rebellions: red (New Left) against inequities of political and economic power; black, against racial injustice; and green (the counterculture) against materialism in all its manifestations including individual and institutional struggles for power. Drug abuse and violent predators took an awful toll among the counterculture's pilgrims (hippies) in the late 1960s. Many fled to form colonies, generally called communes. Others turned to the apparent security of paternalistic religious and secular cults, which have been multiplying at an astonishing rate ever since.

Definitions of “cult” in *Webster's Third New International Unabridged Dictionary* include “a religion regarded as unorthodox or spurious (the exuberant growth of fantastic cults); also, a minority religious group holding beliefs regarded as unorthodox or spurious,” a system for the cure of disease based on the dogma, tenets, or principles set forth by its promulgator to the exclusion of scientific experience or demonstration,” and “great or excessive devotion or dedication to some person, idea, or thing.” Some of Webster's other definitions are even more benign (e.g., America's cult of home fixer-uppers.)

The term “cult” is used here primarily to describe groups that satisfy one or another of Webster's definitions but that also can be properly described as totalist, after Robert J. Lifton, who derived his concept of totalism from Erik Erikson's contribution to *Totalitarianism*. Totalism describes a tendency to “all-or-nothing emotional alignment” that can be exploited by “those ideologies which are most sweeping in content and most ambitious—or Messianic—in their claims, whether religious, political, or scientific. And where totalism exists, a religion, or political movement, or even a scientific organization becomes little more than an exclusive cult.”

The 1985 Wingspread Conference report provided the following definition (slightly modified):

> Cult (totalist type): a group or movement exhibiting a great or excessive devotion or dedication to some person, idea, or thing, and employing unethical, manipulative or coercive techniques of persuasion or control (e.g., isolation from former friends and family, debilitation, use of special methods to heighten suggestibility and subservience, powerful group pressures, information management, promotion of total dependency on the group and fear of leaving it, suspension of individuality and critical judgment designed to advance the goals of the group's leaders, to the possible or actual detriment of members, their families, or the community. There are many religious sects, new and old, that are not cults as defined above.

Totalist cults are likely to exhibit three characteristics: (1) excessively zealous, unquestioning commitment to the group and its leadership by the members, (2) manipulation and exploitation of members, and (3) harm or the danger of harm. Many groups do not fit neatly into a category of sect, commune, or cult. Furthermore, groups may change their characteristics over time, becoming more or less like cults, totalist or otherwise. Terms such as “new religious movement” have been used by some to describe certain cultic groups. A problem with this approach is that it may lend unwarranted respectability to a less-than-respectable enterprise.

Persons between the ages of 15 and 30 are especially subject to cult recruitment. A recent study of students in San Francisco found that half were open to accepting an invitation to attend a cult meeting, and approximately 3 percent reported they already belonged to cultic groups. No single personality profile characterizes those who join cults. Many well-adjusted, high-achieving persons from intact families have been successfully recruited by cults, as have individuals with varying degrees of psychological impairment. However, to the extent that predisposing factors exist, they may include naïve idealism, situational stress (frequently related to normal crises of adolescence and young adulthood, such as romantic disappointment or school problems), emotional dependency, disillusionment, or an excessively trusting nature. Ignorance of the ways in which groups can manipulate individuals is a relatively general characteristic of cult victims—until it is too late. Many contemporary cults in the United States, while not defining themselves primarily in terms of some healing system, do nevertheless claim extravagant healing powers, whether their shibboleths be religious, psychological, commercial, mystical, or related to self-improvement.

Estimates suggest that there are now more than 5000 cults in the United States. Many (but not all) of these are religious and, of course, they are not all alike. Some are very small, between 10 and 50 people; others are large, powerful, wealthy, and international. By definition cults pose significant threats to the personal freedom and well-being of their members. Regrettably, despite all the evidence of misdeeds perpetrated by cults in the name of religion, these threats are largely covered up, minimized, and obscured by the cults, their apologists and protectors, and even the media. Nevertheless, much information has accumulated from exposes of various cult-related scandals; from cult refugees; from families, relatives, and friends of cult victims; and from a few objective studies. Unfortunately, it is difficult to obtain accurate data by direct investigations of cults because they systematically deceive the public and, of course, would-be investigators. They conceal facts; they harass their critics, and they intimidate and dominate their members. All of this is designed to prevent a free flow of information. It is hard to carry out good scientific research when genuine direct access to or truly unrestricted observation of, the phenomena or subject material is forbidden and when the cult leadership controls or can influence the circumstances of scrutiny, the choice of subjects, or the nature of the responses. Even so, existing data now suffice to convince any reasonable person that the claims of harm done by cults are bona fide. Many people are already dead or dying, ill or malfunctioning, crippled or (if young) developing improperly as a result of their involvement in cults. They are exploited; they are used and misused; their health suffers; and they are made to commit improprieties ranging from lying to murder. Their families are often devastated and increasingly seek psychiatric advice. Estimates run as high as 10 million Americans who have been at least briefly involved with cultic groups during the past 30 years.

Many apologists—individuals and organizations—contribute to the cults' veneer of respectability behind which ugly and harmful things are happening. Some apologists appear to be romantics who project onto the cults some of their own hopes for religious reform, spiritual rebirth, rejection of materialism, or even escape from the dangers of the thermonuclear age. Other apologists, including some civil libertarians, take a more pragmatic stand, shrugging off whatever abuses the cults may perpetrate and pointing out that any countermeasures would be unacceptable because they violate freedom of religion as guaranteed by the First Amendment to the Constitution of the United States. Other apologists appear to have been successfully deceived by charismatic cult leaders or their representatives. Certain politicians fall into this category, in some cases after the cult has contributed money to their election campaigns. Some armchair academicians who either have never seen the destructive effects of cults or prefer to deny their reality will happily discuss cults (perhaps using another definition) at length and in elaborate terms as an interesting new ferment in contemporary society or in some other uncritical way. If the apologists are church officials, physicians, or behavioral scientists, the grateful

cults have been known to reward them with grants, awards, published praise, and even “research” opportunities.

The Wingspread Conference pointed out that cults arouse concern because of their unethical or manipulative practices and their lack of consideration for the individual's needs, goals, and social attachments. Of even greater concern is that these practices often result in harm to persons, families, and society at large. A number of specific harms are outlined in the Wingspread Conference report, broken down into five general areas: (1) individuals and families, (2) government and law, (3) business, (4) education, and (5) religion. Although the Wingspread outline of harms is fairly comprehensive, it does not include a classification for certain major crimes, such as fraud, rape, battery, torture, child abuse, and murder, all of which have been committed at the instigation of cult leaders or in cult settings.

There are occasional flurries of public alarm about some cults' methods of recruitment, exploitation of members, restriction on members' freedom, retaliation against defecting members, struggles with members' families engaged in rescue operations (including so-called deprogramming), dubious fiscal practices and the like. Sometimes the public's concern has been increased by death threats against investigative reporters, leaked internal memoranda justifying violence, the discovery of weapons caches and attacks on opponents.

Some cultic organizations are relatively subtle about recruitment, albeit harsh when it comes to defections. Others are tireless in their recruitment activities. Many use techniques that in some respects resemble the political indoctrination methods prescribed by Mao Tse-tong during the communist revolution and its aftermath (1945–1955) in China. These techniques, described by the Chinese as “thought reform” or “ideological remolding,” were labeled “brainwashing” in 1950 by the American journalist Edward Hunter. Such methods were subsequently studied in depth after the Korean War by a number of Western scientists including Lifton, Edgar H. Schein, Albert Biderman, Bernard Siegel, Margaret T. Singer, and this author. Many have noted similarities between the Maoist techniques and those of contemporary totalist cults.

Recruitment and Indoctrination Successful indoctrination of recruits by a typical totalist cult is likely to include many if not most of the following elements:

1. Isolation of recruits and manipulation of their environment.
2. Control over channels of communication and information.
3. Debilitation through inadequate diet and fatigue.
4. Degradation or diminution of the self.
5. Induction of insecurity, fear, and confusion, with joy and certainty through surrender to the group as the goal.
6. Peer pressure, often applied through ritualized “struggle sessions” generating guilt and requiring open confessions.
7. Insistence by seemingly all-powerful hosts that the recruits' survival—physical or spiritual—depends on identifying with the group.
8. Assignment of monotonous tasks or activities, such as chanting or copying written materials or mind-numbing repetitious lessons in so-called classes.
9. Acts of symbolic betrayal or renunciation of self, family, and previously held values, designed to increase the psychological distance between recruits and their previous way of life.

Of course a cult that uses such drastic techniques to control and exploit hundreds or thousands of members does not begin by doing so with each novice. The cult's initial approach is often made by an attractive peer, maybe of the opposite sex, to an individual who seems an appropriate target, perhaps one who is vulnerable through unchanneled idealism, homesickness, uncertainty of purpose; who is traveling or otherwise away from usual surroundings; or who simply happens to be alone. In a friendly way, with much smiling and casual touching, a conversation is generated during which the recruit's interests and background are elicited. The scout then happily announces that some friends who are interested in the same things (e.g., peace, poverty, altruism, racism, self-improvement, the meaning of life) are meeting that very evening, and there will be a free meal and a guest speaker. By such means, aided by intense eye contact, flattery, and personal attention, the recruit is maneuvered into attending the first meeting, study group, or the like. There may be no religious discussion. Instead, there might be a rousing but nebulous lecture followed by cheery talk, sincere smiles, much eye contact, hand-holding, and general expressions of great affection. Toward the evening's end the recruit may be encouraged to attend a 3-day workshop at an attractive home or a ranch located in the country, “to learn more about us and to allow us to get to know you better.” Manipulation, sensory barrage, and indoctrination begin in earnest at the retreat. Long hours, continuous frantic pace, cheering, chants, and constant stimulation by the group are likely to render the young person fatigued, suggestible, and compliant.

Gradually, over a period of days, weeks, or even months, information about the group's identity and the demands it places on members are more fully revealed. But recruits, isolated from their usual surroundings and overwhelmed by the group, lose the ability to evaluate these items according to their usual frame of reference. Perhaps the recruits want to leave, but the cars have been moved. Everyone insists that they should stay. They are wanted. They are loved. They yield. Sometimes they actually become entranced, entering a dissociated state of altered consciousness, with subsequent amnesia for significant portions of these crucial early hours and days.

In the weeks that follow, the recruits are constantly accompanied by members of the group who surround them with love, affection, and camaraderie and increasingly exhort them to surrender their autonomy, relish self-sacrifice, embrace the cult's discipline, and do unselfish work. In return they will receive health benefits, expanded consciousness, mental tranquility, a divine message, inspiration, a new way of life, a sense of absolute security through identification with the all-encompassing group and its omnipotent leader, or the like. When the adaptation process has progressed far enough, the leaders may judge the recruit ready to assume the duties of full membership. Depending on the cult these may include recruiting others, office work, internal housekeeping tasks, menial labor, raising money on street corners or airports, parading and chanting, even scavenging for edible garbage. The new cultist is progressively influenced to turn away from friends, family, and career and to donate material goods and earnings to the organization. Some will be urged to make a will in favor of the leadership, to agree to carry out all commands given by those in charge, to make new contracts for advanced courses, or otherwise to deepen their bondage. As time passes some cult members psychologically deteriorate. They can become incapable of complex, rational thought. Their responses to questions become stereotyped and they find it difficult to make even simple decisions unaided. Their judgments about events in the outside world are impaired. At the same time their insight is so reduced that they fail to realize how much they have changed.

After months or years of membership, such a former recruit may emerge from the cult, maybe rescued by friends or family or perhaps having escaped following prolonged exploitation and suffering that culminated either in revolt against a particular outrage or in gradual, painful disillusionment. Many such refugees appear dazed and confused, unable to resume their previous way of life, and fearful of being captured, punished, and returned to the cult. Those who have worked with these refugees from cults find that many experience thinking difficulties and marked impairment of self-expression. *Floating* is a frequent phenomenon, with the excultist experiencing dissociative symptoms, a resurgence of the cult-derived pseudoidentity, and an impulse to return to the cult and beg forgiveness for having escaped. Other frequent symptoms of these refugees include depression, indecisiveness, a general sense of disorientation, patchy amnesia, flashbacks, emotional numbing, nightmares, and other symptoms of posttraumatic stress disorder. The following criteria apply to most of the cults from which such refugees are likely to come:

1. The venture was initiated by a self-proclaimed leader who claims to have been chosen by a “higher power” to lead such a group or to have discovered some great cosmic or ultrascientific secret justifying this leadership. (Leaders of outer space cults often claim flying saucer and UFO personnel have assigned them their mission.)
2. The cult has developed a double set of ethics to promote the group welfare: one for use within the cult (e.g., to be open and honest with each other and with the leader) and another for use in dealing with nonmembers (e.g., deceive and manipulate). Because of the double standard of ethics in the cult, duplicity is often practiced in fund-raising, the declared premise being that anything that advances the group's glorious ultimate purpose is justified.
3. The cult has required the recruit to undergo a major change in lifestyle.

The United States has at least 10 major types of totalist cults, and within each type the cult exhibits its own peculiar beliefs, practices, and social mores. The list below is not exhaustive, but most of the current American cults can be classified under one of the following headings:

1. Neo-Christian religious cults
2. Hindu and Eastern religious cults
3. Occult, witchcraft, and satanism cults
4. Spiritualist cults
5. Zen and other Sino-Japanese philosophical-mystical cults
6. Race cults
7. Flying saucer and outer space cults
8. Psychological cults
9. Political cults

10. Communal, self-help, or self-improvement groups that have evolved into cults

Cult Indoctrinee Syndrome Various signs and symptoms observed by mental health professionals over the past 25 years suggest that a cult indoctrinee syndrome may be defined. Features include:

1. Drastic alteration of the victim's value hierarchy, including abandonment of previous academic or career goals. The changes are often sudden and catastrophic, rather than the gradual change that might result from maturation or education.
2. Reduction of cognitive flexibility and adaptability. Victims answer questions mechanically, substituting stereotyped cult-specific responses for what their own previously reasoned answers might have been.
3. Narrowing, blunting, or artificiality of affect. The victim may appear emotionally flat and lifeless or almost frantically cheerful and ebullient.
4. Regression. Victims become childishly dependent on the cult leaders, who are expected to make decisions for them.
5. Sometimes there are physical changes, such as pallor or weight loss, with deterioration in the victim's physical appearance, strange or masklike facies, blank stare or darting, evasive eyes.
6. Clear-cut psychopathological changes may appear, including depression, dissociative phenomena, anxiety states, obsessional ruminations, delusional thinking, hallucinations, and various other psychiatric signs and symptoms.

If the opportunity occurs, proper evaluation of a cult indoctrinee should include a thorough history obtained from at least two persons—parents, siblings, spouse, or friends who knew the person well in precult days and (when possible) have had contact with the victim during the cult experience. Special attention should be given to ascertaining the indoctrinee's range of precult intellectual and other interests and accomplishments and to assessing how these presently appear to the informant. Comparison of precult and present behavior is important, even though the family members or friends may not be able to label what they notice with technical terms. Observers often use such descriptions as “spacey,” “zombie,” “programed,” “not herself anymore,” “he's a different person now,” “they changed her somehow,” and “he has a ten-thousand yard stare.” Several examples or instances of each aspect of change should be elicited from the informant, because this gives the professional interviewer a better appreciation of what is being reported.

Cult Refugees, Survivors, or Veterans Mental health professionals are seeing a growing number of excultists as patients. These individuals are returning to society or otherwise trying to resume a normal life after months or years in cults. Some studies report that certain of those who become involved in cults were maladjusted, troubled, or even psychiatrically ill beforehand. However, clinicians with the largest experience agree that most adolescents and young adults who join cults were not seriously disturbed to begin with. Many are fairly well educated. Especially at times of dislocation, disorientation, loneliness or existential crisis, they may become vulnerable to approaches by cults looking for just such persons to recruit. The larger cults instruct recruiters to seek those traveling alone; newly arrived foreign youths; students entering university life for the first time; persons who seem lonely, alienated, or displaced; those seeking companionship and a sense of meaning; or just anyone else who might be a good catch. Even if 9 out of 10 slip through the net, the tenth may be a keeper, and the net can be cast again and again. Any open-minded, honest, idealistic young person who is interested in self-improvement, spiritual development, or making the world a better place is vulnerable. While most contemporary cults recruit mainly young adults, a few also seek elderly adults or entire families. Family life can be profoundly disturbed by cults in many ways. Sometimes a whole family becomes a group of refugees or the family is fragmented when some members escape and others remain in the cult. Certain family backgrounds have been suggested to render young people vulnerable to the lures of cults, and some families do foster a combination of indecisiveness and rebelliousness that could make a cult seem attractive to a young person seeking a more perfect family. Some cultists do come from disturbed family backgrounds; however, most seem to come from the same variety of families as their demographically matched contemporaries. Too much blame is often placed on cult victims or their families for their plight (“blaming the victim”) while the ruthless, cunning, and often sophisticated techniques used by cults to attract, capture, and retain their member-victims are ignored.

Each cult purports to offer an improved or healthier state of mind, an expanded state of being, a moral or spiritual state of righteous certainty, and the privilege of belonging to a superior elite. This supposedly beneficial state can be reached only by following the narrowly prescribed pathways of the particular group. To grasp this approach to life, the new recruit must surrender a critical mind, must yield to the flow of force, must have childlike trust and faith. Numerous methods are used to manipulate recruits into such an accepting state of mind. They are lured, cajoled, induced to suspend the use of rational judgment and urged to limit their attention to what is at hand, to drop ties with the past (in some cases to leave families, friends, jobs, or schools), to shut out all competing ideologies, to block off memories of the past, and to erase all doubt.

These ends require great mental avoidance. Attention must be constricted and contact with families and past life must be minimized or abandoned. Any sense of personal independence or rebellion against the cult leader must be suppressed and an accepting, noncritical mental stance must be attained and maintained. This state of mind is induced by hours of incessant, mind-numbing solitary or group chanting; long repetitive lectures, guilt-inducing dogma, endless classes, and “training” such as prolonged staring at one another; and interpersonal and group methods of every kind. When the desired results are achieved the new cultists do not necessarily appear mentally ill or bizarre. However, family and friends who previously knew them well may observe distressing changes. Attention is now constricted. New information is avoided. “She doesn't seem to register what we say.” “His mind seems closed.” Conversation is monotonous and repetitious, filled with the dogma, catchwords, and phrases of the cult. Dissociation, denial, suppression, and regression are implicated in the victim's maintenance of the cult's formulations of life. Of course such maintenance is reinforced. The more the person conforms to cult requirements, the more approval and affection is bestowed by the group.

By regressing mentally and socially, conforming to the leader's dictates, and identifying with the leader's power, new cultists may feel secure. They are assured that henceforth they need never feel lonely and uncertain. The suspension of critical, rational thought and even verbal intelligence is urged or even required. The guru, prophet, cult leader, or surrogates persuade the follower to accept, surrender, melt, and obey. While maintaining such a state, even for years, some cultists may be laboring up to 20 hours a day in fields or shops, fund-raising, baby sitting, or performing various chores. In some cults they wear used clothing and eat cheap food while the cult leaders wear jewels, drive expensive cars, live in palatial homes, use followers as servants, and control all of the money and resources that the members turn over to the cult. These contrasts are justified by the leaders as being proper, even necessary, for the good of the group and are passively—even gladly—accepted by the followers.

Pseudoidentity in Cult Victims Families and friends of cult victims regularly complain that their loved one has profoundly changed and has “become a different person.” Prolonged clinical experience has led to formulation of a previously undefined alteration of identity, called “pseudoidentity,” to account for this phenomenon. Dissociative features of various types and degrees may be components of various psychopathological entities. However, the distortion or alteration of a person's identity and the appearance of a new and different persona can involve denying the meaning of a great deal of previous experience, cutting off many emotional associations that connect individuals to their personal histories, and distorting recall (if not suppressing portions of the past). Certain types of trauma in childhood are believed to sow the seeds of later malfunctions in the victim's associative resources, with a resulting clinical picture known as dissociative identity disorder. Since the early descriptions by Morton Prince (1906) and Pierre Janet (1907) there have been many psychodynamic theories that largely explain dissociative identity disorder and other major dissociative disorders (e.g., fugue, amnesia, somnambulism) in terms of inner conflicts. Not well studied, however, is how particular forms of environmental stress in adults can disrupt the normally integrative function of identity. Under such conditions, victims may use dissociative mechanisms to change their usual or normal expressions and behaviors that compromise personality and then assume an altered persona or pseudoidentity that facilitates coping with the situation they are in, regardless of how they got there.

Conditions of brutal captivity, such as those experienced by prisoners of war or civilian victims of hostage taking, in which the captor seeks to force a false confession or induce compliant behavior, can generate posttraumatic stress disorder with prominent dissociative features. During the Korean War the Chinese Communists' success in eliciting false confessions of war crimes (e.g., germ warfare), self-denunciations, and participation in anti-American propaganda activities by some captured American flyers was in great part achieved because the captors' absolute control over the prisoners' environment enabled them to inflict a variety of stresses that induced state of debility, (especially through sleep deprivation), dependency, and chronic apprehension or dread. In this state suggestibility is heightened, and identification with the aggressor (captor) may occur.

Clinical and experimental experience is replete with examples of increased suggestibility or controllability of individuals during altered states of awareness induced by hypnosis, psychotropic substances, environmental manipulation, sleep deprivation, sensory isolation, powerful emotions (especially in large groups), and other special circumstances. But pseudoidentity is more than a temporary role assumed by the subject in a laboratory exercise or a transient period of intoxication. It resembles the alter in a genuine case of dissociative identity disorder. However, the pseudoidentity differs from the alter in many important respects.

Pathogenesis Dissociative identity disorder is most likely a consequence of early childhood trauma, with symptoms appearing later in life as a result of inner conflicts combined with some interpersonal or situational crisis. A pseudoidentity is usually generated by external stress originating in the environment of a person who previously may have been quite free of any signs or symptoms of personality malfunction and for whom the new persona represents a transformation required to meet

the demands of a new life situation (e.g., membership in a totalist cult) dramatically different from the previous one.

Psychopathology The genuine dissociative identity disorder patient may have more than one alter (although in the author's opinion, this is rare); but those with pseudoidentity change (swiftly or gradually) to display a single different personality. Under certain conditions the patient may abruptly switch back and forth between behaviors characteristic of the two personalities but without the typical dissociative identity disorder boundaries between the two and without the patient's awareness of one self being separate from the other. In dissociative identity disorder the different alters or personalities primarily reflect facets of the original character; in pseudoidentity the new personality primarily reflects the new situational forces and requirements. In dissociative identity disorder the original identity is usually unconscious of the existence of others as they shift back and forth; in pseudoidentity the original identity remains but is overlaid or enveloped by the new.

Treatment Therapy of both syndromes requires appreciation of the mental mechanisms involved, the reality of traumata or stress—however subtle—in pathogenesis, and the techniques proved useful in managing dissociative disorders. While in psychotherapy for dissociative identity disorder the usual goal is reconciliation and integration of the alters into a new and healthier whole, the therapeutic goal for the patient with pseudoidentity is restoration of the original identity. However, patients then usually require treatment for the residual posttraumatic stress syndrome that is the legacy of the stress that produced and maintained the pseudoidentity syndrome and for the special problems of the restored but battered original identity.

Prognosis Dissociative identity disorder is difficult to treat, and untreated cases rarely remit. The outlook is generally better for the patient with pseudoidentity, although the syndrome may become chronic like any dissociative disorder or (in the old terminology) monosymptomatic major hysteria. Sometimes merely returning patients to their original life situations (or even a neutral environment in which information is freely and honestly exchanged and nonexploitive people are available for support) will result in the abrupt or gradual disappearance of the pseudoidentity. However, these patients then face resuming many long-neglected functions and working through the complex emotional aftermath of having—for whatever period of time and to whatever degree—been a different person. This process usually requires well-informed professional treatment.

Reentry Counseling Perhaps because of the contemporary ubiquity of computers, the terms “programing” and “deprograming” have become part of the cult-relevant language. The social and interpersonal influences and indoctrination methods used by cultists produce the stereotyped responses described above, resembling computer programs. The term “deprogramer” is now used by some to describe a person who gives cultists who have been forcibly extracted or have escaped from the cult information that might cause them to reconsider their commitment to the cult, to leave it or (having left) to understand what happened and to make a new start. Those who do this helping work (many themselves former cult victims) are now usually called “reentry counselors.” They provide information to persons who are considering joining cults, who have already joined cults, or who have left cults. The reentry counselors know how they themselves were persuaded to join, how the cult indoctrinated them to its ways, and what their mental states were while they were members. Some have collected considerable data (e.g., clippings from newspapers, books, videotapes, recorded interviews). Cult members appreciate the facts about their former cults and understand feelings of awakening as they begin to assimilate information previously avoided or denied them by the cults. Reentry counselors and support groups of former cult members can be helpful allies to the mental health professional who is treating a cult victim. Just as there is no single pattern of precult experiences, there is no uniform set of postcult problems. However, in addition to the identity problems and dissociative symptoms described above, three major difficulties are faced by most persons who emerge from cults: feelings of loneliness, difficulty with decision making, and a mood of depression or a pervasive sense of existential meaninglessness. Eventually, ex-cultists remark about great improvements in their mental states after being out of the cult for a time, especially if appropriate treatment, reentry counseling, or both have been provided. Observers often note that cult survivors seem brighter, more resourceful, and more talented than when they first escaped.

FUTURE DIRECTIONS

Some assume that people who enter cults do so (1) as the culmination of a genuine religious pilgrimage, (2) in search of relief from symptoms of psychopathology, (3) as an escape from a bad family situation, or (4) to find an oasis of peace or spiritual serenity. *Ideological hunger* has been described as a common psychosocial characteristic of individuals who were members or former members of a variety of religious cults. Cult recruits are commonly told that they had such a need but did not realize it until their indoctrinators revealed it to them. However, in the clinical experience of many investigators, most former cult members recall having no such ideological hunger before recruitment into the cult, nor do their parents or other informants.

Treatment of cult victims is not easy. They (and often members of their families) have been subjected to peculiar and complex stresses, sometimes for many years. Psychiatric care will of course be dictated by the nature of the illness, the premorbid personality, and the patient's remaining available strengths. However, the treating physician must know as much as possible about cults, especially the one that victimized the patient. The *Cultic Studies Journal*, published in Boston by the American Family Foundation, is a valuable source of objective information. Former cult members now working as exit counselors or reentry counselors may be extremely useful collaborators. Self-help groups composed of former members or professionally directed group therapy involving several former cultists at a time have also proved most worthwhile.

The yellow pages of the telephone directory in any American city with a population of a quarter-million or more (and in many smaller ones as well) will reveal advertisements by a variety of putative mental healers, counselors, hypnotists, spiritual health advisors and self-styled healers of every imaginable stripe. Other practitioners, while not advertised so blatantly, nevertheless attract large followings of those who seek peace of mind, relief from stress, or simply answers to worrisome questions about their health or family problems or about the meaning of life. There are more nonprofessional therapies than can be catalogued, and new ones appear all the time. The health professional must be generally aware of the ubiquity and appeal of cults, quacks, and “alternative” or nonprofessional therapies; to understand their seeming benefits—usually temporary—to some individuals (through the power of suggestion and the placebo effect) but their equally inevitable hazards and harm to others. True professionals must not shrink from warning the vulnerable about these risks and must conduct themselves so that even a confused and bemused public can clearly differentiate scientific medicine and its ethical practitioners from their myriad dubious alternatives.

SUGGESTED CROSS-REFERENCES

Alternative medicine is discussed in Section 28.8. Posttraumatic stress disorder is covered in Chapter 15 on anxiety disorders. Dissociative disorders are presented in Chapter 18. Hypnosis is covered in Section 30.3.

CHAPTER 29. PSYCHIATRIC EMERGENCIES

29.1 SUICIDE

ALEC ROY, M.D.

Suicide is a major public health problem: approximately 0.9 percent of all deaths are the result of suicide. About 1000 persons are estimated to commit suicide each day worldwide. In the United States suicide ranks as the eighth leading cause of death, and there are approximately 75 suicides per day, or one every 20 minutes, and more than 30,000 each year. The suicide rate in the United States has averaged 12.5 per 100,000 in the twentieth century, with a high of 17.4 per 100,000 during the Great Depression. From 1983 to 1998 the overall suicide rate has remained relatively stable whereas the rate for 15- to 24-year-olds has increased two to threefold. The number one suicide site in the world is the Golden Gate Bridge in San Francisco.

RISK FACTORS

Suicide is usually most accurately viewed as a multidetermined act. Risk factors for suicide include psychiatric disorder, social factors, psychological factors, biological factors, genetic factors, and physical disorder.

Psychiatric Disorders Important knowledge about why people commit suicide has been obtained from psychological autopsy studies of suicide victims in the general population. For example, the first such report studied the lives of 134 persons on whom the medical examiner of St. Louis City and County returned a suicide verdict during a 1-year period. Ninety-eight percent were clinically ill (94 percent with psychiatric disorders) and 68 percent suffered from one of two psychiatric disorders—45 percent from mood disorder and 23 percent from alcoholism (alcohol abuse or dependence). This pattern of results has been replicated many times (Table 29.1-1).

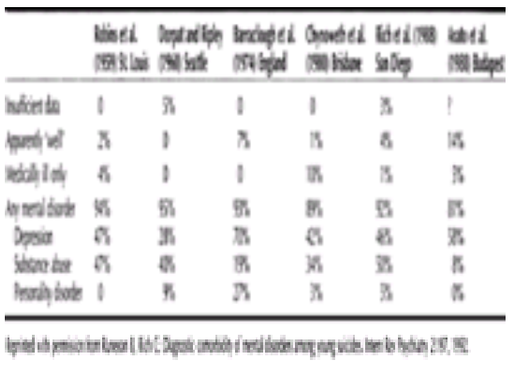

Table 29.1-1 Systematic Postmortem Interview Studies of Consecutive Suicides

There are significant differences between young and old suicide victims. Studies in San Diego and Rochester show that substance use disorders and antisocial personality disorder were found more often among suicide victims under 30 years of age whereas mood and cognitive disorders were found more often among suicide victims aged 30 and over. Precipitant stressors associated with suicide in those under 30 were separation, rejection, unemployment, and legal troubles; physical illness stressors were found more often among suicide victims over 30.

Depressive Disorders Mood disorder is the psychiatric diagnosis most commonly associated with suicide, and thus depression is one of the most important risk factors for suicide. For example, in one general population study, 45 percent of suicide victims were diagnosed as having had a primary depressive disorder, as were 30 percent in a second study and 64 percent in a third study. Follow-up studies report that about one in six depressed patients (15 percent) dies by committing suicide, although many of these studies were carried out before lithium prophylaxis was available.

The characteristics of patients with major depressive disorder who commit suicide was examined by the Finnish Suicide Research Center. Males were overrepresented as 45 of the 71 depressed suicide victims were male (63 percent) and 26 were female (37 percent). Thus, male sex is a risk factor for suicide among depressed subjects. The mean age was 50 years. The majority (85 percent) were complicated cases of depression with comorbid diagnoses, and comorbidity varied with sex and age. For example, males were overrepresented among the third of the depressed suicides with comorbid substance abuse (Table 29.1-2). Older suicide victims had more comorbid physical illness and fewer personality disorders, which were found more among younger suicide victims.

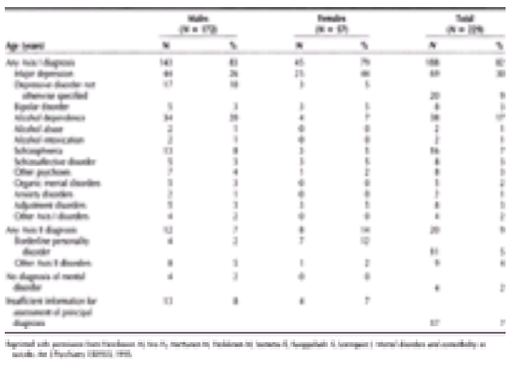

Table 29.1-2 Principal DSM-III-R Axis I and II Diagnoses of 229 Male and Female Suicide Victims

As regards treatment, 75 percent of the depressed suicide victims had a history of psychiatric treatment and two thirds had had psychiatric treatment during the last year. However, only 45 percent were receiving psychiatric treatment at the time of suicide. The mean time from last contact with health care was 39.0 ± 89.8 days. Eighteen percent had had face-to-face contact with a health care professional on the day they committed suicide, 39 percent had visited a professional within the last week, and 66 percent had done so within the last 3 months before suicide. In 60 percent of patients the reason for the visit was psychiatric and in 40 percent it was somatic. However, suicidal thoughts were communicated at only 29 percent of the last visits.

Most depressed suicide victims had received no treatment for depression. The antidepressant treatment of depression before death was either absent or inadequate. Only 3 percent had received antidepressants in adequate dosages, 7 percent had received weekly psychotherapy, and 3 percent had undergone electroconvulsive therapy (ECT) (Table 29.1-3). None of the 24 depressed patients with psychotic features had received adequate psychopharmacological treatment. Only 8 percent

had used antidepressants to commit suicide. Men had received less treatment for depression than women and more often used violent suicide methods.

	Males (*N* = 42)		Females (*N* = 24)		Total (*N* = 66)	
Antidepressant	*N*	%	*N*	%	*N*	%
None	33	79	11	46	44	67
Tricycle equivalent dose (mg)						
0–74	3	7	6	25	9	14
75–149	5	12	6	25	11	17
150–300	1	3	1	4	2	3

Table 29.1-3 Antidepressant Treatment Received by 66 Male and Female Suicide Victims with Major Depressive Disorder

Thus, the Finnish workers found that although about half of the depressed suicide victims were receiving psychiatric care at the time of death, few were receiving adequate treatment for depression. They concluded that for suicide prevention in major depressive disorder, great improvements in treatment and follow-up are required, particularly for males with depression.

Schizophrenia The suicide risk is high among schizophrenia patients: up to 10 percent die by committing suicide. Most persons with schizophrenia who commit suicide do so during the first few years of their illness. Thus, schizophrenic suicides tend to be relatively young and about 75 percent are unmarried males; approximately 50 percent have made a previous suicide attempt. Depressive symptoms are closely associated with their suicide; studies have reported that depressive symptoms were present during the last period of contact in up to two thirds of schizophrenia patients who committed suicide; only a small percent commit suicide because of hallucinated instructions or in order to escape persecutory delusions. Up to a third of schizophrenic suicides occur during the first few weeks and months following discharge from hospital; another third commit suicide while they are inpatients.

Alcohol Use Disorders Alcoholic persons have an increased risk of suicide, with a lifetime suicide risk of 2.2 to 3.4 percent. More men than women are found among alcoholic suicide victims. Alcoholic persons usually commit suicide after years of alcohol abuse. Comorbidity plays an important role; persons with alcoholism who have comorbid depressive disorders are at particularly high risk. Workers in St. Louis examined the relation of alcoholic suicide to specific life events. Among 31 alcoholic suicides, 48 percent had lost a loved one during the year before they committed suicide, and 32 percent had experienced such a loss during their last 6 weeks. The St. Louis group examined the lives of 50 other alcoholic suicide victims. Based on the hypothesis that suicide among alcoholics may represent a reaction to life events, the researchers recorded their opinions about the most important reason for suicide in each case (Table 29.1-4). Loss of a close relationship was the most frequently cited precipitating event; other events included job trouble, financial difficulties, and being in trouble with the law. For only 1 of the 50 suicide victims could no precipitating event be identified.

Presumed Reason	Number
Marital separation/divorce	8
Friction with spouse/lover	9
Expectation of loss (realistic)	5
Estrangement from family	2
Bereavement	2
Friction with family	1
Job trouble	4
Financial trouble	3
Trouble with the law	2
Depressed (as principal or only reason)	6
Feeling of disgrace	2
Feared rehospitalization	2
Inability to control drinking	1
Other	2
No provocation identified	1
Total	50

Table 29.1-4 Presumed Most Important Reason for Suicide Among 50 Alcoholic Suicide Victims

Because only 25 to 40 percent of alcoholic suicide victims suffered a recent loss, other predictors of suicide were searched for. Sixty-seven alcoholic suicide victims were compared with a community sample of 106 male alcoholics on six putative suicide risk factors. These included recent heavy drinking, presence of major depressive disorder, suicidal thoughts, poor social support, living alone, and unemployment. The alcoholic suicide victims differed significantly from the living alcoholics on all six of these risk factors (Table 29.1-5). Every one of the suicide victims had at least one these risk factors; three victims had one factor, three had two factors, and eight had all six factors. By comparison, only one living alcoholic had four risk factors and none had more than four (Table 29.1-6). The researchers concluded that the risk of suicide increases as the number of risk factors increases. The presence of as few as four of these factors may identify four fifths of persons with alcohol dependence at highest risk for suicide.

	Number and Percentage of Subjects	
Risk Factor	Alcoholics Who Committed Suicide (*N* = 67)	Living Alcoholics (*N* = 106)
Recent heavy drinking	65 (97%)	44 (42%)
Talk or threat of suicide	53 (79%)	24 (23%)
Little social support	50 (75%)	28 (26%)
Major depressive disorder	39 (58%)	5 (5%)
Unemployed	36 (54%)	19 (18%)
Living alone	30 (45%)	18 (17%)

Table 29.1-6 Distribution of Risk Factors in White Male Alcoholics Who Committed Suicide and in Living Alcoholics

OTHER SUBSTANCE USE DISORDERS DRUG DEPENDENCE There is an increased risk of suicide among substance abusers. For example, the suicide rate of heroin addicts is about 20 times greater than that of the general population. The availability of lethal amount of drugs, intravenous use, associated antisocial personality disorder, chaotic lifestyle, and impulsivity are some of the factors that predisposes drug-dependent persons to suicidal behavior, particularly when they are dysphoric, depressed, or intoxicated.

The Rochester group found that comorbidity of substance abuse and mood disorders was common among suicides. Among suicide victims with substance abuse, older age at death predicted major depressive disorder, among victims with mood disorders, younger age at death predicted comorbid substance abuse (Table 29.1-7).

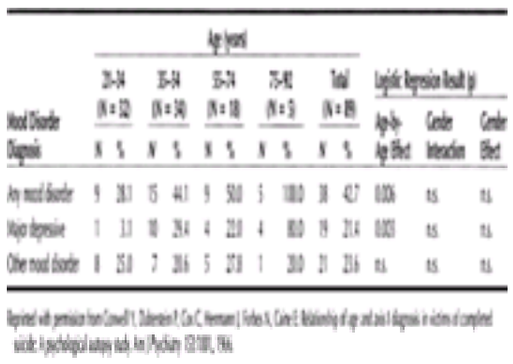

Table 29.1-7 Comorbidity of DSM-III-R Mood Disorders Among 89 Victims of Completed Suicide With Substance Use Disorders

Personality Disorder It is recognized that patients with borderline and antisocial personality disorders have an increased risk of suicide (Table 29.1-8). Recently the Finnish group reported a psychological autopsy study of suicide victims with personality disorders and found that they were almost always (95 percent) associated with current Axis I depressive disorders, substance use disorders, or both.

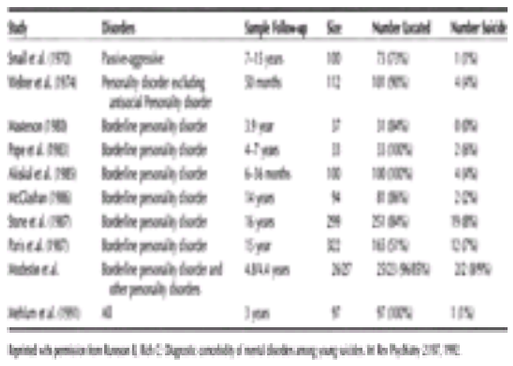

Table 29.1-8 Suicides in Follow-up Studies of Patients With Personality Disorders

The Finnish group also reported that 67 of a random sample of 229 suicide victims had an Axis II personality disorder. About one fifth (*N* = 43, 29 percent) of all the 229 suicides had a cluster B diagnosis (dramatic, emotional, or erratic), compared to the estimated prevalence of 4 to 5 percent in the general population. Ten percent of the sample (*N* = 23) had a Cluster C diagnosis (anxious or fearful), and only 1 person had a Cluster A diagnosis (odd or eccentric).

The next compared the personality-disorder suicide victims with sex- and age-matched suicide victims without personality disorder. Suicides with Cluster B personality disorders were more likely than comparison subjects to have substance use disorders (79 percent versus 40 percent) and previous nonfatal suicide attempts (70 percent versus 37 percent) and were less likely to have Axis III physical disorders (29 percent versus 50 percent). Suicide victims in Cluster B had almost always (98 percent) either comorbid depressive disorders (74 percent), substance use disorders (79 percent), or both (55 percent). They found no evidence of impulsive suicides that would have occurred without Axis I disorders. In contrast, subjects with Cluster C personality disorders did not differ from their controls on any variable.

Panic Disorder Data from the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) Study showed that 20 percent of individuals with panic disorder had made a suicide attempt at some time. This high rate was similar to the rate for individuals with major depression. When patients with panic disorder without comorbidity were examined, the lifetime rate of suicide attempts remained raised at 7 percent. Similarly, individuals with social phobia have increased rates of suicidal ideation and suicide attempts. The Finnish group found that current panic disorder was rare among completed suicides, being found in only 1.2 percent of all suicides. However, panic disorder suicide victims had superimposed major depression and substance abuse, and associated personality disorders. Thus, clinical assessment of suicide risk in panic and phobia patients should include determination of the presence or absence of major depressive disorder, substance abuse, and personality disorder.

Comorbidity Comorbidity is common among suicide victims. For example, the Finnish group reported that while 93 percent of a random sample of 229 suicide victims had an Axis I psychiatric disorder, two or more diagnoses on Axis I were present for 44 percent of the suicide victims. The most prevalent disorders were depressive disorders (59 percent) and alcohol dependence or abuse (43 percent). A diagnosis on Axis II was made for 31 percent and at least one diagnosis on Axis III was made for 46 percent of the suicides. Only 12 percent of the suicide victims received only one Axis I diagnosis without any comorbidity.

Social Factors Emile Durkheim was the first to examine how social and cultural influences impact on the risk of suicide. He found that suicide rates in European countries differed in relation to various demographic and social factors, and concluded that “the suicide rate varies inversely with the integration of social groups of which the individual forms a part.” Egoistic suicide is determined by a lack of meaningful family ties or social interactions. *Anomic* suicide occurs when the relationship between an individual and society is broken by social or economic adversity. For example, suicide rates rose during the Great Depression of the 1930s and fell in nearly all European countries during both world wars. Altruistic suicide results from excessive integration in society (e.g., harakiri, sati).

National Suicide Rates These vary from below 10 per 100,000 (Ireland, Egypt) to over 35 per 100,000 (Baltic states—the highest). Variations between countries reflect cultural and social factors as well as differences in the methods used to report suicide. In general the suicide rate is low in less prosperous countries and higher in more affluent countries; it is high in all Eastern European nations. The United States has a rate in the middle range, around 12 per 100,000.

Age Suicide rates increase with age. Among men, suicides peak after age 45; among women, the greatest number of completed suicides occurs after age 55. Rates of 40 per 100,000 population are found in men aged 65 and older. The elderly attempt suicide less often than do younger people but are successful more often. The elderly account for 25 percent of the suicides, although they make up only 10 percent of the total population. The rate of suicide for those 75 or older is more than three times the rate among the young.

Sex Males at all ages commit suicide more often than females and male-to-female suicide ratios range from 2 to 1 to 7 to 1. Also, males use more violent methods, like hanging, shooting, and jumping; females more often overdose or drown.

Race Ethnic and minority groups tend to be more cohesive and have lower suicide rates. In the United States, blacks have lower suicide rates than whites. The rate of suicide among whites is nearly twice that among nonwhites, but the figures are being questioned because the suicide rate among blacks is increasing. In 1989 the suicide rate for white males (19.6 per 100,000 persons) was 1.6 times that for black males (12.5), 4 times that for white females (4.8), and 8.2 times that for black females (2.4). Among inner-city youth and certain Native American and Inuit groups, suicide rates have greatly exceeded the national rate. Suicide among immigrants is higher than in the native-born population. Immigrants, who are likely to feel alienated, have higher rates than natives of either their adopted country or their country of origin.

Marital Status Married persons have the lowest suicide rates. The suicide rate for single persons is twice that of married persons and that of the divorced, separated, or widowed, four to five times higher (Table 29.1-9). Neighborhood and families ties and religious affiliations affect the risk of suicide. Suicide rates are lower among Jews and Catholics than among Protestants.

	Suicide rate per 100,000	
Marital status	Males	Females
Single	29.44	6.42
Married	18.94	4.68
Divorced	72.61	16.47
Widowed	92.13	8.85

Reprinted with permission from Tsuang M, Simpson L, Fleming J: Epidemiology of suicide. Int Rev Psychiatry 92:117, 1992.

Table 29.1-9 Suicide Rates by Marital Status for Males and Females in 1988

Employment Work, in general, protects against suicide. The unemployed have higher suicide rates, probably owing to an interaction of socioeconomic circumstances, psychological vulnerability, and stressful life events. During economic recessions and depressions and times of high unemployment, the suicide rate increases; during times of high employment and during war, the rate decreases.

Psychological Factors

Freud The first important psychological insight into suicide came from Sigmund Freud. In his 1917 paper “Mourning and Melancholia,” Freud stated that suicide represented aggression turned inward against an introjected, ambivalently cathected love object. Freud doubted that there would be a suicide without the earlier repressed desire to kill someone else.

Menninger Building on Freud's concepts, Karl Menninger in *Man Against Himself* conceived of suicide as a retroflexed murder, an inverted homicide, as a result of the patient's anger toward another person, which is either turned inward or used as an excuse for punishment. He also described a self-directed death instinct (Sigmund Freud's concept of *thanatos*). He described three components of hostility in suicide: the wish to kill, the wish to be killed, and the wish to die.

Recent Theories Contemporary suicidologists are not persuaded that there is a specific psychodynamic or personality structure associated with suicide. However, they have suggested that much can be learned about the psychodynamics of suicidal patients from their fantasies as to what would happen and what the consequences would be if they were to commit suicide. It is thought that the suicidal patients who are most likely to act out suicidal fantasies are those who have suffered the loss of a love object or have sustained a narcissistic injury, who experience overwhelming moods like rage and guilt, or who identify with a suicide victim. Aaron Beck has demonstrated the importance of hopelessness while Edward Shneidman has observed cognitive constriction of choices among the suicidal. Group dynamics underlie mass suicides like those at Masada and Jonestown.

Biological Factors Diminished central serotonin plays a role in suicidal behavior. A group at the Karolinska Institute were the first to note that low concentrations of the serotonin metabolite 5-hydroxy-indoleacetic acid (5-HIAA) in the lumbar cerebrospinal fluid (CSF) were associated with suicidal behavior. This finding has been replicated many times and in different diagnostic groups. Postmortem neurochemical studies have reported modest decreases in serotonin itself, or 5-HIAA, in either the brain stem or frontal cortex of suicide victims. Postmortem receptor studies have reported significant changes in presynaptic and postsynaptic serotonin binding sites in suicide victims. Taken together, these CSF, neurochemical, and receptor studies support the hypothesis that reduced central serotonin is associated with suicide. Recent studies also report some changes in the noradrenergic system of suicide victims.

Low concentrations of CSF 5-HIAA also predicts future suicidal behavior. For example, the Karolinska group examined completed suicide in a sample of 92 depressed patients who had attempted suicide. They found that 8 of the 11 patients who committed suicide within 1 year belonged to the subgroup with below-the-median concentrations of 5-HIAA in CSF. The suicide risk in that subgroup was 17 percent as compared with 7 percent among those with above-the-median concentrations of 5-HIAA in CSF (Fig. 29.1-1). Also, the cumulative number of patient-months survived during the first year after attempted suicide was significantly lower in the subgroup with low 5-HIAA concentrations. The Karolinska group concluded that low CSF 5-HIAA concentrations predict short-range suicide risk in the high-risk group of depressed patients who have attempted suicide.

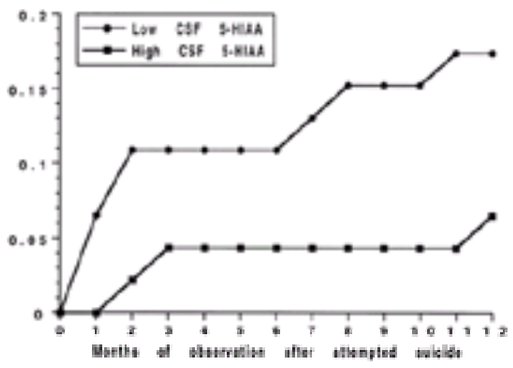

FIGURE 29.1-1 Cumulative suicide risk during first year after attempted suicide in patients with low versus high CSF concentrations of 5-HIAA. Filled circles indicate CSF 5-HIAA concentrations below the sample median and filled squares indicate concentrations above the sample median (87nM). (Reprinted with permission from Nordstrom P, Samuelsson M, Asberg M, Traskman-Bendz L, Aberg-Wistedt A, Nordin C, Bertilsson L: CSF concentrations 5-HIAA predicts suicide risk after attempted suicide. Suicide Life Threat Behav *24:*1, 1994.)

Genetic Factors Suicidal behavior, like other psychiatric disorders, tends to run in families. For example, Margaux Hemingway's 1997 suicide was the fifth suicide among four generations of Ernest Hemingway's family. In psychiatric patients a family history of suicide increases the risk both of attempted suicide and of completed suicide in most diagnostic groups. In medicine the strongest evidence for the possibility of genetic factors comes from twin and adoption studies and from molecular

genetics. Such studies in suicide are reviewed below.

Twin Studies In 1991, 176 twin pairs in which one twin had committed suicide were investigated. In nine of these twin pairs, both twins had committed suicide. Seven of these nine pairs concordant for suicide were found among the 62 monozygotic pairs, while two pairs concordant for suicide were found among the 114 dizygotic twin pairs. This twin group difference for concordance for suicide (11.3 percent versus 1.8 percent) is statistically significant ($P < .01$).

In another study a group of 35 twin pairs of which one twin had committed suicide was collected and the living co-twin was interviewed. It was found that 10 of the 26 living monozygotic co-twins had themselves attempted suicide, compared with 0 of the 9 living dizygotic co-twins ($P < 0.04$). Although monozygotic and dizygotic twins may have some differing developmental experiences, these results show that monozygotic twin pairs have significantly greater concordance for both suicide and attempted suicide, which suggests that genetic factors may play a role in suicidal behavior.

Danish-American Adoption Studies The strongest evidence suggesting the presence of genetic factors in suicide comes from the adoption studies carried out in Denmark. A screening of the registers of causes of death revealed that 57 of 5483 adoptees in Copenhagen eventually committed suicide. They were matched with adopted controls. Searches of the causes of death revealed that 12 of the 269 biological relatives of these 57 adopted suicide victims had themselves committed suicide compared with only 2 of the 269 biological relatives of the 57 adopted controls. This is a highly significant difference for suicide between the two groups of relatives. None of the adopting relatives of either the suicide or control group had committed suicide.

In a further study of 71 adoptees with mood disorder, adoptee suicide victims with a situational crisis or impulsive suicide attempt or both particularly had more biological relatives who had committed suicide than controls. This led to the suggestion that a genetic factor lowering the threshold for suicidal behavior may lead to an inability to control impulsive behavior. Psychiatric disorder or environmental stress may serve "as potentiating mechanisms which foster or trigger the impulsive behavior, directing it toward a suicidal outcome."

Molecular Genetic Studies Tryptophan hydroxylase (TPH) is an enzyme involved in the biosynthesis of serotonin. A polymorphism in the human *TPH* gene with two alleles—U and L—has been identified. As low concentrations of 5-HIAA in CSF are associated with suicidal behavior, it was hypothesized that such individuals may have alterations in genes controlling serotonin synthesis and metabolism. It was found that impulsive alcoholics, who had low CSF 5-HIAA concentrations, had more LL and UL genotypes. Furthermore, a history of suicide attempts was significantly associated with *TPH* genotype in all the violent alcoholics (Fig. 29.1-2); 34 of the 36 violent subjects who attempted suicide had either the UL or LL genotype. Thus, it was concluded that the presence of the L allele was associated with an increased risk of suicide attempts. Also, a history of multiple suicide attempts was found most in subjects with the LL genotype and to a lesser extent among those with the UL genotype (Fig. 29.1-3). This led to the suggestion that the L allele was associated with repetitive suicidal behavior. The presence of one TPH*L allele may indicate a reduced capacity to hydroxylate tryptophan to 5-hydroxytryptophan in the synthesis of serotonin, producing low central serotonin turnover and thus low concentrations of 5-HIAA in CSF.

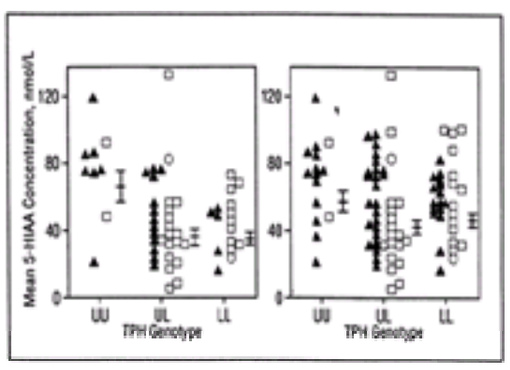

FIGURE 29.1-2 Relationship between tryptophan hydroxylase *(TPH)* genotype, mean (±SEM) 5-hydroxyindoleacetic acid (5-HIAA) concentration, and history of suicide attempts. The 5-HIAA concentrations of the subjects are plotted against their *TPH* geotypes for impulsive subjects (left) and all subjects (right). Triangles represent subjects who had never attempted suicide; squares, suicide attempters; and circles, those who had committed suicide. (Reprinted with permission from Nielsen D, Goldman D, Virkkunen M, Tokola R, Rawlings R, Linnoila M: Suicidality and 5-hydroxyindoleacetic acid concentration associated with a tryptophan hydroxylase polymorphism. Arch Gen Psychiatry *51:*34, 1994.)

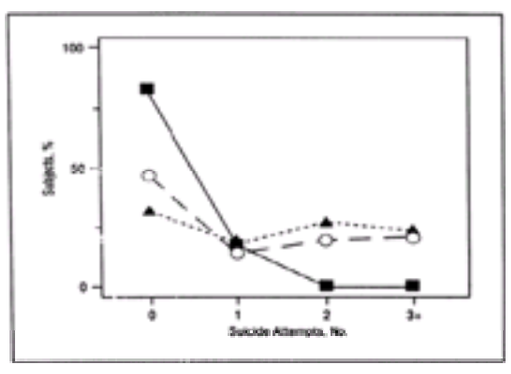

FIGURE 29.1-3 Relation between *TPH* genotype and lifetime history of multiple suicide attempts. For each genotype, the fraction of subjects having each genotype (UU, squares; UL, circles; LL, triangles) is plotted against the number of suicide attempts they have made in their lives. (Reprinted with permission from Nielsen D, Goldman D, Virkkunen M, Tokola R, Rawlings R, Linnoila M: Suicidality and 5-hydroxyindoleacetic acid concentration associated with a tryptophan hydroxylase polymorphism. Arch Gen Psychiatry *51:*34, 1994.)

Physical Disorder Postmortem studies show that a physical illness is present in 25 to 75 percent of all suicide victims; a physical illness is estimated to be an important contributing factor in 11 to 51 percent of suicides. In each instance, the percentage increases with age.

Fifty percent of men with cancer who commit suicide do so within a year of receiving the diagnosis. Cancer of the breast or genitals is found in 70 percent of women with cancer who commit suicide. There are seven diseases of the central nervous system that increase the risk of suicide: epilepsy, multiple sclerosis, head injury, cardiovascular disease, Huntington's disease, dementia, and acquired immune deficiency syndrome (AIDS). All are disease in which an associated mood disorder is known to occur. Persons with epilepsy also have available barbiturates and other medications with which to kill themselves.

Four endocrine conditions are associated with increased suicide risk: Cushing's disease, anorexia nervosa, Klinefelter's syndrome, and porphyria. Mood disorders also attend these disorders. The two gastrointestinal disorders with an increased suicide risk are peptic ulcer and cirrhosis, both physical disorders found among alcoholic persons. The two urogenital problems with an increased suicide risk are prostatic hypertrophy and hemodialysis, both problems in which changes in mood occur. Because of the increased incidence of major depressive disorder in patients with cerebral disease, the association of suicide with cerebrovascular disorders and progressive organic deterioration leading to dementia is hardly surprising.

SUICIDE IN THE ELDERLY

Compared to other age groups, those 65 years and older have the highest risk of committing suicide. For example, the suicide rate for the elderly is 50 percent higher than the rate for teenagers or the U.S. national rate. In the United States 18 elderly persons commit suicide each day, 1 every 80 minutes. The majority of elderly suicides are committed using a firearm. Some older individuals have a higher suicide risk than others: most at risk are males, whites, the recently widowed, and those

aged 75 years or more.

The two psychiatric conditions most associated with suicide in the elderly are depression and alcoholism. Psychological autopsy studies show that approximately 70 percent of elderly suicide victims suffered from depression in the weeks and months before their suicide. Approximately 20 percent of elderly suicides meet the criteria for a substance abuse disorder, usually alcohol abuse or dependence.

Studies show that loss and stress are major etiologic factors in the depression and alcohol abuse found among elderly suicide victims. These include physical losses resulting from poor health, painful illness, sensory deficits, and cognitive decline; social losses like death of a spouse and loss of the work role; and income losses associated with retirement and medical expenses. Such losses may lead to reduced social networks and social isolation, and can produce feelings of despair, loneliness, demoralization, dependency on others, helplessness and hopelessness, as well as suicidal ideation (Table 29.1-10).

Vital Loses	Stress	Despair	Alcoholism
Physical	More vunerable	Helplessness	Helplessness
Social	Less resistant	Hopelessness	Hopelessness
Financial	Failure in coping	Anxiety	Anxiety
Personal	Mechanisms	Decreased self-concept	Decreased self-concept
Emotional	Self-concept	Lowered self-esteem	
Cognitive	Lowered self-esteem	Loneliness	
	Loneliness

Table 29.1-10 A Model of the Aging Process and Suicide

SUICIDE AMONG PSYCHIATRIC INPATIENTS

The great majority of psychiatric patients who commit suicide do so as outpatients. Many of these outpatients suicides occur within the first few weeks or months after discharge from a psychiatric institution, which highlights the fact that the postdischarge period is a period of increased suicide risk for psychiatric patients.

However, up to 15 percent of psychiatric patients who commit suicide do so as inpatients. Many of these suicides do not actually occur on the ward itself but in stairwells, other hospital buildings, on the grounds, near railway lines, or in rivers. Other inpatients commit suicide at home when out on a pass, on weekend leave, or when absent without leave.

The commonest diagnosis among inpatient suicides in the acute psychiatric ward is depression and the suicide risk is highest in the first few days of the admission. Times of staff rotation, particularly of psychiatric residents, are periods associated with inpatient suicides. Clusters of inpatient suicides tend to be associated with periods of ideological change on a ward, staff disorganization, or staff demoralization.

However, suicides also occur among long-term psychiatric inpatients. In hospitals the diagnosis most often associated with suicide is schizophrenia. Surprisingly, inpatients with schizophrenia may commit suicide after having been in the hospital for more than a year. Often, they have previously exhibited suicidal behavior and have been admitted involuntarily (Table 29.1-11). Suicide in such schizophrenia patients may be precipitated by attempts at rehabilitation or discharge.

Patient Characteristics	Suicide Victims N = 37	Controls N = 37	Significance
Past suicide attempt	23	13	P<0.02
Involuntary last admission	26	16	P<0.02
Living alone	26	16	P<0.02
Single	21	20	NS
Separated/divorced/widowed	11	9	NS
Married	5	8	NS

Table 29.1-11 Comparison of Inpatient Suicide Victims and Inpatient Controls

MANAGEMENT OF SUICIDAL PATIENTS

Many suicides among psychiatric patients are preventable. There are occasional patients whose suffering is so great and intense or so chronic and unresponsive to treatment that their eventual suicide may be perceived as inevitable; fortunately, such patients are relatively uncommon. Some have severe personality disorders or are highly impulsive; such patients commit suicide when dysphoric, intoxicated, or both.

Risk factors are useful in assessing the short-term risk of suicide of a patient in an acute crisis. The psychiatric and social risk factors for suicide include a past attempt, a chronic psychiatric disorder, recent hospital discharge, living alone, being unemployed, being unmarried, and being liable to develop depressive symptoms. The immediate postdischarge period is a time of increased risk. However, these risk factors identify too many false-positive and false-negative patients to be useful in the long-range prediction of suicide.

The evaluation for suicide potential involves a complete psychiatric history, a thorough examination of the mental state, and inquiry about depressive symptoms, suicidal thoughts, intents, plans, and attempts. Lack of future plans, giving away personal property, making a will, or having recently experienced a loss imply increased risk for suicide. The decision to admit the patient to a psychiatric facility depends on the diagnosis, the severity of depression and suicidal ideation, the patient's and family's ability to cope, the living situation, the availability of social support, and the absence or presence of risk factors for suicide. Precautions against suicide include removing potentially lethal drugs and firearms from the home and prescribing medication only in weekly supplies.

Useful measures for managing a depressed suicidal inpatient include searching the patient's belongings and person on arrival on the unit for objects that might be used for suicide, and repeating the search at times of exacerbation of suicidal ideation. Ideally, the suicidal depressed inpatient should be managed on a locked unit with shatterproof windows, and the patient's room should be located near the nursing station to maximize observation by the nursing staff. The treating team will have to assess how much to restrict the patient and whether there should be regular checks or continued direct observation. Vigorous treatment with antidepressant medication should be initiated, and if there is no response within a reasonable period of time, or if the suicide risk is too great, a course of ECT should be considered.

LEGAL AND ETHICAL CONSIDERATIONS

Liability issues stemming from suicides in psychiatric hospitals frequently involve questions about the patient's rate of deterioration, the presence during hospitalization of clinical signs indicating risk, and the psychiatrist's and the staff members' awareness of and response to those clinical signs. What the courts require is not that suicide never occur but that the patient be periodically evaluated for suicidal risk, that a treatment plan with a high level of security be formulated, and that

the staff members follow that treatment plan. The role of an aider and abettor in suicide adds another dimension to the legal morass.

ATTEMPTED SUICIDE

Persons who attempt suicide also pose a major health problem. In the United Kingdom, there are 100,000 hospital admissions each year because of deliberate self-poisoning (2.5 percent of all admissions). In England and Wales, self-poisoning is the most common diagnosis of admitted patients under 50 years of age; among women it is the most common reason for emergency medical admission whereas among men it is second only to heart attacks.

Attempted suicide is in many ways an unsatisfactory term. For example, most attempters do not actually wish to commit suicide; their motives are different. Thus, the Edinburgh group introduced the term *parasuicide* in an effort to signify that suicide attempts are not just failed suicides but are a very different behavior.

Rates and Demographics The ECA Study found that 21 percent of adults reported that there had been a period of 2 weeks or more at some time during their lives when they thought about their own or another's death; 7.1 percent said they felt so low they wanted to die; 10.2 percent said that they had thought about committing suicide; and 2.9 percent reported that they had attempted suicide at some time in their lives.

A review of the world literature showed that attempted suicide rates varied between 100 and 300 per 100,000; that there was a preponderance of females in all countries; that about 50 percent of attempters were under 30 years of age; there was an excess of divorced persons; the lower social classes were overrepresented; and that a diagnosis of depression was made in between 35 to 79 percent of cases. Females aged 15 to 19 years have the highest rate of suicide attempts. Up to 1 in 100 in this group may be expected to attempt suicide each year. The highest rate for males is found among those aged 25 to 29, of whom 1 in 200 attempts suicide each year.

Acute Problems The circumstances surrounding a suicide attempt invariably involve recent life change, particularly interpersonal stress. Suicide attempters report five particular events significantly more frequently than controls: serious arguments with the spouse, having a new person in the home, serious illness of a family member, serious personal physical illness, and having to appear as a defendant in court. When event categories are examined, suicide attempters have more undesirable exit-and-entrance events (e.g., birth, marriage) and interpersonal arguments than controls.

Chronic Problems Persons who attempt suicide also tend to have chronic problems with marriage, children, work, finances, health, or alcohol. The Oxford group found that two thirds of married attempters had chronic marital problems and one half had been involved in a recent extramarital affair. One fourth of patients had problems with their children; parents who neglect or abuse their children are particularly likely to attempt suicide. Up to one third of attempters have had a medical or surgical admission in the previous year. Persons with epilepsy are overrepresented among attempters.

Among adolescents who attempt suicide, three quarters report difficulties with one or both parents, one half report problems with their school work or teachers, and one half report difficulties with a boyfriend or girlfriend; others have work problems or experience social isolation.

Psychiatric Disorders Hospital studies show that about 40 percent of those who attempt suicide have a history of psychiatric treatment. Psychiatric assessments reveal that about 50 percent have a personality disorder, and up to 40 percent have other psychiatric disorders. The most common diagnoses that are not personality disorders are depressive disorders (up to 40 percent of women and 30 percent of men).

Studies using observer-rated instruments find that although symptoms like tension, depressed mood, hopelessness, irritability, worrying, and poor concentration are present in 40 to 75 percent of attempters, a definite psychiatric disorder can be diagnosed at admission in only about 30 percent of attempters; this percentage decreases rapidly over subsequent weeks. However, workers in Christchurch, New Zealand, have shown that among serious suicide attempters 90.1 percent had a psychiatric disorder with high rates of mood disorder, substance abuse, and antisocial personality disorder. The incidence of comorbidity was high: 56 percent had two or more disorders. The risk of a serious suicide attempt increased with increasing psychiatric comorbidity.

Motivations, Explanations, and Consequences The majority of suicide attempts are impulsive. Two thirds of such persons report that they had thought about the act for less than an hour beforehand. There is often a discrepancy between the motivations for the attempt as perceived by the medical staff and the explanations given by the patient. In one study, over one third of patients stated that they wanted to die, but their psychiatrists agreed with this in only 50 percent of cases. The most common reason, given by up to 40 percent of both patients and their psychiatrists, was that the suicide attempt was made to get relief from a terrible state of mind. The great difference between the reports of patients and their psychiatrists was in identifying the reason for the attempt as being to frighten, get back at, or make someone feel sorry for the way they had been treated. This hostile or manipulative reason was chosen by about 10 percent of patients but by 70 percent of their psychiatrists.

Erwin Stengel recognized the appeal function of attempted suicide, which he saw as a cry for help. Although there is no specific personality trait, attempters are often immature, egocentric, anxious, dependent, hostile, impulsive, and have difficulties in relationships. Follow-up studies show that in up to three quarters of cases the suicide attempt is followed by improvements in both social problems and psychiatric symptoms. This improvement is largely because responses occur and may partly determine whether there will be another attempt.

Risk of Repetition About 40 percent of attempters have made a previous attempt. Follow-up studies show that between 13 and 35 percent will repeat the attempt during the next 2 years. During this time up to 7 percent will make two or more attempts, 2.5 percent three or more attempts, and 1 percent, five or more attempts. Thus, there appear to be three subgroups of repeaters: the very occasional repeater, the person who repeats several times within a short period, and the chronic on habitual repeater.

There are seven main items that may be helpful in identifying the patient at risk of making another suicide attempt: problems with alcohol, antisocial personality disorder, impulsivity, previous inpatient psychiatric treatment, previous outpatient psychiatric treatment, previous attempt that led to admission, and living alone.

Relationship to Suicide It is recognized that those who attempt and those who commit suicide represent different populations with some overlap. Approximately 1 percent of persons who attempt suicide will commit suicide during the following year. For 8 to 50 suicide attempters, 1 will eventually commit suicide. The risk of subsequent suicide varies with sex and age. For example, at the Karolinska Hospital country in Stockholm the suicide risk over the next 5 years after attempting suicide among men (8.3 percent) was nearly twice the suicide risk among women (Fig. 29.1-4). Both older and younger male suicide attempters are at high risk of suicide (7 percent and 10 percent, respectively), and older women are at higher risk than younger women (6 percent versus 2 percent) (Table 29.1-12). The suicide risk was particularly high during the first year after the suicide attempt.

Table 29.1-12 Male and Female Suicide Risk by Age After Attempted Suicide

Follow-up studies show that other factors associated with subsequent suicide include being unemployed or retired; being separated, divorced, or widowed; living along; having poor physical health; having received medical treatment within the last 6 months; having a psychiatric disorder, including alcoholism; having made many previous attempts by violent methods; the presence of a suicide note; and a history of previous attempts. A subgroup of suicide attempters who have severe personality disorder and interpersonal conflicts, and who often had alcohol or other substance dependence, commit suicide while acutely depressed.

SUGGESTED CROSS-REFERENCES

Mood disorders are discussed in Chapter 14. Anxiety disorders are the subject of Chapter 15. Personality disorders are the focus of Chapter 24. Chapter 11 discusses substance-related disorders; of particular interest is Section 11.2, alcohol-related disorders. Psychotherapies are the subject of Chapter 30. Section 28.5 covers death, dying, bereavement, and physician-assisted suicide.

CHAPTER 29. PSYCHIATRIC EMERGENCIES

29.2 OTHER PSYCHIATRIC EMERGENCIES

BEVERLY J. FAUMAN, M.D.

DEFINITION

A psychiatric emergency is any unusual behavior, mood, or thought, which if not rapidly attended to may result in harm to a patient or others. Psychiatric emergencies arise in the context of chronic psychiatric illness; however, they may also occur as the consequence of medical illness that presents with psychiatric symptoms, or as a result of an adverse drug reaction or intoxication or a drug-drug interaction. Other psychiatric crises may occur when a patient is the victim of severe physical or emotional trauma, and is unable to respond adequately without professional intervention. The social milieu contributes to the definition of a psychiatric crisis by its limitations in tolerating disruptive behavior. A psychiatric emergency may occur in a home, on the street, in an outpatient department, on a psychiatric unit, on a medical or surgical unit of a general hospital, or in the emergency department.

HISTORY

Extensive literature describing psychiatric emergencies and their treatment first appears around the turn of the twentieth century, when psychiatric disturbances occurred during wars and it was necessary to treat soldiers rapidly and effectively in order to maintain troop strength. Battle fatigue, shell shock, or more recently traumatic stress reaction were observed to respond to treatment more quickly when applied as soon as possible after the onset of symptoms, rather than upon evacuation from the front and during extended bed rest. By World War II the United States Armed Forces adopted this approach, significantly decreasing the severe and prolonged psychiatric disturbances that plagued soldiers previously, affecting their quality of life and resulting in multiple and protracted psychiatric hospitalizations. Emergency treatment and the expectation that battle weary soldiers would recover quickly and be able to return to fight improved the response rate fourfold.

It was during the same time period that Erich Lindemann conducted his classic study on the survivors of a tragic nightclub fire in Boston. One significant finding was that the survivors who did well were able to grieve for those who died, and for the fright and physical injuries they had incurred, and that therapy directed towards encouraging grief increased the likelihood of recovery. In addition, patients who seemed to grieve effectively also appeared to have generally gained in coping skills thereafter.

The subspecialty of emergency psychiatry has developed in parallel to the specialty of emergency medicine, as a response to deinstitutionalization and the identification of a large homeless population, the availability of increasingly safer and more effective neuroleptic agents, and the new safer and more rapidly acting antidepressant drugs. A large body of literature attesting to the efficacy of interventions in the emergency department, a formal organization, established protocols and philosophies, and the availability of fellowships for subspecialty training has grown up since the 1960s. The official designation in 1979 of emergency medicine into a specialty transformed emergency rooms around the country from way stations to the morgue into emergency departments, staffed by board-certified emergency physicians and providing which can provide definitive treatment for multiple disorders. The American Association for Emergency Psychiatry was established in 1988. Emergency psychiatric treatment now addresses problems not only in general hospital emergency departments, but all urgent and critical-care settings, including consultation services in hospitals and in outpatient clinics, both psychiatric and nonpsychiatric. In addition, as medical, surgical and obstetrical care become increasingly non-hospital based, psychiatric treatment of even very disturbed patients is being provided by mobile treatment and assertive community treatment programs, in homes, homeless shelters, and at other sites where such patients are causing disturbances. Unique emergency psychiatry facilities have been developed in the past few years that allow clinicians to institute a fairly thorough workup and initiation of treatment for newly diagnosed patients with major psychiatric disorders, often providing from 1 to 3 days of observation, acute treatment, and intensive outpatient programs.

In response to disasters, field hospitals that provide acute care sometimes include psychiatric personnel, not only to treat victims of psychological trauma, but also their families, and to consult with, debrief, and provide emotional support for the rescue workers, who often experience acute stress reactions because of the nature of their work.

Social factors have also demanded that psychiatry develop techniques that produce results rapidly. Health maintenance organizations and utilization review of treatment occurred in response to rising health care costs. It became difficult to justify the position that long-term treatment or long hospitalizations had any advantage over brief outpatient interventions or crisis hospitalization when society or an employer was paying the costs and when patients did appear to respond to many emergency interventions. The problems of homelessness and poverty, diminishing state programs for inpatient treatment of psychiatric problems, substance abuse, and the continuing problems produced by human immunodeficiency virus and related illnesses have increased the role of the emergency department as the primary provider of care for those patients. Although welfare and Medicare programs are being privatized, and the Veteran's Administration also has begun to seek care from private systems in order to cut costs, psychiatric access remains so limited that emergency departments continue to house patients for extended periods, and placement into hospitals or treatment programs becomes a frustrating exercise in intimidation.

DEMOGRAPHICS

The psychiatric emergency patient can be conceptualized in three broad categories, with somewhat different but overlapping demographics. The one that first comes to mind is the patient with an acute episode of a recurrent or chronic psychiatric illness, for whom the usual outpatient facilities are not available. The second is the patient with an underlying medical basis for psychiatric symptoms:intoxication, delirium, drug-drug interactions, or otherwise medically induced psychiatric symptoms. The third group of patients is essentially normal psychologically, but an overwhelming event, such as an accident, crime, or sudden onset or discovery of serious physical illness has strained their psychological capacity. Multiple demographic studies by university-based emergency services tend to measure the first group disproportionately, and find in that population a heavy overrepresentation of abuse of alcohol or illicit drugs as primary or complicating factors. The modal patient is a single female under the age of 40, in contrast to the population at large and also the usual age of a psychiatric outpatient. The elderly tend to underutilize psychiatric emergency services, although when they do present to emergency departments they tend to use a higher amount of medical, psychiatric, and social resources. The proportion of patients who are single (widowed, divorced, separated, or never married) is higher in the emergency population than in the population at large or in the population of outpatient clinic users.

Racial and ethnic characteristics of an emergency department population partially mirror the demographics of the region served. In general, however, African-Americans and those in low socioeconomic classes are overrepresented, while Hispanics and Asians are somewhat underrepresented. City dwellers use the emergency department more frequently than rural citizens, which appears to be more related to accessibility than to any diagnosis or other demographic feature. Most patients come on their own, more frequently after-hours. The most frequent presentations are agitation or anxiety, followed by suicidal or assaultive threats or behavior, and then psychotic behavior. Physical illness or an inadvertent drug reaction accounts for a substantial portion of the rest. Chronic psychiatric illness, with or without substance abuse is commonly determined to be the etiology of these symptoms. A small subset of patients *(repeaters)* habitually use the emergency department for definitive treatment, never following up on referrals to outpatient clinics or drug treatment programs.

BASIC PRINCIPLES OF EMERGENCY PSYCHIATRY

Approach Several aspects of the psychiatric emergency distinguish it from the usual psychiatric contact and dictate management. Such patients do not have an appointment, may appear at any hour, often appear threatening, and frequently do not want treatment. Also, particularly in a very busy emergency service, outpatient clinic, or mobile crisis center several patients may require treatment simultaneously, so a prioritizing mechanism needs to exist.

Initial Evaluation and Management *Triage*, a term derived from military medical practice, means sorting; it is the process of prioritizing patients according to how ill they are and how quickly their problems must be addressed in order to maximize their chance for recovery. Strong consideration is given to the determination of whether delay in treatment will adversely affect the patient's outcome. Traditionally, these decisions have been based on the patient's vital signs, status of airway, breathing, and circulation, which must be attended to promptly in order to preserve the patient's life. For the psychiatric patient, the discriminators are usually more subtle. Furthermore, when the patient presents with disordered behavior, these discriminators are sometimes ignored. Because there is a general scarcity of psychiatrists available to emergency departments, it is especially necessary to triage psychiatric emergency patients accurately. When a patient is evaluated at a freestanding psychiatric facility instead of a comprehensive emergency department, the possibility of an underlying medical condition can be missed. Table 29.2-1 illustrates a method of triage for the psychiatric emergency.

Category	Rationale	Initial Management
Emergency	Abnormal vital signs Threatening behavior	Assess medically Assess control needs Sitter, quiet room, seclusion, restraints
Acute	Overwhelming anxiety Suicidal ideation Patient is unable to explain problem coherently Family expresses extreme concern Patient does not meet criteria for emergency	Emergency pharmacotherapy Assess psychiatrically
Nonacute	Patient requests psychiatric help, but does not meet criteria for emergency or immediate response	Assess psychiatrically, consider referral to psychiatrist or psychiatric clinic

Table 29.2-1 Triage of the Emergency Psychiatric Patient

Somewhat different guidelines for triage apply for a mobile treatment team; in this instance the decision to send a team out must consider the likelihood that on-site intervention will avert the need for hospital treatment, as opposed to guidelines for a paramedic or ambulance call, in which the task is primarily to stabilize the patient in order to allow transport to a hospital. Commonly, the task in the first instance is facilitated by the fact that the patient seen by a mobile team or in an outpatient clinic is known to the team or therapist.

Environmental Measures In the emergency department the physician frequently has to evaluate an unwilling or uncooperative patient, in contrast to the private practice of psychiatry, where considerations such as holding a patient for an adequate evaluation is rare; even if the patient should decide to walk out of an evaluation prematurely, the obligation of the physician is minimal. In addition, the stimulation of a busy emergency department can escalate the patient's symptoms. Environmental controls may be needed to protect the other patients as well as to ensure that the patient does not leave the emergency department unnoticed before the evaluation is complete.

Decreasing the noise, the activity, and the anxiety exhibited by other patients or by medical personnel who are uncomfortable around psychiatric patients can reduce the patient's symptoms. A “quiet room” or a seclusion room is useful in this regard. The patient's vital signs should be obtained before he or she is placed in a quiet room, and then the patient should be monitored visually if possible. Restraints may be needed to hold a patient long enough for a proper evaluation, particularly when the patient is unknown to the staff and the cause of the symptoms is uncertain, the patient is unable to cooperate with the examination, the patient needs a secure environment, or if the patient cannot be left unattended safely. When a disturbed patient leaves the emergency department before an adequate assessment can be done, malpractice actions can ensue, especially if it can be shown that the patient was in an altered mental state when he or she left. In national surveys on the use of restraint in psychiatric facilities, four-point leather restraints remain the most used method of containing an out-of-control patient. Their advantage over medication is that they are immediately reversible, and are an obvious reminder of the patient's condition. Once a diagnosis is clearer, pharmacological management may be used to control the patient's symptoms and behavior and to initiate or resume treatment. Emergency department staff should regularly practice using restraints, and the restraints should be maintained and reviewed regularly, much as hospital crash cart. Seclusion, restraints, and psychopharmacologic management should not be construed as sufficient treatment, nor should these measures ever be regarded as punitive.

Protection of Others There is a growing literature on identification of the potentially violent patient, on staff training in the management of violent or disruptive patients, and on the social network and environment that increases or decreases violent behavior. In most studies, substance abuse, severe psychiatric disorders, and especially the combination of the two are disproportionately disruptive and such patients are more likely to become violent in the emergency department. The presence of uniformed city police and hospital security personnel stationed in the emergency department appears to reduce the incidence of violence and of harm to health care workers. It is not clear how helpful metal detectors are. Willingness to use physical restraints for the patient who has been identified as potentially violent is reassuring to the staff, which in turn sets an atmosphere of calm and a sense that things are under control, which also decreases the incidence of patient outbursts. Other measures that increase the safety and effectiveness of staff are self-defense courses, a protocol for handling violent patients, good lighting, video monitoring of all areas of the emergency department, panic buttons, and secure handling of addictive drugs, syringes, and needles.

Secondary Evaluation of the Psychiatric Emergency Patient Once life-threatening medical conditions have been addressed or ruled out and the patient has been stabilized, the specific nature of the psychiatric problem can be addressed. The decisions to be considered are whether it can be treated definitively in the emergency department, requires a referral for follow-up, or whether more acute measures such as hospitalization, admission to a crisis facility, intensive outpatient treatment, management by a mobile treatment team, or assertive community treatment are necessary. In a traditional outpatient setting, a psychiatric evaluation includes the most likely diagnosis and a treatment plan, and the patient's cooperation is obtained in instituting that plan. The emergency assessment is often quite different. The most important priorities are preservation of the patient's life and well-being, and secondarily, whether definitive care can be completed within the psychiatric emergency system. The modal psychiatric patient presents a systems issue rather than a diagnostic one. In the emergency assessment making a diagnosis may be less significant and more difficult to do, or in the chronic psychiatric patient all too obvious, given the constraints of time and lack of adequate information, than addressing the relationship of the patient to primary support systems. For the chronically mentally ill patient or the substance abuser, the foremost question is not the diagnosis but where the primary support system has failed. A chronically mentally ill patient who decompensates because he has stopped his medication may not need hospitalization if he or she is not suicidal, is aware of the need for treatment, and has a supportive environment such as a community mental health program which will follow him. On the other hand, the acutely psychotic patient who has no obvious social support, is unwilling to acknowledge psychiatric illness, and may be dangerous to others may require hospitalization each time his illness reaches a peak.

An effective treatment plan depends upon the availability of resources, and on the time frame for emergency treatment. Although extended observation in the emergency department may be useful in some instances, in practice this is often a way of postponing a difficult decision. Crisis beds and mobile treatment teams allow for repeated observation of the patient over time, ascertaining whether the initial treatment is working or needs modification. In general, however, the dispositional decision for a psychiatric emergency patient must be made within a few hours. This decision is influenced by the availability of beds or alternative treatment options such as day treatment or crisis intervention programs, the patient's own resources and motivation, and whether any dispositions must be preapproved by a third-party payer.

The disposition becomes more self-evident when the focus of the evaluation is the immediate reason for the use of emergency services, especially when the patient has a long-standing psychiatric illness. If the onset of the illness was acute, an adequate medical assessment as well as a psychiatric one is needed. In a patient who has no known psychiatric history, this is crucial, but even when there is a previous psychiatric history, an acute medical cause can precipitate the disordered behavior. Medical assessment of a psychiatric patient in the emergency department is often problematic. The physical examination may seem magical or intrusive, and is commonly avoided by the psychiatrist, for whom it is not generally routine. There is often a hope that the patient will have been medically assessed and cleared prior to the psychiatric consultation. However, the reverse is often true: a patient exhibiting disordered behavior is frightening to nonpsychiatric physicians, who are reluctant to approach such a patient, let alone complete an adequate evaluation to rule out medical emergencies. It is not uncommon for triage nurses or paramedics to forgo blood pressure, pulse, and temperature measurements on such patients. Some psychiatric services may refuse to evaluate a patient until the patient is

medically clear, and hospitals often will not admit a psychiatric patient without medical clearance. However, every medical condition cannot be ruled out in an emergency department evaluation. The emergency physician generally performs only a focused evaluation, addressing those complaints that are of immediate concern to the patient; most such evaluations take only a few minutes.

Most people find it difficult to believe that a patient is not able to control his or her behavior. Patients with psychiatric symptoms commonly walk into an emergency room (the vertical emergency) rather than being wheeled in or carried in on a stretcher. This makes it difficult to appreciate that they may not be in control of their behavior, and also tends to create the impression that they are less ill. Frequently, the nurse forgets to obtain vital signs. The overall impression is that there is something wrong with the patient's mind, not his body, and that a freestanding psychiatric facility is the appropriate site for treatment. Whereas medical emergencies have clearly recognizable characteristics, such as an obvious injury, the acute onset of pain, seizures, or a fever, the psychiatric patient may be well groomed, physically intact, and ambulatory.

> A 43-year-old physician entered the emergency department, having driven himself to the hospital. He reported to the triage nurse that he had taken 100 lithium tablets and 40 imipramine tablets within the last 15 minutes. He also gave her the name of his treating psychiatrist. Because the patient was so coherent, and perhaps because he identified himself as a physician, standard triage protocols were ignored. The patient's vital signs were not recorded, and the nurse reported the information she had obtained to the emergency physician. The emergency physician also overlooked normal protocols, and proceeded to call the patient's psychiatrist. While he was on the telephone awaiting a response, the patient collapsed and was resuscitated only after strenuous efforts by the emergency department staff.

Patients with chronic psychiatric illnesses who also have a medical illness may interpret their symptoms in psychotic ways, and will request to see a psychiatrist rather than an emergency physician. Chronically ill psychiatric patients also may have learned from experience that they will not be taken seriously by anyone other than a psychiatrist. Even if they do realize that they may have a serious medical illness, they will ask to see a psychiatrist. In addition, their psychiatric symptoms may be exacerbated by the medical illness.

One aspect of psychiatric illness is that the patient frequently does not acknowledge being sick. The patient may actually be experiencing the sudden onset of serious psychiatric illness; not uncommonly, however, symptoms are long-standing but are undiagnosed, until some event brings the patient's behavior to the attention of others. At that point the patient is brought on an emergency basis. The patient may be quite resistant to the notion that he has any psychiatric disorder and will not cooperate with any examination or treatment.

Medical Assessment Four elements in the traditional physical examination will help to rule out significant medical illness: specific historical data, vital signs, certain physical signs, and the mental status examination. The following findings should direct attention to medical evaluation, and carry particular weight when there is no additional medical assessment, as in a psychiatric clinic or with a mobile treatment team.

HISTORY The presence of medical illness should be strongly considered when psychiatric symptoms appear suddenly in a previously well-functioning person. Symptoms significantly different from a patient's usual ones in a patient with long-term mental illness also suggest medical illness or drug reaction. A patient over the age of 30, with psychotic symptoms appearing for the first time, an awareness or conviction that these symptoms are foreign, and especially with concomitant symptoms of cognitive dysfunction should be considered to have a possible organic illness. Clinicians should consider medical and substance–related causes when a patient has a history of a recently diagnosed medical illness, a new prescription, or a change in dosage. A personality change or marked lability of mood noticed by friends or relatives also suggest the onset of a serious medical condition.

PHYSICAL FINDINGS Vital signs should be obtained on admission to the emergency department, even when the patient appears physically healthy or is intimidating because of disturbed behavior. Psychiatric disorders do not affect vital signs to a significant degree; therefore, abnormal vital signs must be further evaluated by a history, physical examination, and appropriate laboratory tests. Elevation of temperature, pulse, or respiratory rate suggests an underlying medical condition. Certain physical findings strongly suggest an organic disorder, including lateralizing neurological symptoms, confusion, and incontinence. Table 29.2-2 lists common medical conditions that frequently present as psychiatric emergencies and may be marked by abnormal vital signs. Table 29.2-3 lists those conditions that, although not common, may also appear initially as psychiatric problems. Delay in recognizing them can be life-threatening. The laboratory tests listed in Table 29.2-4 may clarify the diagnosis; the psychiatric evaluation can proceed while these tests are pending.

Hypothyroidism	Myocardial infarction
Hyperthyroidism	Alcohol intoxication
Diabetic ketoacidosis	Alcohol withdrawal
Hypoglycemia	Chronic obstructive pulmonary disease
Urinary tract infection	Acute liver disease
Pneumonia	Substance withdrawal

Table 29.2-2 Common Medical Illnesses That Often Present as Psychiatric Emergencies

Myocardial infarction	Hypokalemia
Pulmonary embolism	Hypercalcemia
Subarachnoid hemorrhage	Hypocalcemia
Epidural hemorrhage	Splenic rupture
Cocaine intoxication	Subacute bacterial endocarditis
Amphetamine intoxication	Steroid-induced psychotic disorder
Encephalitis	Phencyclidine-induced psychotic disorder
Malignant hypertension

Complete blood count
Electrolytes
Blood alcohol concentration or breathalyzer
Blood glucose concentration
Calcium level
Urine assay for substances of abuse

Table 29.2-4 Laboratory Studies to Assess Potential Organic Causes of Acutely Altered Behavior

MENTAL STATUS EXAMINATION Several mental status examination formats have been used widely to determine the presence of organic disorder. The most widely used is the mini-mental status. Regardless of the instrument used, the important point is that some assessment of the patient's mental status should be obtained consistently and recorded. The patient's appearance, ability to cooperate in the examination, level of consciousness and whether it changes during the evaluation, the lability of affect, cognition, memory, judgment, and the presence of agitation are important in determining an underlying organic basis for disordered behavior. Table 29.2-5 provides a brief mental-status examination for use in the emergency department. The first five questions relate to the patient's orientation and the rest to the patient's memory, judgment, ability to abstract, and interest in the outside world.

1. What is your name?
2. Do you know where you are?
3. Can you tell me how old you are?
4. What is today's date?
5. How did you get here?
6. Can you tell me why you are here?
7. What do you think you need from us today?
8. Tell me something important that you have heard on the news in the past few days.
9. I am going to give you a five-digit number. (Do so). Please repeat it back to me.
10. Spell the word "marble." Now spell it backwards.

Table 29.2-5 Brief Mental Status Assessment for the Emergency Department

Psychiatric Assessment A psychiatric assessment in the emergency department focuses on four specific questions. What is wrong? Why is the patient seeking treatment now? What was the patient like before? What does the patient expect? It is important to know whether there is a previous psychiatric history in the context of these four questions.

WHAT IS WRONG? A patient experiencing a psychiatric emergency may not be able to tell you what is wrong and may not believe that anything is wrong. Because psychiatric patients do not have obvious injuries or physical illness, and may have normal vital signs, they frequently are asked to wait while other, more obvious emergencies are addressed. One result of this inaccurate triage is that others who might have accompanied the patient and could give useful information may leave before they are seen. Police officers often take these patients to jails or detention centers because they can be relieved of responsibility for them much more quickly than in an emergency department. Always consider that the patient may have an underlying medical condition even in the absence of initial findings.

A 74-year-old widow was brought to the emergency department by a social worker who wanted the patient hospitalized until an alternative placement could be arranged as the patient had been evicted from her apartment. Questioning determined that the patient had been evicted from 30 or more residences in the previous five years for creating disturbances that upset other tenants. The patient explained that she stayed awake every night in order to bang on the walls with a broom to keep a gypsy from entering her apartment and spraying her with a poisonous substance. She stated that this harassment had been going on since her husband died, and that she knew it was continuing because when she did fall asleep, she would awaken in the morning to find her legs swollen. A mental status examination was remarkably normal except for that delusion. Medical evaluation revealed congestive heart failure, which quickly responded to digitalis. The patient was placed in a senior citizens' apartment complex without further problems.

A 39-year-old patient was brought to the emergency department stating that she was the “bionic woman.” She did not further clarify that description, but said that her primary concern was her difficulty unlocking the door when she arrived at work that morning. She thought that she should be evaluated by a doctor. Her vital signs were reported as within normal limits, including a temperature of 35°C, blood pressure of 100/40 mm Hg, and a respiratory rate of 15 per minute. Because she looked somewhat disheveled and seemed to be an unreliable historian, the decision was made to hospitalize her on the psychiatric unit of the general hospital, where she received her first physical examination. She was noted to have sparse body hair (she had been wearing a wig), her vital signs were as reported, and she had distinctly hypoactive reflexes. She also had a 14-inch well-healed horizontal scar at the base of her neck, which she said was a result of a thyroidectomy some 20 years earlier. Laboratory studies confirmed that she had virtually no endogenous thyroid hormone. Thyroid replacement led to complete recovery.

WHY NOW? What has changed? Even though it is very helpful to ask this question in a usual outpatient evaluation, in a psychiatric emergency it is essential to know the specific precipitant for the visit at that particular time in order to make a reasonable recommendation for further treatment. For example, a patient may present to the emergency department distraught and depressed. If the psychiatrist has not asked the relevant questions that reveal that the patient's therapist has just left for vacation, a lot of time may be spent in trying to arrange a disposition to outpatient treatment that is not appropriate and will not be effective because it does not address the acute symptoms. A long-term mentally ill patient might appear to need hospitalization when actually the patient has undergone a recent trauma, and needs some crisis intervention in the form of understanding about how difficult the experience was. The insidious onset of a chronic mental illness may only come to the attention of professionals when something untoward has occurred in the environment; the letter carrier, a visiting relative, or a teacher notices that something is amiss and forces the family, who had been ignoring bizarre or isolative behavior for several weeks, to take action. A patient who is known to have a psychiatric illness or who has been prescribed psychotropic medication may exhibit new psychiatric symptoms that are related to a change in the medication or to a drug-drug interaction rather than to the illness.

A familiar experience for house officers in the emergency department is a sudden surge in psychiatric emergencies in July of each year, when residents complete training and transfer their patients to new therapists. The phenomenon of a crisis reaction in response to the loss of a therapist is generalizable to the loss of any empathic caretaker, including an internist, nurse, or relative. Asking why the patient did not contact the previous therapist at this time can quickly get to the root of the present crisis, and often point the way to a more effective intervention.

The time of day that patients come to the emergency department is often an implied expression of their wish for a particular disposition. Patients and families of psychiatric patients who arrive after normal business hours often know that the community mental health clinic or the admitting office to the state hospital is closed, and that the records from a therapist might be more difficult to obtain, forcing an admission that in working hours could be averted.

A 70-year-old woman was depressed following the death of her husband. She lived alone, and although some family members were concerned that she had a significant mental problem, they lived in another city and could not convince nearby relatives and friends that there was something seriously wrong. When her visiting nurse went on vacation, the woman did not recognize the substitute who was sent. She became paranoid and threatened suicide. The substitute visiting nurse immediately arranged to have the patient brought to an emergency department. Thus, although the illness and deterioration had been going on for over a year, it was only the change of the evaluator that defined the situation as an emergency.

A 16-year-old boy became reclusive, and for several months refused to attend school or to participate with his family in any activities, including eating meals or watching television with them or accompanying them on visits to relatives. The family was dysfunctional and ignored the son's abnormal behavior, even allowing him to eat his meals in his room. When a letter carrier arrived with a special delivery letter and found the doorbell answered by a naked, disheveled, and bizarre-looking young man (the rest of the family was out), he notified the city's Department of Social Services. The agency responded immediately by sending an ambulance to bring the boy into the emergency department for evaluation. Although the disorder, paranoid schizophrenia, was well established by that point, it was perceived as an emergency only because a new observer had witnessed the strange behavior.

WHAT WAS THE PATIENT LIKE BEFORE? The primary goals for the emergency intervention is to reestablish the patient's baseline, to place the patient appropriately within the system of health care delivery and to minimize future use of the emergency services. It may be very difficult to determine a baseline when a patient is floridly psychotic, especially if no background information is available. Police or paramedics who brought the patient in or a mobile treatment team that has seen the patient's current living situation may be very helpful in this regard. How the patient is dressed, the level of language used, or the patient's description of daily activities are clues to how well the patient was functioning before the onset of the present illness.

WHAT DOES THE PATIENT EXPECT? Patients have an idea of what will happen when they seek treatment, which may be positive or negative, based on previous experiences or on what they have been told. Generally, these expectations are appropriate or at least directly related to their presenting complaint, for instance to be cured, to achieve symptomatic relief, or to get a prescription. However, when a recommendation has been made or a treatment plan is begun and the patient still seems very distressed, or when the patient returns to the emergency department within the next few hours or days with a fairly similar complaint, it is possible that there were unspoken expectations that had not been considered initially. For instance, the patient may expect to be hospitalized, even arriving with a packed suitcase, when the presenting complaint did not warrant hospitalization. The patient may want a prescription, a letter permitting him to miss work, or a call made to a girlfriend or parents “explaining” some inappropriate behavior or failure. As described earlier, the patient may have the magical expectation that in every medical evaluation, the doctor will have had the foresight to look for and rule out acquired immune deficiency syndrome (AIDS) or cancer. Patients are generally reluctant to ask directly for anything that feels like an excessive demand, especially when it is out of the boundaries of direct medical care. While they may have no trouble requesting, or even demanding a prescription, or an additional lab test, they may find it harder to request a letter for an employer or completion of an insurance form; they may expect physicians to read their minds. These issues appear in most doctor-patient interactions, but are more apparent an emergency because there has not been an established relationship in which these elements have been worked out.

A 47-year-old woman with schizophrenia, chronic paranoid type, presented to the emergency department incoherent and physically out of control. She walked in a bizarre fashion, and periodically her knees would appear to collapse. The psychiatrist recognized her, and was aware that there were no beds available that day on the psychiatric unit. She told this to the patient, and offered intensive outpatient treatment instead. At that point, the patient fled into the main hospital lobby reciting the Lord's Prayer loudly, attracting attention from passersby. The psychiatrist followed her and reiterated that no beds were available, but offered the patient some additional neuroleptic that evening, promising that she would be hospitalized on the following day if it was necessary. The patient became quite coherent and cooperative then, explaining that her son was graduating from high school the next day, and that she was overwhelmed at the thought of trying to provide some sort of celebration for him. The psychiatrist offered to write a doctor's excuse insisting that the patient's medical condition mandated bed rest, and prohibiting a celebration at home. With this note the patient was able to leave the emergency department, and was seen the next day in outpatient follow-up with marked clearing of her inappropriate behavior.

A 50-year-old man with schizophrenia, chronic paranoid type, well-known to the community mental health clinic, staggered into the waiting room clutching his chest, from which serosanguinous fluid was oozing. Clinic personnel sat him in a wheelchair, and ran to call the police, assuming that he had been stabbed. The psychiatrist approached the patient and asked what the problem was. It was determined that the patient had recently had surgery for an emphysematous bleb, and when the wound began to ooze he was reluctant to return to the hospital, choosing instead to come to his familiar clinic for help, knowing he would be cared for and listened to there.

Management of the Psychiatric Emergency Patient After the initial evaluation, when it has been determined that the problem is primarily psychiatric, the physician needs to decide how extensive an intervention to implement. Practical techniques to facilitate recovery focus on diminishing the emergency and defusing the problem sufficiently to allow the patient to utilize more traditional treatments. The goal is not necessarily complete resolution of the patient's problem, but enough clarification of the problem that the solution is evident. This may be accomplished over several visits.

Crisis Intervention During a crisis, the fluid nature of events offers the opportunity to effect major changes in problem-solving that would not occur during more stable periods. If maturation is thought of as a process of mastering small crises over time, then crises are the windows in which growth occurs; the patient does not simply return to a prior baseline when the crisis is over. The emergency psychiatrist provides stability for the distressed patient, and within that relationship helps to identify the elements of the problem, assess the critical issues, consider more effective options, and arrive at a solution.

One group of patients that has been found to respond unexpectedly well to crisis intervention is the seriously or chronically mentally ill, who, in the words of an old joke, may be crazy but are not stupid. It has been shown that addressing the specific emergency with the patient often results in rapid clearing of psychotic symptoms.

In general, the criteria for recommending crisis intervention or brief therapy are a clear precipitant for the patient's decompensation, strong social supports, and good premorbid function. The premise on which the following form of crisis intervention is based is that the reason the patient has been unable to cope with the precipitant was unpreparedness. In brief therapy, a temporary therapeutic relationship with the psychiatrist or other mental health professional will be provided, which will then terminate. However, this termination will be defined either by a termination date or a specific number of sessions so that it can be anticipated, talked about, and mastered. In brief therapy the patient is first encouraged to talk about the acute event, repeatedly and in detail, and then, in the context of planning for the termination of therapy, to discuss how life will go on hereafter.

During brief treatment two lines of thought will be evident: first, the patient will talk about all aspects of the precipitating event, such as the patient's ambivalence, fantasies the patient may have had about anticipating or foretelling the event; and guilt, embarrassment, or subsequent symptoms. Ideally, the patient will then be able to express some anger, (e.g., “Why did she die and leave me!”) More often the anger comes in the form of a metaphor, expressed as abandonment by the therapist, especially around termination. The therapist can point this out as being a displacement from the precipitating event, and continue to facilitate the patient's expression of understandable feelings. When the total treatment time has been defined at the outset, it appears that patients go through the same process and with nearly the same results even in therapy lasting one emergency department visit.

The application of crisis intervention is limited by the ability of the physician who sees the patient initially to see patients in follow-up visits. Relative contraindications to brief therapy are overwhelming suicidal thoughts, poor premorbid functioning, or continuing deterioration over the first two or three sessions. Ideally, if medication seems necessary, it should not be prescribed until the patient has been seen and reassessed in a second session, enabling the psychiatrist to determine the patient's capacity to engage in and profit from the therapeutic alliance.

A 23-year-old building and grounds engineer came to the emergency department complaining of nightmares and panic attacks. He dated the onset of these symptoms to an assault at work at an apartment complex; a man who appeared intoxicated came running at him waving a handgun. The patient fled in his truck and returned to the office of the city housing department, his employer. He described the above episode, gave a detailed description of the assailant, and went home. Over the next several days, he called the office each morning to find out what action they had taken on his complaint. When he met repeatedly with an apparent lack of response, especially coupled with a threat that he would lose his job if he didn't return to work soon, he began to have difficulty sleeping. On the morning that his sick leave expired, he got into his truck to return to work, but within minutes experienced tightness in his chest, shortness of breath, and profound sweating. As unlikely as he knew that was, he feared that he was having a heart attack and drove himself to the hospital. On the initial visit he was evaluated for a cardiac event; findings were negative and he was discharged without follow-up. After the fourth panic attack he decided to seek psychiatric consultation. Therapy, which was completed in four 45-minute sessions in the emergency department, consisted of detailed inquiry into the episode, followed by a similarly detailed discussion of his attitudes about his job. The nightmares changed character from his view of himself as a passive victim to viewing himself as empowered, and then stopped altogether. He also explored other job possibilities, and within one month began work at a higher paying and more challenging job, much more suited to his educational background and abilities.

Emergency Pharmacotherapy Emergency pharmacotherapy is an important adjunct for stabilization of the psychiatric emergency. However, there are several good arguments for caution in the use of medications in the emergency department. If the patient has a chronic psychiatric illness, medical management should be entirely handled by the system that oversees the patient's care. The emergency management of such a patient should be directed towards determining what went wrong within the system that allowed the patient to run out of medications, decompensate, or otherwise fail treatment. Any response that does not take the system failure into account ensures the likelihood of a repetition. If the patient is new to the mental health system or has an acute, new condition, the ideal management would be to enroll the patient with a therapist or clinic as soon as possible, possibly observing him for 24 to 72 hours or having him return to the emergency department several times over the next few days to determine whether the medication is working. If emergency hospitalization is required, administering medication before transferring the patient to the hospital may obscure the presenting symptoms.

A patient should be medicated only for definite target symptoms. Just as morphine can obscure the diagnostic landmarks in an acute abdomen, antipsychotic medication will modify psychotic symptoms caused by a general medical condition just as effectively as in a functional psychosis, without clarifying the diagnosis. Overmedication may delay evaluation by several hours. Acute depressive symptoms might respond to the interpersonal interaction with a psychiatrist alone; prescribing an antidepressant prematurely may blur both the diagnosis and the need for medication.

Under the following circumstances, medication should be administered to the patient in the emergency department.

1. The patient is out of control, and less intrusive means, including a quiet room, the presence of staff members, or restraints, have been used with minimal effectiveness.
2. The patient's behavior is beginning to compromise evaluation or the care of other patients in the area.
3. Medication is being used to control psychotic symptoms that would otherwise interfere with further workup.
4. The cause of the patient's symptoms is established and medication is indicated to gain the patient's cooperation for further care.
5. Medication increases the patient's ability or willingness to cooperate for transfer to a psychiatric facility that has already agreed to accept the patient.
6. The patient is enrolled in a care system that will be responsible for follow-up.

Noncompliance with medications is the major factor in decompensation of the chronically mentally ill patient. Although hospitalization may be averted by resuming the regularly prescribed medication, in order to prevent subsequent decompensations it is very important to determine why the patient had discontinued medication or missed appointment.

RAPID TRANQUILIZATION An acutely agitated or psychotic patient can be calmed in a very short period of time. For several years various protocols for rapid neuroleptization were promulgated; however, it was never demonstrated that rapid relief of acute psychosis led to shorter hospitalizations or that it was in the best interests of the patient to use this treatment. A common practice in the United States is to administer high-potency dopamine receptor antagonist, intramuscularly if necessary, and a benzodiazepine concurrently. This allows for a lower dose of the antipsychotic, and a decreased likelihood of extrapyramidal adverse effects. Although there are as yet no controlled studies regarding the use of the newer seroton-dopamine antagonists or anticonvulsants in emergency room settings, their efficacy and relative lack of extrapyramidal symptoms make them potentially useful alternatives.

Decision to Hospitalize A great deal of time is spent in the emergency department to determine if hospitalization is indicated for a given patient. Locating a bed, obtaining the patient's consent or completing paperwork for certification of the need for hospitalization, procuring a bed, arranging transportation, and verifying the patient's insurance status, especially when the hospitalization must be preauthorized, triples the amount of time spent on psychiatric patients in comparison to the general emergency department caseload. Although alternatives to hospitalization may appear to provide more humane care for patients, they are not well developed yet in most cities.

The efficacy and cost-effectiveness of alternative interventions remain to be proved. Professional involvement is intense, and is not necessarily rewarded by an improved outcome. For patients with a history of prior hospitalizations, costs, outcome and subsequent hospitalization rates are not improved by aggressive outpatient crisis management. The decision to hospitalize a patient is influenced more by the inability of social support systems to deal with disturbed and disturbing behavior than on the patient's diagnosis or severity of symptoms. Enrollees in prepaid health plans are less likely to be hospitalized than are patients with conventional insurance, but this may have more to do with the continuity of care than with restrictions of capitated plans. Ideally, an emergency psychiatric hospitalization should be reserved for patients whose long-term outcome will be otherwise compromised, such as by suicide, drug reactions, or other life-threatening situations.

SPECIAL PROBLEMS

Violence Violent and potentially violent patients evoke anxiety, with the consequence that they may be treated punitively. This includes prescribing neuroleptic drugs before the patient has been adequately evaluated, and in doses that may be dangerously high. Predictors of violence are unreliable, although some protocols have been developed to identify warning signs and useful responses to them, and thus theoretically to minimize violence in the emergency department. Although psychiatric disorders account for a significant number of violent incidents, notable contributors to violence are intoxication, brain injury, or a metabolic disturbance. The environment of the emergency department, which often is noisy, bright, loud, and intense, may drive patients who are already struggling with control over their behavior to become violent.

Management Prevention of violence is easier than regaining control after a patient has caused harm. A protocol for control of violence is effective not only for managing the patient but also for reassuring the staff. At the first indication of threatening behavior, the patient needs to be confronted with the fact that such behavior is frightening and may interfere with provision of care. Ideally, one member of the staff should be the designated spokesperson in these situations. If patients are not able to demonstrate an ability to conform their behavior to the needs of the emergency department, they must be restrained in a humane manner until an adequate evaluation of the reason for the emergency department visit can be completed. Leather restraints and an isolated, quiet area are essential to the management of such patients. Short-term sedation, generally with benzodiazepines, is the common practice in the United States, particularly when there is a suspicion that substance abuse underlies the behavior. Consequences for belligerent, violent, and destructive behavior may include pressing assault charges after the patient's medical needs have been addressed.

Acute Psychosis An acutely psychotic patient, possibly responding to auditory or visual hallucinations, may have a chronic psychiatric illness, or the psychotic symptoms may be an expression of a life-threatening medical condition, injury, or intoxication.

Management Psychotic symptoms may be aggravated by the excitement of the emergency department; the patient may also be paranoid and may interpret offers of help as threats and intrusions. Such patients should be moved from a more stimulating to a less stimulating environment, where they can be evaluated for the presence of an underlying treatable medical condition. If this is a first episode of psychotic symptoms or if these symptoms represent a significant change for a psychiatric patient, this workup is crucial. In addition, serious medical illness may precipitate relapse of a long-standing psychiatric illness.

Unrecognized Depression Multiple vague somatic complaints are common in the emergency department. These are the patients who frequently irritate the nonpsychiatrist because nothing seems to be wrong. Backache, headache, sleep disturbance, stomach upsets, and fatigue do not lend themselves to resolution by laboratory tests, X-rays, or specific diagnosis. Because women are more likely to present with such complaints than are men, they are also regarded less seriously by physicians. When the psychiatrist is consulted it is more often because nothing can be found than because the emergency physician believes the patient has an underlying psychiatric problem. The most likely diagnosis is a depressive disorder, although multiple somatic complaints are also an early harbinger of schizophrenia. Victims of domestic violence and parents who are physically abusing their children also may seek treatment in emergency departments, unwilling or unable to state the true problem but hoping that the physician will recognize their distress. Patients who also fear that they have a very serious underlying medical problem such as cancer or AIDS, but have no specific symptoms of those diseases seek multiple medical evaluations believing that one of these visits will confirm their worst fears. These patients may be depressed, hypochondriacal, psychotic, suffering from somatization disorders or personality disorders, or they may have experienced the death of someone close to them recently, in particular from cancer or AIDS.

Management A patient with multiple or nonspecific physical complaints often experiences relief when the problem is identified as depression. However, depressive disorders are frequently chronic or recurrent illnesses, and should not be treated as an emergency. After determining that there is no threat to life, such as from suicidal ideation or intent, the patient should be referred to an appropriate clinic or therapist for definitive treatment. In terms of the long-term relationship with the emergency physician, the psychiatrist should provide some feedback about the features that distinguish the various possible diagnoses, hopefully minimizing the laboratory tests that reinforce the patient's belief in the existence of a serious medical problem.

Adjustment Disorder Adjustment disorders arising from change and conflict are common occurrences. Although the most common precipitants of an adjustment disorder are changes in relationships, such as through divorce or death, patients who endure a severe medical illness or physical trauma will frequently develop significant psychiatric symptoms, also generally in the form of an adjustment disorder. Sometimes the symptoms arise months after the event, and the patient is unaware of the connection. The patient presents to an emergency department with symptoms of acute anxiety or symptoms of the earlier illness that no longer is present.

The friends and relatives of patients who are being treated for severe injuries or illnesses, or who die in a disaster or after resuscitative efforts in the emergency department, and the survivors of a disaster who suffer minimal or no physical sequelae, experience acute stress reactions. When the symptoms become disabling,

resulting in significant disruption of daily life, physical symptoms, or excess substance use, the patient may seek treatment.

Management Professional intervention is generally not needed for acute stress reactions, and premature intervention of a prophylactic nature may even interfere with a person's ability to master the events. Brief psychotherapy is a very effective treatment for uncomplicated adjustment disorders, and can be administered in an emergency department or in more traditional psychiatric treatment settings.

Substance Abuse Substance abuse as the presenting problem or as a complication of other emergency department presentations is frequent; it is also frequently undetected. Over half of the patients seen in the emergency department because of traumatic injuries sustained in fights or vehicular accidents or because of self-inflicted wounds have positive results to an alcohol or drug screen. The estimates of intoxication in psychiatric emergency patients ranges from 4 to 20 percent. Homelessness and unemployment are more frequent among intoxicated patients, who are predominantly male. Comorbid psychiatric diagnoses seen commonly in the emergency department are panic attacks, anxiety disorders, and depressive disorders. Although alcohol is still the most commonly abused substance, stimulant abuse and intoxication is also frequent.

Management A high index of suspicion and drug and alcohol screens will detect many patients who deny substance abuse or who do not volunteer this information to the physician. Although patients commonly will not follow through on referrals to substance abuse treatment programs, confrontation when there is laboratory confirmation and consistent referrals to established treatment offer the best outcome. Most patients who are not identified or confronted as substance abusers and are not referred to appropriate treatment centers will continue their substance abuse behavior.

Anxiety Disorders and Panic Attacks Patients experiencing anxiety disorders and panic attacks commonly perceive them as acute medical episodes, believing that they are having a heart attack, pulmonary embolism, or other life-threatening event. Hyperventilation may also induce symptoms similar to panic attacks, including lightheadedness, dizziness, shortness of breath, paresthesias, and tingling about the mouth. Patients who have begun to abuse minor tranquilizers for relief of anxiety symptoms seek those medications from many sources, including the emergency department. Anxiety is also a prominent symptom of withdrawal from a wide variety of substances, including nicotine and caffeine.

Management When the true cause of the symptoms is recognized, expensive and unnecessary medical tests, which are often countertherapeutic, can be avoided. The emergency treatment of hyperventilation is straightforward. The cause of the patient's symptoms are explained as rapid breathing, which can be treated by rebreathing into a paper bag. That maneuver causes carbon dioxide to build up in the patient's circulation, which will abort the symptoms. Patients often experience great psychological as well as physical relief from their symptoms by this treatment because it is so concrete and effective. Long-term treatment of anxiety disorders and panic attacks should not be instituted in the emergency department, because the abuse potential for the medications used in treatment of these problems is so high. Such patients should be referred to a psychiatrist or psychiatric clinic for more definitive care of these illnesses.

AIDS AIDS remains the modern-day plague. Because of the high incidence of substance abuse among emergency department patients, there is an increased potential for exposure of emergency personnel to the human immunodeficiency virus (HIV). Universal precautions, including gowns, gloves, and goggles, have become the standard in most emergency departments.

Whatever the initial presentation, AIDS ultimately affects the central nervous system, either directly or secondarily, and so psychiatrists are frequently consulted. Sometimes the first symptoms of the illness are psychiatric, ranging from depression, confusion, or psychosis to sudden delirium. In addition, AIDS patients are especially vulnerable to acute grief reactions to the initial diagnosis, sometimes confounded by the fact that they have seen others who died from AIDS. Encephalopathy is diagnosed before death in as many as 30 to 40 percent of AIDS patients; at postmortem up to twice that number have evidence of central nervous system involvement. Many patients who are at risk may present to emergency departments wanting to be examined or tested because they fear that they have acquired the virus.

Management A careful history may rule out the possibility of exposure to HIV, but patients may remain anxious until there is verification by laboratory testing. Now that home tests are available, this may become less of a problem, but the underlying issue is still the patient's anxiety. This may respond to an emergency intervention, but may require referral to a psychiatric follow-up. For the patient who has an AIDS-related psychiatric disorder, treatment is specific to the presenting symptoms and the overall medical needs of the patient.

SPECIAL POPULATIONS

Trauma Victims Victims of assault are generally brought to the emergency department if there are physical injuries. In a large majority of patients who have been mugged or raped, the physical injuries are minor but the psychological wounds are profound and long-lasting. When the psychological reactions to such traumas are recognized early, treatment can prevent years of dysfunction, nightmares, flashbacks, and substance abuse, and even save marriages and lives. Long-term follow-up of rape victims demonstrates persistence of guilt feelings, low self-esteem, phobias, and irrational lifestyle changes years after the event. The emergency physician sometimes realizes that a traumatic injury was a suicide attempt, either intentional or covertly, and consults a psychiatrist.

Domestic violence is a serious emergency department problem. Some studies suggest that 20 percent of emergency department patients are there because of injuries inflicted by a spouse. Victims of domestic violence may have classic injuries of domestic abuse, or may present with vague complaints such as headache, backache, fatigue, depression or “nerves.”

Management Brief psychotherapy techniques enable many trauma patients to resume good functioning quickly. Victims of rape or domestic violence can be referred to advocacy groups that provide counseling, legal advice, and support for the prosecution of the offender. A few programs provide financial compensation to victims of crimes. Potentially suicidal or self-destructive behavior should be evaluated carefully.

Much like the battered child syndrome, the constellation of symptoms that point to underlying domestic violence may be missed unless there is a high index of suspicion. When the physician fails to identify the domestic violence that underlies the patient's injuries, the patient may be subjected to further injury upon returning home. The abusive spouse, enraged by the prospect of being discovered, may beat the spouse or lover again upon finding out that she has been to an emergency department, even though she did not divulge the fact of abuse to the physician. A patient who has been the victim of domestic violence severe enough to warrant emergency department treatment should be encouraged to take legal action, enter a safe house, or otherwise take steps to be protected from further abuse. Like the patient with a primary substance abuse problem, the victim of domestic violence may require repeated recommendations over a number of emergency department visits to acknowledge that this is a serious life-threatening problem, and that some action needs to be taken to change this.

Emergency Room Repeaters A familiar group of patients, well known to emergency department personnel, show up for a host of problems ranging from trivial complaints to serious ones on such a regular basis that they are known as *repeaters* or even as “groupies.” The staff may regard them with bemused concern, or may feel irritated and taken advantage of when the patient's complaints do not appear to warrant emergency care. Repeaters tend to have psychiatric diagnoses, and in comparison to other patients are significantly more likely to have homicidal or suicidal thoughts, to be intoxicated, and to have a primary diagnosis of substance abuse or schizophrenia. They are also more likely to have had a history of previous psychiatric treatment and psychiatric hospitalizations.

Management When a patient is recognized as a repeater in that visits are frequent, complaints appear trivial, and the patient has not followed any of the instructions for follow-up from previous visits, the emergency department staff needs to discuss their own behavior with regard to previous management of that patient. Potential issues include determining whether they have overlooked an underlying problem (such as organic brain disorder or substance abuse), why there might have been a breakdown in the prior treatment plan or whether the referral was not feasible for the patient, (e.g., because of cost, distance, or unavailability), or whether the patient has been made to feel special in some way. Otherwise, repeaters may evoke frustration that can lead to inappropriate management, which in turn may be life-threatening. The staff must be consistent in their approach, exploring the present cause for the visit and making an appropriate recommendation for follow-up. Mobile treatment programs and integration of emergency services with community mental health treatment programs may minimize repeated visits to the emergency department by chronically mentally ill patients who are in crisis, by identifying crises very early or even preventing them by aggressive case management.

Homeless Mentally Ill It is estimated that 25 to 35 percent of homeless persons suffer from serious, chronic mental illness. Lack of an address interferes with the ability of a homeless individual to receive ongoing care in a psychiatric clinic; furthermore, when there is a daily struggle to find food and shelter a scheduled clinic appointment may not be a priority. In the past few years medical assistance programs in many states have been privatized, meaning that patients must obtain referrals for any specialty care from a health maintenance organization, as well as preapproval for emergency department visits. Whether this will be beneficial or detrimental

to the homeless mentally ill remains to be seen.

Management Treatment in the emergency department should focus on the presenting problem, but follow-up is problematic. In recent years programs in several major cities have addressed the medical problems of the homeless by initiating contact with them on the street or in shelters, acknowledging their need for flexibility in outpatient care, and obtaining medical and other benefits on their behalf to improve access to care and to fill prescriptions. When such patients are able to obtain funds through welfare or other social programs and obtain housing, it is important that such artificial boundaries as catchment areas not interfere with the continuity of care they may have been receiving. There is some evidence that assertive case management improves the patient's long-term quality of life, decreases thought disorder, and increases appropriate interaction with others in the community.

Chronically Ill Young Adults These patients are often brought to emergency departments by families who have become frustrated by the cycle of improvement in the hospital, followed by decompensation when the patient is discharged and discontinues medication. Another large group of chronically ill young adults have lost contact with their families, live a somewhat nomadic existence, and like the homeless mentally ill struggle daily for survival, rather than for good medical care. Many have developed mental disorders due to a general medical condition (e.g., head trauma) and substance-induced disorders.

Management On each visit to the emergency department, the patient must be evaluated for any change in symptoms and for threats to life, such as suicidal ideation. Subsequently, good communication with the appropriate community mental health center, psychosocial rehabilitation program, day treatment program, or sheltered workshop can minimize inappropriate use of the emergency department. An assertive community treatment team and safe, supervised housing can also be helpful for this group of patients.

Elderly Patients Patients over 75 are over one and a half times more likely to seek treatment in an emergency department than the average patient. The usual geriatric patient is a single white female. Entry to the emergency department is more likely to be driven by the frustration of caregivers than by self-referral. In the emergency department the elderly use medical, social, and psychiatric resources disproportionately, and are more likely to need hospitalization because they are more likely to have multiple medical problems, a prior psychiatric history, be on multiple medications, have limited financial resources, and be socially isolated. The most common reason for bringing an elderly patient to the emergency department is unusual or disturbing behavior, which has been present for 6 months or more; the most frequent diagnosis is major depressive disorder. An often-overlooked additional factor to the deterioration of a geriatric patient's function is the overuse of alcohol. Adverse effects or complications from medication are also a frequent contribution.

Management Treatment is targeted to the patient's presenting problem. Because of the greater likelihood of medical illness, drug reaction, or combinations of these producing or contributing to the psychiatric picture, it is strongly recommended that elderly patients be evaluated for medical illness and substance-related causes whenever there is a behavioral change. The brief mental status evaluations referred to earlier should be incorporated into every evaluation of a geriatric patient. Because a change in environment may be confusing or even dangerous for an elderly patient who may have impaired vision and hearing, hospitalization should be avoided. A better alternative is brief, intensive treatment in the emergency department or a short-stay unit, perhaps combined with home visits by nursing, social services, or mobile treatment teams. Family consultation is useful. Coordination of treatment by a generalist, nurse, or social worker maximizes the quality of life for the elderly and for their families.

Children and Adolescents Unlike the modal adult patient in the emergency department, children and adolescents generally reside with one or more other members of a family, and it is commonly within the context of a family crisis that the emergency arises. When children or adolescents come to emergency departments unaccompanied, it is likely that physical or sexual abuse is occurring in the family. Over the past several years the suicide rate for adolescents has gone up, and suicide attempts, gestures, and ideation occur about twice as often as in an adult emergency population. Substance abuse and intoxication are frequent precipitants for emergency department visits.

Management Treatment is focused on the presenting problem. The problems of children and adolescents who present as emergencies are frequently attributable to family crises, and in those instances are best dealt with as system issues in the family. Unless it is obvious that serious physical or sexual abuse is occurring within the family, the child or adolescent patient should be treated like a soldier in wartime would be; rapid intervention as close to the “front line” as possible has the greatest chance of being effective, in terms of the immediate result and of longer-term general functioning. Removing a child from a family abruptly results in many long-term problems of stigmatization, loss of self-esteem, and subsequent difficulties in reintegrating with the family and the community. Adolescents who have separated from their families, emotionally if not physically, can be managed in their own right. This may require attention to problems such as locating housing, funding, and arranging follow-up care.

ETHICAL ISSUES

Because decisions in emergency psychiatry often need to be made quickly and with limited information, it is imperative that the physician considers life-threatening illness, the stigma associated with a diagnosis of mental illness and with hospitalization in a psychiatric facility, and the interests of the society at large. The person making these decisions must be free of institutional pressures, such as filling hospital beds or meeting financial goals. Legal considerations should not divert the psychiatrist from making a medically or psychiatrically appropriate recommendation. In general, there is a wide legal latitude when medical decisions are made in an emergency situation. Emergency psychiatry is often relegated to very junior faculty or relatively inexperienced psychiatry residents. In light of the weight of the decisions to be made and the complexity of many emergency patient presentations, there should be sufficient opportunity for supervision and consultation from experienced clinicians.

RESEARCH AND EVALUATION

Research to date has focused on demographics, decision-making, and the emergency use of medication. The prediction and management of violence, recidivism, comorbidity, and staffing have been addressed in some studies. Specific demographic populations, such as the elderly, children and adolescents, and the homeless have been the subjects of several studies. Current and future research directions include exploration of the resources of electronic information storage and transmission for rapid retrieval of updated information in the emergency setting while preserving confidentiality. Measurements of the outcome of emergency interventions and seeing what types of information improve the patient's outcome and the cost-effectiveness of various emergency interventions are also important areas for future research. Effective research in these areas will be enhanced by standardizing clinician variables in diagnosis, decision-making, and treatment. The changing face of health care delivery, with the privatization of medical assistance and veteran patient populations, will further drive research to look at cost-effective emergency treatments; because of capitation in general medical service provision it will be important to study utilization of primary care services for patients who access the emergency department. Further research is needed also on the cost and impact of mobile crisis intervention programs, continuous-care teams, and the use of newer neuroleptic agents in the emergency setting. For the dual-diagnosis patient, research needs to be conducted on integrated treatment efforts, and on such patient's recidivism, number of crises, and use of the emergency department.

Table 29.2-6 lists in alphabetical order common psychiatric emergencies.

Table 29.2-6 Common Psychiatric Emergencies

SUGGESTED CROSS-REFERENCES

Mood disorders are discussed in Chapter 14, panic disorders in Section 17.1, generalized anxiety disorder in Chapter 15, adjustment disorders in Chapter 23, and the psychiatric aspects of AIDS are discussed in Section 2.8. Adult antisocial behavior, criminality, and aggression are discussed in Section 27.3. The traditional psychiatric interview is described in Section 7.1; medical assessment and more exhaustive laboratory testing relevant to the psychiatric patient are covered in Section 7.7. Section 30.8 provides an in-depth discussion of brief dynamic and crisis therapy, and psychopharmacology pertinent to use in the emergency department is discussed in Chapter 31. More detailed information about the presentation and management of the disruptive child and adolescent patient may be found in Chapter 40. A thorough discussion of the geriatric patient may be found in Chapter 51, and special issues, including abuse of the elderly and medical problems that complicate or otherwise contribute to their psychiatric problems, are discussed in Section 51.6g and Section 51.3a. Physical abuse of the adult, including domestic violence, is discussed in Section 28.7. Chapter 11 covers all aspects of substance abuse. Chapter 52 discusses the economic and community aspects of treating the psychiatric patient.

CHAPTER 30. PSYCHOTHERAPIES

30.1 PSYCHOANALYSIS AND PSYCHOANALYTIC PSYCHOTHERAPY

GLEN O. GABBARD, M.D.

Most psychotherapy conducted in the United States derives from psychoanalytic principles. Formal psychoanalysis, usually involving four or five sessions a week with the patient reclining on a couch, is taught in psychoanalytic institutes throughout the country. During his life, Sigmund Freud (1856–1939), the founder of psychoanalysis (Fig. 30.1-1), predicted that the principles of the "talking cure" would ultimately be adapted into forms of psychotherapy. With some trepidation, he recognized that the "pure gold" offered by psychoanalysis would ultimately be "alloyed with the copper of suggestion."

FIGURE 30.1-1 Sigmund Freud in his Vienna office. (Etching by Max Pollak. Courtesy of Menninger Foundation Archives, Topeka, KS.)

Developments in the field since Freud's death suggest that his trepidation was perhaps unwarranted. Psychoanalytic (sometimes called psychodynamic) psychotherapies have been demonstrated to be highly effective and useful treatments for a wide range of disorders. Recent surveys suggest that psychoanalytic psychotherapy is still the major form of psychotherapy taught in training programs and the form of therapy that mental health professionals choose when they seek their own treatment. This modality usually takes place anywhere from one to three times per week, with the patient and therapist sitting face to face. This type of psychotherapy goes by a variety of names, including expressive psychotherapy, expressive-supportive psychotherapy, insight-oriented psychotherapy, intensive psychotherapy, and exploratory psychotherapy. In addition, a variation known as psychoanalytically or psychodynamically informed supportive psychotherapy is also widely practiced. All three of these modalities are considered in this section. Freud and some of his collaborators are pictured in Figure 30.1-2.

FIGURE 30.1-2 Freud with several of his early collaborators. *Top, left to right:* Otto Rank, Karl Abraham, Max Eitingon, Ernest Jones; *bottom, left to right:* Freud, Sandor Ferenczi, Hanns Sachs. (Courtesy of Louis Linn, M.D.)

HISTORY OF THE PSYCHOANALYTIC METHOD

Psychoanalysis is a treatment derived from psychoanalytic theory, the most comprehensive conceptual model of mental life available. It is based on the notion that early childhood experiences are internalized and, in concert with biological urges from within, form a dynamic unconscious that influences behavior, thoughts, and feelings. The term *psychoanalysis* is used to refer to a theory of the mind, a procedure or method of inquiry, and a type of treatment. The last of these three uses is addressed in this section.

Evolution of Freud's Technique Freud's early use of hypnosis was profoundly influenced by his friend and older colleague, Josef Breuer, a Viennese internist (Fig. 30.1-3). In his work with Anna O., Breuer had discovered that when his patient was placed in a hypnotic trance, her symptoms disappeared as a consequence of their verbal expression. Anna O. dubbed this treatment the talking cure. Freud felt he should be more fully trained in hypnotic techniques, so he spent the year 1885 to 1886 with the French neurologist Jean-Martin Charcot at the Salpetrière in Paris. When Freud opened his practice back in Vienna in 1887, he used hypnosis to remove symptoms through suggestion. His results with this technique were less than encouraging, so he shifted to the cathartic method based on Breuer's account of his treatment of Anna O.

FIGURE 30.1-3 Josef Breuer.

Freud's use of this method led to a coauthored work on hysteria in the mid-1890s, called *Studies in Hysteria*. In this contribution Breuer and Freud discussed their theory that repressed ideas outside of conscious awareness were transformed or converted into symptoms. Through a process of recovering and verbalizing affects with which these repressed ideas were associated, they sought to remove symptoms through abreaction.

In the famous case of Frau Emmy von N., Freud attempted to use the cathartic method in conjunction with hypnosis to identify the etiological origins of hysterical symptomatology. She had consulted him for a variety of hysterical complaints, including phobias, delirium, hallucinations, anesthesia and pain in her leg, and an ovarian neuralgia. He suspected that inhibited sexuality played a role in causing her illness. However, he felt the limitations of his cathartic method prevented fuller exploration.

Freud's abreactive strategy was limited; therapeutic benefits did not persist after the physician-patient contact was terminated. He began to recognize that the personal relationship with the physician might be more important to the therapeutic action of the treatment than the specialized hypnotic techniques he had developed. This hypothesis was further confirmed when one of his female patients woke up from a hypnotic trance and threw her arms around him. This incident led Freud to believe that erotic attachment to the physician might potentially be a major therapeutic force in psychoanalytic treatment.

These observations led Freud to his discovery of transference, which remains a key principle of psychoanalytic theory and technique today. *Transference* is generally defined as displacement onto the analyst of the thoughts, feelings, and behavior originally associated with significant figures from the past. He also had an inkling of the dark side of transference in a passage from *Studies in Hysteria*, where he noted that the patient might be “seized by a dread of becoming too much accustomed to the physician personally, of losing her independence in relation to him, and even of perhaps becoming sexually dependent on him.”

Freud's discovery of transference led him to abandon hypnosis, which he viewed as concealing aspects of the transference. In addition, Freud noted that many patients were not amenable to hypnosis, so he developed the *concentration method* to replace it. This technique was developed during the treatment of Elizabeth von R., who was quite resistant to the abreactive technique. Recalling an observation by Hippolyte Bernheim, a hypnotist who was an adversary of Charcot, Freud believed that forgotten memories could be retrieved when the physician asked the appropriate leading questions. Thus he asked Elizabeth von R. to lie down on the couch and close her eyes. Freud pressed his hand on her forehead and told her that she would recall relevant memories when he questioned her about them.

This approach, in turn, led to Freud's discovery of free association, which continues to be a major principle of psychoanalytic technique in modern practice. Freud noted that his interruptions of Elizabeth von R. and his constant injunctions to remember interfered with her spontaneous flow of thought. Elizabeth von R. informed Freud that she could have told him her thoughts all along but she was not sure he wanted to hear them. This comment showed Freud that his own forceful direction had led the patient to censor her thoughts. As a result, he began instructing his patients to say whatever came to mind, without censoring their thoughts. No matter how unpleasant, unacceptable, or seemingly trivial an association seemed, Freud was convinced that these thoughts should be verbalized and understood. At the same time he abandoned his technique of touching the forehead, allowing the patient to lie on a couch and free associate in an unfettered and nondirected way.

These clinical investigations led to two other fundamental psychoanalytic concepts. Freud noted that a number of patients could not be hypnotized, while others could not recall memories or free associate. Freud labeled this unconscious thwarting of the therapeutic technique *resistance*. He then recognized that some patients who were extremely distressed were also resistant to treatment. Freud concluded that active unconscious forces were excluding unacceptable or unpleasant thoughts as well as distressing memories from conscious awareness. Freud called this active force *repression*.

Freud considered repression crucial to the process of symptom formation. He believed that a traumatic experience or series of experiences, often sexual in nature, occurred in the childhood of neurotic patients. These memories were then repressed because they were painful and unacceptable, but the excitement associated with the traumatic events could not be entirely extinguished, and traces persisted in the unconscious as repressed memories. This original excitement eventually is triggered by a contemporary event, such as a disturbing love affair, leading to the return of the repressed in the form of a neurotic symptom.

Post-Freud: Early Twentieth Century to the Present The history and growth of the psychoanalytic movement from classic psychoanalysis to current practices were marked by repeated revisions by Freud himself, as well as by reappraisals and rebellions by neo-Freudian and non-Freudian contemporaries and descendants, as chronically manifest in internecine conflicts over diverse and intricate points of theory and practice (Table 30.1-1). From the beginning, as described by T. Byram Karasu, some analysts have argued against nearly all of Freud's basic conceptual premises, from the strictly sexual etiology of the neuroses to his views on female psychology. Others have reacted more directly to their clinical concerns that too few patients meet the rigorous requirements associated with orthodox psychoanalysis, and they have attempted to make the treatment more widely applicable, affordable, and terminable.

Table 30.1-1 Historical Development of Psychoanalytic Psychotherapy

In the 1920s and 1930s such analysts as Sandor Ferenczi, Otto Rank, and Wilhelm Stekel tried to broaden the applicability of psychoanalysis to a larger clinical spectrum by shortening treatment time (Rank was the first to propose an end-setting time limit) and emphasizing a more active, affective, caretaking approach, particularly with the use of the therapist as a substitute primary object in the treatment of young children. Stekel's Institut für Aktive Analyse (Institute of Active Analysis) was the first organized attempt at psychoanalytically based brief psychotherapy. Those technical innovations culminated in the establishment in the late 1940s of the school of Franz Alexander and Thomas French, the first group to experiment directly with influencing the transference by varying the frequency of sessions and to emphasize face-to-face interviews. Alexander and French defined the major role of the analyst as providing a corrective emotional experience to compensate for early developmental experiences by being different from the patient's parents. However, those therapies soon sparked a major controversy over whether they could still be considered psychoanalysts. Threatened by the widening scope of psychoanalytic technique, the conservative therapists claimed that any departure from a strictly neutral-interpretive stance would drastically compromise treatment.

Secession From Freud With the widespread dissemination of psychodynamic concepts and applications after World War II, a major turning point in psychoanalytic development occurred in the 1950s. As the practice of psychoanalysis broadened to include a great variety of clinical conditions, especially with the extension of classical analysis to psychoses and character disorders, analysts were obliged to alter both their strategies and the theories they used to explain the changes in perspective. Initially, especially in the earlier era of postwar psychiatry, psychoanalysis was applied almost indiscriminantly to a wide range of mental disorders reflecting every degree of severity of illness; during that experimental period analysts began more actively to recognize the limitations of standard methods.

Those critical years saw the expansion in interpersonal, cultural, and phenomenological directions of the psychoanalytic movement. European and American analytic theorists—including Alfred Adler, Otto Rank, Carl Jung, Erich Fromm, Karen Horney, Harry Stack Sullivan, and Medard Boss—separately seceded from Freud (some to form their own schools) and wrought sufficient theoretical changes to challenge and extend the early boundaries of psychoanalysis.

Karasu points out that Horney's rejection of Freud's libido theory of neurosis in favor of a more social orientation led to an interpersonal approach in the analysis of neurotic patients that drew less distinction between analysis and psychotherapy, gave the analyst a more active role, and dispensed with free association and the couch. Sullivan's pioneering work with a population of schizophrenic patients drew attention to their distorted parataxic thinking (illogical causal connections between concurrent events) in adult interpersonal relationships, and he influenced treatment techniques by defining the face-to-face psychiatric interview that fostered the role

of the analyst as participant-observer. Within the framework of existential analysis (e.g., Boss' *Daseinanalysis*) the role of the analyst was further altered by emphasizing the real, here-and-now encounter. Others, who were engaged in the treatment of patients with character problems, began to acknowledge the increasing need to enlarge the scope of treatment by introducing “parameters” (Kurt Eissler's term) that would help such patients in analysis. That technical direction was influenced by the growing effects of ego psychology on the understanding of ego defects and associated problems. Wilhelm Reich's analysis of character armor, as well as Otto Fenichel's investigations of problems of psychoanalytic technique, expanded the analysis of resistances in determining pathological character traits.

Sigmund Freud's daughter Anna had a major influence in the evolution of ego psychology. In her famous observation that “there is depth in the surface,” she stressed that much of the analyst's work involves analyzing defenses against drive derivatives. These defenses typically manifest themselves as resistances in the analytic process. Anna Freud stressed that analysts tended to overvalue a search for deeply repressed unconscious drive derivatives while not recognizing the complexity of the patient's characteristic defenses. Her father had primarily emphasized repression in his discussion of defenses, but Anna Freud elaborated on his work by providing detailed descriptions of a number of additional defense mechanisms, including regression, undoing, identification, projection, introjection, reaction formation, sublimation, reversal, and turning against the self.

Heinz Hartmann further expanded ego psychology by focusing on adaptation. He stressed that a line of ego development existed independent of instinctual drives. Certain primary autonomous ego functions, such as perception, motility, memory, and intelligence, were thought to arise from a conflict-free sphere of the ego. Edith Jacobson integrated ego psychology with object relations theory. Her views were later supported by Margaret Mahler's research on infants and their mothers during the separation-individuation stages of child development.

As ego psychology continued to develop, a number of clinicians felt that indications for analysis could be broadened to include more difficult-to-treat patients. Edward Bibring, Leo Stone, and Eissler were instrumental in defining the margins of the “widening scope” of psychoanalytic technique. In addition, Merton Gill emphasized the crucial importance of analyzing transference in the here and now.

Interest also grew in the real relationship between analyst and patient. Elizabeth Zetzel and Ralph Greenson argued for a nontransferential element in the relationship between analyst and patient, often referred to as the *therapeutic alliance* or *working alliance*. This construct referred to the relatively nonconflictual aspects of the collaboration between analyst and patient toward commonly held treatment goals.

Parallel to these developments of ego psychology in America, object relations theory was evolving in the United Kingdom. Whereas classical Freudian theory from which ego psychology was derived emphasized drive discharge as the most important motivator for the infant, the British object relations theorists viewed object seeking as the fundamental motivation. However, the original object relations theory evolved from the work of Melanie Klein, who linked internal object relations to drives. Relying heavily on the death instinct for her theory, she believed that the infant's fear of annihilation from the death instinct was responsible for a defensive splitting process early in life. Derivatives of the death instinct, such as hatred, sadism, aggression, and envy, are disavowed by the infant and projected into the mother. This internal splitting process leaves the “goodness” within the infant, while the mother becomes a terrifying “bad object” experienced by the infant as persecutory. This paranoid-schizoid position is ultimately resolved when the infant recognizes that the “bad mother” and the “good mother” are the same person. At this point the split-off bad and good qualities are integrated into an ambivalently held whole object. This integration marks the entry into the depressive position, in which children worry that their own destructiveness might damage the mother.

Influenced by Klein, Wilfred Bion emphasized the role of the mother in containment of affects that the infant found difficult to manage. In his view, psychotic anxieties of infancy are metabolized and detoxified by the mother and returned to the infant in a more tolerable form. Through this process of projection and introjection, the infant eventually builds internal structure.

Influenced by Klein and Bion, the so-called independent, or middle group, of object relations theorists evolved in a direction substantially removed from drives. This group, composed of W. R. D. Fairbairn, D.W. Winnicott, Michael Balint, and others, emphasized a theory of deficit rather than conflict in Kleinian theory. In their view insufficient maternal nurturance created what Balint called the basic fault, a feeling in many patients that something is missing. Winnicott felt that just as the mother provided a holding environment to help the child develop awareness of separateness, the analyst needed to provide a holding environment for the patient.

Personality Disorders The patients described by Sigmund Freud generally fell into the category of symptomatic neurotics. Over time psychoanalysts began to see fewer and fewer patients with hysterical, phobic, or anxiety symptoms and more patients who exhibited character neuroses. These patients presented generalized complaints about problems in living, such as difficulties at work or in intimate relationships. The analysis of character began to take precedence over the analysis of a neurotic symptom.

In the late 1960s and early 1970s, a burgeoning literature developed on narcissistic and borderline personality disorders. As a result, the term *character neurosis* became subsumed under a broader category of personality disorders. Character neuroses represent the neurotically organized variants such as obsessive-compulsive and hysterical personality disorders. Narcissistic and borderline personality disorders, representing much of the spectrum commonly seen by psychoanalysts and psychoanalytic therapists, reflect a level of ego organization intermediate between neurosis and psychosis. Otto Kernberg was extremely influential in his systematic descriptions of borderline personality organization. He delineated the following structural characteristics: (1) nonspecific manifestations of ego weakness, including poor anxiety tolerance, poor impulse control, and poorly developed subliminatory channels; (2) a shift toward primary process thinking, particularly under the pressure of strong affects or in unstructured situations, such as projective psychological testing; (3) a pattern of specific defensive operations, including splitting, projective identification, primitive idealization, denial, omnipotence, and devaluation; (4) pathological internalized object relations based on splitting, so that representations of self and others are alternatingly all good or all bad.

Kernberg regarded narcissistic personality disorder as a variant of the borderline condition. He felt that these patients had the same underlying structural organization as the borderline patient but smoother ego functioning related to an integrated and pathologically grandiose self. Heinz Kohut, on the other hand, viewed narcissistic patients as developmentally arrested because of parental failures of empathy in response to the child's phase-appropriate needs for idealization and mirroring. His ideas evolved into self psychology, which involves a different developmental line than classical theory. Kohut regarded narcissistic personality disorders as requiring selfobject responses from others. In other words, these patients require others to perform certain functions for them to make them feel complete. In this regard, the other person is used as an extension of the patient's self. In the psychoanalytic situation, these needs develop into selfobject transferences of mirroring and idealizing. Kohut believed that the analyst must create an empathic atmosphere to repair the damage from empathic failures in parents. He also stressed a process of transmuting internalization in which the patient gradually internalizes characteristics of the analyst as a way of strengthening the patient's self.

Short-Term (Brief) Therapy The emergence of a variety of short-term (brief) psychodynamic psychotherapies was also a hallmark of the 1970s and 1980s. They are now primary, preferred modalities in their own right. Like other forms of psychoanalytic psychotherapy, they meet several contemporary needs: socioeconomic constraints that make protracted and costlier treatment less viable, the wish to serve larger numbers of patients, and the current pressures for accountability (which calls for systematic studies of psychotherapy outcomes based on specific formats and circumscribed time frames). As a further attraction the earlier fears of symptom substitution as an inevitable consequence of short-term treatment have essentially been quelled, allowing the enduring strengths of the Freudian legacy to be retained as the foundation for newer, more expedient techniques.

Peter Sifneos's anxiety-provoking psychotherapy, David Malan's intensive brief psychotherapy, Habib Davanloo's broad-focus short-term dynamic psychotherapy, James Mann's time-limited psychotherapy, and Lewis Wolberg's eclectic short-term psychotherapy are examples of the range of brief treatments that derive from the psychoanalytic approach. These combined interpretive and noninterpretive techniques, active approaches, and abbreviated time requirements are all accepted features of current psychoanalytic psychotherapy.

Operational guides for psychoanalytic practice have been developed. Hans Strupp and Jeffrey Binder's time-limited dynamic psychotherapy (TLDP) and Lester Luborsky's principles of psychoanalytic psychotherapy, a manual for supportive-expressive treatment, are two examples of the systematic approach to psychodynamic treatment.

A major theoretical trend in recent years that has profoundly affected psychoanalytic technique is the growing recognition that psychoanalysis is both a two-person psychology and a one-person psychology. The image of the analyst as a detached “blank screen” figure dispassionately observing the patient is regarded largely as a mythical construct that is misleading in terms of the realities of psychoanalytic work. In fact, the analyst's own subjectivity has a continuing influence on the patient, just as the patient's subjectivity influences the analyst's perceptions in an ongoing way. This recognition of two psychologies in mutual interaction with one another is often subsumed under the term *intersubjectivity*.

Social Constructivism The perspective of Gill and his collaborator Irwin Hoffman, often referred to as *social constructivism,* has been highly influential in the evolution of the notion of intersubjectivity. Central to the social constructivist view is the notion that the analyst's real behavior significantly affects the shape of the patient's transference. Also, analysts are considered unable to grasp fully how their irreducible subjectivity influences the patient in the analytic process. This point of view owes a debt to the constructivist view within philosophy, which suggests that reality is to some extent a construction influenced by the observer's subjectivity rather than simply an objective set of facts “out there” that are passively recorded by the individual's perceptual apparatus. Hence two individuals are present in the psychoanalytic consulting room, and together they construct a mutually negotiated reality. Another basic tenet of this perspective is that the patient may see something that the analyst is resisting just as the analyst observes resistance in the patient. Consequently, the analyst needs to take seriously the patient's interpretations of the analyst's conscious and unconscious influences on the patient. The social constructivist view emphasizes both spontaneity and personal engagement with the patient that fully acknowledges the contributions of the analyst to the transference.

Analysts who practice from this perspective do not deny that an intrapsychic world of the patient exists that is a valid focus of the psychoanalytic process. The patient arrives at the analysis with a preexisting set of conflicts, internal object relations, and self-structures. There is still a collaborative search for specific truths about the patient's unconscious that forms the basis of psychoanalytic treatment. However, there is now an awareness that the analysand's unconscious is perceived by, and filtered through, the analyst's subjectivity.

Countertransference This emphasis on social constructivism, intersubjectivity, and two-person aspects of the psychoanalytic process occurred in parallel with an increasing awareness of the role played by countertransference in psychoanalytic theory and technique. Terms such as projective identification, role responsiveness, and countertransference enactment have entered common usage and reflect a convergence in thinking among diverse psychoanalytic groups.

Projective Identification Projective identification originated in the work of Klein, who used the term to describe an intrapsychic fantasy of evacuating part of the self and putting it in someone else. Subsequent Kleinian thinkers have expanded the intrapsychic fantasy to an interpersonal process. Bion, for example, explicitly stressed that the analyst actually feels coerced by the patient into playing a role in the patient's fantasy. Thomas Ogden has been the most significant contributor to the contemporary usage of projective identification. In his early writings he described three aspects of the process: (1) an aspect of the patient's self is projectively disavowed by unconsciously placing it in the analyst; (2) the patient then exerts interpersonal pressure that coerces the analyst to experience or identify unconsciously with what has been projected; and (3) the analyst processes and contains the projected contents, leading them to be reintrojected by the patient in a modified form. As his thinking evolved, Ogden stressed that these aspects should not be construed as a rigid, linear sequence of steps, but rather as creating a dialectic in which analyst and patient enter into a relationship. In this relationship, the two members of the analytic dyad are simultaneously “at one” with each other and separate.

Ogden, then, provided a bridge between projective identification and intersubjectivity. Projective identification serves to create an interpersonally decentered subject, what he calls an *analytic third,* created by the two subjectivities. Ogden argues that the totalistic view of countertransference as referring to everything the analyst thinks or feels is not meaningful. He believes that countertransference must be viewed as constituting a dialectic between the analyst as a separate entity and the analyst as a joint creation of the intersubjectivity of the analytic process. He stresses that actually three subjectivities are involved in psychoanalytic work: the subjectivity of the analyst, the subjectivity of the analysand, and that of the analytic third. Projective identification, then, occurs as a mutual process in both parties and creates a newly integrated “subject” in the interpretive space between analysand and analyst.

The patient should not be “blamed” for all the feelings experienced by the analyst. Preexisting feelings in the analyst may interact with the feelings projected by the patient, and ongoing psychological work by the analyst is necessary to differentiate feelings that originate in the analyst from those evoked by the patient.

Patients do not project into an empty container. The process of projective identification requires a “hook” in the internal world of the analyst. Some projections are a better “fit” with the preexisting intrapsychic conflicts and representations within the analyst. Projective identification may feel like an alien force taking control of the analyst, and the analyst's subjective experience may be something like, “I'm not acting like myself.” However, the interaction can best be understood as the activation of repressed self- or object representations within the analyst that have been activated by interpersonal pressure from the patient. Hence the analyst's usual sense of conscious identity is disrupted by the unexpected emergence of these repressed aspects of the analyst's internal world. If a good fit exists between the analyst's internal world and that of the patient, the analyst becomes engaged as a participant in the externalization of the patient's internal object relationship.

Heinrich Racker found it useful to subdivide the analyst's countertransference reactions into concordant and complementary. *Concordant countertransference reactions* involve a situation in which the analyst identified with a self-representation within the patient. *Complementary countertransference* implies that the analyst has identified with a projected internal object representation of the patient. Racker viewed this as consistent with the projective identification model in which the analyst's own conflicts are activated by the patient's projections.

Role Responsiveness Joseph Sandler coined the term *role responsiveness* to describe a phenomenon very similar to projective identification. He made the following observation:

> Very often the irrational response of the analyst, which his professional conscience leads him to see entirely as a blind spot of his own, may sometimes be usefully regarded as a compromise formation between his own tendencies and his *reflexive acceptance of the role which the patient is forcing on him*.

Sandler regarded this process as one in which a patient unconsciously actualizes an internalized object relationship in the transference to the analyst, and the analyst then feels compelled to assume a role derived from the patient's intrapsychic world. He regarded this form of identification as fundamentally similar to Racker's notion of complementary countertransference. Sandler distinguished it from a process of *primary identification,* an automatic mirroring process that underlies analytic empathy. He provides an everyday example of this phenomenon. If one is following a man down the street who suddenly stumbles and leans over to the right to brace his fall, one has a natural tendency to lean slightly to the right as well.

Sandler underscored that one must be wary of assuming a one-to-one correspondence between what goes on in the analyst's mind and what resides in the patient's mind. He said it is erroneous to assume that any intense emotional reaction by the analyst to the patient's words or behavior is most likely projective identification. He argued that the term should be reserved for instances in which the patient unconsciously intends to evoke a specific emotional reaction in the analyst. In other words, he considered it erroneous to assume that all intense countertransference feelings are induced by the patient.

Countertransference Enactment The emphasis on the two-person aspects of psychoanalysis has entered into the literature of American ego psychological analysts through the concept of countertransference enactment. Theodore Jacobs introduced the term as a reference to subtle examples of interlocking transference-countertransference phenomena that operate unconsciously. These enactments may be as subtle as a changed body posture or increased muscle tension. They also may be more flagrant, (e.g., when analysts blurt out something that they wish or that they regret). James McLaughlin observed that the roots of the word *enactment* involve the notion of simulating or playing a part. He argued that both analyst and patient are constantly reacting to each other's behavior. Judith Chused defined countertransference enactment as an instance in which a transference fantasy is actualized and evokes a countertransference reaction in the analyst.

The similarities between Chused's definition and the contemporary view of projective identification are striking. Chused emphasized that individual variations in the analyst might well result in different countertransference enactments in different analysts, even if they treated the same patient.

In general, the way that American ego psychological analysts have written about countertransference enactments suggests a greater emphasis on the narrow view of countertransference. In other words, like Freud, they often conceptualize their emotional reactions to their patients as reflecting experiences from their own past that are revived in the interaction with the patient. Nonetheless, most contemporary analysts affiliated with ego psychology would agree that the analyst's countertransference may convey important information about the patient's inner world.

A common ground has emerged in recent years in the understanding of countertransference. Both the contemporary use of projective identification among analysts influenced by Klein and the British School of object relations and the use of countertransference enactment by ego psychological analysts converge around a view that the analyst's countertransference is a joint creation by both patient and analyst. In other words, the responses evoked in the analyst by the analysand work in concert with the analyst's own internal self and object relations to determine the final shape of the countertransference response.

The wide acceptance of the inevitability of various countertransference enactments in the course of an analysis have led psychoanalytic clinicians to recognize that such enactments can be analyzed and understood in a way that advances the analytic work. Countertransference awareness may only emerge after some

countertransference has been enacted. Owen Renik has argued that analysts must allow for spontaneity so that attenuated enactments can be analyzed and understood within the process. Similarly, members of the American relational school, such as Stephen Mitchell and Lewis Aron, have stressed that the analyst cannot avoid becoming embedded within the analysand's relational matrix. Analysts will play assigned roles even if they desperately attempt to stand outside the patient's internal cast of characters.

Pluralism Another trend in contemporary psychoanalytic discourse is a movement toward pluralism. The hegemony of ego psychology in American psychoanalysis has given way to a point where many analysts regard themselves as eclectic. The way analysts work in the privacy of their consulting rooms often differs rather dramatically from their publicly held theoretical positions. Most analysts probably borrow useful aspects of a variety of theories and develop their own integration with a patient whose psychopathology is multifaceted. Fred Pine has illustrated a sophisticated synthesis of four different theoretical perspectives: drive theory, ego psychology, object relations theory, and the psychology of the self. He stresses that one does not have to adopt the entire edifice of theory to borrow useful aspects of different perspectives that address different clinical phenomena. One theory is unlikely to address all of the complexities one encounters in the clinical situation.

In concert with the new emphasis on pluralism has been a movement away from a number of traditional polarizations within the field of psychoanalysis. These include one-person versus two-person psychology, intrapsychic versus interpersonal domains, drive theory versus relational perspectives, and oedipal versus preoedipal understanding. Many analysts recognize that a dialectical tension must exist between these apparent polarities and that both poles are necessary for a complete understanding of the human psyche.

Karasu has constructed a synthetic approach that attempts to locate generic factors in all psychotherapy. From this overarching principle, he has evolved a developmentalist metatheory that tries to bring deficit and conflict viewpoints under one umbrella. The conflicts and deficits in adult psychopathology are viewed as having origins in different phases of development. In this regard, he has constructed a fourfold matrix that includes dyadic deficit, dyadic conflict, triadic deficit, and triadic conflict. This matrix can be applied to a variety of psychiatric disorders encountered by the analyst or psychoanalytic therapist as a conceptual model for understanding the developmental origins of the difficulties.

Another form of pluralism is the attempt to integrate psychoanalytic thinking with phenomenological and philosophical perspectives. Richard Chessick, for example, has questioned the implicit assumptions upon which the understanding of patients rest. He has incorporated the views of Jean-Paul Sartre, Jacque Lacan, Martin Heidegger, and others who have tried to bring traditional philosophical perspectives to psychoanalytic data.

PSYCHOANALYTIC TREATMENT

Indications and Analyzability Determining which patients are suitable for psychoanalysis has undergone an evolution that parallels the historical changes in theory and technique. The original indications for psychoanalytic treatment were relatively straightforward—only those patients suffering from symptomatic neuroses of a hysterical, obsessive-compulsive, or phobic nature were suitable for psychoanalytic treatment. Freud also believed that as patients age, their lack of psychological malleability makes them less amenable to psychoanalysis. Hence only young patients, generally those in their 20s and 30s, were viewed as ideal candidates for analysis.

Those rather narrow indications are now considered limiting if not archaic. Few patients present to clinicians with complaints of discrete neurotic symptoms as they did in Freud's day. Manifestations of pervasive character pathology, such as difficulties in a patient's ability to love and to work, are likely to be the presenting complaints today. The changes in the conditions that patients bring to psychoanalysis have been mirrored in the advances in technique that are based on developments in self psychology and object relations theory. It is now common to refer to the *widening scope* of psychoanalytic treatment in the context of the expanded indications for such treatment.

Moreover, the age restrictions advocated by Freud have largely been discounted, as increasing research and clinical data attest to the malleability of middle-aged and elderly patients. Adult developmental studies indicate that significant changes in defenses, internal object relations, and self-representations occur throughout the adult life cycle. Analysts now commonly treat patients in their 50s, 60s, and even 70s.

Conditions considered amenable to analysis today include, in addition to the symptomatic neuroses, certain anxiety disorders, highly perfectionistic depressed individuals, some sexual disorders, certain personality disorders, including obsessive-compulsive, histrionic, avoidant, and narcissistic, selected patients at the upper end of the spectrum of borderline personality disorder, self-defeating personality disorder, and many cases of mixed personality disorder. In addition, many patients who do not fit the fourth edition of *Diagnostic and Statistical Manual of Mental Disorder* (DSM-IV) categories may experience significant distress and frequently seek psychoanalytic treatment. Common problems that bring such individuals to analysis include difficulties with intimacy, relatedness, and commitment; lack of assertiveness; avoidant tendencies; self-defeating behavior; problems with authority; shyness; unresolved grief; or problems related to separation or rejection.

The preceding list of indications for psychoanalysis is incomplete, however, without also considering generalized criteria for analyzability that apply regardless of the diagnosis. Significant suffering must be present, so that the patient is motivated to sacrifice the time and financial resources required for psychoanalysis. Also, patients who enter analysis must have a genuine wish to understand themselves, rather than a desperate hunger for symptomatic relief. They must be able to withstand the frustration, anxiety, and other strong affects that emerge in analysis without fleeing or acting out their feelings in a self-destructive manner. Other ego functions that must be intact, in addition to the ability to delay impulses and control affects, are reality testing and self/object differentiation. Without reasonably good ego functioning in those areas, a stable, workable transference will not be established.

Reasonably mature superego development is also necessary for a patient to be analyzable. Patients who are pathological liars, who are morally corrupt, or who commit criminal acts are rarely suitable for psychoanalytic treatment. At least average, if not superior, intelligence is required for analytic work, as is a well-developed capacity to verbalize internal experiences. The patient must have some capacity to regress in the service of the ego but also an ability to reinstitute defenses by the end of the session. One other important criterion of analyzability is a form of thinking that is usually referred to as *psychological mindedness*. Patients who possess this trait can think abstractly and symbolically about the unconscious meanings of their behavior. They tend to look inward for explanations about things that happen to them, rather than externalize responsibility. They also can think by analogy—that is, something that happens in outside relationships is analogous to similar developments in the transference relationship to the analyst.

The psychoanalyst must also take into account certain external life situations in determining the patient's suitability for analysis. It is generally better not to begin analysis in the midst of a major upheaval or life crisis, such as a job loss or a divorce. Sufficient stability in one's work situation is necessary to ensure that a patient will be in the same geographical location for a period of several years. Serious physical illness may interfere with the patient's ability to invest in a long-term treatment process. The patient must have sufficient financial resources so that analytic treatment does not present an unbearable economic hardship. The final decision must take into account those external life factors in addition to a careful psychodynamic evaluation of the patient's ability to use psychoanalysis productively, based on the criteria noted above.

One broadly based indication for psychoanalysis is a history of unsuccessful previous treatments. A survey of 580 analytic patients found that 82 percent of the patients currently in psychoanalysis had undergone other forms of psychotherapy in the past. The mean age at the beginning of the analysis of the sample was 36.2 years, and 59 percent of the patients were female. Of the 580 patients, 71.4 percent had at least one personality disorder diagnosis. Of the Axis I diagnoses, a mood disorder was the most common, and anxiety disorder was second. A significant number of the patients, 27 percent of the total, had been sexually abused or assaulted. High levels of sexual dysfunction, 43.4 percent of the total, were also found in the group.

Analytic Process In formal psychoanalysis, the process is conducted four or five times a week in sessions that last either 45 or 50 minutes. The patient usually reclines on a couch while the analyst sits behind the couch out of the patient's view. The patient is invited to say whatever comes to mind without censoring it or passing judgment on it. This technique, known as *free association,* promotes a useful regression in the patient that encourages attunement to internal processes and establishment of a transference attachment to the analyst. In addition to the process of free association, the patient is expected to mobilize basic ego resources to make connections between the associations that emerge and to gain mastery through insight. In that regard, the patient works in a collaborative process with the analyst, rather than taking a passive position in which the analyst does all the work.

When Freud shifted from the use of hypnosis and suggestion to the technique of free association, his goal was to bring repressed material into conscious awareness, so that the patient gains insight through understanding how dynamically repressed childhood events contributed to the symptoms experienced as an adult. Freud noted that the regression produced by the analytic setting allows reemergence of infantile conflicts in the form of a *transference neurosis,* in which all the feelings and

fantasies involved in the oedipal constellation of childhood are reactivated in the relationship with the analyst.

Psychoanalysis as a therapeutic procedure, then, was originally based on the notion of uncovering and reconstructing the analysand's past through re-creation of that past in the transference neurosis with the analyst. However, the understanding of the analytic process has expanded considerably as a result of increasing interest in the analyst's role in the analytic relationship. The reexperiencing, or reenactment, of the past is now viewed as influenced by the current analyst-patient relationship and the contributions of the analyst to that relationship. Hence the meaning of analytic data in a particular hour is gleaned not exclusively from the patient's historical past but also from the interplay between the patient and analyst in the present. The past is influenced by the present just as the present is influenced by the past in the analytic setting.

Phases of the Analytic Process The analytic process has traditionally been divided into three phases, although the gradations are acknowledged to be somewhat arbitrary and, to some extent, overlapping. The first, or opening, phase involves the patient's establishment of a therapeutic alliance with the analyst. That alliance involves developing trust and a willingness to work collaboratively with the analyst in the pursuit of understanding. The opening phase also provides a chance for patients to tell their story. As this narrative unfolds, the analyst becomes familiar with the details of the patient's personal history and the patient's conceptualization of the origin of the problems that brought the patient to analysis. The second, or middle, phase is characterized by the appearance of a transference neurosis, which is then systematically analyzed and worked through in the analyst-patient relationship. The issues that arise in the middle phase often stem from a mixture of oedipal and preoedipal conflicts. The new emphasis on adult development is accompanied by a growing awareness that issues deriving from latency, adolescence, and adult development also require attention. The third, or termination, phase of analysis requires that the patient mourn and give up infantile attachments to parental figures at the same time that the loss of the analyst as a real person is being mourned. Autonomy, independence, and development of the capacity for continuing self-analysis are also prominent issues to be addressed during the termination phase. Analysts do not typically view an analysis as finished or complete nowadays. All analyses end with a certain degree of unfinished business that the analysand continues to analyze by identifying with the analyst's role and continuing the process of self-analysis.

Principles of Technique Psychoanalytic technique has undergone rather profound changes since its development by Sigmund Freud. Considerable controversy exists about so-called classical technique. Many aspects of the psychoanalytic approach designated by that term appear to distort how Freud himself really practiced. Moreover, Freud clearly ignored some of the recommendations in his technique papers in his actual technique with his patients. Another difficulty lies in how certain of his technical prescriptions became cornerstones of psychoanalytic technique while others were relatively neglected. For example, his statements about abstinence, neutrality, and anonymity are often viewed as inviolate precepts, while his other statements on the importance of flexibility, spontaneity, tact, and openness are omitted from discussions of technique.

Another dimension of this difficulty is that Freud actually wrote a rather limited number of contributions that focus specifically on psychoanalytic technique. Of 300 scientific publications, only about 20 papers focused on how the analyst should conduct psychoanalytic treatment. Most of these were published relatively early in his psychoanalytic career. He also emphasized that rigid rules were not of much use in the practice of analysis. In a 1910 paper on “wild analysis,” he made the following observation:

> It is not enough, therefore, for a physician to know a few of the findings of psychoanalysis; he must also have familiarized himself with its technique if he wishes his medical procedure to be guided by a psychoanalytic point of view. This technique cannot yet be learnt from books, and it certainly cannot be discovered independently without great sacrifices of time, labour, and success. Like other medical techniques, it is to be learnt from those who are already proficient in it.

Freud also made it clear that the technique he evolved was one suited to his own individuality. He allowed for the possibility that other analysts might adopt different technical strategies based on what was most clinically useful to a particular analyst and a particular patient.

Freud's technique was guided by his understanding of the primary task of psychoanalytic treatment, which in his view was to make the unconscious conscious. Hence free association and dream analysis were given privileged status within his psychoanalytic method. The analysis of transference and neutrality were not cornerstones of Freud's clinical work. Because of Freud's emphasis on making the unconscious conscious, he placed great weight on what he designated the *fundamental rule:* the patient must agree to be completely honest with the analyst and say whatever comes to mind. Freud was quite insistent to his patients that they must follow the fundamental rule and overcome their resistances to doing so. This authoritarian stance by the analyst is quite different from the way most analysts practice today. In an international sample of eminent analysts surveyed, only 37 percent followed Freud's recommendations about instituting free association as the fundamental rule of treatment. Many contemporary analysts are concerned that issuing an authoritarian injunction that tells analysands exactly what to do might increase their resistance to the process.

The ensuing discussion of technical principles puts Freud's views into context with more recent innovations in technique.

Resistance One of Freud's greatest insights into the human psyche was that most people, no matter how extensive their suffering, are highly ambivalent about changing. Powerful internal forces oppose the analyst's efforts to produce insight and promote new modes of adaptation. Indeed, those internal forces, which Freud termed *resistance*, were crucial in the evolution of psychoanalytic technique. Hypnosis and abreaction did not produce lasting change, Freud learned, because forces of resistance tenaciously cling to the neurotic compromise formations. In one of his 1912 papers on technique, Freud observed that “The resistance accompanies the treatment step by step. Every single association, every act of a person under treatment must reckon with the resistance and represents a compromise between the forces that are striving toward recovery and the opposing ones.”

Resistances are ubiquitous in psychoanalysis. They may be viewed as the analyst's daily bread-and-butter work. They manifest themselves in every aspect of the patient's behavior and associations and may take a variety of forms, including falling asleep during sessions, forgetting the analyst's observations, withholding important thoughts and feelings from the analyst, demanding symptom relief instead of understanding from the analyst, falling silent during the sessions, failing to pay the bill, and even free associating so literally that none of the material is connected or used constructively to produce understanding.

Although resistance may be either conscious or unconscious, resistance to the analytic process arises automatically as soon as one is invited to free associate. The exercise of a patient's will power is often insufficient to overcome these powerful forces. In Freud's day, he never referred to “analyzing” resistance. Rather, his view was that resistances needed to be overcome. In his well-known technique paper “Remembering, Repeating and Working Through,” published in 1914, he offered the following advice:

> The first step in overcoming the resistances is made, as we know, by the analyst's uncovering the resistance, which is never recognized by the patient, and acquainting him with it. Now it seems that beginners in analytic practice are inclined to look on this introductory step as constituting the whole of their work. I have often been asked to advise upon cases in which the doctor complained that he had pointed out his resistance to the patient and that nevertheless no change had set in; indeed, the resistance had become all the stronger, and the whole situation was more obscure than ever. The treatment seemed to make no headway. This gloomy foreboding always proved mistaken. The treatment was as a rule progressing most satisfactorily. The analyst had merely forgotten that giving the resistance a name could not result in its immediate cessation. One must allow the patient time to become more conversant with his resistance with which he has now become acquainted, to *work through* it, to overcome it, by continuing, in defiance of it, the analytic work according to the fundamental rule of analysis.

In other words, Freud's emphasis was on overcoming the resistance with the assistance of the analyst, who uncovered the resistance for the patient. In Freud's recommendation analysts are not advised to analyze the resistance in terms of its meaning or its complex defensive function. Instead, patients are supposed to push it aside or plow through it while forcing themselves to say what comes to mind. In accounts by his own analysands of how Freud worked, they paint a portrait of Freud as an analyst who tried to convince his patients through appeals to their willpower that they could decide to give up their resistance.

Modern analysts approach resistances with the idea that they must be analyzed. Through the patient's associations to them and the analyst's observations of the setting in which they occur, resistances are investigated with the idea of learning more about their structures, their sources, and the specific affects with which they are associated. Moreover, the form that a patient's resistances take provides a gold mine of information about that particular patient's characteristic defensive operations. Resistance may be conceptualized as the manifestation of the patient's typical defense mechanisms as they appear in the analytic setting. Another way of making the distinction is to say that defenses, which operate intrapsychically, are translated into resistances, which appear interpersonally, when the patient enters an analytic relationship with the analyst. To be sure, some resistance continues to be intrapsychic as well, but even this will become manifest within the relationship of

the analyst and analysand.

Resistance takes many forms. One particular subgroup of special importance is *transference resistance,* which includes fantasies, thoughts, feelings, and wishes that directly involve the analyst. Loving or sexual wishes directed toward the analyst, for example, may serve the function of avoiding the analytic task of developing insight. Transference resistance may also take the form of defending against the awareness of feelings toward the analyst. Also, one set of transference feelings or wishes may defend against awareness of another, more disturbing set. Transference itself may be regarded as a resistance when it interrupts the process of analysis, and the systematic working through of intense feelings is a major task of psychoanalytic treatment.

Since Freud's time, the understanding of resistance has evolved considerably. Freud conceptualized analysis as primarily an effort to allow memories to surface and to make the unconscious conscious. A more contemporary view is that resistance actually resists the analyst rather than the emergence of memories. Moreover, analysands seek to repeat their past experiences in action rather than to reflect and remember them. Hence Freud's definition of resistance as a blockage of emerging memories is considered limiting by contemporary standards. Analysts today would view the natural flow of the patient's thoughts as heading in the direction of unmodified enactments rather than memory per se, and the resistance would be viewed as a revelation of an important desire or wish in a complex object relationship that is manifested in the transference. In working with the resistance, the analyst wants to facilitate both the conscious activation of repressed wishes and a cool contemplation of their significance.

Resistance tends to change character during an analysis. In the opening phase, resistance may take the form of avoiding a meaningful attachment to the analyst. In the middle phase, it may involve intense and irrational feelings toward the analyst. In the termination phase resistance may manifest itself as a return of symptoms that were present at the beginning of the analysis or a reluctance to give up the passive and dependent regressed relationship with the analyst.

Analyses that are conducted from a self-psychological perspective approach resistance in a manner radically different from the classical or ego psychological model described here. As a consequence of the deemphasis on the ego and its defense mechanisms in self-psychology, the role of those defenses as they emerge in the analysis is also minimized. The view of the analytic process is not one of an inexorable unraveling of defenses. Rather, the analyst attempts to empathize with the core subjective experience of the patient in the interest of reactivating growth in the domain of the self. From that standpoint, both defenses and resistances are viewed as healthy intrapsychic activities that safeguard and preserve the integrity of the self. Kohut preferred to speak of the defensiveness of patients, rather than their resistances, and he stressed that defensive attitudes are both psychologically valuable and adaptive. In his supervision of colleagues, he stressed that the patient's material should be taken at face value rather than inverted or investigated for the “real meaning” beneath the surface. Similarly, he stressed that the analyst's technique cannot bypass the patient's subjective experience.

Object relations theory provides yet another perspective on resistance. Particular self-object affect units within the patient gain prominence for compelling intrapsychic reasons, and the patient only reluctantly gives up those object relations paradigms in the interest of developing new forms of object relatedness. The patient's internal object relations are repeated in the analytic setting with the hope that they will be altered in some manner in the context of a new relationship. At the same time, however, relinquishing internal objects and their corresponding self-representations involves feelings of loss and grief. Those feelings are often defended against by the patient's strong propensity to cling tenaciously to familiar self-object affect units.

Transference *Transference* refers to the displacement onto the analyst of attitudes and feelings originally experienced in relationships with people from the past. Transference patterns appear automatically and unconsciously in the analytic relationship. Analysands suddenly find themselves reacting to the analyst with intense feelings that are inappropriate, at least in part, to the current situation. Patients unconsciously reenact a past relationship instead of remembering and verbalizing it. Transference is not unique to the analytic setting. Every significant relationship in adult life is a new addition of the original attachments of childhood. The chief difference between transference in the analytic relationship and transference as it occurs in outside relationships is that transference is analyzed in the analytic setting.

Freud deemphasized analysis of the transference in his own practice because his principal goal was to bring unconscious material into the conscious awareness of the analysand. He felt that certain aspects of transference were the vehicle of cure and should be left alone. Specifically, what he termed the *unobjectionable positive transference* was the perception by patients that the analyst was a helpful clinician trying to collaborate with them in finding a cure for their problems. This type of transference should not be analyzed, in Freud's view, because it does not interfere with the unfolding of the associations. However, Freud identified two other forms of transference that required analysis—the erotic and the negative. In other words, a basic principle in Freud's approach was that the transference did not require analysis unless it was serving as a resistance to free association. Critics of Freud have pointed out that he may have neglected positive transferences that served to conceal negative feelings such as anger and contempt.

Freud held to the view that transference was basically a template existing in the patient's intrapsychic world that derived from meaningful childhood relationships. He was convinced that this transference would necessarily emerge if the patient simply followed the method of free association. He did not distinguish between the real relationship and transference, and he was not concerned that real aspects of his behavior might influence the patient's transference to him.

In the contemporary view, transference is regarded as a mixture of the new relationship with the analyst and a reenactment of a past relationship with a significant childhood figure. The analyst is regarded as an active participant in the therapeutic relationship. In the current conceptual framework, the analyst's personal characteristics exert a powerful influence on the specific shape and intensity of the patient's transference. The notion of opacity is considered a myth by contemporary analysts, and the analyst's real characteristics must be taken into account when the analyst formulates therapeutic interventions.

In the classical view, the transference neurosis is the distinct and pivotal entity that develops in the middle phase of the analysis as a consequence of the replication of the childhood neurosis. The patient's attachment to the analyst is so intense that emotional satisfaction from the analyst becomes more important than the original therapeutic goals. The contemporary perspective on transference is that object relations ideas are more significant than drive-derived aims aroused by the analytic regression. The term *transference neurosis* is seen as lacking specific meaning or utility in the analytic setting; the term has been replaced to a large extent by references to the various transference responses as shifting self-representations and object representations arise in the crucible of the analytic dyad.

Analysts influenced by self psychology and intersubjectivity theory point out that transference has a bidimensional quality. One dimension involves a repetition of past experiences with old objects. The other involves a quest for a new object or selfobject experience that will be reparative and corrective.

Therapeutic Alliance The controversial term *therapeutic alliance,* used interchangeably with *working alliance,* refers to the conscious aspect of the relationship between the analyst and the patient involving the collaborative pursuit of common therapeutic goals. In the therapeutic alliance the patient identifies with the general aims and strategies of psychoanalytic treatment and cooperates with the analyst in the search for understanding and insight. To form such an alliance, the patient must be able to split the ego into a functioning component that is involved in free associating and an observing component that is identified with the analyst's task of analyzing.

Several elements contribute to establishing a viable therapeutic alliance: shared arrangements regarding fees, payment, appointments, and confidentiality; the mutually agreed on goals for the analysis; and a shared understanding regarding the roles and responsibilities of each member of the analytic relationship. Although the therapeutic alliance is often regarded as the patient's ability to collaborate with the analyst, most clinicians would agree that the analyst's contributions to the formation of the alliance are just as important as the patient's.

Many analysts have been critical of the validity of the concept. One source of criticism stems from the seminal work of Zetzel on the concept, in which she linked certain technical recommendations with efforts to enhance the collaboration of the patient. She suggested that the analyst should not be too silent for too long without making supportive comments that acknowledge the patient's anxiety and distress. She was writing in a context of the expansion of psychoanalytic technique to include the treatment of borderline and narcissistic patients. Nevertheless, some critics have viewed her contribution as implying too much reliance on supportive and nonanalytic strategies.

Another source of criticism of the concept is that the distinction between transference and therapeutic alliance is illusory. Just as Freud's notion of the unobjectionable positive transference might lead the analyst to neglect certain concealed feelings behind the overall positive relationship of the analysand to the analyst, the therapeutic alliance construct might also be misused in that way. Some critics would argue that the relatively collaborative and positive relationship between patient and analyst must itself be regarded as a transference that has layers of complexity. If the analyst does not analyze the apparent alliance, the patient may terminate with one sector of the personality largely unanalyzed.

Countertransference The term *countertransference* was coined by Freud in 1910. He actually wrote very little about the phenomenon in the course of his career, but his general use of the term suggested that it was tantamount to transference in the reverse direction—the unconscious conflicts from the analyst's past are displaced onto the patient. In short, countertransference is the analyst's transference to the patient. Freud viewed it as interfering with the analyst's optimal functioning, and he issued a command that the "analyst shall recognize this counter-transference in himself and overcome it."

Freud was greatly concerned about how a number of his colleagues appeared to succumb to the siren song of "love" in the analytic relationship. In a letter dated 31 December 1911, Freud wrote to Jung the following concern:

> Frau C. has told me all sorts of things about you and Pfister, if you can call the hints she drops "telling"; I gather that neither of you has yet acquired the necessary objectivity in your practice, that you still get involved, giving a good deal of yourselves and expecting the patient to give something in return. Permit me, speaking as the venerable old master, to say that this technique is invariably ill-advised and that it is best to remain reserved and purely receptive. We must never let our poor neurotics drive us crazy. I believe an article on "countertransference" is sorely needed; of course we could not publish it, we should have to circulate copies among ourselves.

Freud saw the ravages of countertransference first hand, and his papers on technique sometimes read as a version of the ten commandments (i.e., as an appeal to his colleagues to control their emotional reactions to their patients).

The conceptualization of countertransference as stemming from the analyst's unconscious conflicts displaced onto the patient is often referred to as the *narrow,* or classical, view of countertransference. In modern psychoanalytic theory, the term has undergone considerable revision. A *broad* view is now in wide use among analysts to connote the analyst's total emotional reaction to the patient. That shift was fueled by Klein, Winnicott, and Kernberg—all of whom viewed countertransference reactions, particularly in work with seriously disturbed patients, as stemming more from the patient than from the analyst. In other words, through projective identification the analyst begins to feel powerful affects that are associated with the patient's internal self-representations and object representations. Winnicott referred to one variant of such phenomena as *objective hate* to reflect the fact that certain patients cause everyone to hate them; therefore, the analyst's feelings do not reflect specific unconscious conflicts from the analyst's past.

Another implication of the broadened conceptualization of countertransference introduced by the object relations theorists is that the analyst's feelings provide important information about the analysand's internal world. Moreover, by reacting to the patient in a role-responsive manner, the analyst gains greater understanding about the typical problems that occur in the patient's other relationships. Hence countertransference is regarded not so much as an obstacle to the analyst's functioning but as an indispensable aid to the analyst's ability to understand and to intervene effectively with the patient.

As noted above, each of these views tends to undervalue the fact that both analyst and patient generally contribute to the construction of the countertransference. Psychoanalysts today generally view countertransference as a joint creation involving contributions from both members of the dyad. One of the analyst's principal tasks is to engage in a continuing process of self-scrutiny in which the two components are distinguished and understood.

The contemporary focus on intersubjectivity has made the term *countertransference* somewhat murky. Some intersubjectivists have suggested that countertransference simply cannot be differentiated from the rest of the analyst's subjectivity and that there is no way to sort out which element in the countertransference belongs to the patient and which to the analyst. Others have suggested that subjectivity is a fundamental aspect of the analyst that is present independent of the patient. Countertransference is a phenomenon that evolves in response to the patient. Still others argue that countertransference is basically a component of the totality that constitutes the subjectivity of the analyst.

Interpretation Interpretation is one of the analyst's primary therapeutic instruments in psychoanalysis. It involves an explanatory statement by the analyst that links a symptom, thought, feeling, or behavior to its unconscious meaning. It is the vehicle by which the analyst delivers understanding to the patient. In the ideal situation, interpretation is designed to make the patient consciously aware of unconscious (or preconscious) material that is close to the surface of consciousness.

Freud himself appeared to vacillate between two positions informing the use of interpretation. In some of his writings, he suggested that analysts postpone interpretation until the unconscious material is close to the patient's conscious awareness. At other times, however, he would offer his view of what was going on in the patient's unconscious even though it was quite distant from the patient's consciousness. He often expected his patients to face unpleasant truths about themselves without regard to the readiness of the patient's ego to process the interpretation.

Genetic interpretations are statements that connect thoughts, conflicts, and feelings in the present with their childhood antecedents. The analyst reconstructs the patient's past on the basis of memories, dreams, free associations, and transference distortions to shed light on how the present situation repeats the past.

Transference interpretations, often viewed as the analyst's central mutative activity, explain to patients how their perception of the analyst is a reenactment of a past significant relationship. The historical conceptualization of transference interpretation generally involved genetic reconstructions, but the contemporary view deemphasizes reconstruction and helps the patient see how current wishes and expectations in the analytic setting are influenced by the past. Moreover, analysts today enlist the patient's collaboration in understanding the current interpersonal situation with the analyst and how it is influenced by past relationships. In this regard, an attitude of pathological certainty or extreme authoritarianism is discouraged in the delivery of an interpretation. Rather, an interpretive intervention is presented as a hypothesis about the patient's behavior and its meaning. The analyst is then interested in hearing the patient's thoughts about the hypothesis.

Transference interpretation has two broad categories. The first involves explanations of resistance to the resolution of the transference. The explanations may involve genetic elements or may focus on the here-and-now situation. An example of a genetic interpretation is: "You may not want to give up your erotic attachment to me because you hope that it will lead to getting a response from me that you never received from your father." An example of a here-and-now interpretation is: "You may not want to give up your erotic attachment to me because you have the fantasy that you can control me with your sexual demands." The second category of transference interpretation involves explications of resistance to the awareness of transference. An example is: "I wonder if your sudden need to launch into an extramarital affair is related to the development of sexual feelings for me that you cannot yet acknowledge."

A single interpretation does not resolve either transference or resistance in one fell swoop. The analyst's initiation of an interpretive strategy marks the beginning of a prolonged process that Freud referred to as *working through*. Freud commented that "one must allow the patient time to become more conversant with his resistance with which he has now become acquainted, to work through it, to overcome it, by continuing, in defiance of it, the analytic work according to the fundamental rule of analysis." Similar transference and resistance themes are encountered in a variety of different situations, and the repetitive interpretation process each time those familiar patterns emerge eventually leads to mastery and insight.

From an ego psychological perspective, working through is necessary because of the tenacity of ego defenses. A single demonstration of the impulse-defense configuration does not suffice for the patient to relinquish those defenses and allow the warded off drive components to enter conscious awareness. Repeated confrontations of the defensive strategies are necessary in a variety of situations to accomplish a major shift in the intrapsychic relationships of ego, superego, and id. Paul Gray has stressed that the analyst's principal task is *resistance analysis,* in which the analyst pays close attention to defensive shifts away from sexuality or aggression. Over time patients learn to monitor these shifts themselves and recognize their flight from particular issues they find disconcerting. Gray's vision is one of enlisting the patient's ego in a partnership with the analyst. He advises against making interpretations that attempt to bypass ego functions and speak directly to the patient's underlying drive derivatives.

Object relations theorists view the working-through process somewhat differently than the ego psychologists. Proponents of the British middle group, for example, such as Fairbairn and Winnicott, stress that the analytic setting provides a new object for the patient. Working through involves attachments to the new object, internalizing the new object relationship, and relinquishing the old internal object relations units as the new relationship takes center stage in the patient's psyche.

Self psychologists do not conceptualize the working-through process as involving resolution of intrapsychic conflict. Instead, they regard it as the resumption of previously arrested developmental processes. The patient's relationship with the analyst in the present reactivates that frozen development so that selfobject transferences can evolve. Through the repetitive examination of self-selfobject disruptions in the transference, the patient gradually internalizes the empathic interactions with the analyst to repair defects in the self.

DREAM INTERPRETATION Freud's classic work, *The Interpretation of Dreams* and subsequent papers on the mental phenomena of everyday sleeping and waking

demonstrate that dreams, parapraxes, jokes, puns, and metaphors are not chance or senseless events but are meaningful acts subject to the basic laws governing unconscious processes. Freud believed early on that the analysis of dreams, such as he had conducted on himself, was sufficient for a full self-analysis. As the fastest and surest route to the origins of psychic conflicts—the royal road to the unconscious—dreams remain for many analysts the perfect paradigm of the interpretive process and often supply a source of information that cannot be derived in any other way.

Dreamwork is a distorting process by which latent dream thoughts are condensed, displaced, and converted through symbolic substitution into manifest dream material of which the recollection, upon wakening, is only an unintelligible facade or disguise. The dream is generally looked upon as a microcosm of the major concerns of the patient, especially as a commentary on the events of the preceding day (day residue). For the dreamer it serves a largely wish-fulfilling function behind which resides the original unsatisfied instinctual impulse. Current views also suggest a prospective function of dreams, as a direct attempt to adapt to present stresses or to solve future problems. Despite its salient role in analysis, however, dream interpretation should not be pursued for its own sake but be subject to the same rules that govern all analysis. Excessive attention to dreams can become a form of resistance by drawing the patient away from more spontaneous concerns.

Neutrality, Abstinence, and Anonymity Some of the most striking contradictions between the so-called classical model of technique and the way Freud actually behaved involves the principles of neutrality, abstinence, and anonymity. Part of the confusion clearly relates to the difference between the way that Freud conducted himself in his analyses and some of the statements he made in his papers on technique. For example, he suggested that the analyst should be like a mirror that reflects back to the patient only what is shown to the analyst. In other words, the analyst should eschew too much self-disclosure. At other points in his technique papers, he advises the analyst to proceed with “emotional coldness” and to put all personal feelings aside, “even his human sympathy.” The image projected in these papers is clearly that of a detached scientist dispassionately examining a specimen without any personal or human involvement with the patient. The thinking behind this approach was that by providing a “blank screen” or mirror, the analyst could facilitate the emergence of the patient's transference.

Two sources of information suggest that Freud did not follow these prescriptions in his actual analytic work. Both written reports from his own analysands and his published case material indicate that Freud's personality was very much involved in the analytic process. He gossiped with his patients; he offered his opinions about theories, works of art, and other people, and certainly did not attempt to conceal his political and moral value system. He was transparent regarding his mood and loved to talk with his patients about topics of mutual interest. He was real, often authoritative, and certainly spontaneous.

In fact, Freud did not actually use the word “neutrality” in his writings. James Strachey, his principal translator, translated the German word *indifferenz* as “neutrality” even though another German word carries that meaning more precisely. The German word actually implies an underlying emotional participation by the analyst rather than the detachment that is often connected with the term *neutrality*.

Fundamentally the issues of neutrality, abstinence, and anonymity were irrelevant for Freud. He desired to facilitate the patient's free associations so that the unconscious would emerge. His analysands report that he was far from cold or detached in his own practice. Freud's statements about technique appear to relate more to his concerns about the vulnerability of his colleagues to countertransference acting out and the tendency of some analysts to misuse the analytic situation to talk about themselves.

The fact that *neutrality* is occasionally misunderstood to suggest that analysts should remain cold and aloof does not mean that the term is meaningless. The most widely accepted contemporary meaning is a nonjudgmental stance regarding the patient's feelings, wishes, and behaviors. Anna Freud suggested that the analyst must remain equidistant from the id, the ego, the superego, and the demands of external reality. By maintaining a neutral position, the analyst eventually helps patients become aware that their own critical attitudes are being attributed to the analyst.

Concern, empathy, and emotional warmth are all part of effective analytic work, and a cold, rejecting attitude in the analyst may become an aspect of the real relationship in the present that is incorporated into the patient's transference. The influence of object relations theory on psychoanalytic technique has redefined the analyst's role as one involving participation in the process. When analysts allow themselves to respond in a disciplined yet spontaneous manner to the patient's projections, they find that their role-responsive reactions provide useful information and an empathic sense of the patient's internal world.

The contemporary models of technique have generally argued for a disciplined spontaneity, much like the way Freud himself practiced. Analysts today are aware that anonymity is largely a mythical construct. Various kinds of personal information are available in the analyst's office. Photographs of the family, artwork, books, and other articles of personal interest are fully visible to the patient. The analyst's reactions to material the patient brings to the process are also revealing. Indeed, one could argue that every intervention the analyst makes reveals something about the analyst's personal proclivities. Hence one cannot avoid self-disclosure. The issue becomes one of selecting what is useful to disclose in an explicit verbal mode versus what is preferable to keep to oneself. Analysts still recognize a value in analytic restraint. Although it is impossible to be entirely neutral in the sense of being nonjudgmental, analysts can nevertheless choose how much is verbally revealed about their judgments.

Freud attempted to distinguish between the transference and a personal, real relationship. In Freud's view only the transference required analysis. Contemporary analysts recognize the difficulty in trying to separate out the real relationship from the transference and recognize that each infiltrates the other. Hence the entire relationship with the analyst must be subject to analytic scrutiny.

Abstinence was a technical principle designed by Freud under the same cloud of sexual boundary violations by some of his early colleagues and disciples. He was mainly concerned that extremes of feelings must be kept in check. In a 1919 paper, “Lines of Advance in Psycho-Analytic Therapy,” Freud clarified that:

> by abstinence, however, is not to be understood doing without any and every satisfaction—that would of course not be practicable; nor do we mean what it popularly connotes, refraining from sexual intercourse; it means something else which has far more to do with the dynamics of falling ill and recovering.

What Freud meant in essence was that the analyst withholds gratification of transference wishes so that they can be analyzed rather than relieved. Analysts today recognize that partial transference gratifications occur throughout an analysis. The analyst's warmth, humanity, laughter in response to a joke, and empathic listening are all gratifying. Richard Chessick has described it as follows: “The skill of the therapist is to do just enough so that the patient has some sense of the therapist's recognition that words alone will not suffice, but not to afford so much gratification that the patient has no motivation to change, which would engender an artificial need for more and more gratification.” Indeed, the concept of analytic boundaries has arisen in part to clarify the role of gratification versus abstinence in modern technique.

Analytic Boundaries The notion of analytic or professional boundaries is a relatively recent development in psychoanalysis. The early history of psychoanalysis is replete with phenomena that would now be viewed as unethical or incompetent technique. Freud analyzed Ferenczi, for example, while walking through the countryside. He regularly introduced his patients to his family and often had meals with them. Winnicott broke confidentiality by revealing information about his patients to other patients. Ferenczi engaged in mutual analysis, a process in which after hearing the patient's associations for an hour, he traded places with the patient and free associated himself for an hour. There are numerous cases of analysts falling in love with their patient and interrupting the analysis so the two could embark on a love affair.

In the last two to three decades, a good deal of writing has appeared in this area. Analytic boundaries connote an edge, or limit of acceptable professional behavior. They are not designed to be an arbitrary set of rules by which ethics committees and licensing boards determine whether or not disciplinary measures are needed. They are simply guidelines to facilitate the analytic process. In a 1927 letter to Ferenczi, Freud indicated his intent regarding such guidelines:

> I consider the most important thing was to emphasize what one should not do and to point out the temptations and directions contrary to analysis. Almost everything positive that one should do I have left to “tact,” the discussion of which you are introducing. The result was that the docile analyst did not perceive the elasticity of the rules I have laid down, and submitted to them as if they were taboos. Sometimes all that must be revised, without, it is true, doing away with the obligations I had mentioned.

Indeed the analytic boundaries must build in flexibility. They provide an envelope that creates an optimal environment for the emergence of the analytic process. They must be flexible because different patients require adjustments in the boundaries. Similarly, different patient-analyst dyads find their own optimal conditions under which analysis can be conducted. The relative degree of gratification versus frustration varies given the subjectivities of the two parties. Some patients may benefit from direct self-disclosure of the analyst's feelings about a specific situation, while others may deeply resent it and close down as a result. Nevertheless, a variety of boundary considerations serve as guidelines to assist the analyst in maintaining a professional rather than a personal relationship.

One boundary is that of role. The analytic role allows the analyst to be subjectively involved while also maintaining a certain degree of relative objectivity as a participant in a professional relationship. While libidinal, or sexual, demands cannot be gratified, growth needs, such as empathic understanding, caring, and concern, are often an integral part of the analytic role. In this regard, abstinence can be redefined as the construction of an analytic setting that serves as a holding environment for the containment and processing of powerful feelings. Analysts do not act like lovers or parents, but they try to understand the way in which the patient attempts to re-create the parent-child relationship in the analytic dyad and the similarities that can be identified between difficulties in love relationships and those in the transference.

Time is another boundary in analysis. The usual session lasts 45 or 50 minutes, and the time constraints in the process emphasize that there are limits in the relationship. These may be productively analyzed in terms of how they frustrate the patient's wishes. Extraanalytic contacts are viewed as analytic material that can be productively discussed and understood.

Place and space are also inherent to the analytic boundaries. By meeting in the analyst's office, the patient is clearly shown that the relationship is confined to the analyst's professional workplace. Similarly, a fee is paid for the analyst's service, which makes clear that analysis is work rather than a social hour. A clinician who fails to charge or to collect from a patient may unwittingly give a message to the patient that the relationship is a special one that exists outside the realm of professional services.

Lavish or expensive gifts from analyst to patient or from patient to analyst may also violate a professional boundary. Such gifts may serve as an unconscious bribe designed to suppress anger in either party. Small and inexpensive gifts may be accepted by the analyst when the analyst feels that the acceptance might enhance the process. Even when such gifts are accepted, however, the meaning of the gift to the patient in most cases will be analyzed as an important part of the work.

Clothing and language represent boundaries that are often neglected in the analytic work. An analyst who dresses in a highly revealing or frankly seductive way may convey a misleading message to the patient. Similarly, obscene or profane language may offend some patients and feel like a verbal form of sexual violation.

As noted previously, self-disclosure is an important boundary issue that analysts must attend to in their decisions about interventions. Analysis is by nature asymmetrical. Although two subjectivities are in the room and strong feelings are stirred in both parties, the process is designed to focus primarily on the person who is paying for the service. Self-disclosure by the analyst is inevitable, of course, and the analyst is always making decisions about how useful it would be to disclose certain aspects of the analyst's subjectivity to the patient. It may be extraordinarily useful in some cases to talk about areas of common interest with the patient in the service of building a therapeutic alliance. However, excessive self-disclosure of one's personal problems may unduly burden the patient. Analysts who talk about their own problems misuse the patient's time and money. In some cases, the disclosure of here-and-now countertransference feelings may advance the process in a constructive way. However, telling patients, “I have sexual feelings for you” may shut down the process and make patients feel that they must set the boundaries in the relationship. Similarly, disclosing that one hates a patient or is bored by a patient is rarely useful.

Sexual contact of any form between analyst and patient is unacceptable. This constitutes a firm, inflexible boundary. In the transference the analyst becomes a parent to the patient so that any form of sexual relations is symbolically incestuous. Moreover, because of the transference and the power differential, the patient cannot provide informed consent to such a relationship, even if the patient is an adult and consciously attracted to the analyst. This absolute abstinence regarding sexual contact facilitates frank and detailed discussion of the patient's sexual desires in a safe environment.

Physical contact such as hugs or pats on the back may also be problematic. In general, a handshake is probably the ordinary limit of physical contact between analyst and analysand. An occasional hug in the midst of a personal tragedy, such as the loss of a child, spouse, or parent, might be appropriate if initiated by the patient. However, when the analyst initiates a hug, the patient may readily misconstrue the analyst's motives. Another basic guideline regarding touch is that the impact of such behavior on the patient may be dramatically different from the analyst's intent. Patients may ask for hugs or even demand them, but psychoanalysis is about the wish to be held or hugged rather than the concrete enactment of such wishes. The patient must be engaged in a mourning process to deal with the grief and resentment about the deprivations of childhood, the frustrations in the present, and the insistence of the analyst that the relationship remain an analytic one. When actual physical contact occurs, especially on a regular basis, the distinction between the symbolic and the concrete is lost, and the patient may feel that powerful childhood longings will finally be satisfied by the person of the analyst. This situation will likely evoke false hopes in the patient that can never be gratified.

When one gets outside the realm of extreme boundary violations, such as financial exploitation or sexual involvement between analyst and patient, there are gray areas where certain transgressions of boundaries may actually be helpful in an analytic process. Thomas Gutheil and the author distinguish between a boundary *violation,* which exploits the patient and is harmful or potentially harmful, and a boundary *crossing* that may be benign or even helpful to the analytic process. With the contemporary understanding that countertransference enactments are inevitable, it is sometimes hard to differentiate which enactment is a crossing and which is a violation. Often the meaning of a boundary crossing may be the only real clue to understanding whether the enactment is a violation or not. In general, a countertransference enactment that turns into a useful boundary crossing is attenuated, does not occur on a regular or repetitive basis, and is subject to analytic scrutiny. Boundary violations, on the other hand, are generally part of an ongoing, repetitive pattern of boundarylessness and are rarely subject to detailed analytic scrutiny. Finally, in a boundary violation the analyst's behaviors cause harm to the patient and destroy the viability of the analytic process (Table 30.1-2). Sexual relations between analyst and patient are an example of a boundary violation. The following vignette is an example of a boundary crossing.

Dimensions of analytic boundaries	Professional role, time, place and space, money, gifts, business transactions, clothing, language, confidentiality, excessive self-disclosure of personal problems, physical contact, sexual relations
Boundary violations	Egregious enactments that are often repetitive, not subject to analytic scrutiny, pervasive, and harmful to the patient while also destroying the viability of the analysis
Boundary crossings	Benign, and even helpful, countertransference enactments that are attenuated, occur in isolation, are subject to analytic scrutiny, and extend the analytic work in a positive direction

Data from T. Gutheil, M.D., G. Gabbard, M.D., and J. Lester, M.D.

Table 30.1-2 Analytic Boundaries and Boundary Violations

At the end of a long and frustrating session, the therapist felt like nothing she had said had been helpful. She had been preoccupied with the fact that her own mother was ill, and she had not been as available to the patient as usual. As the therapist and patient got up from their chairs, the patient asked, “So where are you going next week?” Without thinking, the therapist responded, “I'm going to visit my mother in Colorado. She's very ill.” The patient said, “Oh, I'm sorry,” and left the office looking worried. The therapist instantly recognized that she had revealed information that might have burdened the patient with her own problems. As she reflected on her enactment, she recognized that she has been feeling guilty about not having been very helpful because she was so preoccupied and was unconsciously trying to gain some sort of absolution or forgiveness from the patient by explaining the situation to him.

After her 1-week absence, she brought up what had happened at the end of the session with the patient and explained that she probably should not have burdened him with the information she offered. She went on to suggest that they might beneficially explore his reactions to it. In the course of sharing some of his thoughts about what happened, the patient noted that his mother had always confided her problems to him, and he thought something like that was repeating itself in the therapeutic relationship. In this instance no lasting harm was done to the patient, and the event turned out to be a useful focus for further exploration. An important reason why this enactment was constructive was that it was discussible between therapist and patient.

Goals and Therapeutic Action It is customary in most of medicine to speak of cure as a treatment goal, but one must be considerably more cautious in discussing the outcome of psychoanalysis. A key aspect of the analyst's position is avoiding therapeutic zeal. The analyst's task is to analyze, interpret, and provide understanding. The patient's task is to decide how much and in what direction to change. When analysts start to have a specific therapeutic agenda for their patients, they are at risk of creating a situation in which the patient changes to please the analyst or rebels to defy the analyst, a re-creation of common parent-child situations. Hence the goals of analysis emanate as much from the patient as from the analyst. Conversely, without clear therapeutic goals for the analysis, it can meander

aimlessly indefinitely, with both parties ultimately feeling frustrated.

The goals of psychoanalysis are intimately linked to conceptualizations of the therapeutic action of the treatment. The mechanism by which psychoanalysis works is a source of controversy in the field. When Freud first began treating hysterical patients in the 1890s, the therapeutic action was simple and straightforward in his view: through abreaction the analysis would help the patient release dammed up affects and recover previously repressed fantasies, memories, and feelings. After Freud developed the structural model, though, abreaction became less significant, and he regarded the therapeutic action of psychoanalysis as involving a redistribution of the interrelationships among the intrapsychic agencies. In Freud's words, “Where id was, there ego shall be.”

Freud always thought that transference work was crucial to effecting change in the patient. However, Strachey in 1934 most clearly articulated an understanding of how transference interpretation produces change in psychoanalysis. Strachey believed that a harsh superego was at the core of most neuroses and that modification of the superego through interpretation is the essential therapeutic action of psychoanalysis. Strachey identified a vicious cycle that takes place in analysis in which the patient's id impulses and harsh superego are transferred to the analyst. The analyst is then experienced as a dangerous and frightening object. Seeing the analyst as a threat produces further destructive impulses toward the analyst; those impulses are then projected to create an even more hostile object.

That vicious cycle is broken, in Strachey's view, through mutative transference interpretations. After interpretation of the transferred id impulses to the analyst, patients become aware that their hostile impulses are directed toward internal parental objects, rather than real objects in the present, such as the analyst. As those interpretations are repeated in the context of the process of working through, patients realize the discrepancy between their own perceptions of the analyst and the real characteristics of the analyst, who then becomes a much less frightening object. The superego is correspondingly modified.

Mechanisms of change and analytic goals vary according to one's theoretical perspective. Analysts working within the framework of the British School of object relations theory believe that an analysis must do more than alter interrelationships between intrapsychic structures. They stress the need for change in mental representations of self and object and in the affective linkage between those representations. They believe that such changes are brought about partly through interpretation but also through the analytic relationship itself. The provision of a holding environment, the analyst's persistent curiosity and interest in the internal experience of the patient, and the analyst's ability to endure attacks or seductions from the patient, provided a new emotional experience for internalization.

Kleinian analysts emphasize the process of containment in producing change. Through projective identification, the analyst becomes a container of the patient's self- and object-representations, often in association with powerful affective states. Before those projected contents are returned to the patient by the process of reintrojection, the analyst psychologically processes (and thereby modifies) the patient's representations. For example, if a patient projects an abusive internal object representation into the analyst, the analyst feels pressured into behaving abusively toward the patient, but instead attempts to process and understand the projected contents. When the patient reintrojects the abusive internal object representation, it has been modified by the analyst's containment process. The modified object representation then modifies the corresponding internal self-representation. In other words, a new mode of object relatedness has been internalized through the projective identification and containment.

Some object relations analysts, such as Winnicott, view the patient as developmentally frozen. The experience of the analyst as a new object allows the patient to resume development and to experience previously thwarted positive relational and emotional capacities. Some analysts have compared it to a reparenting model in which the analyst conveys acceptance and validation of the patient's uniqueness and autonomy.

Self-psychology views the goal of psychoanalytic treatment as the strengthening of a weakened self so that it can move from a dependence on archaic selfobject experiences to a position of greater self-cohesion that allows for reliance on mature selfobjects. Kohut asserted that the goal was accomplished by laying down psychic structure through optimal frustration and transmuting internalizations. He noted that failures of empathy are unavoidable in analysis and that the systematic interpretation and understanding of those empathic failures provide optimal frustration and the gradual internalization of the analyst as a new object. The essential curative aspect of the analytic process, however, is the establishment of empathic attunement between the self and the selfobject on a mature level. The experience of empathy allows the patient to overcome enslavement to archaic selfobjects in the service of maintaining self-cohesion.

A trend that cuts across theoretical models is the recognition that multiple modes of therapeutic action come into play in most patients. Both insight and a new relationship experience, for example, may be influential in producing change in the same patient. Moreover, different groups of patients may change in different ways. Sidney Blatt identified two types of patients—introjective and anaclitic—who appear to respond differently to psychoanalytic treatment. The introjective patients are ideational and preoccupied with establishing and maintaining a viable self-concept rather than with establishing intimacy. They appear to be more responsive to insight through interpretation than to the relationship with the therapist. On the other hand, anaclitic patients are more concerned with issues of relatedness than self-development and gain greater therapeutic value from the quality of the therapeutic relationship than from interpretation.

Many models of therapeutic action emphasize the analyst's efforts to provide symbolic meaning to the patient's thoughts, feelings and behaviors. The patient's internal object relations, based on early attachment experiences, are encoded in implicit or procedural memory. In psychoanalytic treatment, these patterns appear in the way the patient relates to the analyst. The analyst points out these patterns as a way of helping the patient develop a sense of mentalization or reflective function, that is, the capacity to recognize that behavior grows out of internal feeling states and representations that serve as motivating sources. From a developmental perspective, this mode of therapeutic action is analogous to a parent reflecting on a child's behavior. Children perceive themselves in their parents' minds and develop a sense of self from such perceptions. Similarly, patients may gain a greater sense of who they are from observing their therapists' reflections about them. These interactions also enable the patient to appreciate more fully the separate subjectivity of the analyst.

Conscious mastery of repetitive relational modes is accompanied by nonconscious affective and interactive connections. Many former patients remember moments of emotional engagement with the analyst far more clearly than the content of any specific interpretation. Some changes occur in the realm of implicit or procedural knowledge involving how to act, feel, and think in a particular relational context. Psychoanalysis can be conceptualized as a new attachment relationship that restructures attachment-related implicit memory. Stored prototypes are modified by new interactions with an affectively engaged therapist. At the same time, explicit memory involving a conscious narrative is altered by interpretive understanding.

Regardless of which theoretical school the analyst embraces, patients at the termination of a successfully conducted analysis feel certain predictable changes. They often have a sense of being freed up from previously mystifying internal constrictions. They may feel more creative and productive so that they are able to pursue work and leisure time activities with more enthusiasm. They are also likely to experience a much greater sense of mastery over their internal states. Greater tolerance of anxiety, for example, allows them to use that disturbing affect as a signal to reflect on what internal and external circumstances are causing concern and thereby to understand the source of the anxiety. Most patients at the end of analysis also experience a much expanded capacity to love others without as much contamination by conflicted relationships from the past. Through identification with the analyst, patients have internalized the self-analytic process that can be used to understand and master new situations as they arise throughout the life cycle. All of these changes can be used by analyst and patient to assess the readiness for termination.

Psychoanalytic Psychotherapy Psychoanalytic psychotherapy is based on fundamental dynamic formulations and techniques that derive from psychoanalysis and is designed to broaden its scope. Psychoanalytic psychotherapy in its narrowest sense is the use of insight-oriented methods only. However, as generically applied today to an ever-larger clinical spectrum, it incorporates a blend of uncovering and suppressive measures.

The strategies of psychoanalytic psychotherapy currently range from expressive (insight-oriented, uncovering, evocative, or interpretive) techniques to supportive (relationship-oriented, suggestive, suppressive, or repressive) techniques. Although those two types of methods are sometimes regarded as antithetical, their precise definitions and the distinctions between them are by no means absolute.

Thirty years after delineating four intrinsic criteria of psychoanalysis (centrality of transference, neutral analyst, regression to transference neurosis, interpretation as sole instrument), Gill revised them in 1984 to provide the backbone of modern psychoanalytic psychotherapy: (1) the centrality of transference is broadened to encompass nontransference manifestations; (2) the guiding principle of neutrality is loosened to acknowledge the real personality and attitudes of the analyst; (3) the regressive transference neurosis is supplanted or replaced by less frustration, fantasy, and focus on the past (and greater gratification, reality, and focus on the present); and (4) interpretation is extended to include more nonexploratory methods (with genetic interpretations expanded by here-and-now interpretations. Those intrinsic changes accompany three major extrinsic changes: reduced session frequency, reduced or more flexible treatment duration, and abandonment of the couch.

Psychoanalytically informed psychotherapies are often divided, somewhat arbitrarily, into psychoanalysis, expressive psychotherapy, and supportive psychotherapy. These three modalities actually reside on a continuum with significant overlap and blending occurring among the three categories. An overview of this continuum is

presented in Table 30.1-3.

Table 30.1-3 Psychoanalytically Informed Psychotherapies: A Clinical Continuum*

In general, psychoanalysis and expressive therapy are oriented to analyzing transference and defenses and uncovering unconscious material. Supportive psychotherapy, while psychoanalytically informed as well, is geared to suppressing unconscious conflict and bolstering defenses. These distinctions have been used traditionally to differentiate expressive from supportive modalities. In recent years, however, there is a growing consensus that the traditional dichotomy is misguided. In the Menninger Foundation Psychotherapy Research Project, Robert Wallerstein studied the treatment of 42 patients in great detail and had access to long-term follow-up data. He concluded that all forms of psychoanalytically informed psychotherapy, from the most expressive (e.g., psychoanalysis) to the most supportive contain a mixture of supportive and expressive elements. Commenting on the tendency in the literature to view supportive therapy as inferior to expressive therapy and analysis, Wallerstein also stressed that the changes accomplished by supportive interventions appear to be just as durable as those produced by expressive strategies. He argued that psychotherapy should be viewed as taking place on an expressive-supportive continuum and that the key point in every psychotherapy process is to determine how and when to be expressive and how and when to be supportive. This shift in the way that psychoanalytically informed psychotherapies are conceptualized has led to a tendency in the recent literature to acknowledge the blending of strategies with terms such as expressive-supportive or supportive-expressive psychotherapy. The effective psychoanalytic psychotherapist will ultimately shift flexibly back and forth along the expressive-supportive continuum, depending on the needs of the patient at a given moment in the psychotherapy process.

Despite this tendency for therapists to switch back and forth across the expressive-supportive continuum, many therapies are predominantly expressive or predominantly supportive. This designation is largely determined by two factors: the use of specific therapeutic interventions and the degree to which the transference is analyzed. Supportively weighted psychotherapy is much more likely to be characterized by a greater number of extratransference interventions than are focused on the therapeutic relationship itself. By contrast, expressive therapy attends in much greater detail to the analysis of transference. The therapeutic interventions themselves can be categorized as residing on an expressive-supportive continuum as illustrated in Figure 30.1-4.

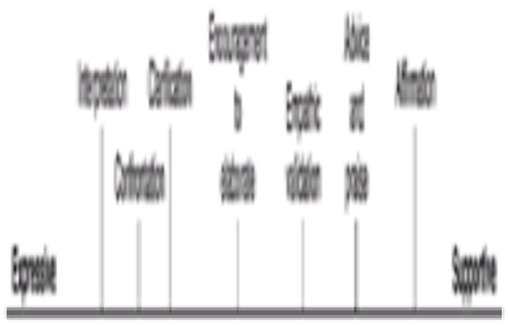

FIGURE 30.1-4 An expressive-supportive continuum of interventions.

Considered the primary intervention in psychoanalysis and highly expressive psychotherapy, interpretation has traditionally designated an intervention designed to make something previously unconscious available to the conscious awareness of the patient. As the concept has evolved, however, the criterion that something unconscious is made conscious has become less absolute. Interpretations often involve explanatory statements that link behaviors, thoughts, fantasies, feelings, or symptoms to their unconscious meanings or origins. They may also link experiences in the transference to parallel situations in current extratransference settings or to the past. For example, the psychotherapist might say to a patient who has forgotten to bring his check so that he could pay for his session, “I wonder if the reason you forgot to bring the check is that you are dissatisfied with the kind of treatment you're receiving here.” Interpretations can also be made on the basis of extratransference phenomena. For example, “It may be that you cannot confront your colleague at work about his unpleasant comments because he reminds you of your father and it revives the same set of conflicts about being forthright with your dad.” Interpretation of unconscious content is generally postponed until the unconscious material is close enough to conscious awareness that the interpretation can be heard nondefensively by the patient.

Confrontation, the next most expressive intervention, generally calls the patient's attention to something the patient is trying to avoid or minimize. Confrontations frequently reflect back to patients the aspects of their behavior that affect others in specific ways. They may also help patients come to terms with disavowed feelings. Although confrontation may have an aggressive connotation, this type of intervention can also be gentle and delivered with sensitivity. For example, “I'm not sure if you noticed, but after I asked you to tell me more about your father, you changed the subject to the car trouble that you've been dealing with recently.”

Clarification is lumped together with interpretation and confrontation as the principal interventions in expressive psychotherapy. Clarification involves an attempt to pull together a number of diverse things the patient has been saying and repackage as a summary of the principal points the patient is making. For example, after listening to the patient for 30 minutes, the therapist might observe: “It sounds like what you're saying is that you repeatedly try to make yourself understood in a variety of situations—with your boss, with your husband, and with your father—and in each situation you have the experience that nobody really grasps what you're trying to say.” As this example indicates, the therapist may help patients articulate something that they have difficulty putting into words.

Encouragement to elaborate, an intervention that lies directly in the middle of the expressive-supportive continuum, may be generally defined as a statement or question that facilitates further elaboration on material the patient is currently discussing. Typical examples are such statements as the following: “I'm interested in hearing more about your feelings about the divorce,” “Does anything come to mind about the dream?” or “How long would you say you felt this way about your dad?” Such questions and statements are used equally in predominantly expressive psychotherapies and predominantly supportive ones.

Empathic validation is a comment designed to help the patient feel understood by demonstrating that the therapist is attuned to the patient's internal state. The therapist may wish to validate the patient's specific feelings being addressed at a moment in the therapy: “I can certainly understand why you would feel outraged at having been treated that way.” The therapist may also acknowledge the adaptive value of the patient's behavior: “I can appreciate from your point of view that the way you behaved seemed like the only viable alternative.” Some self psychologists have suggested that empathic immersion in the patient's internal experience is essential, regardless of where the therapy resides on the expressive-supportive continuum, and that all interventions should be delivered from an empathic perspective.

Advice and praise involve two types of interventions linked by the fact that both reinforce certain activities and proscribe others. Advice, of course, can be defined as direct suggestions to the patient regarding what to do or how to behave. Praise is designed to reinforce certain kinds of feelings, behaviors, or thoughts by expressing overt approval of them. These types of comments are used frequently in supportive therapy. For example, when a patient avoids facing a self-destructive situation, the

therapist might say, “I think it's important that you stop seeing this man in light of his abusive behavior toward you.” If the same patient stopped seeing the man on her own, the therapist might say, “I'm very pleased that you made the decision to stop seeing him because I think it represents a wise choice.” Therapists who use these interventions are departing from a more traditional view of neutrality by offering a value judgment of a particular situation. However, even in certain instances of expressive therapy, therapists often make no effort to completely mask their feelings. Hence advice and praise are used occasionally in expressive therapy as well.

Affirmation is a simple intervention designed to support or affirm the patient's behaviors or comments. In that sense it is linked to advice and praise but is more succinct. Examples are “You're absolutely right,” or “I certainly see exactly what you mean.” Even responses such as “yes” or “uh-huh” may be affirming to the patient.

Expressive and supportive psychotherapy are considered separately below, even though most psychotherapies involve some mixture of expressive and supportive interventions. Indeed, with patients who have limited ego weaknesses, such as those with borderline personality disorder, transference interpretations, which are the most expressive of all interventions, may only be effective after the way is paved with a string of supportive interventions.

Expressive Psychotherapy

Indications and Contraindications According to Karasu expressive psychotherapy is indicated under the following circumstances. (1) Psychoanalysis is diagnostically or clinically contraindicated because the patient lacks sufficient ego strength to tolerate the regression, frustration, or suspension of reality that is required; the patient is deficient in the cognitive resources necessary to achieve deep insight; the patient is not sufficiently motivated because of competing family, social, or cultural influences; or the problem is so pressing that lengthy treatment is unsuitable. (2) Practical or logistical considerations prevail whereby patients otherwise suited for a more lengthy psychoanalysis are unavailable for long-term treatment for reasons of time, money, or geography. For that group the techniques used are closer to those of psychoanalysis proper, because extrinsic rather than intrinsic factors are largely responsible for the change of approach.

Diagnostically, psychoanalytic psychotherapy expressive mode is suited to a range of psychopathology with mild to moderate ego weakening, including neurotic conflicts, symptom complexes, reactive conditions, and the whole realm of nonpsychotic character disorders. The last includes those disorders of the self that are among the more transient and less profound on the severity-of-illness spectrum, such as narcissistic behavior disorders and narcissistic personality disorders. It is also the treatment recommended for some patients with borderline personality disorders, although special variations may be required to deal with the associated turbulent personality characteristics, primitive defense mechanisms, tendencies toward regressive episodes, and irrational attachments to the analyst.

The persons best suited for the expressive psychotherapy approach have fairly well integrated egos and the capacity both to sustain and to detach from a bond of dependency and trust. They are, to some degree, psychologically minded and self-motivated, and they can, at least temporarily, tolerate doses of frustration without decompensating. Patients must have some capacity for introspection and impulse control, and they should be able to recognize the cognitive distinction between fantasy and reality.

They must experience suffering significant enough to motivate them to persevere in the face of frustration, and they should have some meaningful relationships in their lives. The capacity to sustain productive work also reflects the ego strength necessary to engage in expressive treatment. Patients should also be able to regress in the service of the ego and bounce back following the regression. Reflective responses to trial interpretations and the capacity to think in terms of analogy and metaphor also indicate the patient's suitability for expressive work. These characteristics are summarized in Table 30.1-4.

Expressive	Supportive
Strong motivation to understand	Significant ego defects of a chronic nature
Significant suffering	Severe life crisis
Ability to regress in the service of the ego	Low anxiety tolerance
Tolerance for frustration	Poor frustration tolerance
Capacity for insight (psychological mindedness)	Lack of psychological mindedness
Intact reality testing	Poor reality testing
Meaningful object relations	Severely impaired object relations
Good impulse control	Poor impulse control
Ability to sustain work	Low intelligence
Capacity to think in terms of analogy and metaphor	Little capacity for self-observation
Reflective responses to trial interpretations	Brain-based cognitive dysfunction
	Tenuous ability to form a therapeutic alliance

Table 30.1-4 Indications for Expressive or Supportive Emphasis in Psychotherapy

Goals The overall goals of expressive psychotherapy are to increase the patient's self-awareness and to improve object relations through exploration of current interpersonal events and perceptions. In contrast to psychoanalysis, major structural changes in ego function and defenses are modified in light of patient limitations. Instead of systematically resolving the unconscious nuclear conflict, the therapist may opt to resolve some conflict areas and undo specific resistances, intentionally overlooking or reinforcing others. The aim is a more limited, and thus select and focused, understanding of one's problems. Rather than uncovering deeply hidden and past motives and tracing them back to their origins in infancy, the major thrust is to deal with preconscious or conscious derivatives of conflicts as they became manifest in present interactions. Although insight is sought, it is less extensive; instead of delving to a genetic level, greater emphasis is placed on clarifying recent dynamic patterns and maladaptive behaviors in the present. Symptom relief may be an acceptable aim rather than simply a concomitant of the better resolution of conflicts. In more-integrated patients who have the capacity for greater insight, it may be a prelude to further analytic work.

Limitations A general limitation of expressive psychotherapy, as of psychoanalysis, is the problem of emotional integration of cognitive awareness. The major danger for patients who are at the more disorganized end of the diagnostic spectrum, however, may have less to do with the overintellectualization sometimes seen in neurotic patients than with the threat of decompensation from, or acting out of, deep or frequent interpretations that the patient cannot integrate properly.

Some therapists fail to accept the limitations of a modified insight-oriented approach and so apply it inappropriately to simulate the techniques and goals of psychoanalysis. Overemphasis on dreams and fantasies, zealous efforts to use the couch, indiscriminant deep interpretations, and continual focus on the analysis of transference may have less to do with the patient's needs than with those of a therapist who is unwilling or unable to be flexible.

Ms. B., a 34-year-old intelligent and verbal divorced woman, presented with complaints of being unappreciated at work. Always angry and irritable, she considered quitting her job and even leaving the city. Her social life was being negatively affected; her boyfriend had threatened to leave her because of her extremely hostile, clinging behavior (the same reason her ex-husband had given when he left her 9 years earlier after only 16 months of marriage).

Her past included promiscuity and experimentation with various drugs, and currently she indulged in heavy drinking on weekends and occasionally smoked marijuana. She had held many jobs and had lived in various cities. The eldest of three children of a middle-class family, she came from an unhappy and unstable home: her brother had been in and out of psychiatric hospitals: her sister had left home at the age of 16 upon becoming pregnant and being forced to marry; and her overly controlling parents had subjected their children to psychological (and occasionally physical) abuse, alternating between heated arguments and passionate reconciliations.

Initially, Ms. B. attempted to contain her rage in treatment, but it frequently surfaced and alternated with childlike helplessness; she interrogated the psychiatrist regarding his credentials, ridiculed psychodynamic concepts, constantly challenged statements, and would demand practical advice but then denigrate or fail to follow the guidance given. The psychiatrist remained unprovoked by her aggression and explored with her the need to engage him negatively. Her response was to question and test his continued concern.

When her boyfriend finally left her, she attempted suicide (she cut her wrists superficially), was briefly hospitalized, and on discharge was placed on monoamine oxidase inhibitors (MAOIs) for 6 months for her minor but protracted depression. The psychiatrist maintained their regular frequency of sessions despite her greater demands. Although she was puzzled by the steadiness of his interest, she gradually felt safe enough to express her vulnerabilities. As they explored her lack of full commitment to work, friends, and the therapist, she began to understand the meaning of her anger in terms of the early abusive relationship with her parents and her tendency to bring it into contemporary relationships. With the psychiatrist's encouragement she also began to seek work and relationship-oriented minigains. By the end of the second year of treatment, she had decided to remain in the city to stay at her place of employment and continue therapy. She needed to experience and practice her somewhat fragile new self, which included greater intimacy in relationships, additional mastery of work skills, and a more cohesive sense of self. (Courtesy of T. Byran Karasu, M.D.)

Supportive Psychotherapy Supportive psychotherapy aims at the creation of a therapeutic relationship as a temporary buttress or bridge for the deficient patient. As described by Karasu it has roots in virtually every therapy that recognizes the ameliorative effects of emotional support and a stable, caring atmosphere in the management of patients. As a nonspecific attitude toward mental illness, it predates scientific psychiatry, with foundations in eighteenth-century moral treatment, whereby for the first time patients were treated with understanding and kindness in a humane interpersonal environment free from mechanical restraints.

That perspective underlies such diverse developments as milieu therapy for rehabilitating chronic hospitalized patients; crisis intervention to assist otherwise functioning persons through sudden periods of great turmoil or stress; and guidance or counseling practices for children, ex-patients, and nonpatients who need interim help in social, academic, or vocational areas but do not warrant a long-term or in-depth exploration. Supportive psychotherapy has been the chief form used in the general practice of medicine and rehabilitation, frequently to augment extratherapeutic measures such as prescriptions of medication to suppress symptoms, of rest to remove the patient from excessive stimulation, or of hospitalization to provide a structured therapeutic environment, protection, and control of the patient. It may be applied as primary or ancillary treatment. The global perspective of supportive psychotherapy (often part of a combined-treatment approach) places major etiological emphasis on external rather than intrapsychic events, particularly on stressful environmental and interpersonal influences on a severely damaged self.

As a viable modality within the psychoanalytic movement, supportive psychotherapy has been described as the most ill-defined and nebulous of all psychotherapies. It is the treatment to which very difficult, characterologically or intellectually limited patients were referred when no other modality, particularly insight-oriented psychotherapy, seemed suitable. In the late 1940s Alexander and French noted the persistent tendency to differentiate between two main categories of treatment—primarily supportive methods and primarily uncovering methods. The oppositional posture in direct relation to psychoanalysis may be ascribed to its long-standing secondary place within the analytic framework, in which any deviation from the original pure form constituted a compromised or inferior approach.

Role in Analysis With the widening scope of psychoanalysis, supportive psychotherapy has emerged as a specific body of techniques. Today supportive psychotherapy is the preferred modality when primarily supportive (suppressive) strategies, such as suggestion, persuasion, encouragement, reassurance, advice, reality testing, or environmental manipulation, are used (instead of or in addition to insight-oriented strategies) and when caretaking in the form of a positive relationship provides the basic context or milieu for listening to and understanding patients (no matter what specific strategies are used). Not only the actual methods but the entire atmosphere and nature of communication are characterized by support and safety. Its modus operandi has been considered a substitute form of treatment, which temporarily gives patients what they lack or have been deprived of, and which can be therapeutically supplied or at least strengthened. The therapist, as auxiliary or substitute ego, thus offers the patient a secure and nurturing interpersonal relationship as well as specific control, direction, and counsel.

In the psychoanalytic spectrum supportive psychotherapy represents not so much a separate entity as an important emphasis within its expressive-supportive boundaries. Instead of being negatively viewed as a compromised approach for patients unsuitable for analysis, it is positively viewed as effective treatment for a broad clinical range of patients. Concern and empathy are integral to all therapeutic endeavors, but the focus here is on a stance or interpersonal bond that is affectively responsive and oriented to present reality, in which interpretive work in the broadest sense can more readily occur.

Most recent examinations of the subject explicitly recognize the complementarity of expressive and supportive modes of treatment, which can be combined, modified, and individualized according to the needs of the patient. By placing the therapeutic focus more directly on the positive or caring doctor-patient relationship (without analyzing it as a past transference manifestation) and by modifying the analytic technique and verbal communication (less silent and neutral), a supportive philosophy that emphasizes nurturance, real object gratification, and present reality can be used to enhance an analytic structure founded in psychodynamic concepts and expressive techniques.

Indications and Contraindications According to Karasu, supportive psychotherapy is generally indicated for those patients for whom psychoanalysis or insight-oriented psychoanalytic psychotherapy is typically contraindicated—those who have poor ego strength and whose potential for decompensation is high. Amenable patients fall into the following major areas: (1) persons in acute crisis or a temporary state of disorganization and inability to cope (including those who might otherwise be well functioning), whose intolerable life circumstances have produced extreme anxiety or sudden turmoil (e.g., persons going through grief reactions, illness, divorce, or job loss or who were victims of crime, abuse, natural disaster, or accident); (2) patients with chronic, severe pathology, with fragile or deficient ego functioning (e.g., those with latent psychosis, impulse disorder, or severe character disturbance); (3) patients whose cognitive deficits and physical symptoms make them particularly vulnerable and so unsuitable for an insight-oriented approach (e.g., certain psychosomatic or medically ill persons); (4) patients with low anxiety tolerance and difficulty dealing with frustration; (5) patients who lack psychological mindedness and are therefore concrete in their cognitive functioning; (6) those who have difficulty distinguishing external from internal reality; (7) patients with severely impaired interpersonal relationships; (8) those who suffer from poor impulse control and are therefore action prone; (9) patients with low intelligence and little capacity for self-observation; and (10) patients who have an extremely limited ability to form a therapeutic alliance with the therapist. These indications are contrasted with the indications for expressive therapy in Table 30.1-4.

Supportive psychotherapy is usually used when other complications enter the clinical picture, as when the primary diagnosis is physical illness but the patient needs help in dealing with disability, or for long-term mental illness, in which intermittent support and guidance in everyday living augment the control of symptoms through pharmacotherapy and provide out-of-hospital management. Regardless of the diagnosis, a supportive approach is also used in the early phases of virtually all treatments in preparation for the establishment of a firm therapeutic alliance (even when expressive treatment is the predominant mode) or intermittently whenever the patient is in danger of excessive regression.

Because support forms a tacit part of every therapeutic modality, it is rarely contraindicated as such. The typical attitude regards better-functioning patients as unsuitable, not because they will be harmed by a supportive approach, but because they will not derive sufficient benefit from it. In aiming to maximize the patient's potential for further growth and change, supportive therapy tends to be regarded as relatively restricted and superficial, and thus it is not recommended as the treatment of choice if the patient is available for, and capable of, a more in-depth approach.

Goals Supportive psychotherapy has more limited objectives than does insight-oriented psychotherapy because the patient's psychopathology and diminished psychic resources restrict the potential for major intrapsychic change or growth. Because the patient is usually in a decompensated state, all efforts (at least initially) aim at reconstituting and stabilizing the patient's function. Although the individual aims of supportive treatment vary, the general thrust is toward the amelioration or relief of symptoms through behavioral or environmental restructuring within the existing psychic framework. That often means helping patients to adapt better to problems and to live more comfortably with their psychopathology. To restore the disorganized, fragile, or decompensated patient to a state of relative equilibrium, the major goal is to suppress or control symptomatology and to stabilize the patient in a protective and reassuring benign atmosphere that militates against overwhelming

external and internal pressures. The ultimate goal is to maximize the integrative or adaptive capacities so that the patient increases the ability to cope, while decreasing vulnerability by reinforcing assets and strengthening defenses.

Major Approach and Techniques The techniques of supportive psychotherapy are designed to restore or enhance the patient's ego strength by helping the patient to control impulses through direct limit setting, to gain a more accurate picture of reality through the clarification and testing of perceptions, to sustain the adaptive structure by accepting (not analyzing or confronting) defensive maneuvers, and to develop better coping skills through direct teaching and practical advice and through the use of the therapist as a role model and as a constantly reassuring figure on whom the patient can rely. The active therapist serves as a substitute or auxiliary ego until patients can incorporate those assets in which they are deficient, either acutely or characterologically. The safety and security of a controlled and consistent therapeutic atmosphere also act as a holding environment to contain the patients' aggression and dangerous impulses as they learn better to repress or sublimate the tendencies to act out feelings rather than to verbalize them.

Transference management also differs from that of classic psychoanalysis and expressive psychoanalytic psychotherapy. Supportive psychotherapy focuses on the fostering and maintenance of a positive transference at all times and on vitiating the effects of negative transference, should it arise. Instead of facilitating a regressive transference neurosis, complete or partially controlled transference regression is contraindicated, as intense transferences that are allowed to develop in ego-impaired patients can produce sudden, turbulent reactions that have disruptive effects on both the patient and treatment. Although all attempts are made to ensure a positive transference, it is rarely analyzed as such; exceptions are those instances when positive transference may lead to acting out, which can be forestalled by drawing attention to the patient's distorted perceptions and projections. The development of negative transference is minimized by the use of highly structured interventions, with the therapist's assuming a much more direct and active approach than in expressive psychotherapy. That includes discouraging free associations, fantasies, or primary process magical thinking and continually bringing the patient back to reality and the immediate situation.

Techniques are thus designed to focus on conscious external events and on the therapist as a largely nontransferential figure. To accomplish such aims, therapeutic neutrality is judiciously suspended, with much greater direction, disclosure, and gratification offered than would be appropriate in more uncovering approaches. The therapist as a real object serves to validate the patient's reality testing, diminishes the breakthrough of regressive negative transference, and provides a reliable companion to sustain patients until they can function independently.

Limitations To the extent that much supportive therapy is spent on practical, everyday realities and on dealing with the external environment of the patient, it may be viewed as more mundane and superficial than depth approaches: because those patients are seen intermittently and less frequently, the interpersonal commitment may not be as compelling on either the patient's or the therapist's part. Greater severity of illness (and possible psychoses) also makes such treatment potentially more erratic, demanding, and frustrating. The need for the therapist to deal with other family members, caregivers, or agencies (auxiliary treatment, hospitalization) can become an additional complication, as the therapist comes to serve as an ombudsman to negotiate with the outside world of the patient and with other professional peers. Finally, the supportive therapist needs to be able to accept personal limitations and the patient's limited psychological resources and to tolerate the often unrewarded efforts until small gains are made.

Mr. C., a 50-year-old married man with two sons and owner of a small construction company, was referred by his internist after recovery from bypass surgery because of frequent, unfounded physical complaints. He was taking minor tranquilizers in increasing doses, not complying with his daily regimen, and avoiding sexual contact with his wife and had dropped out of group therapy for postsurgical patients after one session.

He came to his first appointment 20 minutes late, after having “forgotten” two previous ones. He was extremely anxious, often lost in his train of thought, and was semidelusional about his wife and sons, suggesting that they might want to have him locked up. He briefly told his life history, which included his coming from a strict and hard-working but caring middle-class family and the death of his mother when he was only 11 years old. He had joined his father's business (taking over on his father's death 2 years earlier), with both of his sons as associates. Describing himself as successful in work and marriage, he claimed that “the only test I ever failed was the stress test.”

Mr. C. explained his lack of compliance with diet restrictions as a lack of will and his constant contact with the internist as his having real physical problems, not yet diagnosed; he rejected the idea of addiction to tranquilizers, insisting that he could quit any time. He had no fantasy life, remembered no dreams, made it clear that he had entered treatment on his internist's instruction only, and started each session by stating that he had nothing to talk about.

After suggesting that Mr. C. was coming to sessions just to pass the “sanity test” and that there was no reason to have him locked up, the psychiatrist encouraged the patient to join him in figuring out the real reasons for his anxiety. Initial sessions were devoted to discussing the patient's medical condition and providing factual information about heart and bypass surgery. The therapist likened the patient's condition to that of an older house getting new plumbing, trying to allay his unrealistic fears of impending death. As Mr. C.'s anxiety declined he became less defensive and more psychologically accessible. As the therapist began to explore his difficulty in accepting help, Mr. C. was able to talk about his inability to admit problems (weaknesses). The therapist's explicit recognition of the patient's strength in admitting his weaknesses encouraged the patient to reveal more about himself—how he had welcomed his father's death and his belief that perhaps his illness was punishment. The psychiatrist also encouraged him to speak about his unrealistic guilt, at the same time helping him to recognize his suspicion of his sons as the reflection of his own wishes concerning his father and his lack of commitment to his medical regimen as a wish to die to expiate guilt. After steady urging by the therapist, Mr. C. returned to work. He agreed to meet monthly with the psychiatrist and to taper off his use of phenothiazines. He even agreed that he might see the psychiatrist for analysis in the future because his wife now jokingly complained of his obsessive dieting, his uncompromising exercise regimens, and his regularly scheduled sexual activities. (Courtesy of T. Byram Karasu, M.D.)

Empirical Research Abundant evidence indicates that psychotherapy is effective. At the end of psychotherapy, the average treated patient is better off than 80 percent of untreated patients. Moreover, the magnitude of the effect of psychotherapy is equivalent to a level that justifies the interruption of clinical trials on the grounds that it would be unethical to withhold such a highly effective treatment from patients.

When the efficacy of psychodynamic therapies is compared with that of other forms of psychotherapy, the results are generally nonsignificant. In other words, overall, psychodynamic psychotherapy is equivalent in efficacy to cognitive-behavior therapy, behavior therapy, and other standardized modalities. Dynamic therapy of depressed patients has been tested in head-to-head comparisons with cognitive-behavior therapy and has been found equally effective. Expressive-supportive therapy of opiate-dependent methadone-maintenance patients has been compared with standard drug counseling. At 6-month follow-up, patients who received the expressive-supportive therapy were doing better on all outcome measures than those with standard drug counseling. Specifically, the psychotherapy patients maintained gains that had been established during the therapy, while those who had standard drug counseling had lost many of those gains. In a large retrospective study at the Anna Freud Centre involving children with anxiety and depressive disorders, intensive psychoanalytic treatment four to five times per week was found to be more efficacious than less-intensive therapy one to three times per week. Treatment length was also positively correlated with better outcomes. Another study showed that intensive psychoanalytic psychotherapy four times a week was more effective in treating children with learning difficulties than once-a-week sessions.

In one controlled outcome study of psychoanalysis, 11 diabetic children were treated with intensive psychoanalytic psychotherapy or psychoanalysis three to four times a week during hospitalizations that lasted an average of 15 weeks. A comparison group was given only standard inpatient medical intervention. At the beginning of the study, all the children had grossly abnormal blood glucose profiles that resulted in repeated hospitalizations. The treatment group showed dramatic improvements that were maintained at 1-year follow-up. Patients in the comparison group returned to their prehospitalization level of blood glucose profiles within 3 months after discharge. In addition, the children treated with intensive psychoanalytic therapy required much less rehospitalization than the comparison group.

Other studies have looked at specific interventions made by the therapist and the link between these interventions and the outcome. Three separate studies have shown that accurate interpretations of the patient's core conflicts predict positive treatment outcome. This finding applies to outcomes within the session of the therapist's interpretation as well as those with short- and long-term follow-up.

Data are accumulating that patients with personality disorders may require more-extended psychoanalytically oriented psychotherapy to achieve significant results. A Norwegian study examined the outcomes of 45 outpatients treated with brief to moderate-length psychodynamic therapy. The patients in the sample had between 9 and 53 sessions of psychotherapy by experienced psychodynamic psychiatrists. For those patients who suffered from personality disorders (but not those without Axis II diagnoses), the number of sessions of treatment directly correlated with the degree of insight they attained 2 years after therapy and with the degree of psychodynamic change 4 years after termination of the therapy.

In another study, 25 patients with personality disorders received extended psychodynamic psychotherapy for a mean period of 25.4 months. They were then followed

up for a mean period of 5.2 years. At the termination of psychotherapy, 72 percent of the patients no longer qualified for a personality disorder diagnosis. At 5-year follow-up, 68 percent did not meet criteria for an Axis II diagnosis, suggesting that the vast majority of patients maintained treatment gains.

In an Australian study of 30 patients with borderline personality disorder, the 12-month period prior to psychotherapy was compared with the 12-month period after the patients received psychotherapy. The psychotherapy itself consisted of twice-weekly psychodynamic treatment for 12 months. There was marked clinical improvement following the psychotherapy period. Medical visits dropped from 3.5 visits per patient per month to 0.5 visits. Incidents of self-harm fell from 3.8 episodes per year to 0.8 episodes. Hospital admissions fell from 1.8 per year to 0.7, while months spent as an inpatient dropped from 2.9 to 1.5 months.

While psychoanalytic psychotherapy is often thought to be prohibitively expensive, this study of patients with borderline personality disorder suggests that in many cases providing such treatment is highly cost-effective. Borderline patients tend to use up a great many health care dollars in visits to emergency rooms, visits to other medical specialists, psychiatric hospitalization, and various diagnostic workups. There is considerable cost savings in providing regular therapy over an extended period of time. Almost all of the outcome measures included a reduction in overall expense as well.

The notion that providing extended psychotherapy reduces the need for hospital treatment is amply supported by other data as well. In 1989 the managed care organization working with CHAMPUS, which covers U.S. military dependents, expanded outpatient psychotherapy coverage under its new utilization review system. The expansion of the availability of psychotherapy resulted in a net savings of $200 million through reductions in psychiatric hospitalization over 3 years. For every $1 spent on psychotherapy, $4 were saved. Similarly, a comparison of the health care expenditures in Australia and New Zealand reflects the cost-effectiveness of having extended psychotherapy available. Unlimited outpatient psychotherapy benefits, including analysis, in Australia led to lower overall mental health care expenditures than in New Zealand, which had limited outpatient coverage. Even though there were twice as many psychiatrists in Australia as in New Zealand, Australia spent $5.7 million per 100,000 population on mental health care expenditures, while New Zealand spent $7 million per 100,000.

The early literature on the economic impact of psychotherapy stressed a concept known as *cost offset*. The notion inherent in this construct was that the addition of psychotherapy would reduce costs of other medical care. Currently, the emphasis in the mental health field has shifted away from this concept to more a complex understanding of how psychotherapy may be beneficial from an economic standpoint. One factor in this shift has been the growing awareness that the narrowly construed concept of cost offset tends to ignore the effects of psychiatric illness on the quality and quantity of life. In other words, implied in the cost-offset notion is that treating mental illnesses is beneficial primarily because it reduces overall costs of other medical care. In this regard it can contribute to the stigma associated with mental illness by suggesting that psychiatric disorders are not devastating in and of themselves and do not deserve treatment.

Another factor in the shift is that many health economists have argued that an exclusive focus on savings in treatment costs may be misplaced. Many discussions of cost-effectiveness stress costs while undervaluing effectiveness. The notion of cost effectiveness should not be regarded as meaning cheap. Rather, it is more accurately defined as meaning high value. In other words, investing a little money in psychotherapy often results in greatly improved productivity on the job and reduced absenteeism from work. Of course an insurance company or managed care company may not view disability improvements as saving them any money. However, there is a broad consensus among health economists that cost-effectiveness can only be defined in terms of the larger societal perspective rather than the narrow interests of a particular business.

In summary, the current thinking on the economic impact of psychotherapy is that it must take into account two different types of costs: (1) the direct costs accruing from actual expenditures for the delivery of the treatment and (2) indirect costs associated with disability, reduced productivity on the job, and mortality costs (i.e., suicide).

A recent German study examined treatment costs connected with 666 patients in either dynamic psychotherapy or psychoanalysis. These treatments decreased medical visits by one third, reduced lost work days by two fifths, and lowered hospital days by two thirds. Successful outcomes were linked to longer duration of treatment. A 1995 *Consumer Reports* survey of 2900 readers who had gone to mental health professionals recorded a similar finding on duration of treatment. Patients who had extended psychotherapy did considerably better than those in short-term treatment, and those whose length of therapy or choice of therapist was limited by managed care interference did worse. One of the repeatedly voiced concerns of managed care and insurance companies regarding the coverage of psychotherapy is that overutilization will result in exorbitant expenditures. Data do not support that speculation. In the most methodologically sophisticated study of the use of psychotherapy under several different copayment arrangements, the Rand Corporation found that even when psychotherapy is offered for free, only about 4.3 percent of the covered population use it and that the average number of sessions is 11.

Several efficacy studies of psychoanalysis have been done in the last half century. These studies, conducted at the Menninger Foundation, Columbia University, the Boston Psychoanalytic Institute, and the New York Psychoanalytic Institute, all suggest that patients who are suitable for psychoanalysis derive substantial therapeutic benefit. The improvement rates recorded in these studies typically range from 60 to 90 percent, and the effect sizes are significant. Three of the studies also found a correlation between length of treatment and therapeutic benefit. Like many of the personality disorder studies mentioned earlier, this psychoanalytic research typically does not use randomized assignment of patients to a treatment group and a control group. Hence one cannot state with certainty that the improvements observed in these studies are definitely related to the treatment provided, because the passage of time may have resulted in some improvements even without treatment.

While a randomized, controlled trial would be ideal, considerable methodological problems exist in trying to use randomization and controls in a study in which the treatment takes 3 to 7 years to complete. These problems include dropout rates decimating the sample, finding a suitable control group, the occurrence of life events that may influence outcome, and the artificiality in the treatment method by the introduction of a treatment manual. Because of these difficulties, a great many research efforts in the area of psychoanalysis in recent years have focused on process measures. Often these involve measuring the impact of the therapist's or analyst's intervention on certain aspects of the patient's characteristics or the process itself. In addition, some highly sophisticated single-case designs have been developed to measure not only process but minioutcomes within sessions.

The editors wish to thank T. Byran Karasu, M.D., for the material on expressive and supportive psychotherapy that appeared in the sixth edition of the *Comprehensive Textbook of Psychiatry*.

SUGGESTED CROSS-REFERENCES

The basic theory of psychoanalysis is also discussed in Section 6.1 on psychoanalysis. As a subspecialty the history and basic tenets of child psychoanalysis are detailed in Section 48.1 on individual psychotherapy of children. Greater elaboration of time-limited dynamic psychotherapy and short-term psychoanalytic approaches appears in Section 30.10 on recent methods of psychotherapy, and more specifically with regard to particular diagnoses in Section 14.9 on psychotherapy of mood disorders. Extending beyond the field of psychoanalytic psychotherapy per se, the relationship of psychoanalysis to other theories or conceptual frameworks is discussed in Section 6.4 on schools derived from philosophy and psychology, including comparison and rapprochement of Kohut and Rogers, and a discussion of integrated views of personality and psychotherapy (i.e., behaviorism and psychoanalysis).

30.2 BEHAVIOR THERAPY

ROLF G. JACOB, M.D., AND WILLIAM H. PELHAM, FH.D.

The term “behavior” in *behavior therapy* is defined as anything a person does. Behavior therapy involves changing what patients do, to improve their health. Behavior therapy includes a methodology, referred to as behavior analysis, for the strategic selection of behaviors to change and a technology to bring about behavior change, such as modifying antecedents or consequences or giving instructions. Today, behavior therapy has not only pervaded mental health care but under the rubric of behavioral medicine it has also made inroads into other medical specialties.

Behavior therapy represents clinical applications of principles developed in behavioral science. Behavioral psychology, or behaviorism, arose a decade after the turn of the century, in reaction to the method of introspection that dominated psychology at the time. John B. Watson, the father of behaviorism, had initially studied animal psychology. This background made it a smaller conceptual leap to argue that psychology should concern itself only with publicly observable phenomena (i.e., overt behavior). According to behavioristic thinking, since mental content is not publicly observable, it cannot be subjected to rigorous scientific inquiry. Consequently, behaviorists developed a focus on overt behaviors and their environmental influences.

Today different behavioral schools continue to share a focus on verifiable behavior. Behavioral views differ from cognitive views in holding that physical rather than mental events control behavior. However, current behavioral orientations differ in how mental phenomena are accommodated. For example, according to methodological behaviorism, mental phenomena or speculations about them have no scientific interest. According to molar or teleologic behaviorism, what seems mental becomes public once the context is considered. Such contexts can be appreciated after the individual has been observed over long enough time. Radical behaviorism treats verbal behavior as a class of behaviors with unique properties; mental events such as thinking are equivalent to the verbal behaviors that describe them.

As new behavioral principles are discovered, new clinical behavioral applications follow, and existing clinical applications may need to be reconceptualized. For example, developments in Pavlovian conditioning require evaluation of treatments developed from earlier Pavlovian models. Advances in the understanding of verbal behavior led to new approaches to treatment and increased the interface with both philosophy and social psychology. Philosophy has a long tradition in the study of logic, which is self-conscious verbal behavior. Social psychology has examined our verbal conventiens with respect to goal setting and emotions.

Behavior therapy uses a precise terminology and represents a specific view of how behavior is influenced. To understand and employ behavioral techniques, the reader needs to learn how to think in a behavioral mode. This mode supplements the normal diagnostic and psychopharmacological mode in which psychiatrists usually function.

BASIC BEHAVIORAL ANALYSIS AND TERMINOLOGY

Behavior therapy uses a precise terminology and represents a specific view of psychopathology. To understand and use behavioral techniques, the therapist must learn to think in a behavioral mode. Much of the terminology used by behavior analysts today is based on the well-known animal learning experiments conducted by B.F. Skinner and Ivan Pavlov that became prototypes for the study of operant and classical conditioning.

Operant Conditioning In Skinner's prototypical experiment, the rate of a specific behavior of a laboratory animal is modified by planned environmental manipulations. Consider the preparation in which a laboratory rat is taught to activate a lever to receive food. Even before being brought into the experimental chamber, the rat is deprived of food or water. This act is called an “*establishing operation*.” After the animal is placed in the chamber, food is delivered repeatedly in a dispenser that opens with a distinctive sound. The rat quickly learns to approach the dispenser upon hearing the sound. Next, food delivery is made contingent on successive approximations to the target behavior, lever pressing (*shaping*). Presenting a food pellet contingent on a target behavior such as lever pressing is a *consequent operation*. If the lever-pressing behavior increases because of the presentation of food, the experimenter concludes that presentation of the food pellets served as a *reinforcer* of the behavior. The process of learning from the consequences of one's behavior is *operant conditioning* or *instrumental conditioning*. The experimental setup can be further modified. For example, the experimenter can arrange to have lever pressing result in access to food only when a light in the chamber is turned on. After some time, the rat will press the lever only when the light is on. Thus, the behavior has come under *antecedent control*. Specifically, it is a form of antecedent control called a *signaling operation*–the signal being that food reward now is available.

Operations in *establishing operations, antecedent operations*, and *consequent operations* refer to behaviors performed by the experimenters rather than the subjects. Thus, these terms were constructed with the notion that the experimenters are the agents and what they do are the operations. This perspective differs markedly from lay descriptions of behavior, in which the subject is the agent, as illustrated in the following two examples:

(1) The rat presses the lever because lever-pressing behavior is reinforced by the delivery of food according to a specified schedule. The efficacy of food as a reinforcer has been established by food deprivation.
(2) The rat is hungry. It presses the lever because it believes that doing so will result in the delivery of food, and it wants to eat the food.

The lay description (2) is mentalistic (i.e., it explains the behaviors in terms of the desires and beliefs of an agent or subject. The mentalistic idiom is characterized by a mental verb such as *knowing* or *believing* followed by the word “that.” This is a grammatical form similar to indirect speech, and logicians who distinguish between meaning as sense and meaning as reference tell us that expressions following the *that* of indirect speech lose their ordinary reference (because one can no longer substitute an expression for another one referring to the same entity). Thus, the philosopher W. V. Quine cautions against the use of mentalistic language in science because it is referentially opaque. Mentalistic talk is used in everyday discourse, however, because it can be shorthand for describing complex behaviors and because such descriptions convey a sense of empathy. It can be used as a means of generating hypotheses about environmental causes. However, the lack of clarity of reference of mentalistic talk provides subterfuge for the recalcitrant witness under cross-examination. Similarly, irresolvable disagreements over the intention expressed in a behavior can contribute to marital distress. As Quine stated in his book *Roots of Reference:* “One must not mistake the familiarity of mentalistic talk for clarity.”

The increasing cultural emphasis on inner-directed goal pursuit during the recent decades, however, the behavioristic idea that an outside agent might control a person's behavior became uncomfortable. Consistent with this *Zeitgeist,* psychological terminology has become cognitive. Below are contrasting examples of cognitive and behavioral language. The cognitive statement is from *Learned Helplessness* by C. Peterson and coworkers:

(3) Individuals decide among goals and choose the most highly preferred.

The behavioral statement is from the glossary in A. C. Catania's textbook, *Learning* (4th edition):

(4) Preferences quantify the relative effectiveness of different consequences as reinforcers

Statement (3) is similar to the mentalistic statement (2). This becomes more obvious if one considers that the verbs that correspond to cognitive entities such as beliefs govern indirect “that” clauses (e.g., “belief” equals “he believes that” or “memory” equals “she remembers that”). Thus, these terms are referentially opaque. Donald Davidson, in his essay “Psychology as Philosophy,” states that mentalistic statements cannot be subject to physical laws as pursued in science: “it is only the events as described in the vocabulary of thought and action that resist incorporation into a closed deterministic system. These same events, described in appropriate physical terms, are as amenable to prediction and explanation as any.”

Pavlovian Conditioning The second prototypical learning experiment on which behavioral terminology is based is Pavlov's famous experiment in which a food-deprived dog is presented with food after sounding a bell. When the food is presented, the dog begins to salivate; this response is called the *unconditional* (or *unconditioned*) *response* to the food, the *unconditional* (or *unconditioned*) *stimulus*. When the sound from the bell is presented before the food for the first time, the dog responds with an *orienting response*. The orienting response is an alerting response reflexively elicited by new stimuli that has the effect of directing the dog's attention toward the stimulus. After repeated pairings of bell and food, the animal will begin to salivate in response to the bell. The sound of the bell, originally a *neutral stimulus*, has become a *conditional* (or *conditioned*) *stimulus* that elicits a conditional response. To determine if a conditional response has developed, a *test trial* is given in which the tone is presented but not accompanied by food. Compared with Skinner's rat, the important difference is that Pavlov's dog is receiving food because of the bell, not because of salivating. The experimenter's actions in Pavlov's preparation included presenting the conditional stimulus and the unconditional stimulus. Presentation of the unconditional stimulus is a *stimulus presentation operation*, whereas presentation of the conditional stimulus is a *signaling operation*—the bell signals the imminent presentation of food.

The process of developing the conditional response is called *classical conditioning*, or *Pavlovian conditioning*. The above example of conditional response (salivation) may give the impression that conditional responses are always the same as, or similar to, the unconditional response. In fact, early Pavlovian theory postulated that the function of the conditional stimulus was to substitute for the unconditional stimulus. However, later observations indicated that this is not true. Table 30.2-1 lists examples of other unconditional and conditional responses. For example, when the food (unconditional stimulus) in Pavlov's experiment is paired with a light rather than a buzzer, the dog often responds by licking the light source. The conditional response to stimuli signaling an aversive unconditional stimulus, such as electric shock or a predator, is freezing.

Species	Unconditional Stimulus	Conditional Stimulus	Conditional Response
Pigeon	Food	Light	Pecking at light (autoshaping)
Rat		Person feeding animals entering room	General increase in activity
		Tone	Lateral head movement (head jerking) in food area.
		Light	Standing on hind legs (rearing)
Dog	Light	Licking light source	
		Tone	Salivation
Rat	Shock	Light, tone	Conditioned suppression of positively reinforced behavior
		Light, tone	Freezing, analgesia
	Nausea, malaise induced by lithium chloride injection	Taste	Rejection of taste
Human	Nausea from cancer chemotherapy	Clinic environment	Fear, nausea
		Taste of food ingested before tx	Taste aversion
	Opioid drug injection	Drug taking environment	Hypoanalgesia

Table 30.2-1 Examples of Conditional Responses

In general, Pavlovian conditioning occurs if a personally relevant unconditional stimulus is surprising. Acquisition of conditional responses is affected by many parameters. Stimuli that were present right before the unconditional stimulus are potential indicators of future occurrences of the event. With repeated presentations, stimuli consistently present before the event but absent without the event are likely to become elicitors of conditional responses. Thus, teleologically, conditional reflexes seem to be designed to help an individual anticipate future important events.

Respondent and Operant Behaviors The behaviors elicited by the conditioned and unconditioned responses are referred to as *respondent behaviors*. Respondent behaviors often studied were glandular or autonomic responses, responses not normally considered to be under voluntary control. Behaviors that changed in response to previous consequences, *operant behaviors*, tend to involve the skeletal musculature. Operant behaviors are often considered to be under voluntary control. In ordinary language, operant behaviors are referred to as *acts*.

The distinction between operant and respondent behaviors just presented, however, is an oversimplification. For example, respondent behaviors such as freezing in response to danger involve the skeletal musculature. Similarly, operant behaviors are supported by appropriate autonomic changes; for example, animals trained to run in a treadmill for food can be expected to show the changes in cardiovascular parameters typical for exercise. The distinction between operant and respondent behaviors remains clinically useful, however, because it directs attention to the primary variables affecting a behavior. Most behaviors have both operant and respondent elements. For example, emotions are evoked by personally important antecedent events; therefore they are respondent. However, the display of emotions is also affected by consequences. An angry individual who wins a fight is likely to show anger and pick fights more often in the future. Furthermore, in some situations, specific emotions may be expressed because it is socially appropriate to do so. Medical personnel who learn about behavior analysis and behavior therapy find operant behavioral principles a major source for revised thinking.

Antecedent Operations Antecedent operations involve controlling a behavior by changing something that precedes the behavior, including establishing operations, presentation of eliciting stimuli, and signaling operations.

Establishing Operations Measures taken to increase or decrease the value (reinforcing capacity) of a particular consequence are called *establishing operations*. Food deprivation increases the reinforcing value of food-related reinforcers, and satiation reduces them. Other deprived states include thirst (water deprivation) and fatigue (sleep deprivation). Aversive stimulation is an important type of establishing operation. The presentation of aversive stimuli establishes the rewarding value of opportunities to escape. Through classical conditioning, stimuli that signal imminent presentation of an aversive event can themselves evoke escape behaviors. Presentation of the conditional stimulus is a *conditional establishing operation*. Escaping from the conditional stimulus may allow the individual to avoid the unconditional stimulus altogether. Behaviors having the latter effect are called *avoidance behaviors*. The behavioral view of anxiety disorders is largely based on what is known about escape and avoidance behaviors.

In everyday life, anything that affects the value of a consequence, even if not deliberately produced, is an establishing condition. For example, the crash of an individual's personal computer in the middle of an important piece of work establishes the value of help from the local computer expert. The computer crash is called an establishing “condition” rather than “operation” because, presumably, it was not deliberately initiated by somebody. The term *setting events* is an alternative term for establishing conditions. (However, historically, the concept of setting events was formulated before “establishing operations,” which has been in general use only for the last 10 to 15 years. “Setting event” is also used synonymously with “conditional discriminative stimuli” or “context,” described below).

In the clinical setting, symptoms from medical disorders establish reinforcers for acts to reduce them in a manner similar to the presentation of aversive stimuli. Furthermore, certain drug treatments function as establishing operations because they can change the value of a reinforcer. For example, stimulants tend to increase reinforcer efficacy, whereas antipsychotic drugs such as chlorpromazine (Thorazine) decrease reinforcer efficacy.

INDIVIDUAL DIFFERENCES AND LEARNING HISTORY Individuals differ in how much they value a specific reinforcer. Thus, individual differences affect behavior in a manner similar to establishing operations. Individual differences are related to genetic factors, learning histories, and their interaction. For example, genetically transmitted differences in the case of forming and extinguishing a conditional reflex to an aversive unconditional stimulus may manifest as *anxiety proneness*. Anxiety-prone individuals are more likely to act to escape or avoid aversive stimulation. Developmental factors also introduce variability in the way behavior is influenced. For example, children are relatively more sensitive to delay in reinforcement than adults. Certain reinforcers (e.g., toys) have greater value for children than adults. Genetic factors can influence the learning history that an individual will acquire. For example, the sex of a newborn baby instantly prompts differential child rearing practices in the parents. More subtly, certain genetically determined temperaments (e.g., “the difficult child”) may affect a parent's child-rearing practices in ways that can create problems later in life. Such a mechanism has been proposed for the etiology of borderline personality disorder.

Certain learning histories result in enduring “learning sets” that influence an individual's learning strategy in future situations. A history of unpredictable aversive stimulation from which the individual could not escape is conducive to *learned helplessness,* in which individuals respond to new aversive situations with passivity. Rats previously exposed to contingencies in which they could successfully escape from shock are relatively resistant to developing learned helplessness (“learned mastery”). More generally, a history of overcoming difficulties leads to *learned industriousness*. A history of overcoming intermittent reinforcement, extinction, or other forms of “frustrative nonreward,” is conducive to greater persistence in new learning situations. In the same vein, a learning history of overcoming delay of reward establishes an increased value for delayed consequences in the future. This is useful in the development of self-control.

Learning histories do not necessarily reflect exposure to actual contingencies. *Observational learning* (i.e., learning by observing the behavior of others) can affect the variables that reinforce behavior. Culturally transmitted values often result from such learning. Furthermore, modeling and observational learning are the primary method is for learning the academic and professional behavioral repertoires required for independent functioning. Obviously, reading and mathematical skills are essential for gainful employment. Lack of social skills can limit the rehabilitation of schizophrenics or social phobics. One of the first questions considered in behavior analysis is whether the individual has acquired the repertoire of behaviors needed to address a problem. Lack of appropriate skills is referred to as a *behavioral deficit*.

Stimulus Presentation Operations, Habituation, and Sensitization Stimulus presentations elicit various (unconditional) reflexive responses. Responses of this kind that are important for the behavior therapist include orienting responses, startle responses, and defensive or emotional behavior. Repeated presentation of the same stimulus can have two consequences: sensitization and habituation. The former involves an increase in responding, and the latter, a decrease. Slow rates of stimulus presentation are relatively more likely to result in sensitization, and rapid rates, in habituation. Habituation does not occur to highly aversive stimuli. After an intervening longer period without a stimulus, a response that had habituated is again elicited (*spontaneous recovery*).

Signaling Operations In signaling operations a stimulus is presented that on the basis of the individual's learning history anticipates (signals) the presentation of another stimulus or consequence. Signaling operations affect both operant and respondent behaviors. First consider these operations in the context of classical conditioning. The relevant operations are summarized in Table 30.2-2. Simple classical conditioning refers to the case already discussed in which a conditional stimulus (A) precedes the unconditional stimulus (US), the latter causing an unconditional response (UR). The term *reinforcement* means that the unconditional stimulus actually follows the conditional stimulus. A test for the formation of a conditional response requires presentation of the conditional stimulus without the unconditional stimulus (i.e., an unreinforced presentation). If conditioning has occurred, a conditional response (CR) is observed. An arrangement in which the unconditional stimulus follows only some of the conditional stimuli is called *partial reinforcement*. Conversely, presentation of the unconditional stimulus without a preceding conditional stimulus is called *noncontingent presentation of the unconditional stimulus*. Both partial and noncontingent reinforcement reduces conditioning. However, noncontingent unconditional stimulus presentations tend to reduce the strength of the conditional response more than a comparable partial reinforcement schedule does.

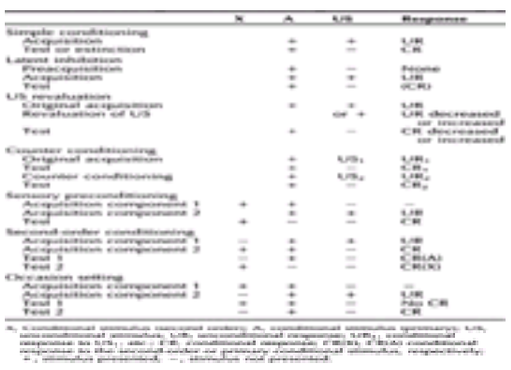

Table 30.2-2 Signaling Operations for Respondent Conditioning

INTEROCEPTIVE CONDITIONING Internal stimuli can become conditional stimuli. For example, if unconditional shock is differentially paired with two different levels of food deprivation (i.e., high deprivation vs. low deprivation), conditional freezing is observed only to the deprivation level that was conditioned. Interoceptive conditioning has a role in the genesis of panic attacks. Internal sensations such as heart palpitations or dizziness that previously preceded panic attacks can acquire the ability to trigger full-blown panic attacks.

EXTINCTION Once established, conditional responses can be modified in several ways: extinction, revaluation of the unconditional response, and counterconditioning. Extinction occurs after repeated unreinforced presentations of the conditional stimulus. After such presentations, the conditional response gradually diminishes and ultimately fails to be elicited. However, even after complete extinction, the conditional response has not been completely unlearned; it may recover spontaneously in a different context or after a longer time interval (*spontaneous recovery*). Furthermore, if the pairings between the conditional stimulus and the unconditional stimulus are resumed, reacquisition occurs more easily.

LATENT INHIBITION Preexposure to a neutral stimulus before conditioning represents a learning history in which this stimulus was present but the unconditional stimulus was absent. If an individual has been preexposed in this manner, a conditional response develops less readily to this stimulus. This phenomenon is called *latent inhibition*. Latent inhibition can be used to prevent adverse reactions to medical treatments. For example, children scheduled for their first surgery do better if they are shown a video of a model undergoing similar procedures. Similarly, preexposure of cancer patients to the chemotherapy environment may reduce the later incidence of conditioned aversive responses to this environment.

POSTCONDITIONING REVALUATION OF THE UNCONDITIONAL STIMULUS Revaluation of the unconditional stimulus involves changing the magnitude of the unconditional response. For example, treatment with opioid decreases unconditional responses to painful stimulation (resulting in devaluation of the unconditional stimulus). In this case, conditional responses to stimuli anticipating the unconditional stimulus also diminish. Conversely, the unconditional response might be increased by increasing the intensity of painful stimulation (inflation of the unconditional stimulus). In this case, conditional responses also increases. For example, patients with spider phobias avoid places in which they are likely to encounter spiders. If they overcome their spider phobia with treatment, devaluation of the spider–unconditional stimulus, should also diminish the fear of places where spiders might reside.

COUNTERCONDITIONING The conditional response can be modified by replacing the unconditional stimulus with another unconditional stimulus that elicits unconditional responses incompatible with that of the original one. For example, an aversive unconditional stimulus might be replaced with an appetitive one. In the treatment of conditional fears in children, presentation of the feared object can be paired with presentation of candy. This method is called *counterconditioning*. The new unconditional stimulus is called a *counterconditioning stimulus*. Counterconditioning thus differs from extinction in that the conditional response not only disappears, it is replaced by a new conditional response appropriate for the new unconditional stimulus. The distinction between extinction and counterconditioning is important for an understanding of various exposure treatments.

SENSORY PRECONDITIONING Signaling operations can involve more than one stimulus. The various permutations of the timing of two conditional stimuli that introduce stimulus configurations and responses can be quite complex; nevertheless, they are important for an understanding of anxiety disorders and their behavioral treatment. Depending on the details of timing, introduction of a second conditional stimulus can lead to second-order conditioning, sensory preconditioning, and occasion setting. In sensory preconditioning, two neutral stimuli, *X* and *A,* are paired without any reinforcement by an unconditional stimulus. The unconditional stimulus is then paired with *A*. If sensory preconditioning has occurred, *X* will elicit a conditional response, even though *X* has never been paired with the unconditional stimulus. Sensory preconditioning may explain why patients with a history of traumatic conditioning develop fears that seem unrelated to the original conditioning event.

SECOND-ORDER CONDITIONING In second-order conditioning, a neutral stimulus (*A*) is first paired with an unconditional stimulus, resulting in a conditional response to *A* (*CR-A*). Thereafter, during some trials, a new stimulus (*X*) is presented before *A*, the unconditional stimulus being omitted during these trials. (The unconditional stimulus is omitted to ensure that *X* is paired with *A* but not with the unconditional stimulus). After a number of such trials, presentation of *X* alone begins

to elicit a conditional response (*CR-X*). (The topography of *CR-X* is not necessarily the same as that of *CR-A*). If the conditional response to *A* is extinguished, the conditional response to *X* is too. Second- and higher-order conditioning may be a mechanism for making phobic reactions persistent. That is, a stimulus (*X*) may have become second-order conditioned to an aversive conditional stimulus (*A*). If the patient fails to escape from *X*, the first-order conditional stimulus *A* will appear and cause escape behaviors from it and in the process reinforce the second-order conditional stimulus *X*.

OCCASION-SETTING STIMULI A stimulus can also be conditioned to *moderate* the circumstances under which the conditional stimulus will elicit a conditional response. To do this, the conditional stimulus (*A*) is preceded by another stimulus (*X*) during some trials, whereas during other trials, *A* is presented alone. The unconditional stimulus occurs only in the *A*-alone trials. For example, suppose the unconditional stimulus was an aversive shock. If *A* is preceded by *X, A* signals "safety." If *A* is presented alone, it signals "danger." The conditional fear response will be elicited only in the latter context. Stimuli such as *X* that moderate the conditional response to a conditional stimulus are called *occasion-setting stimuli*. Occasion setting markedly increases an individual's ability to adapt to new environments. It may be a major mechanism for exposure-based interventions with phobias. Strictly speaking, fears are never unlearned. What is learned with treatment is the safety of the conditional fear stimulus *A* in the context of a new stimulus, *X*, where *X* might represent the delivery of treatment.

CONTEXTUAL STIMULI The function of occasion setting can involve the entire setting rather than just a particular stimulus. For example, if a conditional stimulus is paired with a shock in one setting (setting *A*) but not reinforced in another setting (setting *B*), the conditional response will develop only in setting *A*. The stimuli that define the situation are called *contextual stimuli*. For example, conditional responses may be elicited in the experimental cage but not in the home cage. A human analogue is a resident physician hearing the telephone ringing. In the context of being on call, a conditional stress response will probably be elicited. In the context of vacation, however, the stress response does not occur (except perhaps the first few times).

SIGNALING OPERATIONS IN OPERANT CONDITIONING In operant conditioning, a stimulus that marks the availability of a specific reinforcer is called a *discriminative stimulus* (often abbreviated as S_D; a stimulus signaling that reinforcement is not available is called an S_D, "S-delta"). For example, ringing of the telephone signals that picking it up would result in a conversation.

Signaling operations for operant conditioning can be as complex as those for respondent conditioning. In Table 30.2-2, analogous operant situations can be derived by placing discriminative stimuli in the "X" column, behavior in the "A" column (e.g., key pecking), and the presence or absence of reinforcement in the "US" column. The careful reader will realize that in this arrangement, the S_D or S_d is functionally analogous to occasion setting in classical conditioning; that is, discriminative stimuli set the occasion for reward of the behavior.

The operant contigency that involves a discriminative stimulus, behavior, and consequence is called a *three-term contingency*. The three-term contingency represents the traditional A-B-C (antecedent-behavior-consequence) of behavior analysis. For example, the antecedent might be a red traffic light; the behavior might be driving through the intersection, and the consequence, a traffic ticket. Adding additional levels of conditional stimuli, adds nuance to the stimulus control of behavior. The three-term contingency can be placed under conditional stimulus control, resulting in a *four-term contingency*. For example, only in certain states does a red traffic light cause a right turn to be punished. The discriminative stimulus (the red light) is now the second term in the contingency. The first term (the state) contextually defines the meaning of the discriminative stimulus and is called a *conditional discriminative stimulus*.

DISCRIMINATION, GENERALIZATION, AND CONCEPT FORMATION In both operant and respondent conditioning, stimuli similar to a signaling stimulus can elicit the responses called for by the signal. The more closely the stimulus resembles the signal, the more effective it is in this regard. The relationship between effectiveness and degree of similarity is called a *generalization gradient*. With repeated nonreinforcement of the alternative stimulus, generalization gradients tend to narrow, that is, previously effective alternative stimuli lose their effectiveness. This process is referred to as *discrimination*.

In some discrimination experiments, the alternate stimulus is so similar to the original signal that the difference can barely be detected. When this happens, the laboratory animal may display highly emotional behaviors that persist after termination of the experiment (experimental neurosis). A behavior therapy technique called systematic desensitization was originally developed on cats that had developed experimental neurosis in this fashion.

Generalization and discrimination learning have implications for treatments involving nonreinforced exposure to feared stimuli. For the treatment to have enduring effects, it is considered important to include exposure to the most significant fear (the *core fear*). If the core stimulus is not included, an apparent improvement may just represent discrimination training, leaving the core fear untreated.

In a naturalistic setting, signaling stimuli are rarely identical each time they are presented. In this case, the combined processes of generalization and discrimination may lead to an outcome similar to *concept formation*. Such learning enables us to respond appropriately to new objects. For example, based on past discriminations between many different chairs and nonchairs, one can identify a particular object as a chair, without having seen it before. Humans and animals tend to differ with respect to the information used to form concepts. Animals use principles of similarity (feature learning), whereas humans are likely to form concepts based on semantic (verbal) relations.

Consequent Operations Consequent operations involve presenting or removing a stimulus contingent upon a behavior. If, after this operation, the rate increases, the consequent stimulus is said to be a reinforcer. Reinforcers can be positive or negative. In *positive reinforcement*, a stimulus is added (e.g., food, water, or a drug). In *negative reinforcement* a stimulus that had been previously presented as an establishing operation is removed.

The definition of *punishment* is analogous to that of reinforcement, except that the direction of the behavior change is reversed. "Positive punishment" refers to a consequence that involved adding a stimulus that decreased the rate of the behavior. Negative punishment refers to the operation of removing access to a positive reinforcer. Alternative terms for this latter type of punishment is "fine," or *timeout from positive reinforcement*. This mode of punishment is the one most often used in clinical practice.

Knowing What Will Be Reinforcing Ahead of Time According to the definitions just presented, a reinforcer can be identified only after the behavior has increased. It is tempting to try to avoid this circularity by finding an alternative definition that does not refer to behavior change. One such alternative is to consider "positive reinforcement" as "something pleasurable" or "rewarding." With this definition, one could argue that depriving an animal of enough food to result in significant weight loss introduces an aversive state from which presentation of food would provide relief. Contingent food could be considered equivalent to negative reinforcement (i.e., removal of hunger). Positive reinforcement, in this new context, would be equivalent to gaining access to dessert after completing the main course. Recent neurobiological findings suggest that the brain circuitry involved in food reward differs depending on whether the animal is deprived or nondeprived. The same differences are observed in the case of reward by opiate drugs in nondependent and dependent organisms. To use a mentalistic analogue, "needing" and "liking" may be different phenomena.

Even if the circular definition is retained, certain principles can be used to predict what consequences are likely to be reinforcing. These include the transsituational principle, response deprivation, natural reinforcement, and conditional reinforcement.

TRANSSITUATIONAL REINFORCERS A consequence that has been reinforcing in one situation might be reinforcing in another. Such transsituational reinforcers include food, certain tastes, affection, toys, and devices producing sensory stimulation (such as video games). Attention from others is an important transsituational reinforcer. Attention can serve as a reinforcer even if the resulting interaction is negative.

RESPONSE DEPRIVATION Another principle involves providing or restricting access to another behavior to decrease it below its spontaneous rate. A common example is providing access to TV after homework is completed. For this to work, TV watching must first be restricted to a level below the child's unrestrained TV-watching habits. Therefore, this principle is referred to as response deprivation, or the *Premack principle,* after the originator of a similar method.

NATURAL REINFORCERS As part of social practice, certain consequences regularly follow certain behaviors. For example, a natural reinforcer for artistic behaviors might be public display of a work of art. Natural reinforcers are often contrasted with contrived reinforcers; for example, earning points for art work is a contrived reinforcer.

CONDITIONAL REINFORCERS Stimuli that signal the availability of a reinforcer (discriminative stimuli or conditional stimuli) can themselves become reinforcers. Promises, points, or tokens exchangeable for good or activities are examples of conditioned reinforcers from the clinical arena or everyday life. Their value depends upon their relationship with the primary reinforcer that they signal. Certain conditional reinforcers signal the availability of a number of different primary reinforcers.

Such reinforcers are called *generalized reinforcers,* of which money is one.

Contingency Learning: Contacting New Contingencies How does change in reinforcement produce a change in behavior? The mechanism by which behavior changes after reinforcement is considered analogous to the evolution of species by natural selection; that is, a reinforcing consequent event will select the behavior that preceded it. The initial contact with a contingency may be quite accidental and involves temporal contiguity between the response and the consequence. However, contiguity is not equivalent to causation; an organism's adaptation to the new situation should be enhanced if it can discriminate between a mere contiguity and a causal relationship. Some organisms, including human newborns emit behaviors that have the effect of differentiating between causal and mere contiguous relations between the behavior and the consequence—*contingency-detecting behaviors*. Essentially, contingency-detecting behaviors involve increasing the variability of the behavior to include both very high and very low rates. The low rate tests whether the consequence can occur in the absence of the behavior; the high rate tests whether the behavior is sometimes not followed by the consequence. Increasing the variability of behavior by generating and examining the consequences of a wide range of behaviors is the foundation of a clinical technique called *problem solving*, discussed below.

Even after a contingency has established itself and remains constant, changes in rate of behavior during a session will vary systematically, with an initial increasing trend followed by a decreasing trend. These variations are attributed to the combined effects of habituation and sensitization to the reinforcer. Sensitization tends to take place early in the session, resulting in an increase in behavior, whereas habituation becomes maximal later in the session. A high rate of reinforcement favors habituation; and a low rate favors sensitization.

Intermittent Reinforcement Schedules It is usually easier to shape a new behavior if every instance of the target behavior, or approximations thereof, is reinforced (continuous reinforcement). However, once established, the reinforcement schedule can be thinned (intermittent reinforcement). Behaviors maintained on an intermittent reinforcement schedule tend to be more resistant to extinction than those on a continuous schedule. A large number of different reinforcement schedules have been studied. The most common schedules involve presenting the reinforcer after a specific number of responses (ratio schedule) or after a specific amount of time (interval schedules). These schedules can be either variable or fixed. The variable interval schedule, for example, results in a steady rate of behavior without pauses. The variable ratio schedule often results in very high rates of behavior. In addition to the basic schedules of reinforcement, certain specialized schedules have clinical applications. A schedule in which reinforcement is withheld if the response rate exceeds a certain value is called *differential reinforcement of low rate*. An intervention in which reinforcement is withheld for one behavior and allocated to a different behavior is called *differential reinforcement of other behavior*.

Schedules can be combined to run concurrently or sequentially. They can be signaled by discriminative stimuli, which makes it possible to arrange for an animal to "choose" between different schedules. Reinforcers known to maintain a behavior can also be presented without first requiring a response. Such noncontingent reinforcement decreases the probability of the response.

Multiple Behaviors Competing for a Reinforcer The relative rate of one behavior compared with another tends to be a function of the relative amount of reinforcement allocated to each. This principle is referred to as the "matching law." Of particular interest is the rate of a target behavior relative to the rate of all alternative behaviors. For behaviors maintained by a variable interval schedule, this can be predicted by the formula

$$B = K \times R/(R + R_e)$$

where B is the rate of the behavior (e.g., lever pressing), K is the maximum possible rate of the behavior, R is the rate of contingent reinforcement, and R_e is the rate of reinforcement behaviors other than B. Figure 30.2-1 shows a family of functions relating B to R. Each curve represents different values of R_e or K. As can be seen, each curve shows that increases in the contingent reinforcement rate R are associated with negatively accelerated increases in B, until an asymptote K is reached. The parameter K often reflects specifics of the behavior and recording device (e.g., lever pressing vs. key pecking) and the amount of effort involved in producing B.

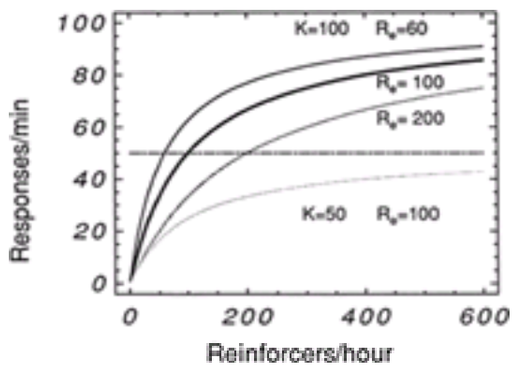

FIGURE 30.2-1 Rate of behavior as a function of R (reinforcement rate), R_e (noncontingent reinforcement), and K (maximal response rate).

The effect of the reinforcement rate R is moderated by R_e, the frequency of noncontingent reinforcement. The larger the R_e, the larger R must be to maintain a given rate of behavior. Environments have been characterized as rich (R_e large) or lean (R_e small). In rich environments, changing the amount of contingent reward, R, will have less effect than in lean environments.

Obviously, one way of increasing a behavior is to increase the reinforcement rate R. If we cannot change R, we can instead increase R_e (i.e., make the environment leaner). A third way of increasing a behavior is to increase K. This can be accomplished by reducing the effort needed to produce the response. The formula above also points toward ways of decreasing a behavior. One way is to stop providing contingent reinforcement ($R = 0$, i.e., extinction). If the reinforcer is stopped abruptly, however, the behavior may increase before it decreases. During this phase, the individual may exhibit emotional behavior indicating frustration. This phenomenon is an example of "frustrative nonreward." An alternative to extinction is increasing the rate of noncontingent reinforcement (increasing R_e), that is, creating a richer environment. Another way of decreasing behavior is to make it more effortful (decreasing K). For example, self-injurious face slapping has been reduced by attaching a weight to the person's wrist.

Another approach to decreasing a behavior is punishment, that is, presenting an aversive stimulus contingent on the behavior. However, like frustrative nonreward, punishment tends to have a number of undesirable effects, including aggression and suppression of concomitant positively reinforced behaviors. Furthermore, punishment attempted for defensive behaviors (i.e., behaviors already under aversive control by negative reinforcement) often further increases the behavior. The punishment method associated with the fewest problems is timeout from positive reinforcement.

Immediate and Delayed Reinforcement In general, the more closely they follow the act the more effective reinforcers tend to be. The strength of a behavior is inversely related to passage of time to the reinforcer. One reason why video games are so reinforcing is that the consequences of the individual's actions appear within fractions of seconds. Certain problems can be attributed to patients being unduly influenced by immediate small rewards at the expense of larger delayed rewards. Examples of such behaviors include overeating, binge eating, risky sexual behaviors, and addictive behaviors.

One puzzling aspect of such impulsive behaviors is that individuals may firmly decide not to engage in them, only to change their mind when the opportunity becomes imminent. The mirror image of impulsive acts is impulsive procrastination. Here the short-term reward comes from escaping or avoiding an unpleasant or difficult task or from timeout from other more rewarding activities in which the individual could have engaged. Why do people change their mind at the last minute and perform impulsive acts that they had resolved to eliminate? Why do people tend to make New Year's resolutions and not keep them? A behavioral answer to this question is shown in Figure 30.2-2. The reinforcing effect of a reward diminishes proportionally with the inverse of the time delay, a hyperbolic function. Figure 30.2-2 shows two hypothetical operant discount functions with identical parameters; one for a large later reward and the other for a small reward occurring relatively soon.

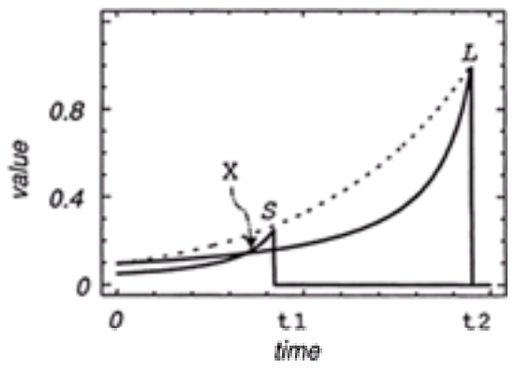

FIGURE 30.2-2 Hyperbolic discount functions associated with reinforcement delay.

Assume that the individual has a choice of two mutually exclusive behaviors. One leads to a relatively small reward *(S)* after a relatively short delay (time t_1). The other leads to a larger reward *(L)* after a longer delay (time t_2). For example, for someone who is reporting an intention to stop smoking, *S* might represent smoking a cigarette at a party scheduled to occur at t_1, and *L* the sum of all long-term benefits of not smoking. At time 0, the discount curve from *L* has a higher value than the one from *S*. Consequently, the person reports an intention not to smoke. As time approaches t_2, however, the discount function for *S* increases faster than the one for *L*, and they cross over at point X. At this point, the person changes his or her mind and smokes, if a cigarette is available, perhaps rationalizing that "I will stop at the next party."

L and *S* can also represent aversive consequences. For example, *L* might be a deadline for a term paper or book chapter and reflect the aversive consequences of missing the deadline. *S* represents the rewarding value of escaping from a difficult task, or the cost of giving up other rewarding activities (e.g., watching television) to start working on the project. Again, as the procrastinator approaches t_1, the motivation to procrastinate becomes more salient. At point X, the motivation to delay becomes stronger than the motivation to start, and the procrastinator puts the project off for the next day. Other examples of impulsive behaviors or delays include staying in bed after the alarm clock has rung, going to a movie instead of studying for finals, or making excessive credit card purchases.

Discount reversals are not limited to operant contingencies. To understand them better, consider some examples from nature. Alert students of high school physics should remember that the apparent brightness of a shining object is related to the square of its distance. Therefore, the brightness of a nearby object increases faster when approached than that of a distant object. If a strong light is far away and a weak one close by, at some point the latter may appear brighter than the former. Similarly, suppose you drive on a road in a valley and see a telephone pole in the distance, in front of a mountain. The top of the telephone pole projects somewhere onto the greenery of a foothill in front of the mountain. As you get closer, however, the pole's visual angle (and apparent size) increases more quickly than that of the mountain behind it. At a specific point close to the pole, the top of the pole will project onto the sky above the mountaintop behind it. This point is the equivalent of point X in the figure, the point of discount reversal.

Discount reversals do not normally occur in economic decision making, because the curve (e.g., compound interest) relating future economic value to the passage of time is exponential. Exponential curves that reflect the same interest rate starting at various time points do not cross over. Figure 30.2-2 also shows an exponential curve that connects *L* with the value of the operant curve from *L* at time zero. An exponential curve from *S* would run parallel to the one from *L* rather than crossing it. For this reason, rational economic decisions do not change as a function of time. It is the discount reversal that occurs with the hyperbolic function that explains many impulsive behaviors.

The model just outlined suggests several approaches to impulsive behaviors. First, any plan to deal with the problem should be made before the crossover point. Reversals of decisions made after that point are suspect. Efforts to prevent relapse of alcoholics include developing the patient's ability to identify such postreversal-point decisions. Such decisions have the appearance of being quite innocent. For example, a compulsive gambler decided to enter a casino "to obtain change for the parking meter." This decision resulted in a relapse of gambling behavior. The term "apparently irrelevant decisions" has been coined to help patients avoid such traps.

Second, measures can be taken to eliminate access to *S*, a method called *precommitment*. This method involves varying degrees of restraint. For example, the smoker discussed earlier may avoid temptation by not going to the party. Patients in weight reduction programs are instructed to plan their meals when they are not hungry and to keep the amount of food in the house at a minimum. Precommitment can also involve physical restraint. This was the method used by Odysseus, when he had himself tied to the mast before sailing past the sirens. Legal restraint was used in a program for drug addicts. Patients wrote incriminating letters and deposited them with the staff. In case of a positive drug screen, the staff was authorized to send the letter to authorities who would have interest in the matter.

Third, *S* could be delayed to a later time (to the right in Fig. 30.2-2). This is the natural consequence of procrastination. When t_1 is moved to a later date by procrastination, the escalating fear of missing the deadline (i.e., the curve from *L*) may finally completely overshadow the aversive consequences associated with getting started. Because of this phenomenon, procrastination tends to be self-limiting. Impulsive behaviors, on the other hand require specific action. Impulsive buyers may reduce their purchases if they establish a habit of first "consulting the pillow" (i.e., delaying the purchase by 1 day by getting a good night's sleep). Similarly, patients with bulimia are advised to remove food from the table as soon as the meal is finished, thus providing a small delay before food is accessible again.

Fourth, the value of *S* relative to *L* could be reduced by modifying its establishing conditions. Binge eating, for example, is in part related to self-imposed dietary restrictions that induce a food-deprived state. These patients can reduce *S* by normalizing their diet. Another way to decrease the net effect of *S* is to increase the noncontingent reinforcement rate, thus creating an environment rich in reinforcement (see section on consequent control). For example, treatment of binge eating includes advising patients to expand their repertoires of rewarding activities, including recreation (i.e., increase those behaviors they like to do rather than ought to do). In the case of procrastination, the punishing value of *S* might be reduced with a technique similar to imaginal exposure called *process simulation*. This involves the patients imagining, or mentally rehearsing, the specific activities involved in working on the project.

An examination of study behaviors of college students before a test found that students assigned to 5 minutes of process simulation started studying earlier, felt less anxious before the test, and had better scores than students assigned to outcome simulation. Process simulation involved the students imagining the specific steps needed to study for the test, including preparing a suitable work area, turning off extraneous stimulation, and going through the study materials.

A final set of possibilities for interventions can be derived from the properties of the delayed consequence, *L*. For example, patients might behave as if they do not sufficiently value *L*. To remedy this, measures are taken to increase the value of *L. L* could be small because the patient has not been informed of its value. Some patients may simply be misinformed, for example, of the value of mammograms or the dangers of smoking or drinking alcohol. An obvious way to increase *L* is to provide appropriate information. Besides increasing *L*, the discount function can be modified, which is mathematically equivalent to reducing the delay in *L*. Obviously, if the function falls less rapidly, the value of *L* at the starting point will be higher. The value of the discount function can be changed by experience. Learning to "delay gratification" in this way is a part of child rearing with demonstrated implications for later adjustment. Even among adults, older individuals tend not to discount delayed rewards as highly as younger individuals. The delay of *L* can be reduced by formulating subgoals or segmenting the time in other ways. In the laboratory, the delay between *S* and *L* can be effectively shortened by the use of conditioned reinforcement or other stimuli that mark, or bridge, the delay interval. This is what may be involved in mentoring. Mentors provide bridging stimuli that help guide their younger colleagues toward distant professional rewards.

Modeling and Observational Learning Learning new behaviors by means of observations is called "observational learning." The individual being observed is called the "model." The model does not have to be a live person; written or verbal instructions represent a special case of modeling sometimes called "symbolic modeling." Modeling can also be done with videotaped or filmed models. In behavior therapy, modeling is the primary method of teaching new behaviors such as social skills. Combined with contingency management, modeling has been used successfully to teach language skills to autistic children. Videotapes of a child undergoing preoperative preparations can be used to decrease preoperative distress in children.

As a consequence of observational learning, the individual matches or imitates the modeled behavior. Given the central importance of modeling in the teaching of new behaviors in humans, it may seem surprising that early behaviorists did not show much interest in it. One reason may have been that Watson, the father of American Behaviorism, during his early career as an animal psychologist, spent two unsuccessful years trying to train cebus monkeys to imitate such behaviors as using a rake

to pull a grape closer to the cage. The monkeys failed to imitate behaviors modeled either by another monkey or by Watson himself:

“Finally, I began showing the monkeys how to draw in the food. I would wait patiently until I apparently had their attention, then slowly hook the T-piece around the grape and slowly draw in the food. The moment the grape rolled near, the animal began to strain at the tether and to attempt to grasp the grape with the paw. The situation was again immediately as before and the rake left near. Never once did any one of the animals push out the rake, hook the blade around the grape, and pull them in, nor did they in any other way ever show any signs of perceiving the relation which ought to exist between the two objects.”

Vicarious Conditioning Besides providing information about how to perform a new behavior, modeling can also provide information on the consequences of behaviors already in an individual's repertoire. After observing the consequences of the model's behavior, the observer is more likely to engage in the same behavior, if the model was reinforced. Such changes in behavior in response to consequences observed with others are said to be a result of “vicarious conditioning.” Thus, there is “vicarious extinction” “vicarious punishment,” “vicarious reinforcement,” etc.

For example, in a street crossing in which the traffic light indicates “don't walk,” one individual walking across the street may prompt others to follow suit. Aggression is another example. The fact that modeling of unpunished aggressive behavior increases aggressive behaviors in the observers continues to fuel the debate about the role of violence on television or in the movies in modeling violent behaviors.

Behavior Systems Principles of operant or classical conditioning are based on the assumption that behaviors and reinforcers can be arbitrarily paired. However, in actuality, response-consequence relations are subject to a number of task-specific constraints. For example, it would be difficult to train a hungry cat to emit grooming behaviors with food reward, but quite easy to shape begging behavior. Similarly, it is easy to condition fear responses in monkeys to neutral stimuli resembling snakes but difficult to do so to neutral stimuli resembling flowers. The principles of Pavlovian conditioning also do not easily predict the nature of the conditional response that will occur for a given conditional or unconditional stimulus (Table 30.2-1).

The topography of the conditioned response can vary with the conditional stimulus–unconditional stimulus interval. In an experiment with laboratory rats, the conditional stimulus consisted of a rolling ball that signaled presentation of a food unconditional stimulus. When the interval between the two was short, the conditional response involved approaching the food tray and digging in it. When the interval was long, however, the conditional responses resembled the behaviors a rat normally emits after it has caught an insect of prey. The conditional responses included chasing the ball, seizing it, carrying it around, gnawing at it, and only reluctantly giving it up to go to the feeder.

Ethological observations suggest that certain biologically important establishing conditions (e.g., hunger) lead to specific combinations of observing and motor responses that combine into fixed sequences of behavior (e.g., looking for food, chasing, eating). These sequential behavioral patterns are called “behavior systems.” More specifically, W. Timberlake defines a behavior system as

> An organized set of sensory perceptual mechanisms, related response components, and motivational processes that evolved because they were correlated with better service of a particular function. In combination with current stimulus conditions, a behavior system can be used to predict and account for the form of responding that emerges.

A feature of this approach that has not been encountered above is stimulus-selection behavior. For example, a hungry traveler will scan the environment for restaurant signs.

The major behavioral systems are organized around the general functions of feeding, reproduction, and defense. In addition, a dominance-submission dimension organizes the social behavior of primates. In humans, the dominance-submission system, along with the reproductive system, has evolved to form various modes of affiliative behavior. A behavioral system has a temporal dimension and a hierarchical dimension. The temporal dimension reflects the specific sequence of behaviors involved in fulfilling the function of the system. For example, appetitive systems, such as feeding or mating, begin with a general search for a suitable object, pursuing and engaging the object, and ultimate consummation or consumption. For the defensive behavior system, the temporal dimension reflects the degree to which danger is imminent, that is, the likelihood of being eaten by a predator. The dominance system might involve behavioral modes of threat and appeasement.

The hierarchical dimension reflects the degree of abstraction used to describe the behavior. The most concrete level contains specific *action patterns*. Sequences of action patterns combine into *modules*, and sequences of modules make up behavioral *modes* (e.g., the general search, chase, and consumption modes of the predatory food acquisition subsystem). The most general level, the *system level*, defines the overall biological or evolutionary task pursued. Table 30.2-3 shows a list of modules and action patterns in the predatory feeding subsystem of the rat. It begins with a travel module, in which environmental stimuli elicit various acts of exploratory locomotion. It normally ends with the consumption module, in which the sensory aspects of food elicit eating behavior.

Module	Activating Stimuli	Act
Travel	Features of general environment	Locomoting
Chase	Distal moving object	Tracking Chasing
Capture	Proximal moving object	Grabbing with mouth and paws
Test	Tactile stimuli	Holding Gnawing
Ingest	Food, taste	Chewing Swallowing
Reject	Bad taste	Spitting out

Adapted from Timberlake W, Silva F: Observation of behavior, inference of function and the study of learning. Psychonom Bull Rev 1:73, 1994.

Table 30.2-3 Examples of Modules Within the Predatory Subsystem of the Rat

The behavioral systems approach can explain the effect of the conditional stimulus–unconditional stimulus interval on the differing topographies of the conditional responses that emerge. Presentation of food defines the endpoint of the feeding system. A long interval elicits conditional responses that are characteristic of a module located relatively early in the temporal dimension of the system. A short interval can be expected to prime behaviors characteristic of later modules of the system. Consistent with this notion, in the case of the rat and the rolling ball conditional stimulus, the chase behavior occurred with the long interval, whereas digging in the food tray and gnawing occurred with the short interval.

Defensive Behavior System The modes in the defensive behavior system include the preencounter, postencounter, and circa-strike modes (Table 30.2-4). These are important for our understanding of phobias and posttraumatic stress reactions.

Mode	Activating Stimuli	Responses
Preencounter	Potential danger	Reorganization of meal patterns
Postencounter	Detecting a predator	Freezing, potentiated startle reflex, opioid analgesia
Circa-strike	Contact with predator	Threat, attack, escape, nonopioid analgesia

Adapted from Fanselow MS, Kim JJ: Neural organization of the defensive behavior system responsible for fear. Psycho Bull Rev 1:429, 1994.

Table 30.2-4 Modes Within the Defensive Behavior System

The preencounter mode is invoked when the organism enters a context that previously was associated with danger but which now lacks signals of imminent danger. That is, the environment is one in which predators are likely but none has actually been identified. The behaviors in this mode include avoidance behaviors, which in the rat lead to alterations in meal patterns. The postencounter mode occurs when a conditional stimulus for an aversive event is presented. In the natural environment, this would correspond to the moment when a predator has been identified. The characteristic behavior for this mode is freezing. Opiate-mediated analgesia is a component of the freezing response. The circa-strike mode is triggered by actual physical contact with the predator. In the laboratory, the circa-strike mode can be evoked by aversive stimulation, such as electric shock. Circa-strike behaviors include threat, counterattack, or escape. The animal that survives the circa-strike experience usually goes back into postencounter mode. Thus, freezing also occurs after a traumatic event.

Behavior Systems, Posttraumatic Stress, and Phobias The behavior systems approach provides a useful perspective for anxiety disorders in humans. For example, in war settings, behaviors appropriate for combat have been described as governed by a survival mode that episodically reappears in the civilian lives of veterans with combat-related posttraumatic stress disorder, manifesting as inappropriate aggressive behaviors. Survival mode behaviors may be equivalent to the circa-strike behaviors of the defensive system. Other symptoms of posttraumatic stress disorder (i.e., freezing, numbing, or dissociation) seem to be reminiscent of the postencounter mode. Parallels have also been drawn between the defensive behavior system and animal phobias. However, some animal phobias (e.g., fear of spiders, cockroaches, rats, maggots) go with the emotion of disgust rather than fear. Disgust fits better with rejection of food (i.e., poison). This function is better included in the appetitive behavior system as a postingestion module (Table 30.2-3).

As anticipated by William James, agoraphobic avoidance might be functionally equivalent to preencounter behaviors.

> Again, take the strange symptom which has been described of late years by the rather absurd name of agoraphobia. The patient is seized with palpitations and terror at the sight of any open place or broad street which he has to cross alone. He trembles, his knees bend, he may even faint at the idea. Where he has sufficient self command he sometimes accomplishes the object by keeping safe under the lee of a vehicle going across, or joining himself to a knot of other people. But usually he walks around the sides of the square, hugging the houses as closely as he can. The emotion has no utility in a civilized man, but when we notice the chronic agoraphobia of our domestic cats, and see the tenacious way in which many wild animals, especially rodents, cling to cover, and only venture on a dash across the open as a desperate measure—even then making for every stone or bunch of weeds which may give a momentary shelter—when we see this we are strongly tempted to ask whether such an odd kind of fear in us be not due to the accidental resurrection, through disease, of a sort of instinct which may in some of our ancestors have had a permanent and on the whole a useful part to play?

In primates, a *dominance-submission social system* determines an individual's social status within a group. Social phobic symptoms appear to be related to this system. The main unconditional stimulus eliciting social phobic responses, including shame and embarrassment, is a prolonged stare by a more dominant member of the group.

Implications for Behavior Therapy The behavior systems approach has implications for behavior therapy that would not be immediately obvious from an operant or Pavlovian perspective.

MODE-SPECIFIC STIMULUS CONSTRAINTS A characteristic of behavior systems is that eliciting stimuli selection depends on the prevailing behavioral mode. Such constraints tend to be more pronounced late in the temporal dimension and seem to be particularly prominent in the sexual behavior system. The human counterpart to sexual behavior systems has been called a sexual script; *scripts* refer to plans or guidelines of what to do when being sexual. If scripts differ too much between partners, sexual dysfunction may develop.

PROGRESSING ALONG THE TEMPORAL DIMENSION Gaining access to the next module serves as a natural reinforcer for the behavior in the current module. For example, catching the prey is the natural reward for the chase. A high degree of deprivation is not needed for such natural reinforcement, as owners of satiated bird-chasing cats can verify. Incidental teaching is a method in which a patient or child's access to the next module is contingent on completing some small task.

The temporal dimension can be violated, either by moving along too quickly or by moving in the reverse direction. Such violations cause problems. A human example of an endpoint being scheduled too soon is proposing marriage on the first date. Conversely, forcing a move from a later module to an earlier one (i.e., further away from the ultimate goal) would be going against nature and the equivalent of an aversive event. For example, few individuals would enjoy having to go to the grocery store (a general search act) just after having served (but not yet eaten) a meal.

PRIMING A DIFFERENT SYSTEM Some of the most dramatic behavior changes occur when a switch is induced from one system to another. This can be done by presenting a salient stimulus (priming) from the other system. For example, a barking dog can be quieted by presenting food—the food being a priming stimulus that evokes the feeding system. A human example of this might be spending the proverbial first date buying a dishwasher or having a parent enter the room during a romantic interaction. Similarly, presenting stimuli priming an entertainment mode of affiliative behavior may derail development of aggressive dominant behaviors.

Behavior Systems and Molar Action Patterns Describing behavior as involving sequences of subroutines organized into larger functional units is not unique to the behavioral systems approach. In a form of contemporary behaviorism called *molar behaviorism*, behavior descriptions can be arranged on a continuum from “molecular” to “molar.” Sequences of molecular actions combine into “action patterns,” which can be part of still larger units of behavior described at increasingly molar levels of abstraction. At the highest level, such patterns can be described as transitioning into “values.”

A behavioral fragment can have different functions depending on the overall context in which it is embedded. Identifying this requires extending the observation time. For example, “swinging a hammer” can be part a number of different contexts (e.g., “hammering a nail,” “smashing a radio,” or “engaging in aerobic exercise”). Hammering a nail, in turn, can be part of “building a house” or “putting a sign on a tree.” “Building a house” can be an instance of “providing shelter,” whose significance might be “supporting one's family.” The latter might be regarded as one of the functions of “being a good parent.”

The molar behavioral view includes an interesting approach to the phenomenon of time. Acts such as singing a song or going to a movie tend to have natural endpoints, and such acts can represent one unit of behavioral time. The occurrence of reinforcement or other natural endpoints segments a person's time into units of behavioral time. For example, molar behavioral analysis of gambling behavior suggests that the stream of gambling behaviors is punctuated by periodic “settling of accounts.” “Compulsive” gamblers tend to settle accounts only after winning a bet, never after loosing a bet. For this reason, they will leave the gambling table only after a win. It can be shown mathematically that this pattern of stopping after a win increases losses. An approach in which the gambler stops after a certain number of bets is not associated with a similar bias toward loss.

A consequence of the molar behavioral analysis of time is that a behavior described at a molar level involves fewer behavioral time units than the same behavior considered at a molecular level. At very high molar levels (e.g., “being free from sin”), accounts may never be settled, in which case a unit of behavioral time is lifelong. The self-control paradigm discussed above described how long-term desirable consequences are offset by immediate but incompatible reinforcers. In a molar approach to this problem, the duration to L, in behavioral time, can effectively be functionally shortened by considering the molar (meaningful) aspects of the behaviors that precede L. That is, the patient needs to engage in behaviors that represent alternatives to—and, ideally, are incompatible with—the impulsive behavior. Furthermore, these alternative behaviors need to be considered at a molar level.

A patient with an alcohol problem joined Alcoholics Anonymous and successfully completed a year's abstinence. A former amateur pilot, the patient had resumed a hobby of building airplanes in his garage. Because drinking was not compatible with building and flying airplanes, the molar airplane-building pattern may have contributed to his success.

VERBAL BEHAVIOR: MAJOR DETERMINANT OF HUMAN BEHAVIOR

It has been speculated that phylogenetically, brain structures supporting speech and sequential motor behaviors tended to develop in synchrony and were adjacent to each other. The ability to manufacture and make use of tools preceded or developed in tandem with speech, both requiring sequencing of behaviors in time. The

sequencing of behavior can also occur across individuals (e.g., taking turns at communal meals). Complex cooperative behaviors (e.g., having one watch out for enemies while the other gathers food, or even mass migration) could be coordinated with the help of verbal behavior defining immediate or extended time frames. The relevant verbal behaviors may have included assertions (e.g., the location of food or sources of danger), commands, and promises (e.g., “I will share the food if you follow the command”). From assertions and promises, mentalistic concepts of beliefs and intentions may have evolved.

With (perhaps) the exception of observational learning, the principles of behavior discussed above apply equally to animals and humans. What is unique to humans is their facility with a special form of communication, verbal behavior. A verbal description of a situation transforms a multichannel, instantaneous sensory experience into output involving a single channel extended in time. The fact that verbal behavior is extended in time may be why humans developed the capability to plan sequences of behavior. It has been speculated that phylogenetically, verbal behavior emerged together with tool use and group living. Both of these activities require sequencing of behaviors, such as taking turns when eating a communal meal, or using tools sequentially (hammer, anvil, and raw material) when building a shelter or making hunting gear. Brain structures involving speech and sequential motor behavior are closely linked.

Communication via Evocative Signals In primates, communication occurs via vocalization visual displays, and facial emotional expressions are part of this communication system. This mode of communication can elicit sympathic emotional states in the recipient. For example, monkeys who have been reared apart from other monkeys tend not to be fearful of snakes but can develop such fears after observing other monkeys acting fearfully with snakes. In humans too, the visual and vocal channels are important for transmission of emotionally tinged information. For example, observation of facial expressions and other nonverbal behaviors constitute one channel for developing empathy with a patient. (The other channel for empathy is derived from information about a patient's situation, i.e., contingencies of reinforcement).

Verbal Behavior The main communication system in humans is verbal behavior. Compared with evocative communication, verbal communication is less prone to sympathic emotional responses in the recipient. The difference between the two modes can be appreciated by inspecting advertisement for cigarettes. The unobtrusively displayed warning label required by federal law represents transcribed verbal information, whereas the advertisement itself contains evocative information. In everyday situations, both verbal and evocative modes of communication are used. The content of the verbal and evocative modes can be inconsistent at times. For example, sarcasm involves positive verbal content but negative vocal content, whereas friendly banter may include verbal insults in the congenial context of the locker room. Verbal behaviors can be classified according to their function (reinforcing consequences). Among the verbal behavior categories proposed by B. F. Skinner, the best known are the “mand” (request) and the “tact” (description of an event). An important component of treating individuals with mental retardation is teaching them to mand, thus obviating the need for other attention-getting behaviors.

The relation between semantic and phonic components of a word is arbitrary, differing across languages, and under reinforcement control to conform to the norms of the verbal community. Ignoring developmental issues, verbal expressions are learned in three ways: by observing someone pointing to an object while naming it (ostension) by explicit definition (a synonymous phrase), and by implicit definition, which involves explaining a variety of sentences in which the word is used.

Behavioral Characteristics of Verbal Stimuli Research findings over the last two decades indicate that verbal stimuli have one unique property, the potential to form a bidirectional relation with the object denoted. As Steven C. Hayes and Linda J. Hayes said in *Rule Governed Behavior,* “The relation between a word and a referent is bidirectional. A word “stands for” the referent only if the referent ‘is called' the word.”

Bidirectionality thus means that a word can evoke the responses that the object would have elicited and the object prompts utterance of the word. The word and the object are in an *equivalence relation* with each other. For example, when people look at a lemon, they may think or say “lemon.” Conversely, when they hear the word “lemon,” they may experience sympathic salivation, especially if they elaborate by describing its color, its shape, the aroma of lemon zest, and the typical sensations that follow squirting lemon juice on the tongue. Similarly, patients with panic disorder are often reluctant to give detailed descriptions of their symptoms, lest such descriptions operating in the reverse direction evoke symptoms of panic. Bidirectionality at times causes confusion between “use” and “mention” of a sentence.

The behavioral concept of bidirectionality comes from the “matching to sample” experimental paradigm. In a paradigmatic experiment, a laboratory pigeon faces three different response keys aligned horizontally. The middle key displays a sample stimulus, either a square or a circle. The lateral keys are the matching keys, which present a color stimulus, either red or green. An experimental trial consists of the sample key lighting up, presenting the sample stimulus. If the sample stimulus is a square, the pigeon is reinforced for pecking the red matching key.

After many successful trials, the roles of the sample and matching stimuli are reversed; that is, when red is presented on the sample key, the correct response is choosing the matching key depicting a square. A bidirectional relation between square and red could be inferred, if the pigeon picked the square immediately, without reinforcement. Pigeons cannot do this, but verbally competent human subjects are. Perhaps the verbal behavior of naming enables bidirectional relations to emerge without explicit training.

Equivalence relations are not limited to pairs of stimuli. An equivalence class refers to several equivalent stimuli. The relations among the members of an equivalence include reflexivity ($A = A$), symmetry (if $A = B$, then $B = A$), and transitivity (if $A = B$ and $B = C$, then $A = C$). Furthermore, if the experimental design is modified to reinforce matching based on criteria other than identity, verbal stimuli become related on the basis of the logical relation reinforced (e.g., larger than, opposite).

Verbal Relations and Logic The recent behavioral insights into verbal behavior constitute a paradigm shift, whose end result is similar to and was anticipated by the linguistic turn of analytic philosophy more than a century ago (although the turn came from a different direction). For this reason, although the behavioral analysis of verbal behavior is not the same as logic, the study of philosophy has acquired renewed interest for the behavior therapist.

Quine's behaviorally inspired philosophical writings on verbal behavior are particularly relevant. Among categories of verbal sentences, an important one is the “observation sentence,” the description of a verifiable stimulus event of limited duration (e.g., the patient is screaming). The “standing sentence” reflects the truth of an event independent of subsequent stimulation (e.g., “the Sunday paper has arrived”). The “theoretical sentence” is a standing sentence referring to theoretical relations. The *observation categorical* is an observation sentence implied by another observation sentence (“if Bob is teased he gets angry”) or theoretical sentence (“whenever uranium's critical mass is exceeded, it will detonate”).

The total of all verbal relations can be conceptualized as a semantic network. At the periphery, the observation sentences constitute the interface with the world. Centrally in the network are the theoretical sentences that may concern abstract objects (e.g., molecules), dispositions (e.g., solubility), and logical truths (e.g., something cannot be both true and false). The relations between the nodes of the network are subject to change, either from direct experience or indirectly through changes in the relations of the central units. The individual's verbal community exerts its standardizing effect only at discrete points in the network, leaving much to be undefined. At the interface between the network and the world, observation sentences can be either affirmed or refuted. When an observation categorical is refuted, its premises must be reconsidered, and changes in these premises require reconsideration of the sentences that implied them. Sentences that are “logically true” (tautological) provide other anchors for the verbal community. For example, when a woman introduces a man as “my husband, the bachelor,” a listener suspects that the woman's use of language was idiosyncratic.

Verbally Defined Stimuli and Verbal Reasoning Because of their capacity to form bidirectional and other relations, verbal stimuli not only can become functionally equivalent to actual stimuli, but also can serve to create new entities (e.g., numbers, square strawberries, the king of U.S.A, metaphysics). For example, when novelists develop a fictitious character, they create a large number of new relations among the verbal stimuli. A well-developed, seasoned character may appear to us as real as a live person. Thus, the role of verbal behavior is not limited to the function of communication, it also serves to create new verbal realities that can be as stimulus-like and as unquestioned as physical objects. Such entities are called *verbally defined stimuli*. In the clinical arena, verbally defined stimuli may evoke maladaptive behaviors. For example, suicidal behavior is made possible by grasping the verbally defined constructs of “future” and “death.” Interestingly, animals do not commit suicide; the behavior of suicide requires a verbally competent agent.

A further example of verbally defined stimuli is the concept of the “self.” According to one behavioral analysis, the self is a verbally defined stimulus complex that develops as a result of concept formation from sentences that include first person pronoun, the word “I.” The section on stimulus presentation operations discussed how the concept of a “chair” developed as the intersection of repeated discriminations and generalizations from chairlike and nonchairlike stimuli. The concept of self might develop similarly, as the intersection of multiple I-statements. This process involves mastering the semantics of the first person pronoun. First person pronoun statements include “I am here,” “I am thinking about I statements,” “I am not over there,” “yesterday I had pain in my shoulder,” “If only I did not have to take that exam next month,” “I remember the bicycle I got as a child,” “When I am 65 I will retire at the beach. (The selected examples concern different time frames, which illustrates how, as the common denominator in these and other examples, the concept of “self” tends to acquire a sense of timelessness.)

Verbally defined stimuli also support the behavior of thinking or verbal reasoning. An important aspect of verbal reasoning is that it follows logical rules, in contrast with nonverbal reasoning, which (based on the principles of conditioning) is governed by perceptual similarity and learned discrimination. Nonverbal reasoning is also called “intuitive,” or “emotional,” reasoning. The two modes of reasoning sometimes lead to different conclusions; for example, patients with panic disorder report that “intellectually” they know that panic attacks are not dangerous, but “in their heart” they fear them anyway. Logical reasoning sometimes leads one astray because of the paradoxical contradictions inherent in self-referential logical situations. Here, it is advantageous to have the nonverbal mode available for “common sense” guidance.

Verbally Governed and Contingency-Shaped Behavior In nonverbal organisms, behavior change is mainly brought about by the shaping of operant responses. In humans, however, instructional control of behavior is the dominant mode of behavior change. Behavior controlled by verbal instructions is called *verbally governed behavior,* whereas behavior controlled by physical contingencies of reinforcement is called *contingency-shaped behavior*.

Verbally governed behavior is classified into several categories. In *tracking*, the instruction is followed because the behavior results in favorable adaptations to the environment, for example, putting a piece of prefabricated furniture together by following an instruction manual. A second category, *pliance* (derived from “compliance”) contains behavior affected by consequences for complying with the instruction itself, regardless of whether or not the instruction is useful. Some law abiding behaviors are of this type. A third category, *augmenting,* contain verbal establishing operations. For example, the statement “a drink sure would be nice” increases the reinforcing value of a drink.

Behaviors that look identical may be functionally different depending on the type of controlling stimuli. For example, putting on a sweater may be either verbally governed or contingency based. In the latter case, reinforcement is based on removal of the aversive effects of cold weather. If verbally governed, putting on the sweater may constitute a response to a mother's command, “put your sweater on” (i.e. a ply) or it could be a track (i.e., a response aimed at not getting cold in response to information that it is cold outside). Finally, it might be augmental, in response to hearing that a certain famous person wears this type of sweater. In many situations, it is preferable to arrange for tracks than for plies. This is especially true in conflictual relationships in which deliberate disobedience might be reinforced. This can result in self-destructive behaviors (e.g., a child failing a test to upset the parent.

Verbally governed behaviors are better than contingency-shaped behaviors when the individual is faced with a new situation. Verbally governed behavior also helps individuals pursue their long-term goals. Verbal stimuli can bring distant goals closer in time and thus enable the individual to choose a larger delayed reward over the immediate gratification from an impulsive act.

On the other hand, verbally governed behaviors can also be associated with problems. Verbally governed behavior is often described in terms of behavioral performance, whereas contingency-shaped behaviors are described in terms of their consequences. Instructions therefore tend to focus on the topography of a behavior rather than the result. The expression “going through the motions” illustrates the case in which a contingency-shaped behavior is being replaced by an instruction-following behavior that replicates its topography but not the accomplishments.

“Expertise” in an area implies exposure to the direct consequences of one's behavior. To generate such expertise without an initial tedious trial and error period, instructions are given to generate a behavioral performance that is good enough to be reinforced by natural contingencies. As instructions are later withdrawn, the behavior comes under the control of the natural contingencies and develops further because of shaping by these contingencies. The process of coaching in sports training represents a careful balance between instructions and behavioral practice in contact with natural contingencies. Excessive instructional control may reduce performance. (This is why compliments can be used to interrupt an opponent's winning streak.)

It may be particularly difficult to change a verbally governed behavior to a contingency-shaped one when the behavior is performed primarily to please the instructor (i.e., can be categorized as a ply). This may be one reason why some verbally governed behaviors are reported to be relatively insensitive to changes in the natural contingencies. For example, a therapist providing treatment according to a detailed manual is engaging in verbally governed behavior. In a research setting (and perhaps future managed care settings), the therapist may be subject to additional contingencies from treatment fidelity assessments. Such contingencies would discourage the therapist from engaging in contingency-detecting behaviors. Under such circumstances, therapists seem to run the risk of becoming immunized against the possibility of learning from direct experience. On the other hand, some interventions (e.g., exposure and contingency management) require strong compliance from the patient. In this case, it may be an advantage for the therapist to be bound by a treatment manual, since it leaves no room to negotiate with a patient who tries to change the treatment program.

Another problem arises when instructional control is attempted but is not possible. For example, spontaneous social behaviors are contingency shaped. In social skills training, patients learn many rules of interpersonal conduct. Such patients may display a robotlike quality in their learned social behaviors (e.g., too much eye contact rather than too little). Thus, a social behavior should be practicing under naturalistic conditions so that contingency control can be established.

Private Events Private events refer to stimuli or actions accessible only to the individual. Private events elicit ambivalent feelings among behaviorists. B.F. Skinner succinctly stated the problem as follows:

> In a sense, verbal behavior which cannot be observed by others is not properly part of our field. It is tempting to avoid the problems it raises by confining ourselves to observable events, letting anyone extend the analysis of his own covert behavior who wishes to do so. But there would then be certain embarrassing gaps in our account. In intraverbal chaining, for example, necessary links are sometimes missing from the observable data. When someone solves a problem in “mental arithmetic,” the initial statement of the problem and the final overt answer can often be related only by inferring covert events.

Private events can be divided into those that seem similar to stimuli and those that are similar to responses. Private stimuli are interoceptive sensations, such as proprioceptive or visceral stimuli, which are important in our understanding of panic disorder. In panic disorder, fear behavior can become conditioned to interoceptive stimuli that regularly precede a panic attack.

During childhood, the individual is taught to name private stimuli. Because the private events are, strictly speaking, not accessible to the teacher, names for these stimuli are learned by indirect means. For example, a report of “nausea” may be anchored by visible physiological responses. In other cases, extending observation time tends to clarify the nature of a private event to a bystander. For example, a toothache may be validated by a later finding of tooth decay; the feeling of hunger can be inferred from the individual's consumption of a large meal. Metaphorical extension of public stimuli to private events gives a listener a tangible impression of the quality of the sensation. For example, pain can be sharp, dull, burning, etc.

Private behaviors can be categorized along a dimension of observing versus acting. Mental behaviors similar to observing include attending, imagining, or recalling. Mental behaviors similar to acts include thinking, reasoning, planning and goal setting. Still others have elements of both, such as categorizing, reformulating, or calculating.

One distinction of clinical importance is the difference between imagining and thinking. Psychophysiological studies indicate that imagining is associated with autonomic responses appropriate for the image being imagined. For example, imagined fear-inducing consequences are associated with increases in heart rate or changes in skin conductance. Worries, on the other hand, are mostly verbal. Thinking worrisome thoughts, unlike imagining, is not associated with pronounced physiological reactions. However, if one specific worry is pursued beyond its normal duration (i.e., if the patient is prevented from changing the subject of worry), a fearful image may appear concomitantly with escalating anxiety levels. Patients with generalized anxiety disorder normally switch to a different worry before this happens. Thus, although experienced as anxiety, worrying may have the function of avoiding even greater fears.

A conceptually tricky issue is whether mental behaviors can be verbally governed (i.e., deliberately changed). Successfully instructing someone to attend to a particular stimulus seems possible, at least temporarily. Similarly, subjects can be asked to set certain immediate goals (i.e., intending, the mental counterpart of promising) or to apply certain strategic modes of thinking (problem solve). However, this control is only partial. For example, it is easier to maintain attention if the stimulus is changing, than if it is constant.

Verbal instructions to change a verbally defined mental behavior risk paradoxical failure. For example, when the change attempt involves not attending to a stimulus or not thinking about something, the verbal instruction provides the very stimulus that is to be avoided. It is impossible to follow the instruction “don't think about pink elephants” and impossible to report seriously that the change attempt was successful. At other times, the mental experience targeted for change becomes inextricably confounded with the instruction of changing the experience. This occurs when a person attempts to change a behavior defined as spontaneous. For example,

deliberately trying to increase one's love for a person is a case of “wanting to love,” which is the anathema of romantic love. (That is, being told “I want to love you” is not as pleasing as being told “I love you.”) Similar difficulties are inherent in wanting to believe, wanting to want, or wanting to desire. For example, patients with hypoactive sexual desire disorder may inadvertently aggravate the problem by recognizing it as a problem. A therapeutic approach to all these paradoxical situations is finding a way to extricate the target behaviors from verbal control. Acceptance and commitment therapy was developed for this very purpose.

Emotions as Descriptors of Contingencies of Reinforcement Recent social psychological research findings suggest that verbal reports of specific emotions suggest specific antecedent conditions, action tendencies and reinforcing consequences. Emotions can be differentiated by whether the eliciting event represents something desirable or undesirable and is located in the past or in the future (e.g., fear). Furthermore, if the event was in the past, a further consideration is whether it was caused by a deliberate act by another person, was accidental, or was a self action (e.g., anger vs. frustration vs. guilt, shame, or embarrassment). Furthermore, emotional behaviors are followed by natural consequences similar to the endpoints of a behavior systems mode. For example, the action tendencies of anger converge on a goal of retribution. The simplified account below should help the therapist to understand how a patient's verbal report of emotional responses reflects that patients life situations.

Fear and Relief Verbal descriptions of fear-inducing situations indicate that the unconditional stimulus for fear is an undesirable event in the future signaled by a conditional warning stimulus in the present. Characterized by the action tendencies of avoiding, freezing, or running away, fear is accompanied by autonomic symptoms such as heart palpitations. The emotional expression of fear (e.g., fear vocalizations and facial expressions) tends to elicit vicarious fear reactions in others—including the therapists when accompanying patients are undergoing exposure treatments. Successful escape behaviors tend to be accompanied by a feeling of relief. From an operant perspective, the feeling of relief is a marker for negative reinforcement. Therefore, for patients with agoraphobia, a history of many episodes of relief suggests a history of frequent negatively reinforced escape behaviors. The experience of relief may lead to sensitization rather than desensitization.

Sadness and Joy Joy marks the attainment of an endpoint of an appetitive behavioral mode. Depending on its intensity, joy tends to be signaled by the behavior of smiling, laughing, jumping up and down, or dancing. (Such behaviors are commonly displayed or enacted by the winners in game shows on television.) Conversely, sadness implies a situation in which the positive reinforcer is no longer available. Behavioral models of depression postulate that depressed individuals do not receive enough positive reinforcement. The action tendency for sadness is giving up. Display of sadness tends to elicit helping behaviors that may restore the lost reinforcer.

Social psychological research indicates that a person's goals are hierarchically organized, with intentions at the lowest levels, and life goals, or ideal selves, at the highest. (This goal system is yet another way of describing of hierarchically organized sequences of behavior.) Two types of life goals have been described, positive (ideal self) and negative (feared self, e.g., teenagers goal of differing from their parents). Depending on the distance from the goal, the affect associated with the pursuit of the ideal self tends to vary along the positive affect dimensions, (i.e., progress from sadness to elation). Affects associated with the avoidance of the feared self, on the other hand, tend to vary along the negative affect dimension (i.e., progress from anxiety to relief).

The difference between the positive affect and negative affect dimensions is reflected in our language. The positive affect dimension reflects things we want to do, whereas the negative affect dimension reflects things we ought to (or should) do. (Note that the issue of free will mostly tends to be raised with respect to the latter.) The distinction between wants and shoulds has been used therapeutically to increase the rate of positive reinforcement in a patient's life, thus creating an environment richer in positive reinforcement. As discussed in the consequent operations section, this enrichment reduces the effect of the reinforcer maintaining dysfunctional behaviors, such as alcohol or drug intake or bulimic behaviors.

Anger Past undesirable events deliberately caused by another person, such as receipt of punishment, is the primary stimulus for anger. The difference between anger and frustration is that anger is evoked by a deliberate act by another person, whereas with frustration, the event was an accident. Patients with chronic medical disorders should have ample reasons to report frustration. In addition, they may be angry with their physicians for not helping them enough or at the opposing party in a workman's compensation scenario. The action tendency for anger is hitting. The goal associated with anger is punishment of the offender. (However, this punishment is likely to be reciprocated in a coercive escalation.)

Pigeons exposed to schedules of reinforcement involving frustrative nonreward or aversive stimulation will work for a reinforcer that is an opportunity to attack an innocent pigeon in an adjoining cage. That is, for both pigeons and humans, innocent bystanders can become targets for retaliatory behaviors. For example, when in the survival mode, patients with combat-related posttraumatic stress disorder often act abusively toward their spouses. Attacking (or expressing anger) is equivalent to an appetitive or approach behavior. This means that the individual experiences the opportunity to punish the perpetrator as desirable. The appetitive nature of anger was confirmed in a recent brain imaging study in which anger induction resulted in changes typical of appetitive behaviors rather than defensive behaviors.

Some behavior therapists recommend the use of unreinforced exposure to treat anger. As we will see later, the purpose of exposure is to extinguish conditional responses to signals for undesirable future events. However, in anger the unconditional stimulus has already occurred; therefore, there are no antecedent conditional stimuli to extinguish. Exposure to past anger-inducing events (e.g., circumstances of a patient's hostile divorce) may even result in increased brooding over this event. Such brooding increases, rather than decreases, anger. Furthermore, behavioral treatment of posttraumatic stress disorder in rape victims was less effective for patients who reported much anger. However, exposure to anger-inducing stimuli may be helpful if the problem is one of fear of anger.

Modification of excessively angry behaviors is difficult. Specific techniques might include validation, education, reevaluation of the offense, avoiding escalation, avoiding alcohol or recreational drugs, derailment by the priming of other behavioral systems, and finding alternative means of resolution. When angry individuals come for psychiatric or behavioral help, the behavioral system view predicts that they initially try to enlist the therapist as an “ally” to punish the offender. This type of alliance, however, is not what is normally considered a therapeutic alliance. Nevertheless, the appropriate therapeutic response in this situation is validation, which means that the therapist agrees with the patient's point of view. The next step might be clarifying the nature of the initial offense. Perhaps the offense was less deliberate than the patient reports. If the source of the anger involves a parent, for example, one strategy might be to perform a behavioral analysis of the parent. This might lead to an understanding of the contingencies controlling the parent's behavior and make it seem less deliberate.

Another approach is to educate the patient about the general nature of anger. Often it is helpful to point out that a particular situation (e.g., chronic innitus) is destined to make the patient frustrated or angry. This intervention tends to be more effective if done even before the patient mentions any such feelings. Explain to the patient that individuals in an angry mode selectively look for things to be angry about and respond more quickly and decisively (but also more impulsively) to small frustrative events. They are irritable and lash out at innocent bystanders. All these effects will be amplified if the patient is intoxicated. A final target for anger treatment is to modify the goal of the anger action tendency. The goal of punishment is replaced by one of forgiveness or one of negotiated resolution. The latter seems to be a favored method among elementary school teachers, who encourage the use of words rather than fists. Assertiveness training is often used for patients who lack an adequate repertoire of negotiating behaviors.

When the patient is in a state of acute anger (in survival mode), a partner or bystander must not escalate with counteraggression. It may be best for the partner to leave the situation altogether until things cool down. Patients can be taught self-control measures that involve the priming method already discussed. For example, watching a comedy show (entertainment), going fishing (general search behavior), or seeking out pleasant odors (e.g., baking a cake) may derail the anger mode.

Disgust Disgust is a specific emotional response to decayed animal matter or body waste. It seems to be most closely associated with the olfactory sensory modality. Disgust thus may serve a principal function of avoiding ingestion of harmful substances, and it supports hygienic behaviors of various kinds. A variant of disgust is also involved in a sexual rejection system in which an individual does not want to be touched by a pursuer. Disgusting stimuli follow a special logic called the law of sympathetic magic. For example, the disgust-eliciting function from a stimulus can be transferred to other stimuli that were in physical contact with it or are similar to it in other ways. This logic is also observed in many patients with obsessive-compulsive disorder who avoid touching door knobs touched by others and engage in excessive cleaning behaviors. Blood and injury phobias and phobias of animals of the creeping or crawling type constitute disgust responses rather than fear responses. The distinction has practical importance in that the eliciting stimuli are unconditional, rather than conditional, stimuli.

Shame, Embarrassment, and Guilt Shame, embarrassment, and guilt are three self-conscious emotions for which the individual's own behavior is the antecedent condition. They can be conceptualized as modes in the dominance/submission system or a larger affiliative behavior system. These emotions reflect various ways of regaining acceptance by the group after an infraction. In guilt, the stimulus is a specific act that caused harm to another person. The action tendency for guilt is undoing and perhaps self-punishment. The undoing aspect can be constructive and lead to conflict resolution. Show of guilt might have a function of preventing punishment by others. For example, criminals may get lighter sentences if they show remorse.

Shame occurs in response to humiliation, or publicly revealed substandard performance. The expression of shame, such as hiding one's face, reflects an action tendency of submitting or hiding. Shame is also related to anger; that is, having one's shameful acts exposed may belong to the class of anger-inducing events.

Individuals who report shameful experiences (i.e., shame-prone individuals) tend to be more aggressive in anger-inducing situations than individuals who are guilt prone; the latter tend to use conflict-resolution strategies instead.

Embarrassment occurs when an individual violates a social convention in front of an audience. Stimuli that reliably elicit embarrassment include seeing oneself singing on a video tape, seeing someone else get embarrassed, being the target for teasing, and being praised too effusively. The expression of embarrassment includes a controlled smile, averting one's gaze, and blushing and is thought to have an affiliative function. For example, the blushing response, being only skin deep, is physiologically similar to the blush that occurs in sexual presentations. The natural consequences for embarrassment include sympathy, humor, and forgiveness.

Surprise Surprise occurs when something that was expected did not occur or when something that was not expected did occur. As discussed above in the section on Pavlovian conditioning, such surprisingness is necessary for conditioning or learning to occur. For example, if an agoraphobic entering a feared situation is unpleasantly surprised by the high intensity of the anxiety response, sensitization might occur. Pleasant surprises, on the other hand, are conducive to desensitization.

Feelings About Feelings Emotional responses can serve as stimuli for secondary emotional responses. For example, an individual who has a childhood history of losing fights may be fearful of getting angry. Fear of fear tends to develop when the fear responses interfere with task performance. For example, musicians with stage fright fear the effects that being fearful will have on their performance. Similarly, fear of blushing may contribute to the development of social avoidance behaviors. Individuals often attempt to cope with fears of emotions by suppressing the emotional complex. However, this only leads to frustration that further compounds the problem. The reader will recognize this scenario as one leading to emotional avoidance, a target behavior suggesting a treatment-approach based on acceptance.

FUNCTIONAL BEHAVIORAL ANALYSIS EXAMPLES

The following sections contain functional analyses of three prototypical clinical problems. The first involves self-injurious behaviors in patients with mental retardation and focuses mainly on the consequences of the behavior. The second problem is a geriatric inpatient with dementia who is “resistant to care,” in which analysis emphasizes establishing conditions and contextual control of behavior. The third problem is parasuicidal behaviors in patients with borderline personality disorder. The behavior analysis of this problem led to the design of dialectic behavior therapy and considers early learning history, current behavioral deficits and contingencies, and principles of choosing among multiple target behaviors.

Self-Injurious Behaviors in Patients With Mental Retardation Self-injurious behaviors are common among individuals with mental retardation. Single-subject designs can be used to identify the relevant controlling variables for the individual patient. In a study summarizing 152 functional analyses, the most common behaviors were hitting head (58 percent), head banging (43 percent), biting (37 percent), hitting body (16 percent), and scratching (16 percent).

The functional analyses were conducted as single subject designs, which varied the consequences of a self-injurious behavior. One consequence, negative attention, involved the experimenter reprimanding the patient and physically interrupting the self-injurious behavior. Another experimental condition, escape from demand, first engaged the patient in a task (as an establishing operation). Contingent on a self-injurious behavior, task material was removed, thus permitting the patient to escape from the task. Other conditions, called “Play” and “Alone” were included in which self-injurious behavior led to no specific externally administered consequence. In the play condition, the experimenter would interact with the patient in a friendly manner on a predetermined fixed time schedule (such as every 10 or every 30 seconds). Some play conditions were modified to follow a differential-reinforcement-of-other-behavior schedule, in which no self-injurious behavior could have occurred for 5 seconds prior to initiation of a play interaction. In the alone condition, the patient was in the therapy room without any play material, this condition represented a test for automatic reinforcement (sensory stimulation).

Contingent escape from task demands accounted for the occurrence of self-injurious behavior in most of the patients. Negative attention (contingent reprimands) came second. The most common cause for self-injurious behavior was contingent escape from task demands. The second most common cause was negative attention (contingent reprimands). In 20 percent of the patients, no environmental cause was identified. In these patients, the self-injurious behavior was hypothesized to be maintained by self-stimulation. Treatments that targeted the reinforcers identified by the functional analysis were more effective than treatments that targeted contingencies irrelevant for the patient's self-injurious behavior. Treatments involving timeout and extinction worked for patients whose self-injurious behavior was maintained by negative attention but not for patients whose self-injurious behavior was maintained by escape from either task demands or automatic reinforcement. Treatments that worked relatively well for all three subtypes of self-injurious behavior included noncontingent play or play interaction during the differential-reinforcement-of-other-behavior schedule. That noncontingent play worked may seem surprising, but it provides an example of how a behavior can be decreased by introducing a rich reinforcing environment.

Aggressive Behaviors in Inpatients With Dementia

> The patient was a 72-year-old female with dementia, who also suffered from urinary incontinence and an arthritic condition in her shoulder. She was able to walk only with support. She had been admitted to a psychogeriatric inpatient unit for being “resistive to care.” On the unit, the patient communicated mostly by nodding or shaking her head or with occasional one-word answers, at times smiling and at other times looking fearful, visually scanning the room. Mental status examination indicated that she knew her own name and that of her daughter, but she was never able to learn the names of her caregivers. She was disoriented to time and place. Specifically, she did not identify her current environment as a hospital. The patient mostly sat quietly in a chair in the dayroom. The target behavior, “resistance to care” occurred in the morning when getting out of bed, in the evening when getting back to bed, or during bathroom visits. These activities required two or three staff members. To reduce the incidence of incontinence, her daily routine included regular visits to the bathroom. The following event constitutes an example of “resistance to care.” Two male staff members approached her for her scheduled bathroom visit. She motioned them away. Ignoring this, the staff members began to lift the patient by her upper arms. The patient responded by scratching one of the staff members. The staff members terminated the interaction. A “level II” was called, and three safety officers in identical blue jackets appeared.

Establishing Conditions The verbal deficits in patients with dementia deprive them from a primary mode of communication. This makes it difficult for the patient to make her needs known. She may have been unable to communicate, for example, that certain ways of lifting resulted in pain in her shoulder. The lack of verbal repertoire also results in deficits in verbally governed behavior, which includes sequences of behavior directed toward a goal. The dementia also eradicates the patient's learning history. This may contribute to the emergence of previously punished behaviors (disinhibition), including aggressive or intrusive behaviors. Impaired hearing or vision reduce access to positive reinforcers, setting the stage for depression. Sensory deprivation also may establish self-stimulatory behaviors such as repetitive screaming. Fatigue may establish requests for various activities as aversive. Medical conditions associated with pain, if accentuated by staff interventions, may lead to reinforcement of escape behaviors.

Interventions aimed at modifying establishing conditions include a careful medical evaluation, which may identify sources of distress that can be relieved by situational adjustments or specific treatment. Hearing aids or intervention to improve vision (e.g., cataract surgery) may restore access to lost reinforcers. Treatment with antidepressants may increase reinforcer efficacy. Fatigue can be addressed by scheduling the activities around the patient's natural diurnal cycle. For example, aggressive behaviors occurring primarily in the morning after the patient has been awakened can be ameliorated simply by letting the patient remain asleep until she wakes up naturally.

Contextual Control The fragmentation of the patient's learning history also affects antecedent control of behavior, particularly by the complex stimulus constellations involved in contextual control. Being disoriented to place, the patient may not respond appropriately to the context of hospital, where behaviors appropriate for “being a patient” include tolerating having one's privacy invaded. The prevailing custom for nursing staff in psychiatric hospitals to wear street clothes rather than nursing uniforms further masks the hospital context. In fact, the only uniforms the patients see are worn by safety personnel and may be reminiscent of police uniforms. What remains is a public place populated by strangers, a stimulus configuration consistent with the context of perhaps a hotel lobby or a railroad station. In these contexts, when a stranger violates an individual's personal space or disrespects his or her physical integrity, aggressive responses can be seen as adaptive.

Treatment interventions might be aimed at restoring the salience of the “hospital” context. For patients with reasonably intact verbal repertoires, frequent reminders that “you are in a hospital” may work. It would be interesting to examine whether the incidence of aggressive behavior would be reduced in an environment where the staff routinely wears white nursing uniforms.

Stimulus Control The most common antecedent of aggressive behavior involves requests from a staff member for patients to cooperate in the execution of activities of daily living. Treatment includes appropriate use of touch and slowing the pace of the staff member's verbal behavior. The principle of *behavioral momentum* can be used to prime a set of complying with requests. This principle states that a behavior is likely to continue once it has started (gained momentum). Thus, compliance

with a request should be more likely if patients have just complied with another, perhaps smaller, request. Specifically, patients might be asked for “a small favor,” one that they are unlikely to refuse (such as helping the nurse with something). After one or more such granted requests, patients should be more likely to comply with the targeted request (e.g., taking medication).

Consequent Control The behavior of patients with dementia is highly affected by reinforcer delay. Thus, it is unlikely that aggressive behavior is reinforced by increased attention from staff in most patients. Screaming behaviors often appear to be self-stimulatory and are difficult to modify with behavioral techniques. The behavior of grabbing at a staff member's body parts may be reinforced by the sensory consequences of grabbing. Such behavior can be modified by promoting other behaviors that accomplish similar sensory consequences. Patients could be given an equivalent object to hold, such as a softball, pillow, or stuffed animal.

Suicidal Behaviors in Patients With Borderline Personality Disorder The functional analysis of borderline behaviors illustrates the behavioral analysis of complex patients. In such cases, behavior therapists attempt to identify functional classes of target behaviors and their dynamic interrelationships. Certain problems may be caused by the consequences of other more primary problems. For example, in many patients, symptoms of generalized anxiety disorder are driven by a perfectionistic way of responding to contingencies. A decision is also made as to what target behaviors need to be addressed first. The initial treatment efforts may need to be focused on target behaviors that would interfere with future treatment of the primary targets.

A systematic behavioral analysis of borderline personality disorder began as an analysis of suicidal behaviors and evolved into a treatment called dialectic behavior therapy. The term *dialectic* was chosen to reflect the approach of finding a third way (synthesis) to resolve opposing contingencies affecting these patients.

Establishing Conditions in Early Childhood: An Invalidating Environment The section on verbal behavior above, reviewed how a sense of self can be seen as a result of a contextual definition of the word “I.” Thus, a concept of “I-ness” is formed by abstracting over many sentences that contain the word “I.” Problems in the development of a sense of self can arise when other persons assume control over children's labeling of their private events. This reasoning has led to the inclusion of the important therapeutic principle of validation into dialectic behavior therapy and other recently developed treatments.

Besides the basic problem with invalidation, patients may have been raised in either chaotic, abusive families, or in families that had low tolerance for emotional, expressive behaviors. Expecting more or different behaviors than a child can emit, the parent resorts to coercive control. This leads to problems inherent in such control, including diminished exploratory behaviors, restricted problem-solving abilities, and skills deficits. In addition, unavoidable punishment leads to learned helplessness, anxiety depression, and posttraumatic stress symptoms.

Current Contingencies

ESTABLISHING CONDITIONS Behavioral deficits in regulating emotional behaviors, tolerating distress, interacting with others, and problem solving reduce access to positive reinforcers. This contributes to a lean reinforcement environment that increases dependency on the few reinforcers available to the patient. Consequently, the patient may be unable to leave current chaotic or abusive relationships.

A history of physical abuse establishes rewarding consequences for avoidance and escape behaviors. Self-mutilatory behaviors may function as escape behaviors. For example, physical abuse administered on a noncontingent time schedule (e.g., whenever the parent is drunk) may establish “passage of time without punishment” as a conditional aversive establishing stimulus. In such a schedule, the lowest probability of punishment occurs immediately after an abusive episode. In adult life, the patient may functionally “reset” the clock with an episode of self-mutilatory behavior, thus shortening the agony of “waiting for the other shoe to drop.”

ANTECEDENT CONTROL As mentioned above, borderline patients are often subject to conflicting contingencies. For example, 2 patients who rely on instructions from others are often placed in conflict by inconsistencies in the standards advocated by different people. This results in a problematic degree of inconsistency in their behaviors. As treatment progresses, the therapist becomes an important source of stimulus control. For example, these patients frequently show increases in borderline behaviors when the therapist is unavailable (e.g., vacations).

CONSEQUENT CONTROL Parasuicidal behaviors, unsafe sexual behaviors, and aggressive behaviors are impulsive behaviors. Such behaviors are maintained by certain immediate reinforcers and are insufficiently affected by undesirable but delayed consequences. In addition, the patient may respond to idiosyncratic, verbally constructed, future realities that serve as reinforcers for avoidance or escape behaviors.

Consequences implemented by the therapist become an important countermeasure. Withdrawal of attention can serve as a timeout from positive reinforcement. This can be applied contingent on a parasuicidal behavior; such withdrawal also is a useful strategy to counteract the therapist's natural tendency to increase attention for (and thus reinforcing) such behaviors. On the other hand, positive reinforcement is needed to retain the patient in treatment. Validation by the therapist is an important positive reinforcer. Therapists can also serve as “mentors,” functionally providing bridging stimuli to maintain behaviors toward delayed larger rewards. Verbally constructed realities can be addressed by cognitive techniques or by recontertualization (see section on acceptance and commitment therapy).

SELECTION OF TARGET BEHAVIORS Dialectic behavior therapy begins with efforts to address current problems; and among these, the first efforts are focused on behaviors that directly interfere with further treatment. Such therapy-interfering behaviors include suicidal behaviors, substance abuse, high-risk sexual behaviors, criminal behaviors, dysfunctional relationship behaviors, vocational behaviors, and housing-related behaviors (e.g., living in shelters). The second stage of treatment addresses symptoms related to posttraumatic stress. The third stage seeks to help the patient move toward individual goals and may include clarification of values or other desired long-term life patterns. In dialectic behavior therapy, patients attend group sessions in which specific skills are taught, as well as individual sessions with a primary therapist. The individual therapy component was inspired by a related treatment program called “functional analytic therapy.”

FUNCTIONAL ANALYTIC THERAPY. Functional analytic therapy is a behavioral analogue to insight-oriented individual therapy. No empirical outcome data have been published for this treatment program, but its system of target behaviors is of interest. Functional analytic program therapists use the term “clinically relevant behavior” (CRB) for a target behavior that occurs within the session. CRBs are of three types (CRB1–3). CRB1s are within-session behaviors representative of the patient's presenting problem. For example, for a patient with “difficulty making friends,” CRB1s might include poor eye contact, poor listening skills, difficulties in progressing with treatment because of imperative crises of various kinds taking precedence. CRB2s are new within-session behaviors indicating improvement in CRB1s. Such behaviors are reinforced by the therapists. Because the patients are adults, exuberant statements that often work with children, such as “wonderful” or “that's terrific” are ineffective. Finding effective social reinforcers or bridging stimuli for adult clients showing signs of improvement is an art. Straightforward praise or overly enthusiastic demeanor often is counterproductive, perhaps because it evokes embarrassment (see section on emotions) or because the patient fears that improvement will lead to an undesired increase in responsibilities. The first author, who is not a functional analytic program therapist, highlights the positive by using such nonverbal behaviors as leaning forward, note taking, and vocalizations. When patients take a particularly significant step, he might interview them about their strategy of overcoming the difficulties, using a model of the television sportscaster interviewing someone who just won a challenging race. Functional analytic program therapists use natural reinforcers that are not specified in advance. For example, the therapists might allow themselves to become more active in moving the session along. Because the CRB2s are affected by similar eliciting and consequent stimuli both within and outside a therapy session, changes in CRB2s are assumed to generalize to the patient's daily life.

CRB3s are the patients' description of contingencies affecting their behavior. CRB3s represent the behavioral analogue to insight. The therapist initially models CRB3s by describing or interpreting relevant behavioral processes as they unfold in the session (e.g., “I've noticed that each time you started talking about your spiritual beliefs, I've changed the topic, and you no longer bring it up.”). Behaviors similar to CRB3s are also a mainstay dialectic behavior therapy, in which patients perform detailed behavioral analyses of crisis events as chains of behavior.

In functional analytic therapy patients with a poor sense of self because of invalidating childhood environments may be asked to engage in free association exercises, in which they are asked to verbalize anything that comes to mind, with minimal cues from the therapists. Such exercises set the stage for I statements, which (as mentioned) form the basis for development of a sense of self. Patients are instructed to tell the therapist anything that enters their mind, without censoring. Basically the patients are encouraged to observe their private experiences and describe them as “I” statements. Patients with a poor sense of self become highly anxious during such exercises.

BEHAVIORAL DEFICITS AND SOCIAL SKILLS TRAINING

The treatment of behavioral deficits does not differ in principle from educational activities that take place in any school setting. However, behavioral therapists typically focus on deficits in social behavior rather than academic skills, hence the term *social skills training.* Variants of social skills training include assertiveness

training, generalized social skills training, communication skills training, and general strategies for problem solving.

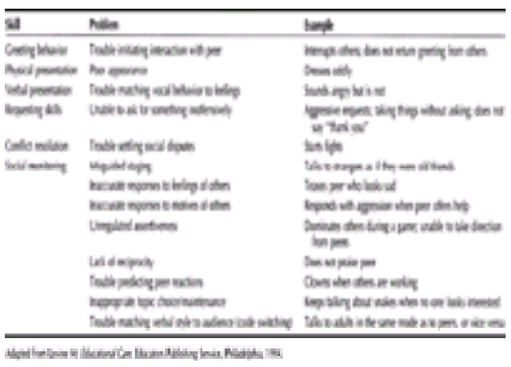
Assertiveness Training Assertiveness training was first used in behavior therapy to countercondition social anxiety. With the publication of *Your Perfect Right* by R. E. Alberti and M. L. Simmons in 1970, learning assertive behavior became a goal in its own right. Since then, assertiveness training has been extensively covered in the popular media and has become part of our culture. Assertiveness is defined as follows:

> Assertive behavior enables a person to act in his or her own best interest, to stand up for herself or himself without undue anxiety, to express honest feelings comfortably and to exercise personal rights without denying the rights of others.

The goal of standing up for oneself in the definition above overlaps with that for aggressive behaviors, but aggressive behaviors (e.g., bullying or intimidating) deprive others of their rights, whereas assertive behaviors reflect a spirit of cooperation in which the rights of both parties are respected.

Two types of situations frequently call for assertive behaviors, setting limits on pushy friends or relatives and such commercial situations as countering a sales pitch or being persistent when returning defective merchandise. Early assertiveness training programs tended to define specific behaviors as assertive or nonassertive. For example, individuals were encouraged to assert themselves if somebody got in front of them in a supermarket checkout line. Increasing attention is now given to context, that is, what would be assertive behavior in this situation depends on circumstances.

Social Skills Training Children learn a number of social skills. Deficits in social skills make children vulnerable to adverse overtures from peers. Table 30.2-5 shows examples of social skills deficits often found in children with impulsive disorders or learning disabilities. Social skills can be enhanced by the parent reviewing (perhaps at night after the child has gone to bed) problematic situations observed during the day. In a coaching mode, the parent can later discuss or suggest possible alternative behaviors. Educational social skills training groups or interventions are available in some settings.



Skill	Problem	Example
Greeting behavior	Trouble initiating interaction with peer	Interrupts others; does not return greeting from others
Physical presentation	Poor appearance	Dresses oddly
Verbal presentation	Trouble matching vocal behavior to feelings	Sounds angry but is not
Requesting skills	Unable to ask for something inoffensively	Aggressive requests; taking things without asking; does not say "thank you"
Conflict resolution	Trouble settling social disputes	Starts fights
Social monitoring	Misguided staging	Talks to strangers as if they were old friends
	Inaccurate responses to feelings of others	Teases peer who looks sad
	Inaccurate responses to motives of others	Responds with aggression when peer offers help
	Unregulated assertiveness	Dominates others during a game; unable to take direction from peers
	Lack of reciprocity	Does not praise peer
	Trouble predicting peer reactions	Clowns when others are working
	Inappropriate topic choice/maintenance	Keeps talking about snakes when no one looks interested
	Trouble matching verbal style to audience (code switching)	Talks to adults in the same mode as to peers, or vice versa

Adapted from Gresham M (Educational Care. Education Publishing Service, Philadelphia, 1994).

Table 30.2-5 Examples of Social Skills Deficits in Childhood

After social skills are learned, they can also be lost. This is particularly true for patients with schizophrenia. The negative symptoms of schizophrenia essentially involve social skills deficits.

The negative symptoms in schizophrenic patients constitute behavioral deficits that go beyond difficulties with assertiveness. These patients have both inadequate expressive behaviors and inappropriate stimulus control of their social behaviors (i.e., they do not pick up social cues). Similarly, patients with depression often experience a lack of social reinforcement because of a lack of social skills, and social skills training is efficacious in the treatment of depression. Patients with social phobia similarly often have not acquired adolescents' social skills. In fact, their social defensive behaviors (e.g., avoiding eye contact, making brief statements, and minimizing self-disclosure) increase the probability of the rejection that they fear.

Social skills training programs for schizophrenics cover conversation skills, conflict management skills, assertiveness skills, community living skills, friendship and dating skills, work and vocational skills, and medication management skills. Each of these skills has several components. For example, assertiveness skills include making requests, refusing requests, making complaints, responding to complaints, expressing unpleasant feelings, asking for information, making apologies, letting someone know you are afraid, and refusing alcohol and street drugs. Each component involves specific steps. For example, conflict management includes skills in negotiating, compromising, tactful disagreeing, responding to untrue accusations, and leaving overly stressful situations. A situation in which conflict management skills might be used is when the patient and a friend decide to go to a movie and their choice of movie differs.

Negotiating and compromising, for example, involves the following steps:

1. Explain your viewpoint briefly
2. Listen to the other person's viewpoint
3. Repeat the other person's viewpoint
4. Suggest a compromise

Communication Skills Training The courses in interviewing techniques that mental health professionals take in their training are examples of training in communication skills. The communication skills of summarizing, reflecting, validating, and using “I” statements and eye contact are also taught in the context of marital therapy. However, a recent prospective study found that such communication patterns had no predictive value with respect to either the future duration of a marriage or happiness in a marriage. Instead, predictors of successful marriages included the husband's willingness to give up power to his wife, and the wife's capacity to use humor when providing feedback to her husband.

Physician-Patient Communication Physicians' communication behaviors with their patients are not always characterized by high levels of social skills. Based on the first author's experiences in a Psychiatric Medicine clinic, this seems to be particularly true when a patient's medical condition is not improving and the patient persists in complaining. Poor communication and bad treatment contribute equally to a patient's decision to file a malpractice suit. Consequently, efforts are under way to improve physician communication patterns.

A recent study showed that residents in internal medicine could learn such skills in a structured program that involved a 1½-day workshop followed by six small group sessions and six one-to-one feedback sessions during the following 6 to 8 months. The residents were taught how to greet patients, acknowledge the patient's chief complaint, be responsive to the patient's emotional expressions, and clarify the purpose of the consultation. They were taught to specify the amount of time available in advance and signal a change of interview mode ahead of time, (e.g., when a formal review of systems is to begin). Introducing the mind-set of treating the patient as an equal partner in decision making, the residents were taught to provide detailed information of assessment results, preliminary diagnosis, etiology, and treatment options and prognosis, while at the same time remaining sensitive to patient's emotional responses.

Parent-Child Communication Certain ways that a parent phrases a request to a child (particularly one with problems of conduct or attention) are likely to result in noncompliance. Table 30.2-6 shows that these include multiple commands, vague commands, commands phrased as questions, repeated commands, and commands that require compliance over an extended time.

Table 30.2-6 Effective and Ineffective Parental Commands

Giving effective commands requires getting the child's attention (e.g., asking the child to look at you). The parent's tone of voice should be neutral but slightly louder than usual. A positive tone of voice is more effective than a negative one. Commands should be limited to a few manageable steps. Finally, the same command should not be given repeatedly (i.e., nagging); rather, the parent should define the time interval for compliance (e.g., by the count of five) and apply predetermined consequences for noncompliance.

Problem Solving Learning problem-solving strategies benefits most psychiatric patients, particularly patients with social phobia, generalized anxiety disorder, and depression. It is an integral part of dialectic behavior therapy and of behavioral marital therapies. Problems can be classified as changeable or unchangeable. Unchangeable problems include natural disasters and socioeconomic trends beyond the control of the individual (e.g., unemployment due to plant closing). Problem solving is a systematic way of verbally generating new behaviors that can then be applied to contact new contingencies. The problem-solving heuristics developed by d'Zurilla and coworkers are widely used and involve the following steps.

1. Problem Orientation. Patients are taught that good problem solvers respond to problems as normal events that constitute challenges rather than threats. They realize that problem solving may take time and involve effort and do not give up when no quick fix is available. A problem-solving mind-set is primed by first discussing problems in society and their possible solutions. Patients are given a homework assignment—keep a diary of problems as they occur so that one or two can be selected for detailed analysis.
2. Problem Definition and Formulation. The problem is described in behavioral detail, including what happened, where and when it happened, who was involved, what feelings were involved, what goal or current concern was involved, and how much distress was experienced. Problems are defined in terms of specific behaviors rather than undesirable personality traits. Obstacles for earlier attempts to solve the problem are reviewed.
3. Generation of Alternative Solutions. The patient brainstorms a number of different potential solutions. For example, patients might be asked to generate at least five potential solutions. The solutions proposed should not be variations on one theme or be limited to those that worked in the past. The deferment of judgment and variety principles guide this process. If the problem is not changeable, solutions are selected involving emotion-focused coping. These may include behavioral techniques to modify anxiety or distress, or interventions aimed at cultivating acceptance.
4. Deciding on a Solution. A determination is made whether enough information is available to decide on a specific solution. If there is, the list is screened clearly inappropriate. The patient is asked to anticipate the outcome for each remaining solution in terms of short-term possibilities and long-term consequences.
5. Solution Implementation and Verification. The specific actions required for the chosen approach are listed, along with obstacles or barriers to their implementation. List making and self-monitoring may facilitate adherence. Environmental changes to facilitate the solution may be considered, such as placing reminder notices at strategic places.

CONTINGENCY MANAGEMENT

Contingency management is the use of principles of operant conditioning to change the patient's behavior by modifying discriminant stimuli or consequences. Contingency management techniques are implemented by someone other than the patient. Because they require precise control over the patient's sources of reinforcement, operant procedures are particularly used in the treatment of children, institutionalized individuals, and drug addicts on replacement therapy.

Paradigmatic examples of operant behavior therapy below focus on the treatment of an attention-deficit hyperactivity disorder. The techniques are representative of those used for the other disruptive disorders of childhood such as conduct disorder and oppositional disorder. Although the underlying principles are simple, contingency management interventions not only require careful attention to detail, but also necessitate skills in interacting with teachers and other individuals in the patient's larger system. Hence contingency management procedures are discussed in more detail than other behavioral techniques.

Classroom Contingency Management in Specialized Settings In special classrooms, contingency management procedures include point, or token economy, reward systems, timeout, and response cost (losing tokens for undesirable behavior). The procedures are implemented by a consulting professional, an expert teacher, or a trained paraprofessional. Patients treated in this setting include children with severe problems (e.g., comorbid aggression). The question has been raised whether interventions based on positive reinforcement alone are sufficient or whether punishment procedures are needed such as reprimands, timeout, and response cost (loss of privileges). Research has shown that with children with conduct disorder, positive reinforcement alone is insufficient. The same conclusion applies to the treatment of attention-deficit/hyperactivity disorder. Positive consequences alone are neither sufficient nor necessary, but prudent negative consequences are essential. Nevertheless, most behavioral interventions programs for attention-deficit/hyperactivity disorder include both positive and negative consequences.

Home-Based Reinforcement Programs The behavioral intervention most commonly used in clinical settings is best described as outpatient-based, clinical behavior therapy. This approach involves training parents to implement behavior management programs with their children and concurrently training teachers to use classroom management strategies with the patient.

Parent Training Parents are taught learning principles and standard behavioral techniques during 8 to 16 educational group sessions in the skills training format described in the previous section. A typical list of all topics appears in Table 30.2-7. One or more of these sessions focus on how to give effective commands (i.e., principles discussed in the previous section).

1. Review of attention-deficit/hyperactivity disorder and its treatment
2. Overview of social learning and behavior management principles
3. Home/school daily report card
4. Giving effective commands and reprimands
5. Time out
6. Attending, rewarding, and ignoring skills
7. Establishing and enforcing rules—when-then contingencies
8. Home point systems—reward and response cost
9. Home reward and response cost
10. Planned activities and setting generalization outside of the home
11. Homework problems
12. Facilitating peer relationships
13. Level systems
14. Dealing with the school
15. Parental stress, anger, and mood management

Table 30.2-7 Topics in Parent Training Sessions

Working With the School System Federal law requires that children with attention-deficit/hyperactivity disorder must be accomodated in these classroom settings. The Individuals with Disabilities Education Act (IDEA) requires that these children be evaluated for special services and receive an Individualized Education Plan

(IEP), including special education placement if indicated. The Rehabilitation Act of 1973, section 504, requires that special accommodations be made in the classroom setting of a child with attention-deficit/hyperactivity disorder (generally labeled a 504 Plan) even if the child is not eligible for special education.

Given these laws, one might assume that schools would automatically institute appropriate interventions, but more often than not, this is not the case. Thus it is incumbent upon the therapist to ensure that the child receives an adequate school-based intervention. The specific procedures that implement the regulations vary across states and school districts, and clinicians therefore must become familiar with how these regulations are implemented locally. Parents must know their rights under these laws, so that they can remind school administrators to support appropriate interventions with their children.

Before contacting school officials, the therapist needs to be aware of any special considerations involving the target child, parents, school, or district. These include the parents' relations with the school, the child's status regarding special education placement, and district policies regarding attention-deficit/hyperactivity disorder, the IDEA, and section 504 of the Rehabilitation Act.

The initial contact between the therapist and school should always begin with a phone call informing the school principal that the child's parents have solicited the therapist's services. The therapist briefly describes the goals and nature of the classroom program that will be developed with the teacher, obtains the principal's permission and support, and establishes a mechanism for keeping the principal informed. The principal also needs to be aware that treatment will likely continue in subsequent school years, so that plans for long-term continuation need to be built into the program.

Working With the Teacher The classroom-based interventions for attention-deficit/hyperactivity disorder involve standard contingency management procedures. Regular or special education classroom teachers, with help from school support staff or outside consultants, can implement most of these programs. Teachers can be taught contingency management techniques using handbooks, texts, or training programs. Table 30.2-8 shows a sequence of topics typically included in such training. A significant component of the program is a home-based reinforcement system involving a daily report card. The report card provides feedback from the teacher to the parents on the child's school performance, and parents provide a reinforcing consequence at home. The report card is discussed in detail below.

1. Introduction to attention-deficit/hyperactivity disorder, rationale for and overview of treatment (assess teacher knowledge and use of behavioral procedures, and design content of subsequent sessions accordingly)
2. Home/school daily report card
3. Classroom rules and structure; instructional modification for an individual child
4. Ignoring mild, inappropriate behaviors that are not reinforced by peer attention and praising appropriate behaviors
5. Giving effective commands and reprimands
6. When-then contingencies
7. Classwide interventions
8. Group contingencies
9. Response cost/reward point or token system for the target child
10. Time out (classroom, office, systematic exclusion)
11. Discussion of special services or special class placement

Table 30.2-8 Topics in Behavioral Teacher Training

In mental health settings the therapist commonly has a single meeting or telephone contact with a teacher. However, research clearly shows this is inadequate for the program to be implemented and maintained successfully. Rather, consultations with the teacher might involve up to 10 contacts—weekly at first and tapered over time, depending on success. In the initial contact, the therapist's main task is obtaining the teacher's cooperation, keeping in mind that unless the teacher referred the child, the teacher has not asked for this assistance. Some teachers are willing and even eager to cooperate, but more commonly, teachers have misgivings. For example, they may be concerned about the amount of time required or express doubt about the validity of attention-deficit/hyperactivity disorder as a disorder and the efficacy of behavior modification or medication as treatments.

Table 30.2-9 lists important topics covered during meetings with the teacher. The therapist should develop the program in collaboration with the teacher rather than unilaterally imposing a particular approach; the teacher's involvement in treatment is essential for success. The teacher is being asked to make changes that will last for the entire school year; therefore, it is important to address concerns the teacher may have regarding time commitments. Teachers might be reminded that they are already spending a great deal of time managing the target child. Granted the behavioral program requires an initial investment of extra time, but if the treatment is successful, the teacher will have saved time in the end. The therapist also assesses the teacher's current methods of classroom management and knowledge of behavior management principles. Many teachers, especially the younger ones, have had formal training in a behavioral approach. If explanation is necessary, it is most efficiently offered in terms of functional analysis of behavior. Thus, target behaviors are defined and relevant antecedents, consequences, and setting events are identified.

Introduce information about attention deficit/hyperactivity disorder, including prognosis without treatment, common treatments
Ascertain the teacher's commitment and build rapport; if the meeting is live (vs. phone), observe child and teacher informally before or after meeting as part of assessment
Discuss the teacher's current teaching practices (e.g., classroom structure and classroom management procedures in use)
Ensure that teacher has appropriate list of class rules, as "follows rules" will almost always be a target behavior
Discuss problematic child behaviors with goal of identifying specific target behaviors for modification; form a preliminary list of target behaviors
Discuss basics of observing and recording with teacher and develop baseline tracking procedures for target symptoms

Table 30.2-9 Items Covered in Initial Meetings Between Therapist and Teacher

Subsequent teacher contacts involve discussions of ways to implement behavioral procedures, specifically with the patient, and the patient's response to treatment. The therapist and teacher work together to develop procedures to modify the antecedents, consequences, and setting events identified in the functional analysis. Procedures must be implemented consistently by both teachers and parents. The behavioral program is set up in the shaping paradigm, initially targeting small improvements and gradually going for more. Treatment responses are monitored continually, and interventions are modified when they fail to have sufficient impact or are no longer needed.

Daily Report Card Daily report cards are the most basic and necessary component of classroom interventions with attention-deficit/hyperactivity disorder children. The report card serves several purposes. First, it can be used to provide feedback to the child. Second, it informs parents of the child's behavior during the school day. Third, it establishes a channel for regular communication between parents and teachers. Finally, it provides a way for parents to reinforce the child daily for improvement in target behaviors. The steps involved in establishing a daily report card–based intervention are the following:

1. **SELECT THE GOALS TO BE ACHIEVED** Treatment goals are determined at a molar level based on examination of rating scales, testing, and teacher/parent interviews. Examples of goals are improvement of academic grades, classroom behavior, or relationships with peers or adults. The goals must be socially valid, that is, chosen so that reaching them is likely to result in reduced impairment and improved outcome for the child.
2. **FORMULATE TENTATIVE TARGET BEHAVIORS** Once selected, a goal is operationalized in terms of a set of specific target behaviors. Target behaviors are molecular representations of the molar goals previously chosen. They need to be defined in a manner that permits objective and reliable measurement (i.e., resulting in a quantitative score). The teacher, child, parents, and therapist must all be able to agree whether or not a target behavior has occurred.

To avoid loopholes, the language that describes treatment goals as sets of target behaviors may have a legalistic flavor. For example, the general goal of improved academic grades might be broken down into specific behaviors that include (1) having the materials and assignments necessary to do tasks, (2) completing assigned academic tasks, (3) being accurate on assigned tasks, and (4) completing and returning homework. Similarly, the general goal of improving relationships with teachers and peers can be broken down into such target behaviors as (1) does not interrupt other children during their work time, (2) does not tease other children, (3) plays without fighting at recess, (4) obeys the teacher when commands are given, and (5) refrains from talking back to adults.

3. **GATHERING BASELINE DATA FOR TENTATIVE TARGET BEHAVIORS** Baseline recording involves daily observing or monitoring of the target behaviors for a week or more until a stable pattern is obtained without any intervention. The data collected provide objective information about the validity of the goal selection. If valid, they are also used to define and titrate the criteria for reward used in the initial steps for change.

   Developing methods of quantifying behavioral observations is an area of methodological research in behavior therapy. For the applied setting, the principle the simpler the better holds. One avenue for quantifying behavior involves measures of achievement or performance aspects of a behavior (i.e., the visible traces of a behavior). For example, a student's performance can be measured as school grades, and a salesman's performance, as number of dollars earned. For the child with attention-deficit/hyperactivity disorder, an achievement measure of classroom seatwork might involve recording the percentage of assignments completed during each day and the accuracy of this work. In applied work involving the daily report card, the number of yes responses (see below) is a convenient achievement measure.

   Another approach records the performative (movement) aspects of the behavior. Many behaviors have individual instances (bouts) that can be identified and counted; these can be monitored as frequencies (i.e., how many times the behavior occurred during the school day). Counting individual bouts of behavior is impractical when the target behavior is frequent (e.g., child interrupts 100 times a day). In this case, recording could be done for the portion of the day that is especially problematic. Another (methodologically less respectable) solution is to monitor the behavior on an interval basis (e.g., proportion of 15-minute intervals in which the child interrupted at least once).

4. **DECIDING ON FINAL TARGET BEHAVIORS** Using the baseline data, the therapist and teacher decide which target behaviors to include on the daily report card. There should be no more than five to eight target behaviors—fewer for an elementary school child. The initial criteria defining success for each target behavior are specified.

   Figure 30.2-3 shows an example of a daily report card. The criteria for success (earning a “Yes”) in each target behavior determine the level of performance required for home reinforcement. Initially, these criteria are targeted to require the child to improve a certain amount over the baseline level. A good criterion is one that the child fulfills 70 percent to 90 percent of the time, or a 20 percent improvement over baseline. A success rate below 70 percent indicates that the criteria are too difficult.

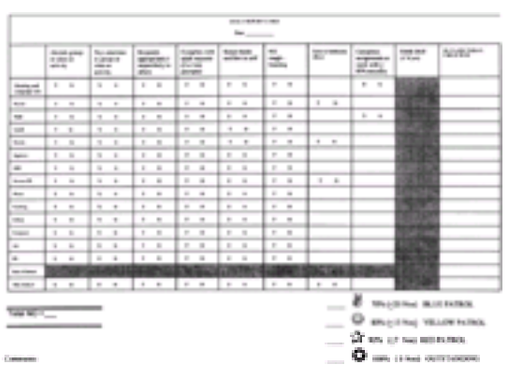


FIGURE 30.2-3 Daily report card for a child with attention-deficit/hyperactivity disorder. The daily report card provides a tabular framework reflecting days, times of day, subject areas (or if the child has different teachers, for each subject by teacher). For each target behavior, the child can earn a “yes” or “no” in each of the daily subdivisions. The patients using this card, a first and second grader, had problems in classroom behavior, relations with peers and the teacher, and academic performance. Each of these domains is reflected in the student's card.

5. **EXPLAINING THE PROGRAM TO CHILDREN** The daily report card is presented to children as a way of focusing during the day on things that are problems and learning how to overcome those problems. Children earn rewards at home for their behavior and performance at school. This is done to help them learn new ways of getting along with others and doing well in the classroom and on schoolwork. The daily report card is reviewed in detail with the children in age-appropriate language, including the target behaviors and their exact definitions.

   For example, for the target comply with adult requests (Fig. 30.2-3) the list included Do what grown-ups ask you to do. Do not say “why should I” or “no” and Stop when grown-ups tell you to stop. Children are also informed how the target behaviors will be monitored, exactly what criteria will mean a “Yes,” what the rewards are, and what their responsibilities are.

   Children are asked to recite back the information. They will be responsible for presenting the daily report card to each teacher for evaluation and a signature and for taking the card home. Once the program has begun parents or teachers or both review the daily report card targets with the children at the beginning of each day.

6. **ESTABLISHING THE HOME-BASED REINFORCEMENT SYSTEM** The parents' job is to reward the children for attaining the goals that have been established on the daily report card. Both daily and weekly rewards are established. Daily rewards provide immediate feedback to the children and increase their motivation to make the desired behavioral changes. Weekly rewards (e.g., for having three or four positive daily report cards during the week) further this goal, begin to develop the children's ability to delay gratification, and establish the efficacy of delayed reinforcement.

   Parents sometimes raise objections about giving their children rewards for work that they “should be doing anyway.” The therapist might counter that although the children should be doing their work, they are not (because of their disorder). This is why the intervention is necessary. In brainstorming for possible reinforcers, the principles outlined above for knowing what is reinforcing ahead of time are useful heuristics. Rewards are set up as a menu of choices. The possibility of choice is important because of the possibility of reinforcer habituation (this is particularly true for the daily reinforcers). Weekly rewards might include going to a favorite restaurant or renting a movie video. The rewards on the menu must only be available to the children when they earn them. At the same time, once the children have earned a reward, it must be given. Specifically, it cannot be withheld in response to misbehavior at home occurring after the children have earned their reward.

   The child in Figure 30.2-3 had a cumulative daily reward structure. For the lowest level of reinforcement (yellow patrol, 70 to 80 percent Ys), the reinforcement menu included the privilege of riding in a preferred seat in the car. (Because the child rode home with his parent, this reinforcer had a relatively short time delay). The next level (blue patrol, 89 to 90 percent Ys) qualified for a yellow patrol reinforcer plus the added privilege of watching TV. Red patrol (90 to 99 percent) was rewarded with either of these plus ice cream. Finally, the case of the child bringing home all Ys (100 percent) evoked a highly celebratory mood. In addition to the lower level rewards, the child became eligible for staying up 30 minutes past the regular bedtime. Even years later, this child would occasionally come home after a difficult day asking for a reward (“I need a reward for not hitting when my friend teased me”). An example of weekly rewards, earned if all five school days had been at least a yellow patrol, was a trip to the bookstore to buy a book.

   Some teachers worry about causing the child to be punished if they send home a negative report. Such worries can be allayed by the fact that the parents have specific instructions for this event. When the child brings home a daily report card meeting criteria for a certain reward level, parents praise the child for the behavior. On the other hand, when a child brings home a card on which criteria are not met, the parents respond in a neutral, matter-of-fact, nonpunitive manner. They explain that since the goals were not reached, there will be no reward. The parents also express confidence that the child will be able to do better

the next day.

Children with attention-deficit/hyperactivity disorder may at times forget to bring the daily report card home. If this is a major problem, parents can provide a reward for this behavior alone. Once the behavior for bringing the daily report card home has been established, if it does not come home for any reason, parents assume that the child received all Nos and do not reward the child.

7. **MONITORING AND MODIFYING THE DAILY REPORT CARD** The key to the success of the daily report card is that it must be monitored continually. Changes in target behaviors are tallied and criteria for reward are adjusted. If a criterion is consistently reached (e.g., at a 90 percent rate), the criterion is changed to require an increased level of performance. At the same time, criteria must be increased gradually enough to maintain the child's success a relatively high proportion of the time (shaping). Once the criterion for a target is consistently at an acceptable level (i.e., a level within the range shown by nonproblematic children in the classroom), the target behavior is dropped from the daily report card. The child is told that he or she is doing so well that the target isn't needed any longer. Similarly, new targets may be added if the child exhibits new behavioral problems.
8. **TROUBLE SHOOTING** After establishment and implementation of the daily report card, the therapist's further interactions with the teacher include anticipating and addressing problems. Trouble-shooting evaluations are indicated if, for example, the child's success rate, during a 10-day window, falls below an average of 70 percent in any one of the target behaviors. Table 30.2-10 lists a set of guidelines that can be used to trouble shoot the daily report card. The therapist updates the functional analysis, evaluating each treatment component with respect to fidelity (adherence to intervention plan) and efficacy. This might include direct observation in the classroom, which can be compared with the teacher's reports on the daily report card. The therapist discusses the results of the observations with the teacher and provides feedback. If necessary, additional teacher-administered interventions are added, such as contingent praise or timeout from positive reinforcement.

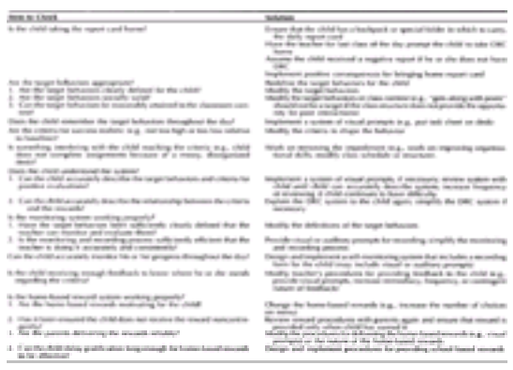

Table 30.2-10 Trouble-shooting a Daily Report Card

9. **TEACHING PARENTS HOW TO WORK WITH SCHOOLS** The need to taper therapist-teacher contact over time places great importance on teaching the parents how to work with the schools. This process begins with the therapist meeting with the parents and teacher simultaneously, thus modeling the behavior required. Over several months, the major responsibility for contact with teachers is shifted from the therapist to the parents. The therapist may provide outlines or scripts to the parents and correct feedback of specific interactions. In addition, if parents experience problems with cooperation in the school, the therapist provides guidance in trouble-shooting. The parents of the child whose daily report card is shown in Figure 30.2-3, were able to develop and monitor the daily report card for 2 years without contact with a therapist.
10. **TERMINATING THE DAILY REPORT CARD** The therapist's contact with the teacher and school should not be terminated prematurely. Toward the end of the school year, the therapist conducts programing for maintenance and relapse prevention, including procedures for bridging from one school year to the next, involving both the child's current and future teachers.

When all daily report card targets are consistently (e.g., during a 10 day window) at or above 90 percent criterion, and no other target behavior remains to be shaped, the daily report card can be phased out. Several procedures are possible. For example, the daily report card could be overall implemented only in the morning, gradually reducing the time covered, until the child is functioning without it. Alternatively, the daily report card could be eliminated on some days, and then used only on alternate days, every third day, and so on up to a week. With either method, card use is phased out as long as the 90 percent or better criterion continues to be reached for all targets over the 10-day window. The child in Figure 30.2-3 self-recorded his “Ys” for a period, with his reliability checked by the teacher.

Teachers and parents should maintain at least a weekly report of some type for the child with attention-deficit/hyperactivity disorder. For example, the daily report card may need to be used again after a hiatus, if gains are not maintained or new problems arise. Furthermore, school problems for these children often worsen in middle school and junior high school, and weekly feedback systems may be quite useful in those grades.

Intensive Treatment Programs Outpatient behavioral treatment, even at the intensity described above, may not suffice for many children with attention-deficit/hyperactivity disorder, particularly those with concomitant aggressive behaviors. For a number of years, the second author has conducted the Summer Treatment Program, an 8-week partial treatment for children with attention-deficit/hyperactivity disorder, located in a summer camp–like setting. This program has been named a Model Service Delivery Program in Child and Family Mental Health by a task force of the American Psychological Association.

The program runs for 9 hours a day, 5 days a week, for 8 weeks. Children are placed in age-defined groups of 12 children and 5 staff members, and group members stay together throughout the summer. Each group spends 2 hours daily in the classroom. The classes are either led by a teacher or involve individualized paper and pencil or computer-assisted instructions. The remainder of each day consists of recreationally based group activities, during which an integrated behavioral program is implemented. The backbone of the behavioral intervention in the Summer Treatment Program is a point system, backed up by both rewards and costs. The system is in effect in every setting throughout the day. Points are exchanged for privileges (e.g., weekly field trips), and social honors. Children also receive a daily report card on which their progress in individualized target behaviors is tracked and rewarded by the parents. Children are disciplined for certain behaviors, with discipline in the form of loss of privileges or time out from ongoing activities. If the standard interventions do not produce the desired behavior change for a child, a functional analysis of the problematic behavior is conducted, and an individualized program is developed.

The Summer Treatment Program was expressly developed to focus on treating difficulties in peer relationships, an area in which clinical behavior therapy and medication have not had major impact. Deficits in peer relationships are arguably the most severe area of impairment for children with attention-deficit/hyperactivity disorder, and they predict a poor long-term outcome. These children are annoying and aggressive toward peers, and so, they are actively rejected. The primary technique in treating peer relations are dyadic interactions, cooperative talks, social skills training, and group problem solving, all integrated as part of the system and recreational activities. The Summer Treatment Program integrates treatment for peer difficulties into daily activities in which children engage with peers (e.g., soccer, basketball), thus allowing observation and direct modification of a child's dysfunctional peer interactions in a setting close to the natural contexts in which children interact with peers.

Summer Treatment Program staff members expend considerable effort on positive social interactions with the children, frequently praising the children's behavior and their academic and athletic efforts. A 2:1 ratio of point awards and social reinforcement to point loss is targeted, which results in a positive atmosphere. Children like the program in spite of the rigidly applied point system and the ubiquitously implemented rules.

Combined Pharmacological and Behavioral Interventions As discussed above, treatment with certain drugs, particularly those affecting dopaminergic neurotransmission, serves as an establishing condition for the efficacy of reinforcers. It is therefore not surprising that combining behavioral and pharmacological treatments for attention-deficit/hyperactivity disorder has several advantages. First, the behavioral component of treatment can usually be reduced in scope and complexity. Second, the cost-effectiveness of treatment is improved. Third, drug and behavioral treatments often have complementary effects. Stimulant medication can reduce problematic behaviors that are difficult or impossible to treat with practical behavioral programs (e.g., low-rate, peer-directed aggression and stealing that occurs in the absence of adult authority). Finally, if the addition of stimulant medication reduces the complexity of the behavioral intervention, parents and teachers may be more likely to maintain it.

Conversely, adding behavioral treatment to medication could improve long-term outcome. Medication effects on antisocial behaviors are enhanced when behavioral contingencies supporting prosocial behavior are in effect. Furthermore, children with attention-deficit/hyperactivity disorder lack cognitive and behavioral skills that are necessary for academic and social adjustment. To the extent that these skills must be acquired for successful long-term outcome, medication alone would not be

expected to be a sufficient treatment. Studies conducted in the Summer Treatment Program suggest that more than 40 percent of children maintained on medication only would show incremental benefit from the addition of behavioral treatment. Conversely, close to 80 percent of children treated with behavior therapy can be expected to benefit from added stimulant treatment.

Behavioral recordings can be used to titrate the optimum stimulant medication dosage. In addition, such recordings can identify the treatment response profile of a child. Individual responses to combined-treatment approaches differ widely. These differing responses are illustrated in the three cases depicted in Fig. 30.2-4. All three were boys with attention-deficit/hyperactivity disorder participating in the Summer Treatment Program. Beginning on the tenth day of the program, all received 0.3 mg/kg methylphenidate (Ritalin) twice a day or placebo, randomized over days. The figure shows the percentage of time each boy followed activity rules (Cases 1 and 2) or rate of noncompliance (Case 3). The figures graph the children's behavior separately for placebo days and methylphenidate treatment days.

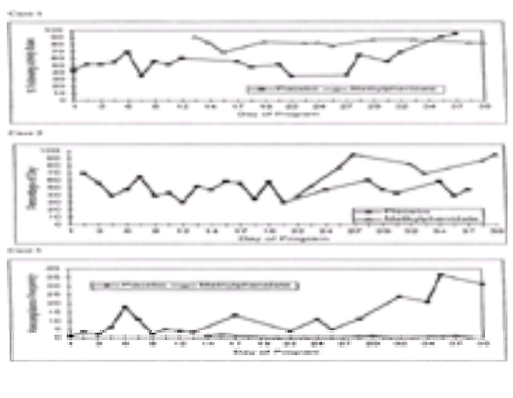

FIGURE 30.2-4 Data for responders to behavioral treatment (Case 1), behavioral and drug treatment combined (Case 2), and drug treatment with methylphenidate (Case 3). The dependent variable for Case 1 and Case 2 is the percentage of daily activities during which the child followed rules. For Case 3, the dependent variable is the daily frequency of noncompliance with commands.

The first boy (age 10) had attention-deficit/hyperactivity disorder only, no comorbid externalizing disorders. The data for behavior therapy plus placebo show that his compliance with activity rules improved dramatically throughout the summer. Addition of methylphanidate resulted in high compliance that remained. By the end of the program, his behavior on placebo days was slightly better than that on medication days, and combined treatment was no longer necessary. Thus, medication was incrementally effective for this child but it did not interact with the behavioral treatment.

The second boy (age 8) had a comorbid diagnosis of oppositional-defiant disorder. Behavioral treatment alone did not sufficiently improve his rate of following activity rules, as evidenced by the lack of an improving trend over the days on behavior therapy plus placebo. However, on days when a 0.3 mg/kg dose of methylphenidate was added to his treatment regimen, he showed gradual improvement, and he reacted good levels of rule following by the end of the summer on medication days only. This boy thus exhibited improved behavior only when medication was combined with behavioral treatment.

The third boy (age 9) had conduct disorder as well as attention-deficit/hyperactivity disorder. The data displayed for him indicate noncompliance (thus, in contrast with the first two cases, lower values are better). His graph shows that noncompliance behaviors steadily worsened over the course of treatment. However, he showed an immediate, positive response to 0.3 mg/kg methylphenidate. Moreover, the drug apparently prevented the deterioration in behavior that the child showed when unmedicated. This boy showed considerable variability in treatment response across domains of dependent variables. Rule-following behaviors responded better to treatment than the noncompliance data shown. This type of finding suggests the effects of a behavioral intervention need ongoing monitoring across relevant behavioral domains and not just on a single target behavior.

These examples show that some children derive benefit from a combined treatment regimen while others do not. This raises an important question: how does a clinician select among different doses and combinations of medication and behavioral treatments to ensure the best possible treatment for an individual child? The answer is through systematic assessment, using ecologically valid individualized measures of behavioral functioning. The daily report card is such a measure and is a sensitive method of assessing whether medication yields additional benefits beyond behavioral interventions.

MODIFICATION OF AUTOMATIC BEHAVIORS (HABITS)

As noted repeatedly above, behavior tends to be organized hierarchically and sequentially. This is true in terms of life goals, intermediate goals, and subgoals and in terms of molar acts versus molecular action patterns. With repeated practice, execution of a lower-level act tends to require less and less attention (i.e., it becomes more and more automatic). For example, learning a new dance involves steps that become more automatic with practice; eventually one can attend to other things, such as conversing with the dance partner.

Early behavioral theorists, such as E. R. Guthrie, postulated that behaviors become linked to each other by movement-produced stimuli, and so, habits develop as chains of behavior. (This view has not fared well in the face of experiments in which curare was used to block such movement-produced stimuli; however the model is still useful for generating ideas for the change of automatic behaviors.) The behaviors in a behavioral chain are prompted both by external stimuli and by stimuli from the previous link. With practice, the movement-produced stimuli become more important, and the external stimuli less so. Finally, response-response chains are created that require very little external input. Concomitantly, the associated movements become simpler, more localized, graceful, and fluent.

Once established, automatic behaviors may continue even without reinforcement by the stimuli that established them, because they are still cued by their own movement-produced stimuli. Therefore, some habits, such as nail biting or hair pulling, may persist indefinitely.

Because they do not require attention, ingrained habits can escape detection even by individuals highly sophisticated in the psychology of habits. Guthrie reported the following event:

> Most smokers, while busily engaged in activities not associated with smoking, can go for long periods with no craving. Others find that the craving is strictly associated with such things as the end of a meal, if it has been their practice to smoke at that time. I once had a caller to whom I was explaining that the apple I had just finished was a splendid device for avoiding a smoke. The caller pointed out that I was smoking at the moment.

Learning New Habits Many preventive health behaviors need to become regular occurrences (i.e., occur automatically) to make a difference. Such behaviors include using seat belts, using condoms, flossing or brushing teeth, or taking prescribed medication. To build a new habit, one can identify regularly occurring behaviors and use the stimuli from these behaviors to prompt the new habit.

In interventions to increase medication compliance, patients are asked to identify regularly occurring behaviors, the settings in which they occur, and the time of day when they occur. Examples of such events include brushing teeth, drinking coffee, or taking another medication. The patients are then asked to identify habits that could be paired with an additional step of medication taking, considering how regularly the habit is performed (e.g., coffee drinking on weekends vs. weekdays) and how easily it might be disrupted. For example, brushing teeth tends to be a regularly performed habitual behavior. Once the existing habit has been chosen, the medication bottle is placed adjacent to the habit-evoking stimulus (e.g., the toothbrush). The patient is advised to take the medication contingent on this stimulus (i.e., prior to the habitual behavior).

Unlearning Habits A habit can be unlearned by interfering at multiple points in the behavioral chain or, more easily, by sidetracking the habit by attending to events at the beginning of the chain.

As an example of sidetracking, consider the famous problem of the child who has developed a habit of entering the house with dirty shoes. The child left muddy tracks through the hallway into the kitchen. In response to the mother's admonition, the child would take the shoes off in the kitchen. However, despite repeated sequences that end in the kitchen, the child continued to enter the house with dirty shoes. As a sidetracking intervention, this mother told the child entering the kitchen in dirty

shoes to (1) go outside, (2) reenter the house, and (3) take the shoes off immediately at the designated proper location. The maladaptive habit was sidetracked because the entry point into the house now prompted the desired behavior.

Habit Reversal Training Habit reversal training is a comprehensive approach toward eliminating dysfunctional habits that can be used to treat nail biting, hair pulling, and tics, including the verbal tics of Tourette's syndrome. Research indicates that the essential components of habit reversal training are awareness training and the contingent use of a competing response. If applied to children, positive reinforcement by the parent is valuable. Habit reversal can be taught in a few sessions.

AWARENESS TRAINING The patient is asked to describe the habit verbally in great detail and to demonstrate it to the therapist. To increase awareness further, the therapist might ask the patient to interrupt the behavioral chain at any point. Attention is also given to attempts to conceal the behavior (e.g., pretending to clean the space between teeth while actually nail biting).

Awareness training also involves identifying the triggering stimuli. For example, the patient's hands must be unoccupied for hair pulling or nail biting to occur. Stuttering occurs particularly when a patient is speaking on the telephone or interacting with unfamiliar people; conversely, singing or shouting tends to prevent stuttering. Behaviors that represent the beginning of the dysfunctional habit are also identified. For example, patients may breathe shallowly or hold their breath before they begin to stutter. Touching the face in some manner tends to precede nail biting or hair pulling. As a homework assignment, patients can be asked to write a brief report of the steps involved in the habit and the circumstances leading up to it. They also begin to self-monitor the frequency of the habit using golf counters or self-recording forms.

COMPETING RESPONSES AND REPAIRING BEHAVIORS Competing responses are designed to be incompatible with the habits. Patients apply the competing response when they enter a habit-prone situation or as soon as they find themselves engaging in a prehabit or habit behavior and maintain it for 1 to 3 minutes, or until their subjective urge diminishes. Thereafter patients engage in repairing behaviors, to remove stimuli that might prompt future incidences.

For hair pulling and nail biting, the competing responses include a fist-clenching maneuver, followed by a repairing response and (if necessary) additional clenching. For nail biting, repairing involves smoothing rough edges with an emery board. For hair pulling, repairing involves combing or brushing the hair. In the competing response, clenching, the patient grasps something or simply makes a fist, with the fingers closing over the thumb with enough tension to feel pressure in the fingers but less than is required to whiten the knuckles. Care is taken to keep the competing response from being obvious to others. For example, while reading a book, the patient might hold the open book firmly with both hands.

For stuttering, the competing response involves altering the pattern of respiration before and while speaking. This includes prolonging the inspiration preceding speech, avoiding breath holding, and exhaling about one third the air before beginning to speak. Also, vowel sounds are lengthened slightly. Importantly, the flow of air during exhalation should not stop at the onset of speech. Instead, patients are instructed to “breathe into” the word and continue to exhale past the end of the phrase spoken. Phrases should be kept short so patients do not run out of breath. Patients first practice with vowels, then consonants, and then by reading aloud. If they have trouble with particular sounds (such as /P/ or /K/), the dictionary can be consulted and reading exercises can focus on those sounds. In situations likely to lead to stuttering, patients should think about what to say before speaking. If a stutter occurs, they immediately stop speaking and use the competing response.

Initial research studies found these techniques quite effective. Table 30.2-11 lists a number of these studies, selected to illustrate the variety of competing responses. However, a recent clinical replication series obtained disappointing results. Among patients treated with a 9-session program in which one of the sessions was devoted to habit reversal, 12 of 14 patients who completed the treatment responded, but after follow-up, most of them had relapsed. However, since only one of the sessions was devoted to the component that had proved essential in other studies, perhaps these results can be improved.

Table 30.2-11 Overview of Habit-Reversal Procedures

RELAXATION THERAPY

Muscle relaxation is used either as a component of treatment programs (e.g., systematic desensitization) or as treatment in its own right (relaxation therapy). Relaxation is characterized by (1) immobility of the body, (2) control over the focus of attention, (3) low muscle tone, and (4) cultivation of a specific frame of mind, described as contemplative, nonjudgmental, detached, or mindful.

In the United States the first proponent of relaxation therapy was Edmund Jacobson, who created progressive muscular relaxation at the beginning of this century. His book *Progressive Relaxation* was published in 1929. In Germany, Johannes H. Schulz created a relaxation method based on autosuggestion, called *autogenic training*. The first edition of his book *Das autogene Training,* appeared in 1932. Relaxation therapy as practiced today also includes elements from Eastern meditative practices. Assimilation of these practices into the Western clinical arena occurred in several waves and continues today. For example, the 1970s saw the clinical applications of techniques based on mantra yoga (i.e., transcendental meditation or the Benson One). More recently, mindfulness meditation has entered the clinical arena.

The physiological changes that take place during relaxation are the opposite of those induced by the adrenergic stress responses that are part of many emotions. Muscle tension, respiration rate, heart rate, blood pressure, and skin conductance decrease. Finger temperature and blood flow to the finger usually increase. Relaxation increases respiratory heart rate variability, an index of parasympathetic tone. Recent findings suggest that opioid antagonists can block the effect of relaxation on stress responses.

Indications Because the effects of relaxation seem to be the opposite of those of acute stress, relaxation therapy has been advocated for conditions thought to be related to adrenergic stress responses. Empirical findings indicate that relaxation therapy is effective for migraine and tension headaches and insomnia. Relaxation therapy has also been advocated as a treatment for hypertension. In the first author's experience, however, relaxation has not been more effective than attention placebo for this condition. Relaxation therapy reduced blood pressure during relaxation sessions and “white-coat” hypertension but not ambulatory blood pressure. Relaxation or temperature biofeedback has also been advocated for Raynaud's disease. However, a recently completed multicenter trial showed that the effects of temperature biofeedback did not surpass those of pill placebo.

In psychiatry, relaxation therapy is mainly used as a component of multifaceted broad-spectrum programs. Its use in desensitization is mentioned above. Relaxing breathing exercises (see below) are often helpful for patients with panic disorder, especially that considered to be related to hyperventilation. In the treatment of patients with anxiety disorders, relaxation can serve as an occasion-setting stimulus (i.e., as a context of safety in which other specific intervention can be confidently tried [see section on exposure]).

Contraindications and Side Effects Relaxation therapy has few contraindications. Some claim that patients with severe asthma should use caution when practicing relaxation because the decrease in sympathetic activity could increase airway resistance. In addition, the authors would not recommended relaxation therapy for acutely psychotic patients, patients with agitated depression, or those prone to dissociation because the lack of proprioceptive cues during prolonged immobility might facilitate outer body experiences. For certain indications, self-report of mild depressive symptoms seems to be a negative prognostic sign. For example, in our hands,

relaxation therapy for tension headaches mainly helped patients with a Beck Depression Inventory score of 4 or less.

When patients perform a relaxation exercise for the first few times, they sometimes report feelings of increased anxiety. Some may even have panic attacks. This phenomenon is called relaxation-induced anxiety, or relaxation-induced panic. Relaxation-induced anxiety may be elicited by exposure to feared bodily cues, letting go, intrusive images or thoughts, remembering traumatic events, or discomfort with the interpersonal aspects of the relaxation session. The latter may involve paranoid or sexual ideation. In patients with panic disorder, an increase in carbon dioxide tension may be the cause of relaxation-induced panic.

Ironic Processes and Relaxation Simply telling a patient to relax does not ensure that a relaxed state will be achieved. In fact, trying too hard to relax can have paradoxical effects, as demonstrated in the following experiment conducted by D. M. Wegner and co-workers:

In a recent study, skin conductance measures were used as an index of stress arousal in two groups of normal subjects. Subjects in one of the groups were instructed to relax in the following manner. “Relax as much as you can. Using any technique, I want you to remove all anxiety, reduce all tension in your muscles, and become completely and totally relaxed. It is very important that you feel thoroughly relaxed. Please become relaxed as quickly as possible, but I will give you 5 minutes to achieve deep relaxation.” Subjects in the other group were told to “just sit there” for a 5-minute baseline. Then both groups were required to answer questions from a “new I.Q. test.” The results showed that subjects instructed to relax had higher levels of arousal than subjects told to just sit. This difference was apparent at baseline. In addition, during the quiz the subjects who had been instructed to relax showed larger increases in skin conductance. Thus, deliberate relaxation made the subjects more tense.

In clinical practice, the paradoxical effects of trying too hard are often addressed by referring to the difference between active and passive volition. *Passive volition* refers to a mind-set of letting, rather than making, things happen. For patients who seem to be overly focused on achieving immediate results, the first author has found it helpful to share his observation that the effect will happen “when they least expect it.” Practitioners of mindfulness meditation cultivate nonjudging, patience, beginner's mind, self-trust, nonstriving, acceptance (of what is already a fact), and letting go.

Progressive Muscular Relaxation Progressive muscular relaxation involves sequential tension and relaxation of individual muscles. Tension is included to help the patient focus attention on specific muscles or identify the sensations of a tense muscle. Variants of progressive muscular relaxation differ with respect to how many muscle groups are practiced in a session. Some work with one or a few muscles during a session; others focus on total body relaxation during the first session.

Jacobson's Method Early in this century, a frequently prescribed remedy for various ailments was protracted rest. In Jacobson's own words, progressive relaxation was developed to “seek by scientific means, the most effective form of rest.” Jacobson observed that:

> When an individual lies “relaxed,” in the ordinary sense, the following clinical signs reveal the presence of residual tension: respiration is slightly irregular in time or force; the pulse-rate, although often normal, is in some instances moderately increased as compared with later tests; voluntary or local reflex activities are revealed in such slight marks as wrinkling of the forehead, frowning, movements of the eye balls, frequent or rapid winking, restless shifting of the head, a limb or even a finger; finally, the mind continues to be active, and once started, worry or oppressive emotion will persist. It is amazing that a faint degree of tension can be responsible for all this.

Learning relaxation, therefore, involves cultivating a muscle sense. To develop the muscle sense further, patients are taught to isolate and contract specific muscles or muscle groups, one at a time. For example, patients flex the forearm while the therapist holds it back to observe tenseness in the biceps muscle. (Jacobson used the word “tenseness” rather than “tension” to emphasize the patient's role in tensing the muscles.) Once this sensation is reported, Jacobson would say, “this is you doing! What we wish is the reverse of this—simply not doing ... relaxation is simply a negative.” Patients are repeatedly reminded that relaxation involves no effort. In fact “making an effort is being tense and therefore is not to relax.” As the session progresses, patients are instructed to let go further and further, even past the point when the body part seemed perfectly relaxed.

Patients would work in this fashion with different muscle groups, often over more than 50 sessions. For example, an entire session might be devoted to relaxing the biceps muscle. Another feature of Jacobson's method was that instructions were given tersely so they would not interfere with the patients' focus on muscle sensations; suggestions commonly used today (e.g., “your arm is becoming limp”) were avoided. Patients were also frequently left alone, while the therapist attended to other patients.

Later Adaptation of Progressive Muscular Relaxation Joseph Wolpe chose progressive relaxation as a response incompatible with anxiety when designing his systematic desensitization treatment (see next major section below). For this purpose, Jacobson's original method was too lengthy to be practical. Wolpe abbreviated the program to 20 minutes during the first six sessions (devoting the remainder of these sessions to other things such as behavioral analysis). In a later modification of progressive relaxation, patients completed work with all the principal muscle groups in one session. The specific muscle groups and instructions for this type of progressive relaxation are listed in Table 30.2-12. Once the patients have mastered this procedure (typically after three sessions), these groups are combined into larger groups. Finally, patients practice relaxation by recall (i.e., without tensing the muscles).

Muscle Group	Instruction
Dominant hand and forearm	Make a tight fist, now
Dominant biceps, triceps	Make your upper arm tense by countersensing muscles
Nondominant arm, forearm	Make a tight fist, now
Nondominant biceps	Make your upper arm tense by countersensing muscles
Forehead	Lift eyebrows
Orbital and nose muscles	Squint and wrinkle your nose
Lower cheeks and jaws	Bite your teeth together and pull the corners of mouth back
Neck and throat	Pull your chin toward your chest but prevent it from happening by countersensing muscles in front and back
Chest, shoulders, upper back	Take a deep breath, hold it, and pull the shoulder blades upward (if sitting) or backward (if supine)
Abdominal or stomach region	Make your stomach hard, as if you were going to hit yourself
Dominant thigh	Counterpose extensors and flexors
Dominant lower leg	Dorsiflex foot
Dominant foot	Curl toes upward (not down to avoid cramps)
Nondominant thigh	Counterpose extensors and flexors
Nondominant calf	Dorsiflex foot
Nondominant foot	Curl toes upward (not down to avoid cramps)

Table 30.2-12 Outline of Initial Progressive Relaxation Session, All Muscle Groups

Autogenic Training Autogenic training is a method of self-suggestion that originated in Germany. It involves the patients directing their attention to specific bodily areas and hearing themselves think certain phrases reflecting a relaxed state. In the original German version patients progressed through six themes over many sessions. The six areas are listed in Table 30.2-13 along with representative autogenic phrases.

Theme	Examples of Self-Statements
Heaviness	“My left arm is heavy”
Warmth	“My left arm is warm”
Cardiac regulation	“My heart beat is calm and regular”
Breathing adjustment	“It breathes me”
Solar plexus	“My solar plexus is warm”
Forehead	“My forehead is cool”

Table 30.2-13 Sample Autogenic Phrases

Autogenic relaxation is an American modification of autogenic training, in which all six areas are covered in one session. Autogenic training became popular in the United States in the 1970s. It has been used particularly in the treatment of migraine headache.

Biofeedback Biofeedback has received much media attention and thus is well known. Briefly, biofeedback involves the recording and display of small changes in the feedback parameter. The display may be visual, such as a big meter or a bar of lights, or auditory. Patients are instructed to change the levels of the parameter, using the feedback from the display as a guide. This treatment was based on a discovery that laboratory animals could control their autonomic function using biofeedback under stringent conditions that appeared to eliminate possible mediation by skeletal muscle activity. However, these relevant experiments have not been replicated, a circumstance that removes the scientific basis for biofeedback as a method of control over autonomic function. Biofeedback can be used by itself or in combination with relaxation. Patients with urinary incontinence use biofeedback alone to regain control over the pelvic musculature. Biofeedback is also used in the rehabilitation of neurological disorders.

Biofeedback-Assisted Relaxation The most common biofeedback modalities used in biofeedback-assisted relaxation include frontalis electromyographic feedback or feedback to increase finger temperature. Temperature feedback is particularly interesting as a therapeutic modality because ironic effects from trying too hard are particularly salient with this treatment. Temperature feedback generates tangible events that can be used to discuss such effects with patients.

Mindfulness Practice When relaxation therapy is used as a single treatment, the purpose is to produce some benefit in the patient's everyday life; that is, the effects generated during a relaxation session should eneralize to the patient's everyday activities. Two quite different approaches to ensure such generalization are mindfulness and applied relaxation. Mindfulness training is a component of dialectic behavior therapy. In dialectic behavior therapy, patients are taught the construct of the wise mind, which provides context for the mindfulness attitude. Individuals are instructed to cultivate mindfulness by taking a nonjudgmental stance, focusing on one thing in the moment (one-mindfulness), and doing what works. Mindfulness is taught as having three components: observing, describing, and participating.

Applied Relaxation Applied relaxation involves eliciting a relaxation response in the stressful situation itself. Discussion above showed that this is not advisable right away because of the possible ironic effects of relaxation. Therefore, patients should first practice relaxation in nonstressful circumstances. The method developed by Lars-Göran öst and coworkers in Sweden has been proved efficacious for panic disorder and generalized anxiety disorder. Establishing the relaxation response in the patient's natural environment consists of seven phases of one to two sessions each: progressive relaxation, release-only relaxation, cue-controlled relaxation, differential relaxation, rapid relaxation, application training, and maintenance. Details are provided in Table 30.2-14.

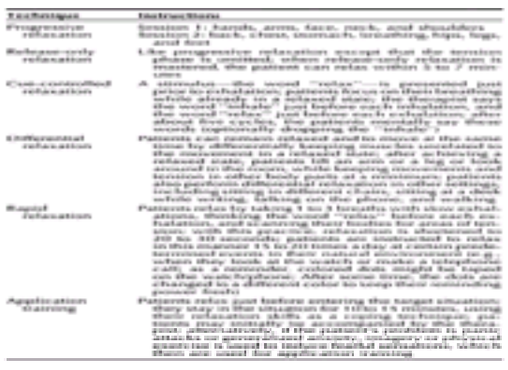

Table 30.2-14 Steps in Applied Relaxation

Applied Tension Patients with blood and injury phobia show a unique, biphasic response when exposed to a phobic stimulus. The first phase is associated with increased heart rate and blood pressure. In the second phase, however, blood pressure suddenly falls and the patient faints. Isometric muscle contractions increase blood pressure. A technique that is the opposite of relaxation, applied tension, can be used to counteract the fainting response.

The treatment extends over four sessions. In the first session patients learn to tense the muscles of the arms, legs, and torso for 10 to 15 seconds (as if they were bodybuilders). The tension is maintained long enough for a sensation of warmth to develop in the face. The patients then release the tension but do not progress to a state of relaxation. The maneuver is repeated five times at half-minute intervals. This method can be augmented with feedback of the patient's blood pressure during the muscle contraction; increased blood pressure suggests that appropriate muscle tension was achieved. The patients continue to practice the technique five times a day. A side effect of treatment that sometimes develops is headaches. In this case, the intensity of the muscle contraction and the frequency of treatment are reduced.

During the next two sessions, the patients are shown a series of slides of mutilated bodies. They are coached in identifying early warning signs for fainting, such as queasiness, cold sweats, or dizziness, and in applying the learned muscle tension response quickly, contingent on these warning signs. During the final two sessions, patients perform applied tension while donating blood or watching a surgical operation.

Breathing Retraining Breathing exercises are among the most ubiquitously prescribed interventions within and outside behavior therapy. Given this, surprisingly little empirical information is available to evaluate their effects critically. For example, the common advice for patients to frequently take a deep breath when symptomatic does not make sense from a physiological perspective.

Physiological Effects The breathing exercises used in behavior therapy were originally associated with Eastern meditative practices. They typically involve slow breathing through the nostrils, with exhalation longer than inhalation and an emphasis on diaphragmatic, as opposed to thoracic breathing. Changes in breathing produce a number of physiological effects. Switching from thoracic to abdominal breathing decreases both cardiac output and peripheral resistance. Switching from mouth breathing to breathing through the nostrils should increase dead space and hence alveolar carbon dioxide tension. It also leads to greater swings in intrathoracic pressure, which in turn affects the venous blood flow into the thoracic cavity and the heart. This effect may be even more pronounced in alternate-nostril breathing, in which the patient occludes one nostril at a time with the finger.

Slowing the respiration rate to eight cycles per minute increases arterial carbon dioxide tension, reduces cardiovascular reactivity to stress, and increases respiratory sinus arrhythmia, an index of parasympathetic tone. Parasympathetic tone has been of interest recently, because reduced respiratory heart rate variability (consistent with decreased vagal tone) may constitute a cardiovascular risk factor, at least in post–myocardial infarction patients. Breathing more deeply also increases respiratory sinus arrhythmia but may increase heart rate and muscle blood flow. Holding one's breath substantially decreases the heart rate.

Clinical Methods of Breathing Retraining The principal methods of breathing retraining are natural breathing and paced breathing.

NATURAL BREATHING Involves abdominal breathing through the nostrils. Upper chest breathing (the heaving bosom) is avoided. Patients let their breathing occur at its own natural rate. Before natural breathing can occur, however, faulty breathing habits must be corrected. Patients suffering from anxiety often hyperventilate—their respiration tends to be either too deep or too rapid. Even so, they often complain of air hunger. This may be related to a habit of not allowing complete exhalation, as they begin the next inhalation too soon. In addition, such patients may previously have been told to take deep breaths as a way to relax; however, because deep breathing increases dead space ventilation, carbon dioxide tension (PCO_2) should decrease, resulting in the symptoms of hyperventilation (e.g., dizziness).

Patients can learn abdominal breathing by placing one hand on the abdomen and the other on the upper chest and watching the degree of excursion. Patients may be encouraged to let the rate and volume of breathing decrease by prolonging the exhalation phase and allowing a brief pause at the end of exhalation. Exhaling against a partially closed glottis (making the sound of the letter H but with mouth closed) is a way of prolonging the expiration. Since this involves exhaling against slight resistance, making the H sound should be accompanied by an increase in intrathoracic pressure during exhalation similar to (but much less than) what occurs during the Valsalva maneuver. This might lead to an increase in vagal tone. A breathing technique used in the rehabilitation of patients with chronic obstructive pulmonary disease is exhalation through pursed lips. Pursed-lips breathing tends to prolong exhalation and increase expiratory load. This technique increases arterial oxygen

saturation in pulmonary patients. (It is possible that the H-sound technique has similar effects, although no data seem to be available.)

PACED BREATHING Involves inhaling and exhaling for specific durations. Patients may be instructed to inhale while counting to 2, then exhale while counting to 4 (one count per second). They then work slowly on prolonging the cycle. Breath holding may be added between the inhalation and exhalation (e.g., inhaling for 2 seconds, holding breath for 4 seconds, exhaling for 4 seconds). Paced breathing is useful for patients who feel they have no sense of control over their breathing, including patients who hyperventilate. It might work by providing a therapeutic context for respiration-produced stimuli that had been anxiogenic.

THERAPEUTIC EXPOSURE

Along with contingency management procedures, the treatment of phobias is one of the most important contributions of behavior therapy. The behavioral treatments for phobia have one feature in common, namely, exposure to the feared stimulus. Historically, exposure-based treatments were based on principles of Pavlovian conditioning as they were formulated in the late 1940s. Below, exposure techniques are introduced in this context; in later sections, these and other techniques are discussed from the perspective of newer theoretical developments.

Behavioral methods to treat anxiety were developed on the assumption that stimuli induced fear because they served as warning stimuli, or conditional stimuli, for the future occurrence of an aversive unconditional stimulus. It was further assumed that by the time the patient sought treatment, the conditional stimulus–unconditional stimulus contingency was no longer operative. However, because of persistent avoidance or escape behaviors, the patient had not been able to contact the new contingencies, which resulted in maladaptive fears. Behavioral methods, in essence, seek to bring the patient in contact with the prevailing contingencies. This means that the individual must be brought in contact with (i.e., be exposed to) the warming stimulus, to learn firsthand that no dangerous consequences will ensue.

Exposure-based treatments were developed according to two competing rationales, counterconditioning and extinction. Methods based on counterconditioning are called *desensitization*. The presentation of the fear-evoking stimulus is paired with a behavior that induces an emotional state incompatible with anxiety (i.e., counterconditioning; see section on signaling operations). In the first reported application of counterconditioning by Mary Cover Jones in 1924, a child's fear of rabbits was treated using food as a counterconditioner, but food is not a good universal counterconditioner for adults. Another way of creating an anxiety-inhibiting state is through deep muscle relaxation. In this case, patients attend to the phobic stimulus while they are in a state of deep muscle relaxation. If anxiety develops, the exposure episode is terminated. Less common counterconditioners include assertive behaviors, relief from an aversive stimulus such as mild electric shock or holding one's breath, or the therapist's encouragement and support.

For counterconditioning to work, the anxiety level experienced with the phobic stimulus has to be minimal. In addition to using the counterconditioner, treatment is arranged to begin with stimuli that induce minimal levels of anxiety. Only after exposure to this stimulus occurs without anxiety does treatment progress to a stimulus with higher anxiety potential. To this end, a number of anxiety-evoking stimuli are collected and ordered by their anxiety-inducing potential. Treatment is then implemented on this hierarchy of situations. For example, in the child treated by Jones, a rabbit was placed closer and closer to the child (little Peter) while he was eating.

In methods using the extinction rationale, the aim is to arrange for unreinforced exposures to the conditional stimulus; that is, the signal is presented but the feared consequence does not appear. These methods involve prolonged exposure while escape behaviors are being blocked. In this case, anxiety first increases and then diminishes when the feared consequences do not materialize. These methods, associated with high levels of anxiety, are referred to as “flooding.”

The methods just discussed can be applied to imagined stimuli or real stimuli (in vivo). This results in four basic approaches: in vivo exposure, including in vivo flooding and in vivo desensitization, and imaginal exposure, including imaginal desensitization and imaginal flooding. A related procedure is “implosion,” which is similar to imaginal flooding, but the therapist takes greater liberty in embellishing the stimuli to come closer to the inferred core fear in the patient's condition. “Graduated in vivo exposure” means exposure to real-life situations arranged in a hierarchy but without an emphasis on counterconditioning.

Treatments also differ in being self-administered or requiring the participation of a therapist. Thus potentially, eight different treatment approaches exist. “Programed practice,” for example, refers to self-administered, graduated, in vivo exposure. Not all of the eight permutations are viable treatments, however; self-directed flooding is one example.

The most commonly used treatments are the in vivo exposure methods. Imaginal exposure is used when the scenarios feared by the patient cannot easily be created at will. This tends to be the case in posttraumatic stress disorder and some cases of obsessive-compulsive disorder or social phobia. In general, these treatments are highly effective in the treatment of phobias. In fact, one-session exposure treatments lasting half a day have been used for some specific phobias such as fear of spiders. Imaginal flooding and some vivo methods may induce very high degrees of distress that make compliance problematic. In agoraphobic patients undergoing in vivo exposure, heart rates of 160 to 180 beats per minute are common. It is therefore prudent to inquire about the patient's cardiovascular health before embarking on such treatment.

Imaginal Systematic Desensitization Imaginal systematic desensitization was pioneered by Wolpe, a founding father of behavior therapy. Comparative outcome studies have indicated, however, that imaginal desensitization is not as effective as in vivo exposure, particularly with agoraphobic patients. Wolpe himself argued that agoraphobia is a heterogeneous condition requiring a broader behavioral approach that includes targets such as marital conflict, dependency, and medical conditions (e.g., seizures and Mènière's disease. Imaginal desensitization also requires more sessions than in vivo procedures and tends to be tedious to administer. For these reasons, imaginal desensitization is not commonly used in the clinical treatment of phobias today. However, it remains an option for patients who require a low-anxiety approach, such as children or medically compromised patients.

Patients who are candidates for systematic desensitization are first taught deep muscle relaxation. They also receive instruction in rating their current anxiety levels numerically; these numbers are referred to as “subjective units of distress.” The subjective units of distress scale has predetermined anchor points (e.g., 0 = no anxiety, 100 = maximal anxiety). Information elicited about the patient's fears is catalogued and organized into groups unified by a theme. Within a theme, scenes are rank-ordered according to anxiety level. During the first desensitization session, patients initially practice imagining a pleasant scene. This enables the therapist to determine the patients' ability to visualize and (incidentally) to screen for relaxation-induced anxiety. The treatment then proceeds to the scene lowest in the hierarchy. The scene is presented verbally by the therapist. The patient is instructed to raise an index finger when the image is clear. The therapist then lets the patient imagine the scene for 5 to 7 seconds. At this time, the patient provides a subjective unit of distress rating and then focuses on cues associated with relaxation. After about 20 seconds, the next scene is presented. Depending on the rating, this scene is either the same or the next one in the hierarchy. The desensitization program involves about 10 scene presentations in early sessions and more in later sessions. The duration of treatment ranges from 6 to more than 100 sessions.

Imaginal Flooding In contrast to systematic desensitization, imaginal flooding involves only one scene. This scene corresponds to the one on top of a systematic desensitization hierarchy. Below is an imaginal flooding scene from S. M. Turner and D. C. Beidel for a female patient with social phobia.

Jim has invited you to attend Christmas dinner at his family's home. You are very nervous about this because you know there will be a lot of people there. You get to Jim's house and walk in the front door. Everyone turns to look at you and you introduce yourself as Jim's girlfriend. At the dinner table everyone is sitting rather quietly when Jim's father looks straight at you and says, “Why don't we have Jim's girlfriend say the grace for us tonight.” You feel the adrenaline flow as the center of attention is focused on you. You want to run away from the table but you know that you can't. Your mouth is very dry and your heart is pounding. Your face feels very hot and you are sure that it is red. Just then one of the children points at you laughing and says, “Look how red she is getting!” You try desperately to regain your train of thought but you can't. Your mind is blank. All you can focus on is your pounding heart and your red hot face. Everyone is looking at you, intently waiting for you to start the grace. ou manage to recall a very simple dinner prayer that you used to say as a child but as you begin to speak you hear that your voice sounds very shaky. You finish and you notice that many of the people around the table are now staring at you in surprise and pity. They think you are the most nervous individual they have ever seen. You can hear the whispers around the room as Jim's family members are astonished at how shy you are. You hear things like, “Poor girl. I really feel sorry for her,” and “Boy, Jim sure got himself a quiet one this time.” One of the children blurts out, “What's wrong with her, mommy?” and the child's mother says, “She's awfully shy, honey.” All you can do is look down at your food and avoid eye contact until this nightmare is over, but you continue to hear the comments during the entire dinner and you can feel the stares from the people around the table.

A scene like this is constructed on the basis of material obtained in interviews with the patient. Care is taken to include (1) the sensory qualities of the scene, (2) the patient's action tendencies and responses, and (3) the patient's interpretations (i.e., the personal significance of the scene). Examples of sensory statements are “You go in the front door” and “At the dinner table, everyone is sitting rather quietly,” and “Jim's father is looking straight at you.” Examples of responses or action tendencies include “All you can focus on is your pounding heart,” and “You look down at your food and avoid eye contact.” Examples of significance descriptions

include “People are looking at you in surprise and pity,” “What's wrong with her,” and “They think that you are the most nervous individual they have ever seen.” These significance descriptions are related to the essence, or core, of the fear. The duration of flooding treatment depends on the target problem. The treatment program for social phobia from which the flooding scene came extends over 12 weekly sessions. Flooding sessions tend to be more successful if scheduled more often than once a week.

Imaginal flooding sessions last for 90 to 120 minutes. Patients are seated comfortably, with tight clothing loosened. The room is dimly lit and quiet. The patients are instructed to close their eyes and imagine the scene as described, as clearly as possible. The scene is read slowly and clearly, and the reading is repeated after a few minutes. The flooding session may involve several repetitions of the scene. The interscene interval can gradually be lengthened to 5 to 10 minutes or more. During the session, the therapist stays in touch by periodically asking the patients about their success in imagining the scene. Patients may be asked to describe details of the scene visualized. In addition, the patients are asked to perform subjective units of distress ratings once every 10 to 15 minutes (some therapists ask for ratings every 5 minutes and also ask for ratings of the clarity of the image). Typically, the subjective units of distress levels rise rapidly during the first 10 minutes, peak after 40 minutes, and then slowly decline. The session is terminated after 90 minutes or if the ratings have declined below 50 percent of the peak level. If this has not happened, the session is continued. (This lack of fit with the “50-minute hour” is a major impediment to the use of flooding treatments in fee-for-service settings and has contributed to the current popularity of cognitive-behavioral methods.)

The report of anxiety indicates that the patient has successfully imagined the scene. Patients are not allowed to engage in any coping methods to reduce anxiety. Care is taken so that the patient does not dissociate during the scene, a problem occurring in individuals with posttraumatic stress disorder. Dissociation functionally represents an escape behavior and is managed by the therapist staying in verbal communication with the patient and providing reorienting cues.

In Vivo Exposure Methods In vivo exposure methods are among the most effective behavioral mental health treatments. In vivo exposure is the treatment of choice for phobias and obsessive-compulsive disorder (particularly when symptoms are largely limited to washing compulsions). The two main approaches are flooding and graduated exposure.

Flooding and graduated exposure can be compared with two ways of entering a swimming pool of cold water. Flooding would be equivalent to jumping off the diving board. Graduated exposure, on the other hand, involves repeated immersions of increasingly larger body areas, alternating with strategic retreats. The advantage of the latter method is its more humane nature. For example, mothers teach their children to play in the water using this method, often using facial and vocal cues of support as a counterconditioner. The disadvantage, however, is that the individual might decide that the water is too cold, after all, and therefore fail to complete the procedure.

In Vivo Flooding In vivo flooding involves exposure to a maximally fear-inducing situation, which can be real or contrived. Contrived situations are feasible in anxiety clinic settings with sufficient staff or student resources and can be structured to resemble the core situation avoided by the patient.

> The patient was a 33-year-old female with social fears of eating in public. In particular, she was afraid of being observed by others when chewing and swallowing, particularly at dinner parties. A contrived situation was arranged in which the patient came to the session with a prepared meal and drink. She entered a conference room in which five people in professional attire were already seated along a table. The patient was instructed to eat her meal in front of these individuals. Between bites, she was instructed to look at them often, and they had been instructed to avoid staring contests. She was not to distract herself from her anxiety symptoms. She was to eat her meal slowly, paying attention to the behavior of the observers and to her anxiety symptoms. (e.g., dry mouth or difficulty swallowing). No conversation between the patient and observers was permitted. The observers would look at her and observe her chewing and swallowing behaviors, at times writing comments in a notebook. Occasionally observers would communicate by whispering to each other, exchanging written notes, or giving knowing glances and smiles. The only other communication occurred between the patient and therapist, and this was limited to providing her subjective units of distress rating. The session lasted 90 minutes.

Note that this situation may seem quite traumatizing. However, because the exposure session is long and continued until ratings decline, the patient does not become sensitized.

Graduated In Vivo Exposure Often used for specific phobias, agoraphobia, and obsessive-compulsive disorder, this treatment involves exposure to situations organized along a hierarchy of gradually more fear-inducing situations. When the anxiety is pervasive, several hierarchies might be constructed. The hierarchy must involve only small steps. If patients anticipate that the next situation on the hierarchy involves a large increase in fear, they might engage in avoidance behaviors. They might drop out of treatment before reaching this step; if they go through with the step and experience a surprisingly large increase in anxiety, sensitization may occur, even of the steps already completed.

However, it is sometimes advisable to schedule the most difficult situations in the middle of treatment. This has been advocated in the treatment of patients with obsessive-compulsive disorder so that more time is available for this situation. In addition, because there is less time to build up anticipatory anxiety, approaching the peak in the middle of treatment may make patients less likely to drop out of treatment.

Self-directed Exposure (Programed Practice) During programed practice, patients are on their own or with a safe person other than the therapist. For example, for a patient with fear of driving through tunnels, the tunnels in the area are surveyed and rated for the amount of anxiety they generate. Further permutations can be created by considering whether the patient is riding, driving accompanied, or driving unaccompanied. Again, the steps between successive items should be relatively small. For example, a patient with fear of bridges was treated with a programed practice hierarchy of situations involving decreasing distances to a local bridge. The patient performed all the steps but dropped out before the crucial one, driving across the bridge.

The length of the session depends on how rapidly anxiety levels decline. Patients can be instructed to identify the peak subjective units of distress rating and terminate the session when the maximal rating within a run has declined to 50 percent of baseline. Alternatively, patients who are not quantitatively inclined can monitor whether coming out of the tunnel is associated with a feeling of relief. Relief suggests negative reinforcement of leaving the tunnel, which means that further trials are needed. On the other hand, if the patient begins to feel bored, it suggests that the patient's anxiety has decreased sufficiently and the session can be terminated.

Adaptations of Exposure Methods This section discusses adaptations of classical exposure methods, including response prevention and contamination of the patient's home setting.

Response Prevention Compulsive behaviors in patients with obsessive-compulsive disorder are considered functional neutralizing behaviors that temporarily reduce anxiety. With neutralizing behaviors, patients can quickly undo the effect of formal exposure sessions. Therefore, for exposure to be effective, these patients need *response prevention,* that is, they are kept from performing their compulsive behaviors.

If the patient's compulsions are pervasive or highly imperative, hospital admission is indicated. However, for the admission to be of optimum benefit, the staff must be trained in carrying out exposure and response prevention. For this reason, such patients are best treated in programs with a programatic focus on obsessive-compulsive disorder. During the hospital stay, daily sessions involve imaginal or in vivo exposure to individualized anxiety-inducing stimuli. These are accompanied by response prevention on a 24-hour basis. Such treatment programs are typically completed in 2 to 3 weeks.

Exposure and response prevention often create extreme distress and feelings of revulsion in the patients, making it difficult to ensure their cooperation. In the original inpatient program designed in England, patients were physically restrained when necessary. However, restraints have been replaced by patient cooperation ensured by an adequate treatment rationale, reminders, and persuasive efforts.

Patients with obsessive-compulsive disorder often engage in subtle avoidance behaviors that require alertness and experience on the part of the therapist. For example, one inpatient with contamination fears undergoing response prevention showed remarkably little distress during her inpatient stay. The lack of anxiety suggested that the stimuli driving her anxiety had not been found. One day, clean clothes were discovered sealed in a plastic bag in her dresser. When this bag was opened and the clothes were contaminated, she showed considerable distress. Thereafter, progress was made in treatment.

Contamination of the Home Environment Over the years, patients have often trained family members to help them with their compulsive behaviors. To keep family

members from enabling the patient's compulsive behaviors, they need to be coached in limit setting and other assertive behaviors.

Some patients with obsessions related to contamination have succeeded in creating a virtually sterile home environment; successful response prevention requires that the therapist visit the patient's home to restore a normal degree of contamination. The therapist deliberately contaminates all conceivable areas that the patient has managed to keep clean. This is easier said than done. An excerpt from Turner and Beidel of a patient's report of a home-contamination session illustrates the comprehensive nature of the intervention.

[The therapist] started touching everything very slowly. I was told to follow behind and touch everything she touched. It was like we were spreading the contamination. She touched doorknobs, light switches, walls, pictures, and woodwork. She opened drawers in each bedroom and touched the contents. She opened closets and touched clothes hanging on the rods. She touched the towels and sheets in the linen closet. She went through the children's rooms, touching dolls, stuffed animals, models, Star Wars figures, transformers, and books.

[The therapist] kept talking to me quietly and calmly all the time we went along. I had been anxious when we started, but, as we continued, my anxiety level decreased. At one point, when I had begun to think the worst was over, she pointed to the attic door and said we were going inside. I said “No, that's where the mice were.” She told me I didn't want to have a place in my home that was off limits. I agreed but became very anxious. It was very hard for me to go inside. I began touching the boxes too, but I was very upset. Then, she put her hands down on the floor and wanted me to do the same. I said, “I can't. I just can't.” Julie said “Yes you can.”

[The therapist] spent several hours with me that day. Before she left, she made a list of things for me to do by myself. Twice a day I was to go through the house touching everything the way she had done with me. I was to invite a friend of mine who had a pet to come and visit and also friends of my children who had pets.

Exposure to Stimuli Presented in Virtual Reality Advances in computer technology have made it possible to present environmental cues in virtual reality for exposure treatment. Beneficial effects have been reported with virtual reality exposure of patients with height phobia, fear of flying, spider phobia, and claustrophobia.

Exposure for Problems Other Than Anxiety Although mostly used for anxiety-related problems, exposure-based treatments can be used for other problems as well.

Bulimia Nervosa Two methods of exposure are used in the treatment of bulimia nervosa. One involves exposure to cues that have triggered binge-eating episodes. Of course, patients are not allowed to binge during such exposure (response prevention). Another method involves exposure to stimuli that occur after a meal (e.g., feeling bloated), with response prevention for purging. Exposure treatments are included in multicomponent treatment programs. Outcome data for exposure treatment of bulimia nervosa are variable but suggest that for exposure to be effective, several sessions of 90 to 150 minutes must be included.

Alcohol Craving Exposure with response prevention has also been used for alcohol-related cues. For example, T. Sidhartan and coworkers showed that this treatment decreased drinking behavior in volunteers with acknowledged problems with alcohol use. Cue exposure was provided over six weekly 90-minute group sessions for 3 to 4 clients. Cue exposure resulted in greater reduction in both the amount and frequency of drinking than a standard cognitive-behavioral intervention.

A treatment rationale was provided consistent with scientific knowledge of stimulus-elicited cravings (cue reactivity). For example, the context of a bar, the presence of drinking buddies, and the smell of alcohol or priming doses of alcohol can all be expected to increase the probability of drinking behavior. During the next 30 minutes, subjects were asked to consume priming doses of their favorite drink. Male subjects consumed three, and female subjects consumed two. After these priming drinks, the subjects poured another drink. This time, however, they had to refrain from drinking during exposure to alcohol-related cues. These cues included (1) looking at the drink for 3 minutes, (2) holding the glass in their hands for 3 minutes, and (3) holding the glass near their mouths for 3 minutes, sniffing the content regularly. After a 5-minute break, the exposure sequence was repeated. To prevent cognitive avoidance behaviors, the subjects were encouraged to share their thoughts about drinking, including their desire to drink and any change therein. However, they could not assist other group members.

Between sessions, the subjects practiced this method in their normal drinking situations, after first being introduced to the principles of graded in vivo exposure. They surveyed the coming week with respect to potential drinking-related situations and were instructed to have the same number of priming drinks and then refrain from further drinking. During the next session, the clients shared the results of their homework assignments with the group.

Exposure to Private Events In the historical development of exposure techniques, the treatments were targeted at stimuli that were external to the patient (i.e., phobic stimuli). Although in imaginal desensitization or flooding the actual stimuli are private, they were seen as representations of the external world. However, even with optimal treatment, some patients with agoraphobia relapsed in response to panic attacks. One unexpected panic attack could undo many months of treatment. For this reason, current treatment programs for panic attacks include exposure to the internal sensations that characterize panic attacks. Exposure can also be directed at remembered events, as in the treatment of posttraumatic stress disorder.

Interoceptive Exposure Interoceptive exposure is part of many treatment programs for panic disorder. Interoceptive stimuli are created by maneuvers such as deliberate hyperventilation, spinning in an office chair, or performing jumping jacks. The therapist discourages subtle avoidance behaviors detected during these exercises. Further on in treatment, patients are instructed to arrange exposure through naturalistic activities (e.g., having a cup of coffee, going to aerobics class, eating heavy food, wearing a tight collar, relaxing in a sauna, or driving in a hot car).

Implosion In implosion, exposure is arranged to both remembered events and hypothesized events. Imagined scenes are embellished by the therapist, often along psychodynamic lines, in a successive approximation toward the patient's core fear.

In a newer variant of implosion, the therapist lets the patient take the lead by successions of revised scripts that include material recalled during the presentation of previous scenes. The material is selected on the basis of similarities in exteroceptive cues (e.g., objects such as knives), response-produced cues (e.g., eating, drinking, sex), thoughts (e.g., revenge or death), and emotional stimuli (e.g., guilt, shame). As the scripts evolve, the patient may remember new, previously avoided (repressed) material. The visualization of such scenes evokes intense anguish, described as protopathic pain. Often the event ultimately recalled is one involving severe abuse. The patients may assume childlike behaviors as if they were reliving the scene.

Eye Movement Desensitization and Reprocessing The exposure component of eye movement densensitization and reprocessing involves attending to a recalled traumatic event. During exposure, therapists move their fingers back and fourth in front of the patients; the patients keep their eyes open and follow the therapist's fingers with their eyes. Whether the inclusion of eye movements and other features of this techniques is associated with superior efficacy than that of other forms of exposure treatments is controversial. Although eye movement desensitization and reprocessing has shown efficacy compared with control conditions, superiority over other exposure methods has not been proved. The originators of this technique advise prospective therapists to obtain formal training in the method; elaboration of scenes can take directions that the naive therapist does not anticipate and may find frightening.

In the initial step of eye movement desensitization and reprocessing, patients identify a scene to be worked on (i.e., the remembered event currently causing the most distress) and describe the image, emotions, and body sensations associated with the memory. They also identify a negative thought associated with the memory and consider an alternative positive thought. They then perform a subjective units of distress rating and rate the believability of the alternative positive thought.

During the desensitization part of the treatment patients concentrate on the images, emotions, body sensations, and negative thoughts associated with a traumatic event. At the same time, they perform the rapid-tracking eye movements. The therapist's fingers are kept about 18 inches from the patient's eyes. During the visualization, which lasts 12 to 30 seconds, 24 to 60 eye traverses are done. After the visualization, patients briefly report any changes in the images or concurrent experiences. Then a new visualization cycle is begun, during which patients focus on any new spontaneously generated associations. Similar cycles are repeated until the original scene no longer elicits discomfort. They then perform a body scan; residual sensations suggest that something is left unprocessed and needs continued work. Otherwise, they proceed with the next step, reprocessing. While patients imagine the original scene, they mentally rehearse the positive thought, performing the eye movements as before.

Recent Theoretical Perspectives on Exposure-Based Methods The treatments discussed thus far have been based on models in which a conditional anxiety response was reduced by counterconditioning or extinction of conditional stimulus. These models have several weaknesses. First, conditioning events are less common in patients with phobias than seems reasonable if these methods work primarily by extinguishing conditional anxiety responses. Second, because conditional stimuli are readily extinguished in the laboratory, simple conditioning models do not explain well why avoidance behaviors in phobias are so persistent without treatment. These findings suggest that often times the fear-inducing stimulus should be thought of as an unconditional stimulus rather than a conditional stimulus.

Another issue is whether individuals actually unlearn their fear. Animal experiments suggest that fear conditioning is not unlearned but contextually controlled.

Devaluation of the Unconditional Stimulus The situation described above involving the social phobic patient visiting her boyfriend's family for the holidays would induce social distress in most people. It contains a priming stimulus of the dominance-submission system—the dominant person in the group (the boyfriend's father) staring at the patient—who being an outsider is at the lowest end of the dominance hierarchy. It is hard to imagine how this scene could ever be a neutral stimulus. It makes more sense to consider this scene an imagined unconditional stimulus (which probably is in a bidirectional relation with a real situation and thus is functionally equivalent). The way exposure reduced anxiety to this scene can be described as habituation of an unconditional stimulus, not extinction. The result would be equivalent to devaluation of the unconditional stimulus, a phenomenon described above. As another example, for individuals with fear of spiders, the spider is not a warning signal for something else; it is a primary, unconditional stimulus that belongs to the food rejection module of the feeding system. Spiders often elicit disgust rather than anxiety in these patients.

If exposure is used for habituation, the general idea is for the patient to get used to the unconditional stimulus. The success of exposure for habituation depends on the nature of the unconditional stimulus. Not all stimuli habituate. Patients with chronic pain or tinnitus are exposed to pain or auditory stimuli for prolonged periods without habituation. On the other hand, habituation to disgust appears to occur rather easily.

Habituation is just one way of devaluing an unconditional stimulus; other methods might thus represent alternative approaches to treatment. In humans, additional information about the unconditional stimulus can devalue it. In fact, Wolpe always emphasized that correcting misinformation is an important part of treatment. For example, a gun aimed at you normally evokes a fear response, which would quickly dissipate upon discovery that the “gun” is a toy.

Besides habituation and instructions, an unconditional stimulus can be devalued a third way, based on the intensity of the unconditional response (response feedback). The way this feedback is framed may affect the value of the unconditional stimulus. For example, a social comparison can be made showing that the experience the patient is having is normal and common. In the case of a first panic attack, it might help a potential panic patient to know that onclinical panics occur in one third of the general population. However, framing the feedback as a social comparison may not work, if the unconditional response is highly aversive.

Patients with vestibular dysfunction sway more than normal comparison subjects in response to certain characteristics of the visual environment exemplified by heights. Patients with vestibular dysfunction also tend to have a fear of heights. The increased sway in high places constitutes response feedback that suggests an increased risk of falling, and therefore leads to unconditional stimulus inflation of height stimuli in these patients. However unconditional stimulus devaluation may occur if patients learn how this effect develops and how to cope accordingly.

Research in the authors' laboratory suggests that the fear of heights is an expression of space and motion discomfort that occurs because individuals with vestibular dysfunction prefer visual information over vestibular spatial information. The long visual distances that characterize heights reduce the visual feedback contingent on body sway that a person would normally obtain in closer surrounds. Therefore, even normal persons show increased body sway in high places, and the visually dependent person is even more vulnerable. When patients find themselves swaying for no apparent reason, they may interpret their responses as having an urge to jump. The authors tell patients that their height vertigo has a physiological explanation. It will diminish if they sit down or focus on proprioceptive cues from their feet and ankles.

Debriefing of future unconditional stimuli can also be used to prevent anxiety. For example, riding in the space shuttle during launch and subsequent microgravity presents many fear-inducing stimuli to an inexperienced passenger. Yet astronauts are trained and debriefed for years before launch. A report by an astronaut of his subjective experiences suggested (to the first author) that his lack of fear might have been a consequence of his training, which was geared to minimizing the possibility of unpleasant surprises.

DEVALUING WORRISOME IMAGES BY COGNITIVE EXPOSURE Research reviewed above showed that fearful images of an unconditional stimulus can elicit fear responses and that these may habituate upon prolonged exposure. However, if the patient cognitively escapes from the image (e.g. by directing attention to another thought) the fear remains. This type of reasoning has been used to develop new treatments for generalized anxiety disorder.

When a situation arises that is ambiguous, an individual responds with an increase in vigilant behaviors. Increasing vigilance may result in obtaining information that decreases the ambiguity. However, the increased vigilance comes at the expense of increasing somatic sensations, which may be accompanied by frightening, intrusive images. Verbal worries are less arousing than the imaged fearful events; thus verbal worries may represent escape or avoidance of imaged fearful events. The images can be conceptualized as unconditional stimuli. The purpose of treatment is to devaluate them by prolonged attention to the frightening image. As this is done without interruptions, physiological responses to the image should habituate. This is the principle for a technique called *functional cognitive exposure*.

This treatment involves identifying the most threatening images among the patient's worries, and arranging the images in a hierarchy. Care is taken to identify the most frightening image. One method of finding it is asking serial “what if—” questions (i.e., sequentially asking what will happen after a feared event has occurred). The patient's description of the scary image is recorded on tape. Using a Walkman-type tape recorder, the patient uses the tape for exposure. During the exposure, the patient engages in *cognitive response prevention,* in which methods that the patient uses to reduce fear are identified and proscribed. This technique of cognitive exposure and response prevention is also applied to patients with obsessive-compulsive disorder with pure obsessions.

Worry prolongation, another exposure approach to worries, does not require tape loop technology. This technique is part of a comprehensive cognitive-behavioral program for worry. In preparation, patients first make a short list of their major worries, identifying the worst possible outcome in each of them, regardless of whether or not the outcome seems realistic. They write the worry down or record it on tape, making sure to include the scariest consequence of the event worried about. Two worries are identified in this fashion. The patient will start exposure to the one that is less anxiety provoking.

The actual worry exposure session lasts about 30 minutes. It begins by the patient visualizing the chosen worry image, taking care to include contextual sensory cues in different sensory modalities, as well as action tendencies and feelings. Image formation tends to be easier the scarier the worry is. Thus, lack of success in visualization could mean that the patient chose an aspect of the worry that is not scary enough or that the worry is depicted too abstractly. Once the image is reasonably clear, visualization continues for 25 to 30 minutes. During the visualization, anxiety levels decrease; if they do not, the patient may have inadvertently switched to another worry. Alternatively, the worst consequence of the target worry may not have been included, because it still is being avoided by the patient. The designers of worry prolongation treatment also included a problem-solving task of generating alternatives for the worst possible outcome.

Occasion Setting and Contexts of Safety According to current Pavlovian understanding, neither extinction nor counterconditioning of a fear means that the fear is unlearned; rather, the behavior is brought under the influence of new contextual cues. In a typical animal experiment, a conditioned fear response is first established by classical conditioning. Then, treatment is provided in the form of extinction (presentation of the conditional stimulus without the unconditional stimulus) or counterconditioning (presentation of food after the conditional stimulus). The treatment may occur in the same setting as the original fear learning or in a different setting. Finally, the effect of treatment is tested by examining fear responses to the conditional stimulus in various contexts or by examining how quickly a fear is relearned.

After treatment is completed, typically the conditional stimulus no longer elicits a fear response. However, findings of contextual control on renewal, reinstatement, and reacquisition of the conditional response indicate that the conditional stimulus still has fear-evoking capabilities. *Renewal* means the extinguished fear behavior immediately recovers if the conditional stimulus is presented in a context different from the one in which the treatment occurred. *Reinstatement* means that the fear behavior to the conditional stimulus reemerges after the unconditional stimulus is presented, without a warning signal; importantly, reinstatement occurs only in the context in which the original learning took place.

When the original conditional stimulus–unconditional stimulus contingency is reinstituted, conditional responses are learned much faster than the first time. Reacquisition is especially easy if the second set of pairings is presented in the setting of the original conditioning. Conversely, reacquisition is slowed down if (1) treatment is provided in a setting different from the one in which the original learning occurred; (2) the reacquisition trials are held in a setting that resembles the one in which the treatment was provided, or (3) if cues from the treatment setting are introduced into the reacquisition setting. Research has also shown that fear acquisition generalizes more easily across contexts than does extinction. To compensate for this effect, the treatment effect should be more stable if treatment is provided in multiple contexts.

These findings imply that what is learned is what specific contexts are safe. To obtain robust treatment effects, treatment should be conducted in multiple contexts, including those resembling previous unsafe contexts. When implementing treatment in a previously unsafe context, a salient cue available from a safe context is

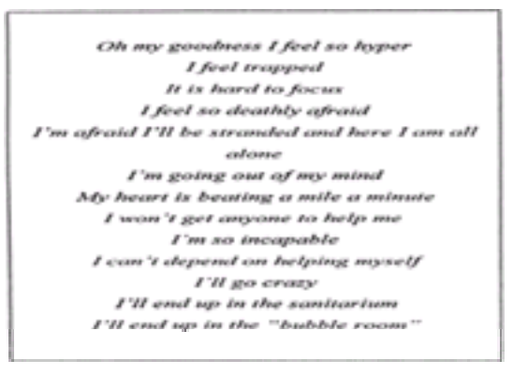
helpful.

METHODS OF INTRODUCING NEW CONTEXTS One way of introducing a new context is to provide a coherent rationale for treatment that suggests that “this time it is different.” Practitioners have long been intuitively aware of the importance of having the patient understand the treatment rationale. However, they probably did not think of their rationale-giving behavior as equivalent to providing cues for a new context or as having the effect of devaluing the unconditional stimulus.

Other techniques may be analogous to introducing new contexts or occasion-setting stimuli. In treatment programs for posttraumatic stress disorder, patients are frequently asked to write down their experiences in detail to provide material for the imaginal exposure scenes. However, the writing also provides a new context in which the traumatic experiences are viewed. Incidentally, writing one's deepest thoughts surrounding a trauma can have beneficial health effects even when no other treatment is provided.

In a technique called deliteralization (or semantic satiation), borrowed from acceptance and commitment therapy, a particular word is repeated rapidly for about 1 minute. As the word is repeated, the meaning tends to fade away and attention becomes focused on the sound of the word. Thus, if reading about the lemon exercise in the beginning of this section had sensory effects on the reader, this effect can now be undone by saying “lemon” 40 times within 1 minute. Using the same method for the word “fish” should also be informative.

The first author tried deliteralization as a context-introducing device in the treatment of a 38-year-old female advertising professional. In the past, she had received training as an actress. The patient had a nearly 20-year history of panic disorder with agoraphobia and posttraumatic stress disorder. She also had a 14-year history of medical problems including vestibular dysfunction, chemically induced porphyria, chronic fatigue syndrome, asthma, seizure disorder, and benzodiazepine dependence. She had known the therapist for years. Because she had to take a trip out of town for business reasons, the session was spent preparing her for the trip. During the session, she was asked to list thoughts that she would have in an agoraphobic situation. These were first written on the blackboard in the therapist's office and then transcribed and printed out in a font typical for greeting cards (Fig. 30.2-5). This format was used to increase the salience of a new context for these statements.



Oh my goodness I feel so hyper
I feel trapped
It is hard to focus
I feel so deathly afraid
I'm afraid I'll be stranded and here I am all alone
I'm going out of my mind
My heart is beating a mile a minute
I won't get anyone to help me
I'm so incapable
I can't depend on helping myself
I'll go crazy
I'll end up in the sanitarium
I'll end up in the "bubble room"

FIGURE 30.2-5 Agoraphobic sentences in a new context.

She was asked to read this list aloud. However, she was afraid that the events described in the statements would actually happen if she read them and was quite reluctant to do this. She began to show signs of dissociation approaching this task. The patient agreed, however, to read the statements, using a Southern dialect. She would repeat the reading several times during the rest of the session, experimenting with various intonations. Along with the humorous responses this produced, the change to Southern dialect made the new acoustic context more salient. The same technique had been used successfully in a previous session involving elevators. It probably also evoked a molar action pattern of acting, which she had done with some success earlier in life. After this session, the patient completed her trip and reported that for the first time in years, she had been able to ride in a taxi by herself. She had made plans to go to a Halloween party dressed up as a southern belle. After the session the patient continued to carry the greeting card with these sentences in her purse. This can be interpreted as a reminder stimulus of the deliteralized context created in the session that facilitated the transfer of safety learning to other contexts.

Guided Mastery Treatment Among the exposure-based treatments in current use, guided mastery treatment, although developed with a self-efficacy rationale, seems to provide the best conceptual fit with the mechanisms involved in therapeutic exposure. This approach has been used successfully with various phobic conditions and may be particularly successful for refractory cases of agoraphobia. However, no empirical data are available for its effectiveness for posttraumatic stress disorder or obsessive-compulsive disorder.

The aim of guided mastery is to enhance self-efficacy. In the context of exposure treatments for agoraphobia, self-efficacy refers to how certain the patients feel that they will be able to stay in the situation for a specified time. Increased self-efficacy after an exposure situation seems to be related to the pleasant surprise response discussed in the section on emotions above as necessary for conditioning to lead to therapeutic changes. Agoraphobic patients were asked to predict how fearful they would be during a 90-minute session of in vivo exposure they were about to start. A situation consistent with pleasant surprise would have patients overpredict their fear (i.e., the fear actually experienced is less than predicted). Results indicated that those who had overpredicted their fear showed the greatest increase in self-efficacy after the session.

In general, the most powerful way of changing self-efficacy is through the success or failure of relevant behaviors. Guided mastery treatment thus creates success experiences in phobic patients through change in behavior. Successful coping with an unconditional stimulus should devalue it. In patients with multiple phobias, the one in which performance is the most impaired provides the most room for improvement. Therefore, such phobias are treated first; generalization of the treatment effect may automatically improve the minor fears as well.

The goal of mastery treatment is to increase the patient's performance in phobic situations. By framing the goal that way, the context is changed from eliminating fear to gaining mastery. This distinction is followed through even in minor details of the treatment. For example, rather than rating their anxiety levels subjective units of distress at regular intervals, patients rate their confidence on a scale from 0 to 100. Traditional exposure treatments emphasize enduring high anxiety levels and allowing the anxiety to diminish with time. In guided mastery, patients learn to manage more effectively in the presence of scary stimuli, regardless of whether they are anxious or not. Nevertheless, as patients learn to function in the presence of high anxiety, their fear responses tend to decrease incidentally.

The role of the therapist, or field helper, is to promote the patient's proficiency, flexibility, and independence when carrying out the exposure task. Flexibility means that the patient can carry out the exposure task in several different ways. Independence is promoted by providing less help as the patient's proficiency increases. In the early stages of treatment, the therapist often stays closely involved. If a task becomes too difficult for a patient, the therapist can improvise and create tasks at levels that the patient can do.

For some patients, touching a feared object such as a spider may be impossible. Remember that the fear in such patients is highly mixed with disgust (i.e., law of sympathetic magic). The method used for such patients is *contact desensitization*. In this method, the patient touches the therapist, who is touching the spider. The first step in a typical hierarchy might be having the spider in a glass jar and the therapist touching it with a pencil. The patient, wearing rubber gloves, is asked to touch the therapist's elbow. Next, the patient and therapist might both hold the pencil touching the spider. The next item could be the same except the patient now takes off the gloves.

Later in treatment the therapist enhances the flexibility of performance, by having patients abandon defensive rituals, including self-protective coping behaviors. Information about coping can be elicited directly from patients. One way of setting the stage for greater behavioral fluency is to try a more difficult task first and then return to an easier task. Jokingly called the “piece of cake” principle, this appears to be a good way of setting up pleasant surprises. Patients are also encouraged to vary their behaviors during both the exposure sessions and their everyday lives. For example, a patient who coped with agoraphobia by parking in a specific place at work might be advised to vary where she parks. This approach appears to approximate learning safety in multiple contexts (discussed above).

Finally, the patient's independence is fostered by the therapist withdrawing assistance as soon as possible. For example, a height phobic proceeding from a lower floor, where he had received the instructions described in the last vignette, might be told, “Now do the same thing here that you did on the previous floor.” In addition,

learning the underlying rationales for treatment means the patient can ultimately assume greater self-direction and better maintain treatment gains.

MODIFICATION OF VERBAL RELATIONS—ACCEPTANCE AND COMMITMENT THERAPY

Our search for manipulable causes of behavior has also identified variables that are not manipulable. For example, in the section on private behaviors, several important nonmanipulable variables covaried with behavior, including wanting, believing, feeling, and some forms of thinking and attending. The section on emotions described patients with feelings about feelings. Attempts to eliminate such behavior not only are certain to be unsuccessful, but also are compounded by the additional aggravation from frustrative nonreward. The behavioral mode primed by such frustrative nonreward does not differ fundamentally from that of someone who tries to fix a broken piece of equipment by kicking it. In both cases, the problem is worsened and the individual fails to do what is called for, backs off and searches for controlling events that can be changed.

Acceptance and commitment therapy was developed to address problems that stem from such misguided attempts at self-control, collectively labeled “emotional avoidance.” It capitalizes on behavioral insights into the nature of verbal behavior described above. Acceptance and commitment therapy seeks to countermand learning histories indicating that problematic behaviors are initiated by thoughts or feelings. Patients are taught to look beyond their thoughts and feelings and focus their efforts on altering manipulable causes of behavior.

The word *acceptance* in acceptance and commitment therapy is synonymous with comprehensive distancing. The distancing involves patients dropping their futile attempts to control their mental events. *Commitment* means patients successfully getting on with their lives, in accordance with their values, by selecting only targets that can be deliberately changed. For this purpose, all the behavior therapy techniques described above are at their disposal.

Some of the components of acceptance and commitment therapy can be found in earlier therapeutic modalities, including existential, gestalt and brief strategic therapy. However, these imports have been honed by theoretical insights, especially with respect to verbal behavior. The resulting treatment strategies aim to modify deep-seated verbal conventions, conventions of which most of us would not be aware.

The need for acceptance is introduced to patients by pointing out the futility of trying to reduce their mental distress by willpower. Various metaphors illustrate this. For example, the “struggle” is compared with being trapped in Chinese handcuffs. Another metaphor involves the patient, blindfolded, trying to get out of a large hole. The method used—digging with a shovel—only makes the hole larger.

The patients' mental control behaviors are identified and labeled (e.g., digging). An emotional avoidance–type problem can be summarized succinctly by the maxim, “If you aren't willing to have it, you've got it.” Because of these discussions, patients may experience feelings of hopelessness framed as creative. At the same time, they may feel validated by having their intuition about the futility of all previous rational solutions confirmed.

Acceptance committment therapy includes procedures aimed at undermining, or deconstructing, unhelpful verbal constructs. To facilitate the development of a questioning attitude with respect to verbal stimuli, patients might be told not to believe what the therapist says. Misleading features inherent in our language are exposed, such as the failure to distinguish between valuations and physical attributes. For example, the expressions “a wooden chair” and “a bad chair” have the same semantic structure, yet the attribute “wooden” would persist even in the absence of humans, while the value “bad” would not.

Deliteralization is used in acceptance and commitment therapy to help deconstruct the semantic context of language, not to reduce symptoms. Deliteralization shows a phonetic context for words as an alternative to the usual semantic context. Another technique of language deconstruction involves having patients deliberately change the way they refer to mental events. For example, instead of saying “X,” patients are taught to say “I have a thought that X”; instead of “this bad chair,” patients might say, “I have an evaluation that this chair is bad.” These reformulations prompt patients to find out where did the thought (evaluation) come from (i.e., antecedent and consequent conditions affecting the thought).

Patients are also taught to differentiate between observing and acting, which contribute to time-varying and time-invariant aspects of the experience of self. Exercises are performed in which patients observe the flow of their thoughts like a spectator watching a parade, noting how long it takes until they are hooked by a particular thought and leave the spectator role.

Values are constructs developed in acceptance and commitment therapy for the commitment aspect. The goal of therapy is described as “putting values into action.” The construction of values involves distinguishing between various aspects of the values concept. To introduce a long-term time perspective, patients might be asked what they would like their epitaphs to say. Distinctions are made between values as feelings (not modifiable) and values as acts (modifiable).

Another distinction contrasts chosen and imposed values. Imposed values are pliance based (i.e., maintained by approval from the patient's culture, parent, or therapist), and the patient can provide verbal reasons for them. Values based on choice, on the other hand, are contingency based and so are not easily justified. For example, most people cannot explain why they chose a particular flavor of ice cream.

The patient is engaged in discussion about ideal values in various social roles. Patients are asked (without being encumbered by reality constraints) to specify their values in ten areas: marriage, family relations, friendships, employment, education, recreation, spirituality, citizenship, physical well-being, and therapy. For example, for family relations, patients are asked to write vignettes about the kind of brother, sister, child, or parent they would like to be. These vignettes are reviewed at a later session. Care is taken to identify pliance-based values. Additional distinctions involve achievable versus unachievable goals, and interventions are targeted at the latter. As the values discussions continue, new suppressed values may become apparent. Patients may also be asked if certain values could be further improved.

If the patient has followed a practice of waiting for the right feeling before acting on a value, this pattern is questioned. Acts of love are possible, even when the person does not presently feel love. Acting according to a value is sometimes referred to “valuing with one's feet.” For example, the patient might be asked, “In the direction of what valued end are your feet taking you?”

OUTCOMES WITH BEHAVIOR THERAPY

Standards for Treatment Efficacy In the field of psychotherapy outcome research, recent efforts have focused on identifying treatments for which effectiveness is supported by empirical data. These efforts required a reexamination of what the standards for such empirical data should be for behavioral interventions.

One set of such standards concerns internal validity. For a treatment to be considered efficacious, the outcome data must show statistically significant superiority of treatment date. The outcome measures of the study have to be reliable, and minimum design standards must be met. A single-group design or single-subject design limited to pre- and post-measures has insufficient internal validity. For a treatment to be considered efficacious, a group design must include a minimal intervention control group, including waiting list or assessment only. The most stringent design is one that permits factoring out of improvement related to nonspecific effects of therapist's attention. The minimum requirement for a treatment to be considered specific is a design that permits comparisons with a placebo.

A second set of standards concerns external validity. For example, the results obtained by a treatment must be assessed by relevant measures. External validity also includes the expectation that a result can be replicated, methods must be specified in detail. Treatments are usually effective only for particular problems, thus inclusion and exclusion criteria must be specified and assessed reliably. Finally, since investigators with a special allegiance to a particular treatment tend to obtain the best outcomes with that treatment, the treatment effect must be replicated by an independent investigating team. For a treatment to be considered efficacious or specific, all internal and external validity standards have to apply. A possibly efficacious treatment is one shown to be efficacious by only one investigating team.

Childhood Disorders Other Than Attention-Deficit/Hyperactivity Disorder Important empirically supported treatments for childhood problems (other than attention-deficit disorder) are listed in Table 30.2-15. Cognitive-behavioral treatments are efficacious for internalizing disorders such as childhood anxiety disorders and depression. For externalizing disorders, the efficacy of parent-administered contingency management is well established. One of the most outstanding accomplishments of behavior therapy is the result of intensive operant treatment of children with autistic disorder. Compared with normal children, autistic disorder children tend to show less transfer of learning to previously unlearned behaviors. This means that each new social behavior must be laboriously shaped. Nevertheless, the outcome seems well worth the effort: Compared with control children, treated children showed markedly higher I.Q. scores and were significantly more commonly placed in regular classrooms.

	Contingency Management	Skills Training	Cognitive and Behavioral	Exposure	Specialized live remarks	Relaxation	Self-Control	Remarks
Anxiety disorders			E	X				
Depression		P						
Oppositional and aggressive behaviors	E	X	E					Skills problem solving parenting skills
Autism	P							Spectacular results
Obesity	P							
Preparation for medical and dental procedures					X

E, efficacious; P, probably efficacious; X, treatment is part of a multicomponent program.

Table 30.2-15 Empirically Supported Treatments for Childhood Mental Disorders Other Than Attention-Deficit Disorder

Attention-Deficit/Hyperactivity Disorder A task force of the American Psychological Association to evaluate empirical support for psychosocial treatments recently reviewed all the treatment outcome studies for attention-deficit/hyperactivity disorder. This review used criteria different from those discussed above for empirically supported treatments. Clear empirical support was shown for the efficacy of behavioral approaches to parent training and classroom interventions for this disorder. However, there were no empirical studies of efficacy for many of the psychosocial treatments for attention-deficit/hyperactivity disorder that are most commonly used in mental health settings, such as individual therapy and play therapy. This finding is consistent with extensive meta-analyses showing that there is little reason to believe that nonbehavioral psychotherapeutic interventions have any impact on disruptive behavior disorders.

COGNITIVE INTERVENTIONS Many different types of cognitive-behavioral treatments have been applied to children with attention-deficit/hyperactivity disorder, including verbal self-instructions, problem-solving strategies, cognitive modeling, self-monitoring, self-evaluation, self-reinforcement, and others. Outcome studies are remarkably consistent in showing that cognitive-behavioral interventions do not produce clinically important changes in the behavior and academic performance of children with this disorder. Limited evidence indicates that other types of cognitive-behavioral interventions—such as social skills training and problem solving—may have some clinical efficacy in the treatment of attention-deficit/hyperactivity disorder when they are combined with intensive multicomponent behavioral treatment programs. It might reasonably be argued that these interventions could have enhanced value in maintenance and generalization as adjuncts to a lengthy and intensive behavioral treatment program. No studies have addressed this issue.

DIRECT CONTINGENCY MANAGEMENT IN THE CLASSROOM Numerous studies of classroom response cost programs reveal that they yield dramatic improvement in disruptive behavior and academic productivity, often raising treated children to normative levels of functioning. The acute effects of contingency management, although substantial, are typically not as large or as comprehensive as the acute effects of medication while medication is active.

CLINICAL BEHAVIOR THERAPY Behavioral interventions have been used for children with the specific diagnosis of attention-deficit/hyperactivity disorder for more than 20 years, and more than 60 studies have demonstrated efficacy (Table 30.2-16). Studies have consistently revealed improvement in both classroom and home settings. Thus, clinical behavior therapy of the sort that is likely to be implemented by therapists in community mental health, primary care, and private practice settings yields clinically important improvement on multiple measures in home and school settings. These treatments therefore meet the American Psychological Association task force criteria for a well-established treatment.

Table 30.2-16 Categorization of Studies Reviewed

Although the short-term improvements obtained with clinical behavioral interventions are substantial, they are typically not as large as those obtained in short-term studies with medication, as long as medication is still being administered. However, the skills taught in behavioral interventions are maintained if parents and teachers continue the programs, while the effects of medication disappear when medication is discontinued.

INTENSIVE TREATMENT PROGRAMS The summer treatment program discussed above results in large treatment effects as shown by parent, teacher, and staff ratings of improvement; standardized parent ratings of disruptive behavior; and direct observations of social and academic behaviors, self-esteem, and parental satisfaction. Pretreatment to posttreatment changes in self-concept and disruptive behavior were twice the size of those reported in studies using clinical behavior therapy. Notably, these positive treatment effects were also present for children with characteristics indicating poor prognosis with clinical behavior therapy, including those with comorbid aggression, from single-parent or from low income families. The dropout rate was 3 percent, compared with rates up to 50 percent that characterize other treatment approaches in outpatient settings.

An area that remains to be addressed concerning behavioral treatment of attention-deficit/hyperactivity disorder is cost-effectiveness. On one hand, behavioral treatments are much less cost-effective than stimulant medication. The essential question, however, is the long-term cost-benefit ratio. Medication is inexpensive but has no long-term impact on outcome; that is, it does not reduce costs associated with such outcomes as special education, dropping out of school, delinquency or criminal behavior, and alcohol or substance abuse. The long-term impact of psychosocial treatments has not yet been evaluated. Nevertheless, the summer treatment program cost of $2500 a child (in 1997) might enable a child to stay in the regular classroom who otherwise would have been placed in special education (about $5000 a year), residential treatment ($25,000 a year), or juvenile incarceration ($50,000 a year).

COMBINED BEHAVIORAL AND STIMULANT TREATMENT In 1986 a review was conducted of the 19 studies in which a combination of behavioral and stimulant treatments was used in children with attention-deficit/hyperactivity disorder. Most studies showed superiority of combined treatment on at least one essential dependent measure. For the average child treated in these studies, a combined intervention resulted in greater improvement than did either treatment alone. Studies conducted in the decade after that seminal review have supported this conclusion, routinely demonstrating the superiority of a combined approach to treatment.

One study compared (1) an 8-week clinical behavioral intervention (mainly parent rather than teacher training), (2) stimulant medication with relatively high doses of methylphenidate, and (3) both treatments combined. Outcome was measured after the behavioral treatments had ended, but children in medication groups were still medicated. All groups showed substantial improvement over baseline. However, on a variety of measures the combined-treatment group demonstrated improvement over those receiving either treatment alone. Figure 30.2-6 illustrates this outcome for the three groups on psychiatrist, parent, and teacher ratings of global improvement. Further, the combined-treatment group was superior to both the behavioral and methylphenidate groups in bringing treated children to a normative range.

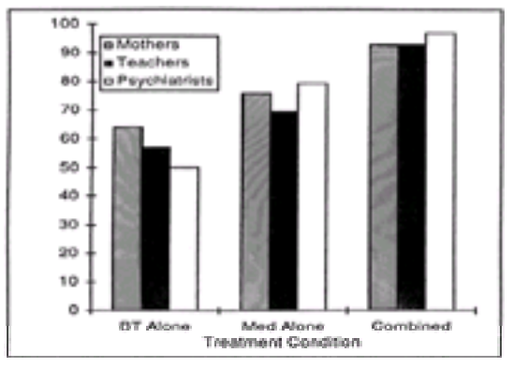

FIGURE 30.2-6 Percentage of patients rated improved by mothers, teachers, and psychiatrists as a function of treatment. (Data from Klein RG, Abikoff H: Behavior therapy and methylphenidate in the treatment of children with ADHD. J Attention Disord *2:*89, 1997.)

A study conducted in a summer therapy program classroom environment showed that both the behavioral intervention and 0.3 mg/kg methylphenidate (slightly less than 10 mg per dose) had salutary effects. However, the combination of the two resulted in behavioral improvement equal to that obtained with a dose of methylphenidate twice as high. This means that it should be possible to reduce the effective dose of methylphenidate—from a high dose to a low-to-moderate dose—by adding a behavioral program in the classroom. This would be particularly valuable for children who develop adverse effects (tics, slowed growth) on high dosages of psychostimulant medications.

Psychiatric Disorders in Adults Table 30.2-17 summarizes recently published reviews applying the standards discussed above for empirically supported treatments for adult mental disorders. The table is limited to those that included a behavioral component. Because early behavior therapists were relatively unconcerned about psychiatric diagnoses, a number of older studies are not included because they were conducted before the need for careful specification of inclusion or exclusion criteria was recognized.

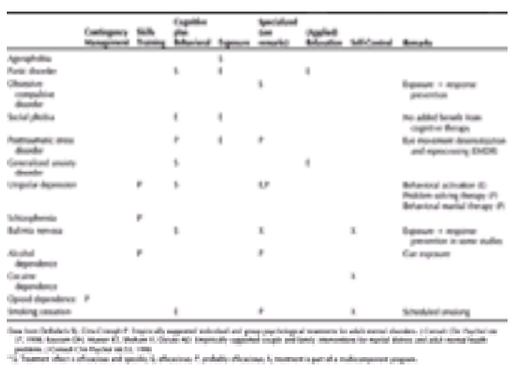

Table 30.2-17 Empirically Supported Behavioral Treatments for Adult Psychiatric Disorders*

Six targeted interventions are considered both efficacious and specific. These include exposure therapy for agoraphobia, exposure and response prevention for obsessive-compulsive disorder, and cognitive behavioral treatment for panic disorder, depression, and bulimia nervosa. The cognitive behavioral treatments represent combinations of behavior therapy and cognitive therapy, as described in the chapter on cognitive therapy. Attempts have been made to identify the active components of these combinations. In our view, the preponderance of the evidence suggests that at least for anxiety disorders, exposure is the most essential component. Exposure plus response prevention has also been used in bulimia nervosa. In those studies in which exposure proved to be an important component, the session length was 2 hours, and exposure was included in most of the sessions. There is room for improvement over the treatments currently available; only 55 percent of patients are in remission at follow-up. The cognitive treatment of depression includes an initial behavioral component aimed at activating the patient. A recent study comparing the full cognitive behavioral program with a condition involving only the behavioral activation component showed no differences between these treatments.

Eight treatments are considered efficacious but not specific. These include cognitive-behavioral treatment for social phobia and cognitive-behavioral treatment for smoking cessation; the behavioral component in these treatments is exposure and self-control procedures, respectively. The list of efficacious treatments also includes exposure therapy for panic disorder, social phobia, and posttraumatic stress disorder, and applied relaxation for panic disorder and generalized anxiety disorder. In general, treatments for generalized anxiety disorder leave room for improvement. Finally, the list includes behavior therapy for depression. Behavior therapy for depression aims at increasing pleasant events during the patient's daily life. The sources for the table did not mention social skills training for depression, although it has been found to be as effective for depression. The reason for its lack of inclusion may have been the absence of treatment manuals (these studies were conducted before the need to “manualize” research treatments had been uniformly recognized.)

Ten treatments are considered possibly efficacious. For anxiety disorders, these include cognitive (nonbehavioral) therapy for obsessive-compulsive disorder, cognitive-behavioral treatment for posttraumatic stress disorder, and eye movement desensitization and reprocessing for posttraumatic stress disorder. For depression, they include problem-solving training and behaviorally based marital therapy. For alcohol or drug abuse, possibly efficacious treatments include social skills training and cue exposure for alcohol dependence, relapse prevention (education in self-control procedures) for cocaine dependence, and contingency management for opiate dependence. Of these, much debate has centered on eye movement desensitization and reprocessing. Does the evidence support claims that it is more effective for posttraumatic stress syndrome than other exposure-based treatments? Most evidence indicates that this therapy can help patients with various anxiety disorders, including posttraumatic stress disorder. However, claims of superior effectiveness compared with other treatments cannot be supported at this time.

A problem with compiling empirically supported treatments is that newer treatments are not well represented, simply because less time has been available to perform the relevant studies. Therefore, two newer treatments are briefly discussed, dialectic behavior therapy and acceptance and commitment therapy.

EFFICACY OF DIALECTIC BEHAVIOR THERAPY In a study evaluating the effect of a 1-year treatment program for patients with borderline personality disorder, dialectic behavior therapy was compared with usual care. Overall, dialectic behavior therapy subjects showed improved behavioral adjustment, although they continued to report feeling distressed. Specifically, they had a lower dropout rate (16 percent), a lower incidence of parasuicidal behaviors, less severe suicidal acts, lower admission rates and inpatient days (8 versus 39), and greater reductions in self-report of angry affect. At a follow-up assessment 18 to 24 months later, dialectic behavior therapy patients showed superior social adjustment and better work performance. They also continued to show fewer parasuicidal behaviors, anger, and fewer inpatient days. In a second cohort, dialectic behavior therapy patients again showed lower anger ratings and better social adjustment. On the other hand, in both cohorts, symptoms involving depressive affect were not differentially affected.

ACCEPTANCE AND COMMITMENT THERAPY Acceptance and commitment therapy was compared with cognitive behavior therapy and a treatment called “partial cognitive therapy.” The latter treatment was included because the complete cognitive therapy program includes elements consistent with distancing. In cognitive therapy, distancing is derived from reframing facts as beliefs; that is, rather than responding to their negative cognitions as facts, patients respond to them as beliefs. The results of this study indicated equivalent improvements in all three groups, with 7 of the 10 to 11 patients in each group classified as treatment responders. Unlike acceptance and commitment therapy, cognitive therapy decreased scores on questionnaire measures of dysfunctional attitudes, suggesting that the effects of these two therapies were not mediated by the same process.

Recently, data have been published concerning the use of acceptance and commitment therapy in an outpatient managed-care setting, using patient measures of problem severity, coping, and acceptance. Eight masters-level psychologists were trained in acceptance and commitment therapy. In addition, 10 therapists did not participate in the training but had taken workshops in other treatment modalities. The patient sample consisted of more than 200 individuals with a variety of

psychiatric disorders or relationship problems. About half were treated before the experimental therapist had been trained in acceptance and commitment therapy, and half were treated after the training. After training, the trained therapists produced better coping outcomes among their patients and significantly improved an acceptance index compared with pretraining outcomes, but the severity of the problem was not affected. These trained therapists also initiated fewer referrals for medication. Interestingly, 80 percent of patients who received acceptance and commitment therapy completed their treatment by 5 months and agreed with their therapists that the treatment was complete. By comparison, after 5 months, 50 percent of patients of untrained therapists thought their treatment was still in progress, although only 22 percent of their therapists thought so.

Behavioral Medicine Treatments The Introduction mentions that behavioral treatments have made inroads into clinical medicine. Table 30.2-18 lists the empirically supported indications for behavioral treatments in the management of medical disorders. An operant-based multicomponent inpatient program has been shown to specifically reduce dysfunctional pain behaviors in low-back pain patients. Biofeedback of the back muscle electromyographic activity is considered a possibly efficacious treatment. Relaxation therapy, at times augmented with cognitive therapy or biofeedback, is a common denominator of the remaining multicomponent interventions. Cognitive-behavioral treatment is rated efficacious and specific for rheumatic diseases and efficacious for reducing distress in cancer patients and reducing the symptoms of irritable bowel syndrome. With respect to the latter indication, however, in one study, cognitive-behavioral treatment did not surpass the effect of a sophisticated attention placebo procedure. Temperature or frontalis electromyographic biofeedback-assisted relaxation is considered efficacious for migraine headaches. Finally, relaxation therapy and systematic desensitization have been used to reduce anxiety or nausea associated with cancer treatments.

SUGGESTED CROSS-REFERENCES

For further information on the theoretical foundations for behavior therapy, see Section 3.3 on learning theory. Behavior therapy with adults is often administered concomitantly with techniques of cognitive therapy, which are covered in Section 30.6. Behavioral techniques are used in the service of psychiatric rehabilitation, covered in Section 48.7 and Section 48.8. Behavior therapy also shares features with brief psychotherapy covered in this section. Outcome research is discussed in Section 5.3. Further information on many clinical disorders discussed in this chapter can be found in chapters focusing on them, including attention-deficit/hyperactivity disorder (Chapter 39), tic disorders (Chapter 42), stuttering (Section 37.4), mental retardation (Chapter 34), personality disorders (Chapter 24), eating disorders (Chapter 20), and anxiety disorders (Chapter 15).

30.3 HYPNOSIS

HERBERT SPIEGEL, M.D., MARCIA GREENLEAF, PH.D., AND DAVID SPIEGEL, M.D.

Imagination, a faculty highly developed in humans, facilitates cognitive restructuring, planning, initiation, and implementation of behavior change. Hypnosis, once dismissed as “nothing but heated imagination,” is in fact a powerful means of directing imagination, imagery, and attention to control physical response to stress and pain, change habits, manage dissociative symptoms, and enhance control over psychological and somatic function. With appropriate therapeutic design, this variant of imagination can be activated, identified, measured, controlled, and used for specific therapeutic purposes. Hypnosis can be understood as a form of controlled imagination.

Hypnosis is a useful instrument for the psychotherapist, much as the scalpel is for the surgeon. The hypnotic trance state per se is not therapeutic, but rather it allows the clinician to make systematic use of a person's psychological resources for change; it also facilitates and accelerates the impact of a psychotherapeutic intervention.

As a phenomenon, hypnosis has held an important place in the study of human psychology, ranging from Jean Martin Charcot's and Pierre Janet's early work on through psychoanalysis, through cognitive psychology, to brain imaging. As this body of research continues to grow, hypnotic techniques are becoming more understandable and useful. It is now understood that trance states and hypnotic phenomena occur spontaneously and frequently, with or without formal induction. When persons with trance capacity act with high motivation, concentrate intensely, or find themselves under duress, they tend to shift into spontaneous trance states. Learning to recognize trance phenomena is important in clarifying diagnoses and making treatment choices, even if hypnosis is not used in the formal sense.

The word “hypnosis” (from the Greek root *hypnos*, meaning sleep) is misleading in some ways because the phenomenon to which it refers is not a form of sleep; rather, it is a complex process of attentive, receptive concentration. Although peripheral awareness is reduced in both sleep and hypnosis, focal attention, which is diffuse in sleep, is heightened during the hypnotic trance.

HISTORY

Eastern and Western philosophy, literature, and religion are replete with descriptions of various trance states, ecstatic states, and spontaneous dissociation among both healers and those being healed. These phenomena were first formally described as therapeutic instruments in the eighteenth century with Franz Anton Mesmer's controversial theory that magnetic energy or an invisible fluid could be channeled from a therapist or an object to correct imbalances and restore health to an individual with illness. His unorthodox methods and explanations of magnetic forces attracted negative attention from the scientists of the day and the French government. In 1784 a panel of experts that included Benjamin Franklin, the famous chemist Anton Laurent Lavoisier, and the infamous Joseph Ignace Guillotin met in Paris at the behest of the king. They concluded that the phenomenon was nothing but “heated imagination.”

James Braid, a physician and surgeon in England during the 1840s, observed phenomena similar to what Mesmer had reported. He found he could produce trance states using eye fixation and eye closure. In 1847, Braid departed from the discredited magnetic influence theory and created a psychological concept he called “monoideism”—mental concentration on a single dominant idea. In this state subjects were highly suggestible and could focus their attention on specific ideas that would influence behavior.

Charcot considered the hypnotic state a neurophysiological phenomenon (*sommeil nerveux,* nervous sleep) and a sign of mental illness, “ *un etat* nerveux *artificiel ou* experimental” (an artificial or experimental nervous state). This position about hypnosis was supported by Janet, but both were opposed by Hippolyte Bernheim, who believed that hypnosis was a function of the normal brain. Sigmund Freud studied hypnosis with Jean Martin Charcot, and it was central to his classical work on hysteria with Breuer. Freud documented in his autobiography the moment that he gave up the formal use of hypnosis. A patient threw her arms around his neck during a hypnotic trance: “I was modest enough not to attribute the event to my own irresistible personal attractions, and I felt that I had now grasped the nature of the mysterious element that was at work behind hypnotism. In order to exclude it or at all events to isolate it, it was necessary to abandon hypnotism.” In Freud's mind, the transference underlay hypnosis, and to control or eliminate it, he decided to stop formally using hypnotic inductions, but he retained the couch and turned his attention to the process of free association rather than trance as a therapeutic technique. However, this formal change did not eliminate the occurrence of spontaneous trance in the course of psychotherapy.

Because of the high incidence of shell-shock during World War I, Ernst Simmel, a German psychoanalyst, became interested in hypnosis for the treatment of war neurosis. He developed a technique for accessing repressed material, which he called *hypnoanalysis*. During World War II, hypnosis played a prominent part in the treatment of pain, combat fatigue, and neurosis. Some of the first research on memory recall and control of physiological activity with hypnosis was carried out at the U.S. Army School of Military Psychiatry.

In 1955 the British Medical Society formally recognized hypnosis and recommended that it be taught in medical schools. In 1958, the American Medical Association and American Psychiatric Association followed this example. About this time, the scientific study of hypnosis was made possible by the development of scales for measuring hypnotic capacity.

DEFINITION AND THEORY

Hypnosis can be understood as attentive, receptive focal concentration with diminished peripheral awareness. It is also typified by a feeling of involuntariness; movements seem automatic, and suggested perceptions can alter or replace ordinary ones. The hypnotic state can be entered and exited in a matter of seconds. All hypnosis is, in essence, self-hypnosis, but when a person allows this form of concentration to be structured by another, the hypnotic experience is also characterized by an intense and sensitive interpersonal relatedness between the two, with a relative suspension of critical judgment. This intense concentration can be actively initiated and structured to achieve agreed-upon goals.

Hypnosis is currently understood in a manner consistent with the conceptualization of Bernheim of the Nancy, as a normal activity of a normal mind. The trancelike experience perhaps most familiar in everyday life is absorption in a good novel, play, or movie to the extent that distracting stimuli are ignored and involvement in the activity is intense. It resembles the suspension of disbelief that typifies a good theater experience. Research has demonstrated that persons who report having such intense absorbing experiences can be shown by formal measurement to be relatively highly hypnotizable. In a therapeutic relationship, this facilitates change by teaching an individual to become so focused on a specific theme or goal that they ignore old associations and can more easily accept new thoughts and feelings. Thus the use of the hypnotic state can accelerate therapeutic change.

Laboratory and clinical researchers have demonstrated that hypnotizability is a stable and measurable trait. While it does vary somewhat throughout the life cycle, peaking during the late childhood years and declining for some during adolescence, it remains relatively stable throughout maturity, and then declines further during senescence. A longitudinal study demonstrated a remarkable .7 test-retest correlation for scores on the Stanford Hypnotic Susceptibility Scale over a 25-year interval.

SPECTRUM THEORY OF HYPNOSIS

Hypnotizability has implications beyond the choice of hypnosis to facilitate treatment. Hypnotizability represents a convergence of biopsychosocial phenomena. The hypnotic experience is a process that transforms a trait into a state. The measurement of hypnotizability can be effectively used in the clinical setting to assess and initiate hypnotic experience while making clinical decisions about the type and direction of treatment. The degree of hypnotizability provides useful information about the way in which an individual relates to the self and the social environment.

Components of Hypnotizability The range of ability to experience an attentive, receptive state of concentration with a relative decrease in peripheral awareness and cognitive evaluation is based on sensitivity to inner cues as well as cues from the hypnotist, the external environment, or both. Experiencing hypnotic concentration requires a convergence of three essential components—all of which are necessary to some degree—absorption, dissociation, and suggestibility (Fig. 30.3-1).

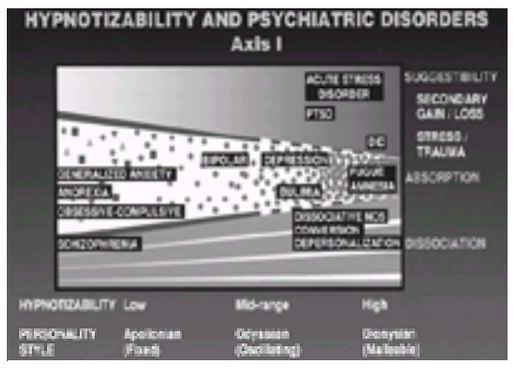

FIGURE 30.3-1 Model of the shift from normal to hypnotic attention. Hypnosis involves narrowing the focus of attention, with concomitant increases in dissociation of thoughts, perceptions, and feelings at the periphery and increased suggestibility. (See Color Plate 8.)

1. *Absorption*—an ability to reduce peripheral awareness to facilitate greater focal attention, analogous to looking through a telephoto lens. The object of attention is seen with great detail, but relatively devoid of context. The shift into the hypnotic state is something like a psychological zoom lens that can shift toward highly focused attention. As attention becomes more intense and focused, awareness of orientation in time and space decreases.
2. *Dissociation*—a functional separation of elements of identity, memory, perception, consciousness, or motor response from the mainstream of conscious awareness. The more absorbed one is in focal attention, the more likely information at the periphery of awareness is to slip out of consciousness. Thus components of self-awareness, temporal orientation, perception, and physical activity may occur without consciousness, or seem involuntary.
3. *Suggestibility*—a tendency to perceive and accept signals and information with a relative suspension of customary critical judgment. The intensity of focus in hypnosis tends to suspend (but not eliminate) the evaluative component that allows us to judge our responses. Motivation, secondary gain or loss, and the degree to which one can suspend cognitive process affect suggestibility. For the highly hypnotizable person, response to input can seem almost compulsive. Less hypnotizable individuals may still respond with a sense of automaticity.

NEUROPHYSIOLOGIC CORRELATES OF HYPNOSIS

Power Spectral Analysis of Electroencephalograms Since the beginnings of hypnosis scientists have been trying to learn more about its neurological basis. Electroencephalographic (EEG) studies and power spectral analyses of brain electrical activity have provided relatively little help in understanding the physiology of the hypnotic state. Even though initially described as a form of nervous sleep, today hypnosis and sleep are known to share no psychological or neurological characteristics. Actually the brain electrical pattern of a hypnotized subject is more similar to that of a fully awake and attentive individual than to the pattern of a sleeping person. Hilgard Ernest and colleagues reported increased alpha activity among highly hypnotizable individuals, which is present whether or not the subjects were in trance. They also found an alpha laterality difference favoring the left hemisphere among highly hypnotizable persons. This difference suggests that hypnosis may preferentially involve the right cerebral hemisphere, since alpha is the noise the brain makes when resting but alert. Thus relatively less alpha on the right suggests more activity. More-recent studies suggest that theta power, especially in the right frontal region, best differentiates high from low hypnotizable individuals. However, no clear signature of the hypnotic state has been found.

Event-Related Potentials Event-related potential (ERP) studies of the effects of hypnosis on perceptual processing have been more productive. ERP studies indicate that alteration of perception under hypnosis changes portions of the waveform affected by inattention and meaning. In particular, a hypnotic hallucination designed to obstruct perception of visual and somatosensory stimuli results in reduction of amplitude of early (P100) and late (P300) components of the waveform. Thus the subjectively reduced perception typical of, for example, hypnotic analgesia, is accompanied by reduced ERP amplitude to perception in that modality. In the visual system this finding has been localized to the left occipital cortex, consistent with work indicating imagery generation in that region. More-recent investigation has identified both common reductions in components such as P100, which are attention-related, and others that are not (P200; Fig. 30.3-2). This finding means that hypnotic alteration of perception differs from simple inattention to the stimulus.

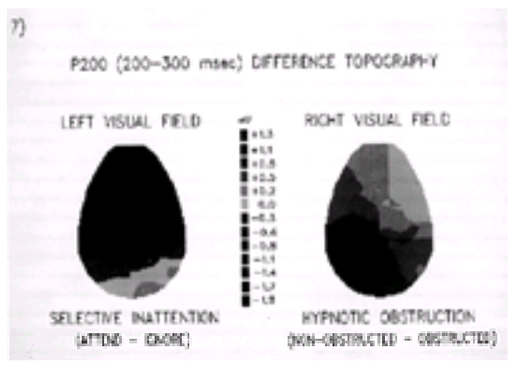

FIGURE 30.3-2 Brain electrical activity mapping of visual event-related potentials comparing the effects of selective inattention to a visual stimulus (attending to the other visual hemifield) and hypnotically hallucinating an obstruction to that stimulus. Selective inattention involves increased amplitude anteriorly, while hypnotic hallucination produces decreased amplitude in the occipital cortex. (See Color Plate 8.)

Similarly, hypnotic amnesia affects attentional components of the ERP and a late negative component (N400) but not late positive components, consistent with intact implicit (but not explicit) memory processing. Recent position emission tomography (PET) studies show that response to true and false recollections can be distinguished through activation of parietal auditory association cortex. Thus modulation of perceptual response to stimuli in the primary sensory association cortices could affect storage and retrieval of memories of these events, potentially linking dissociative responses during trauma that might modulate perceptual encoding to dissociative amnesia afterward.

Similar changes have been found in a small study of ERPs of patients suffering from conversion disorder. The literature has described the effect of selective attention to somatosensory eventrelated potentials (SERPs) and the presence of a characteristic signal appearing about 140 msec after the somatic stimulus is given, known as the N140. It has been suggested that if indeed these patients are constantly monitoring the affected body part or side, they should show the classic N140 signal on the unaffected side, compared with what he calls the enhanced N140 on the affected side. In fact, so far, the small sample in this study has proved this to be the case. Even more interesting, in at least one subject the difference in N140 amplitude completely reverted to normal under hypnosis after suggestions for normal sensation

and functioning of the affected side were given. This normalization disappeared when the subject was allowed to come out of the hypnotic trance with his deficit, as the patient was not ready to give up his symptoms.

Positron Emission Tomography Two PET studies have demonstrated effects of hypnosis in the region of the anterior cingulate gyrus, especially during hypnotic analgesia. This makes sense since that portion of the brain regulates attention focusing along with the frontal cortex. This suggests that during hypnosis there is specific activation of the anterior attentional systems involving focusing (anterior cingulate) and arousal (frontal, especially on the right). Therefore, these imaging techniques may prove useful in further identifying subsystems within the brain devoted to specific types of perceptual and cognitive processing involved in the hypnotic process. Indeed, hypnotizability is correlated with homovanillic acid concentrations in the cerebrospinal fluid (CSF), suggesting the role of the dopamine system (homovanillic acid is a dopamine metabolite), which is heavily represented in the frontal cortex. Homovanillic acid concentration in the CSF primarily reflects activity in the frontal cortex and basal ganglia, which are rich in dopaminergic synapses. Leo Hollister suggested that administration of dopaminergic agents such as amphetamine, may enhance hypnotizability. The automaticity observed in hypnotic motor behavior could represent an activation of the basal ganglia, which is involved in both implicit memory and routine motor activity.

MISCONCEPTIONS ABOUT HYPNOSIS

Despite the aphorism that myths are beliefs that never were true and always will be, there have been so many misconceptions and misunderstandings about hypnosis that it is worth examining and clarifying some of the most prominent ones.

Myth 1: Hypnosis Is Sleep On the contrary, hypnosis is aroused, attentive concentration. EEG studies demonstrate that the hypnotic trance state is consistent with a state of resting alertness and inconsistent with sleep by EEG criteria.

Myth 2: Hypnosis Is Projected Onto the Patient Hypnosis is best understood as the activation of an inner capacity to experience a focused hypnotic state. The use of a hypnotizability test early in treatment can reinforce the idea that the therapist's job is to evaluate the patient's responsiveness, rather than project or force a particular mental state onto the patient. The role of the therapist is to provide an occasion during which persons may identify, explore, and mobilize their own trance capacity. This understanding helps both clinician and patient maintain a proper perspective on the role of hypnosis as an adjunct to a primary psychotherapeutic strategy, whether or not the patient can experience many hypnotic phenomena.

Myth 3: Only Weak or Sick People Are Hypnotizable This tried and untrue proposition has been held at least since the time of Charcot and Janet. It is true that the hysteric patients studied by these men often had symptoms such as conversion paralysis, fugue states, and abreactions, that could be understood as spontaneous, undisciplined trance states. However, the vast majority of highly hypnotizable persons do not have mental disorders.

The capacity to experience hypnosis has, in general, been associated in recent research with relative mental health. Germaine Lavoie and Michel Sabourin noted the absence of highly hypnotizable persons among a population of schizophrenic patients. The authors have found significantly lower hypnotizability among patients with thought, character, and affective disorders. The clinician must bear in mind, however, that about 5 percent of mentally healthy persons are not hypnotizable. On the other hand, some disorders have been found to be associated with high hypnotizability, including posttraumatic stress disorder and dissociative disorders. These observations offer the possibility of a clinical measurement of the capacity for focused attention and treatment responsiveness, which can also be helpful in differential diagnosis. For example, finding that a patient is highly hypnotizable makes a diagnosis of schizophrenia unlikely and dissociative identity disorder or brief reactive psychosis more likely. There are no gender differences in relation to hypnotizability.

Myth 4: Hypnosis Is Therapy The trance state is like an intensely focused beam of light that can illuminate something and allow the subject to absorb it. However, while it may be a pleasant and relaxing state, it is not in and of itself therapy. Indeed, there is no hypnotherapy. Rather, hypnosis is best used to facilitate a primary treatment strategy.

Myth 5: Hypnosis Is Dangerous Nothing in the trance state itself is inherently dangerous, but exploitation by the operator and abuse of the patient using hypnosis can be harmful. This issue is not unique to hypnosis. No one has ever been lost in a trance state or been psychologically damaged merely from entering a trance state under the guidance of a competent therapist. Compared with other psychiatric interventions, which include medication adverse effects and potential for misuse, hypnosis is a benign and safe facilitator of treatment. Furthermore, hypnosis does not occur only when a doctor decides to use it. When concentrating intently in certain private reveries or interpersonal situations and in various responses to stress, approximately 75 percent of the population can spontaneously enter trance states to varying degrees. If the therapist does not recognize spontaneous trance, the therapist-patient interaction can be impaired.

Myth 6: Symptom Removal Is Dangerous Because hypnosis is often used in a brief, symptom-oriented treatment strategy, the theoretical issue of symptom substitution needs to be addressed. Some segments of the psychiatric community still believe that the removal of a psychologically determined symptom before the development of insight regarding the meaning of the symptom by working it through in transference leaves the original conflict unresolved and predisposes the patient to development of a new and possibly more serious symptom. Symptom-oriented treatment is also seen from this classical closed-energy psychoanalytic perspective as undermining the process of psychological growth by making the therapist an ally with the forces of repression of unconscious conflict.

There are two major problems with this position—one theoretical, the other empirical. First, it is difficult to be certain that what is called insight regarding the cause of the symptom is not really a rationalization constructed by the therapist and the patient to explain the conflict. An explanation or narrative truth is not necessarily an insight or the truth. Psychotherapists of various theoretical persuasions may come up with different but equally plausible explanations for the same symptom. Furthermore, the conflict that may have given rise to the symptom may well have long since receded in importance when the patient presents for treatment. The factors that perpetuate a symptom—including secondary gain and loss, habit, and humiliation—may take precedence over the original conflict in importance. Human beings do not fit the paradigm of a closed hydraulic energy system. The therapeutic problem becomes one of breaking the habit and providing a socially face-saving way for patients to change their behavior. The few existing reports of harmful symptom substitution in the literature are less than compelling and do not provide data about patient, doctor expectancies, or use of coercion.

CONTRAINDICATIONS

In general, formal hypnosis is remarkably safe when used with sound clinical judgment in a goal-directed setting. However, clinical hypnotic mischief is more prevalent and occurs when the therapist is not aware of the patient's hypnotic proneness and unwittingly generates iatrogenic phenomena by the way questions are asked or statements are made. Spontaneous trance, without formal induction, can readily occur in patients with midrange to high hypnotic capacity when they are under stress or simply focusing attention. Thus, with trance proneness and formal inductions, some precautions need to be observed.

The clinician should explain briefly and directly the nature of hypnosis, emphasize the importance of hypnotizability as a trait to reduce anxiety about performance or coercion, state that the patient may discontinue the trance experience at any time, and clarify the goals of the hypnotic intervention. From a clinical perspective, hypnosis should not be used in an atmosphere that is threatening or coercive. Patients still may perceive the therapist as exerting considerable power over them, and awareness of and willingness to discuss and diffuse such concerns can be helpful.

Certain types of patients should be approached with caution. Suspicious or paranoid patients usually avoid or resist efforts at hypnosis. Such patients, in whom unconscious fears and suspicions are evoked, may reduce their anxiety by refusing to cooperate with a hypnotic induction. An occasional patient may respond to a trance induction with a spontaneous abreaction. If this occurs, it is important to explore and restructure the patient's experience calmly, using it to enhance the patient's access to and control over upsetting memories, fears, and fantasies. Certain fragile patients who have already suffered many painful failures may be vulnerable if their expectations regarding the hypnotic experience are unrealistic. Discovering that they are not hypnotizable or that they do not achieve symptomatic relief by using hypnosis may constitute an additional failure. Depressed patients usually fail to respond to their full capacity until the depression is treated with more-traditional psychotherapy, medication, or both.

Because perceptions can be temporarily altered by hypnotic signals and attentional focus is narrowed, hypnotized persons may to some extent suspend their usual critical judgment within the trance and depart substantially from their usual conduct in compliance with the hypnotist's signal, despite some resistance and discomfort about it. The more hypnotizable the person is, the greater the likelihood that this can happen, especially if pressed.

In the clinical situation the therapist must accept responsibility for helping to structure the setting appropriately. This means being clear and structured, indicating the beginning, assessment, hypnotic work, and end of the hypnotic experience precisely. More important, highly hypnotizable persons must be taught about their own

vulnerability to exploitation, so that they may take steps to protect themselves from it. The authors have seen more than a few patients who have been manipulated by persons who wittingly or unwittingly used hypnotic techniques to get the patient to comply with their wishes, be they sexual or financial, during a relative suspension of the patient's otherwise intact critical judgment.

One successful businessman found himself signing over an interest in his business to a contractor who, it was later discovered, used hypnosis to get the businessman to abandon his usual business judgment. The examination of hypnotizability helped him to learn a rather expensive lesson regarding his own vulnerabilities.

ASSESSMENT OF HYPNOTIC CAPACITY

A clinical scale to measure hypnotizability must meet many criteria. On one hand, it must be reliable and valid and, on the other hand, it needs to be brief and aesthetically acceptable in the clinical setting. The Hypnotic Induction Profile, a 5-minute clinical assessment procedure, was standardized on a clinical population in a treatment context and meets these criteria (Table 30.3-1). This clinical scale has a moderate positive correlation with the longer laboratory-based Stanford Hypnotic Susceptibility Scale. A derivative of the Stanford Hypnotic Susceptibility Scale developed for clinical use requires about 20 minutes for administration. It was standardized on a nonclinical student population and is highly correlated with the parent scale. The Stanford scales measure behavioral compliance and suggestibility. The Hypnotic Induction Profile measures the convergence of suggestibility with absorption and dissociation and enables the discovery and observation of the degree of involuntariness. Both tests, developed from different perspectives, represent an attempt to make measurement of hypnotizability clinically relevant.

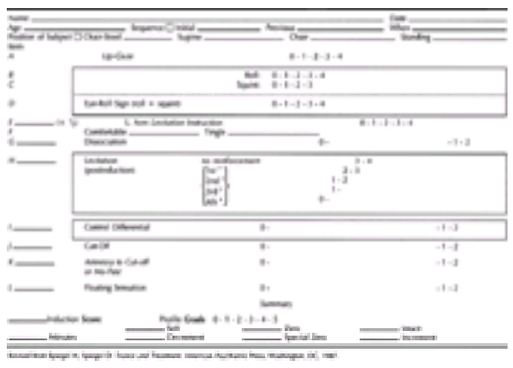

Table 30.3-1 Hypnotic Induction Profile Evaluation Sheet

Hypnotic Induction Profile Administration of the Hypnotic Induction Profile can be a routine part of the initial visit and evaluation. The test begins with the eye-roll sign, a presumptive measure of biological ability to experience dissociation. In the test procedure for eye-roll sign measurement, the patient is told “Hold your head looking straight forward; while holding your head in that position, look upward, toward your eyebrows—now toward the top of your head [up-gaze]. While continuing to look upward, close your eyelids slowly [roll].

The up-gaze and roll are scored on a 0 to 4 scale (Fig. 30.3-3) by observing the amount of sclera visible between the lower eyelid and the lower edge of the cornea. If an internal squint occurs, the degree is scored on a 1 to 3 scale (Fig. 30.3-3). The squint score is added to the roll score. This procedure takes about 5 seconds. The eye-roll is a part of the hypnotic induction, which is also scored as an initial indicator of the potential for hypnotic experience. The eye-roll provides a rapid hypnotic induction that gives initial information that can be compared with more traditional perceptual and motor items that follow.

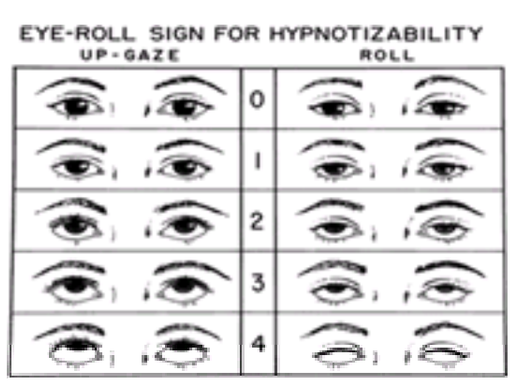

FIGURE 30.3-3 Scoring of eye-roll response to hypnotic induction (© Spiegel 12/76).

Subjects are then instructed to keep their eyes closed but let them relax and concentrate on a subjective experience of floating. As they do that, they are told that their left arm will feel light and buoyant and will float into the air, even after the formal hypnotic experience is ended until a cutoff signal (touching the left elbow) is given.

There are seven scoreable items:

1. Speed with which the subject learns to produce lightness and buoyancy in his left hand and arm
2. Degree of dissociation experienced after the first arm levitation
3. Amount of verbal reinforcement needed to get the arm to rise after its been pulled down by the examiner
4. Absence or presence of involuntariness
5. Speed of response to the cut-off signal
6. Presence or absence of spontaneous amnesia
7. Alteration of somatosensory awareness during the hypnotic experience

The degree of capacity and responsivity as well as the resonance or dissonance between the two correlate with (1) personality style; (2) presence or absence of cognitive flow, implying diagnoses on a health-illness spectrum; and (3) degree of hypnotizability. The degree of hypnotizability provides an initial prediction of the utility of techniques involving hypnosis and likely responses to different treatment approaches.

In conducting research on hypnotizability with the Hypnotic Induction Profile, a population of 6522 consecutive patients in one sample and 2274 consecutive in a second sample (a total of 8796 consecutive patients) were assessed with the Hypnotic Induction Profile by two different therapists. The analysis of data showed the same distribution within each patient population in each therapist's sample. There was confirmation and agreement between the samples that about 75 percent of the subjects were hypnotizable (20 percent low, 48 percent midrange and 7 percent high) and about 25 percent were not. Most of this latter group showed evidence of cognitive impairment because of various psychiatric disorders. These findings are remarkably similar to the Manhattan Project which found that 23.5 percent of the city's population revealed marked to severe psychiatric problems.

The total sample of 8796 out-patients in the study is large enough to suggest that the findings provide stable values for generalization: the results support the hypothesis that hypnotizability can be measured on a continuum, indicating a probable presence or absence of psychopathology. Instructions for the Hypnotic Induction Profile are presented in Table 30.3-2.

Table 30.3-2 Instructions for the Hypnotic Induction Profile

Clinical Correlates of Hypnotic Capacity From a clinical point of view, there are two broad types of response to the test: intact and nonintact. When the sensorimotor responses are approximately consistent with the biological indicator eye roll, the response is intact, which indicates usable hypnotic capacity. When the sensorimotor responses are considerably below the biological prediction, the response is classified as nonintact (soft or decrement). The biological potential for hypnosis as measured by the eye roll can be interfered with by some psychological, neurological, or pharmacological problem and, therefore, is not behaviorally expressed. The more disturbed population—those with thought, character, affective, and some neurological disorders—prove to be considerably less hypnotizable or nonhypnotizable. Approximately one quarter of the adult population has little or no usable hypnotic capacity. In some cases, this is a product of normal development while in others, it is associated with some disorder that impairs concentration. An absence of usable hypnotic capacity indicates that other forms of treatment, either psychotherapeutic or psychopharmacological, are likely to be more effective.

Within the range of intact hypnotic capacity, as measured by the Hypnotic Induction Profile, it is clinically useful to distinguish three broad types of personality style. Those with low hypnotizability, in the 6 to 9 range on the induction score, seem to have Apollonian features. These persons are cerebral and not affect oriented, tend to be inflexible, organized, and somewhat controlling in relationships, have a heightened sense of responsibility, are relatively untrusting, tend to live more in the past that is usually divided among different issues or points in space at the same time. They excel at contrasting and comparing. They often prefer the written to the spoken word. Should they decompensate, they tend toward obsessional symptoms.

Those with high hypnotizability have Dionysian features and reveal an induction score in the 14 to 16 range on a 0 to 16 scale on the Hypnotic Induction Profile. They are relatively heart-oriented and are prone to such intense absorption when they concentrate that they become momentarily disoriented when the task, play, or movie is over. They tend to relinquish control in interpersonal relationships, to be trusting and to value the spoken over the written word, and to learn by affiliating with experience, rather than by critically examining it. They often have exceptionally good memories, and if they decompensate, it is usually in the direction of hysteria or depression. Their trance proneness becomes a vehicle for them to experience and express intrapsychic and interpersonal stress.

Those in the midrange group (scores of 10 to 13) have characteristics that represent a compromise between the two extremes, reminiscent of the compromise made by Homer's wandering hero, Odysseus. The Odyssean time orientation is more a balance of the past, present, and future. They do not have the immersion in the present that characterizes the Dionysians nor the avoidance of the present characteristic of the Apollonians. They tend to have balanced relationships in terms of control and trust, and they learn by accommodating to the new material, rather than by either assimilating it or affiliating with it. If these persons decompensate, they are prone to periods of depression, a syndrome of alternating action and despair.

Psychopathology When a patient presents with a psychiatric problem, the provocation may be related to internal factors (e.g., genetics, drugs, biological deficits) or external factors (e.g., stress, deprivation, trauma), which result in an impairment of psychological function. The authors hypothesize that these factors interact in identifiable patterns consistent with the correlation of hypnotizability and personality style and manifest as predictable Axis I clinical syndromes or Axis II personality disorders (Fig. 30.3-4 and Fig. 30.3-5).

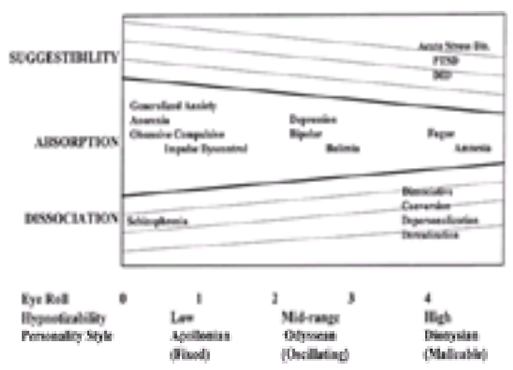

FIGURE 30.3-4 Relation between hypnotizability and Axis I psychiatric disorders.

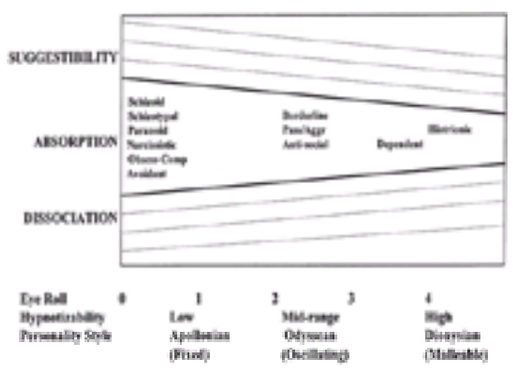

FIGURE 30.3-5 Relation between hypnotizability and Axis II disorders.

For example, the “cerebral” Apollonian type may develop cognitive impairments, with avoidant interpersonal styles and proneness to despair—for example, obsessive-compulsive disorder, anorexia nervosa, generalized anxiety disorder, and schizophrenia (Axis I) and schizoid, paranoid, and avoidant personality disorders (Axis II). The “oscillating” Odyssean type may develop problems of intimacy, fluctuating assumptions, and beliefs with resultant confusion and is subject to mood swings—for example bipolar disorders, major depressive disorder, bulimia nervosa (Axis I), and borderline, passive-aggressive and antisocial personality disorders (Axis II). The “ecologically sensitive” Dionysian is prone to experience disruptions of self-integration and dependency to the point of helplessness and is vulnerable toward major depression—for example acute stress disorder, dissociative identity disorder, dissociative fugue, dissociative amnesia, somatization disorder, conversion disorder, depersonalization disorder, posttraumatic stress disorder (Axis I), and histrionic and dependent personality disorders (Axis II). There is an accumulating body of evidence to support that characteristic coping skills and psychopathology correspond with the different degrees of hypnotizability (Table 30.3-3).

	Apollonian	Odyssean	Dionysian
Primary conflict area	Cognition (Intrusions)	Interpersonal Space (Intimacy)	Self-Concept (Ego Integration)
Interpersonal style	Avoidant	Oscillating	Dependent
Affect			
Anger	Diffuse	Other-directed	Self-directed
Depression	Despair	Bipolar disorder Dysthymic disorder Major depressive disorder	Major depressive disorder

Table 30.3-3 Characteristic Psychopathology

CHOICE OF PSYCHOTHERAPY

Clinical generalizations have proved useful because they help the therapist select the most appropriate problem-solving approach or choice of therapy. Apollonians, in general, prefer intellectual, introspective, insight-oriented therapy, including that of the psychoanalytic type. In contrast to this why-oriented therapeutic approach, Dionysians with psychological problems require a more structured psychotherapy that focuses on what they should do with their lives rather than why they should do it. Their tendency to comply with signals from others is presented to them as a problem in an interpersonal sense and is also used by the therapist to help them structure their approaches to problems. Those in the midrange seem prone to make good use of existentially oriented therapy as they fluctuate between periods of intense immersion in the world and times of withdrawal and questioning. A psychotherapy that helps them work through various disappointments and problems frees them to resume more-active involvement in life.

Highly hypnotizable persons are particularly vulnerable to inappropriate therapy, especially because they tend to affiliate with new premises while suspending critical judgment. The introspective, analytic approach can lead to confusion for such patients because they emphasize compliance with the process, rather than developing insight.

> T.S. was a 22-year-old law student with an excellent academic record who sought psychiatric help after becoming profoundly depressed when someone at a party flippantly implied that he was homosexual. His anxiety impaired his ability to study and he took a leave of absence from school. On the advice of the school physician, he entered analysis and became progressively more depressed during 7 months of therapy. Despite his anxiety about coping during his analyst's 1-month vacation, he noted that his depression improved. When the analysis resumed, his symptoms again increased, and his parents insisted on an outside consultation.
>
> The Hypnotic Induction Profile revealed that he was highly hypnotizable (16/16 on the induction scale). He stopped his analysis and began a psychotherapy that emphasized ego support and guidance. His homosexual anxiety was treated not as a profound truth demanding unconscious exploration, but rather as a function of his proneness to affiliate with the premises of others, no matter how irrelevant. His depression resolved, and he graduated with honors. He has since married, has two children, and is in a successful law practice.

Role of the Therapist Hypnotizability assessment can help the therapist to understand and respond to a given patient's intrapsychic and interpersonal style. A given individual presents with a “cluster of both conscious and unconscious awareness of self, beliefs, assumptions, values, judgments, fantasies, myths, philosophies, spiritual and social striving, and goals.” This includes “the concepts of ego, self, and identity” and can be considered the individual's myth-belief constellation—the private filter system through which persons view themselves, the world, and the flow between the self and the world. This postmodern perspective emphasizes understanding the form more than the content of the particular person's belief system at the time of the treatment intervention. Clinicians choose diagnostic approaches that enable them to learn enough about the person's interpersonal and intrapersonal processes to formulate the problem at hand, respect the aesthetics of the individual, and establish realistic and meaningful therapeutic goals.

Individuals at the low end of hypnotizability tend to be relatively rigid and controlling, and react with an internally driven compulsivity. A person in the midrange of hypnotizability is less rigid and more moderate and most likely to respond with a combination of internal and external processing. Persons at the high end of hypnotizability are so extremely flexible that their processes could be considered an externally driven compulsivity.

At both ends of the spectrum, there appears to be a narrowing of individual choice. However, at the fixed end of the spectrum (low hypnotizability), the person's attachment to content and lack of flexibility in process makes it most difficult to intervene. It is at the most flexible end of the spectrum (midrange to high hypnotizability) that the most promise for change is found.

The task is to identify which aspects of the person are relatively fixed (ecologically insensitive) and which aspects are relatively malleable (ecologically sensitive). With the Hypnotic Induction Profile, these different features are identified and the clinician can observe where the person places on the fixed-flexible continuum. By assaying the components of hypnotizability and identifying personality style and a person's myth-belief constellation, therapists can sharpen their judgment in deciding on the most effective treatment strategy for the person in the given clinical context. This is a nonlinear, multilevel process, with each aspect of information interacting with each other and the whole.

RESTRUCTURING THERAPY: LIFESTYLE CHANGES AND SYMPTOM MANAGEMENT

Since the days of Hippocrates, medicine's main accomplishment has been symptom relief and containment more often than cure. Not only may the goals be more practical, but symptom-oriented work helps build a therapeutic alliance. The starting point of therapy is easily identified by both therapist and patient.

Traditional therapeutic approaches that analyze why a problem exists or explore developmental dynamic interactions may be unnecessary to treat habitual Axis I problems such as smoking or overeating, phobias, anxiety, conversion symptoms, and chronic pain control. These problems can respond quickly, many times in a single session, when patients are taught self-hypnosis with a strategy to take charge of their lives and develop a new perspective on the problem. Regardless of the problem and the basic therapeutic approach, it is useful to teach the patient self-hypnosis to use outside of the therapeutic dyad. The authors use a method derived from the Hypnotic Induction Profile. The patient is taught:

> One, look up toward your eyebrows, all the way up; two, close your eyelids and take a deep breath; three, exhale, let your eyes relax and let your body float.
>
> As you feel yourself floating, you permit one hand or the other to feel like a buoyant balloon and allow it to float upward. As it does, your elbow bends and your forearm floats into an upright position. When your hand reaches this upright position, it becomes a signal for you to enter a state of meditation and increase your receptivity to new thoughts and feelings.
>
> In this state of meditation, you concentrate on this feeling of imaginary floating and at the same time concentrate on (see 3 critical points to stop smoking below).
>
> Reflect on the implications of these critical points and then bring yourself out of this state of concentration called self-hypnosis by counting backward in this manner: Three, get ready; two, with your eyelids closed, roll up your eyes (do it now); and, one, let your eyelids open slowly. Then when your eyes are back in focus, slowly make a fist with the hand that is up; and, as you open your fist slowly, your usual sensation and control returns. Let your hand float down. That is the end of the exercise, but you can retain a general overall feeling of floating.
>
> By doing this exercise 10 different times each day, you can float into this state of buoyant repose. Give yourself this island of time, 20 seconds, 10 times a

day, in which to use this extra receptivity to reimprint these critical points. Reflect upon them, then float back to your usual state of awareness, and then continue with what you ordinarily do.

To make the technique more useful, the patient is taught a camouflaged method to enter the self-hypnotic state with the eyelids closed and bringing one hand up to the forehead. To an outsider, it looks like the person is in deep thought.

The impact of a variety of strategies is intensified with hypnotic concentration to internalize new perspectives on old problems. The principle of restructuring is to help a person master something new rather than fight against an old problem or pattern. The therapist and patients form a collaborative relationship, with the therapist as a teacher, encouraging patients to develop their own executive control. This sets the stage for the next phase of treatment, if necessary, to deal with comorbid psychiatric disorders.

Keeping in mind that human beings use their imaginations to create explanations and meaningful narratives, formal hypnosis helps the person discover relevant control of unconscious process and cognitive self-awareness to develop mastery over anxiety, confusion, panic, and unhealthy life choices. Critical points and suggestions are reinvoked by patients with a method of self-hypnosis that they have learned in the session.

INDICATIONS

Smoking Cessation Hypnosis has proved surprisingly effective in helping people stop smoking. There are several mechanisms by which it may contribute to smoking cessation. The ritual of the hypnotic exercise may provide a substitute for the “breathing exercise” that accompanies the act of smoking; the positive affirmations often used in self-hypnosis provide positive reinforcement for behavior change and promote positive self-image; its use enhances self-observation and self-monitoring; and it can facilitate cognitive restructuring of the smoking habit.

It is not most effective to tell the patient who wants to stop smoking “don't smoke.” This can have the paradoxical effect of directing more attention toward the smoking habit. Rather, the patient is presented with a paradigm shift from “smoke/don't smoke” to “respect my body.” Many points are made to emphasize the power of taking a stand for one's own body rather than against smoking. Emphasis is placed on the significance of learning to use one's mind to protect one's body from the damage inflicted by smoking. The hypnotic state is used to illustrate the importance of focusing on a mental theme that has more power than a physical urge. The patient is taught a method of self-hypnosis (see above) and these three critical points:

1. For my body, smoking is a poison.
2. I need my body to live.
3. I owe my body this respect and protection.

Patients reflect on the personal meaning of this for themselves and then exit the trance state. The self-hypnosis exercise takes 20 seconds and is prescribed to be practiced 10 times a day (until it becomes an integral part of the person's mind-body pattern) as a private meditation to reinforce independence and mastery with an ability to transform an urge to smoke into an act to protect the body. The success of this single-session intervention compares favorably with other techniques, including pharmaceutical treatments.

A number of studies demonstrates the efficacy of hypnosis as a tool to facilitate control of smoking habits. These studies show success rates in cigarette abstinence after treatment with hypnosis ranging from 13 to 64 percent. In these studies abstinence is defined as no smoking during a follow-up time of at least 6 months. The first author of this section developed a single-session approach for smoking cessation that is widely used. His results have been replicated and shown to produce outcomes of 20 to 35 percent long-term complete abstinence. Others have reported abstinence rates as high as 40 percent at 6 months. These numbers are better than the rates of unassisted quitting. Studies have also shown that higher hypnotizability predicts better outcome. While there is no evidence that treatments using hypnosis are more effective than other interventions for smoking cessation, they may be more efficient because patients can use a self-administered treatment strategy (self-hypnosis) to reinforce a more-adaptive cognitive restructure, while providing them with an exercise on physical relaxation.

Weight Control Typical of the generally modest results seen in weight-control regimens, rarely is hypnosis alone considered the treatment of choice for weight problems. It is usually employed as an adjunct to a comprehensive dietary and exercise control program for weight reduction and management. Also, the concept of going on a diet leads to long-term failure despite short-term success, since few people are able to live indefinitely on a diet, and failure to stay on a prescribed plan becomes self-defeating. The cycle of losing, gaining, and losing weight can lead to medical complications, and periodic starvation actually further dysregulates response to hunger signals and therefore control of eating behavior.

Like the use of self-hypnosis in the control of smoking described above, the purpose is to restructure the patient's relationship to food. In trance, patients are taught to (1) develop a personal plan and focus on eating behavior, (2) clarify and differentiate eating from overeating for their particular body type and goals, and (3) learn to eat on the basis of respect and protection for their bodies.

The hypnotic modality is used to develop a new perspective, provide a way to initiate feelings of affirmation and control, and simultaneously avoid the traps of deprivation, failure, and self-deprecation. Patients are instructed to learn to eat with respect for their bodies, to focus on what they are for rather than what they are against. An important component of this approach consists of teaching the patient to use self-hypnosis training to control the urge to overeat. This is better accomplished by preparing a list of foods that constitutes eating with respect and then comparing an urge with the list. If the desired food is on the list, patients are encouraged to eat it as a gourmet would, focusing intently on all aspects of the eating experience and enjoying it. If the food is not on the list, patients are asked to recognize the desire, rather than fight the urge. Then patients are encouraged to use self-hypnosis to compare this urge with their overall commitment to protect and treat their body with respect and therefore to eat with respect. By using this method patients can see their desire to eat not as an occasion to feel deprived, but rather as one in which they are enhancing their mastery of the urge by choosing to protect their body.

This technique was examined in a randomized trial with 45 subjects. The addition of hypnosis to a behavioral intervention resulted in significantly greater weight loss at 3-month follow-up (6.4 kg vs. 1.3 kg, $H_c = 4.7$, $P < .05$). Furthermore, hypnotizability as measured by the Stanford Hypnotic Susceptibility Scale, form C, and weight loss were significantly correlated ($r = –.56$, $df = 13$, $P < .03$). A meta-analysis performed by Irving Kirsch on 18 studies in which adjunctive use of hypnosis was compared with other psychotherapeutic treatments demonstrated that hypnosis substantially improved treatment outcome. This hypnotic supplementation effect was strongest for the treatment of obesity. However, the magnitude of this effect was questioned by D.B. Allison and M.S. Faith because of computational inaccuracies and methodological problems in one study. Clinical experience suggests that those within 20 percent of their ideal body weight may obtain some benefit from such restructuring techniques with self-hypnosis, when combined with a regimen of a balanced diet and exercise.

Enhancing Medical Care In medicine, hypnosis is becoming a more accepted modality to help patients with symptom control (pain, nausea and vomiting, itching, edema), anxiety secondary to illness and procedures, altering the course of physiological responses, and reversing the helpless and hopeless feelings that frequently occur during and after hospitalization. Issues of transference that frequently need to be worked through in long-term psychotherapy can create a powerful sense of support for the patient in brief medical psychotherapy, which adds to the patient's feelings of self-worth and, in turn, can support independent action. The use of the hypnotic modality and the relationship that ensues between the therapist and the patient, can be used to identify individual capacity for increased self-care and control over responses to illness and symptoms. The hypnotic procedure can become a bridge to transmit caring, comfort, and respect; maximize patient participation, and enhance feelings of independence and mastery over somatic responses to anxiety, fear, and anger. Such interventions may facilitate medical recovery, since patients who have the most stable blood pressure and respiratory function along with minimal bleeding and a perception of pain control recover more quickly and at less risk than those who are unstable in these areas.

Psychological interventions involving hypnosis have been successful in alleviating physical symptoms due to asthma, allergies, dermatological problems, blood pressure instability, bleeding, burns, wound debridement, warts, gastrointestinal disturbances, impotence, contractures of the hand, migraine and tension headaches, enuresis, and obstetrics in both adult and pediatric populations. Hypnosis is useful in rehabilitation after accidents and stroke as well as with psychogenic symptoms. In diabetes, cancer, heart disease, renal failure, orthopaedics, and somatoform disorders, the use of hypnotic interventions has been associated with better symptom management, decreased depression, less pain, and improved psychophysiological function. Approaches vary according to the presenting symptoms, problem formulation, degree of hypnotizability, motivation, an individual's belief system, mutually acceptable therapeutic goals, and the type and stage of medical problem.

The various techniques of self-hypnosis become an adjunct to other, more primary psychotherapeutic interventions. In support group settings, where the primary emphasis is on supportive/expressive group psychotherapy, self-hypnosis has been helpful in decreasing pain that amplified depression. Approaches for habit control,

pain management, phobias, and some manifestations of anxiety tend to be rapid and direct, with strategies taught to be under the control of the patients who initiate their own entry into trance states and review the therapeutic strategies on their own, outside the therapeutic dyad.

Relevant strategies are as crucial in dealing with the psychological sequelae of medical illness as they are in psychotherapy. The phase of illness, the nature of the problem, and the patient's individual resources are important factors in selecting the treatment strategy. If patients have the mental and physical capacity to initiate and use their own mental, imaginative processes, hypnotic ceremonies involving long induction procedures and techniques that emphasize the direction of the therapist can have a counterproductive effect by creating yet another situation of dependent and passive behavior. Yet if the patient is in the terminal stages of illness that require considerable mental and physical exertion, direct suggestions that do not involve patient initiation can be useful.

A hospitalized 56-year-old woman with metastatic breast cancer was anhedonic, refusing food, and lying in a fetal position and had revealed suicidal ideation to the nurse in charge of her care. In the initial interview, her response to the Hypnotic Induction Profile identified her as highly hypnotizable (induction score of 16). She was taught to enter a hypnotic state and was given the following instruction: “Imagine you are safely surrounded in every direction by luminous serenity and a protective calmness. You can be safely breathing and comfortably breathing in this energy as though surrounded by your own private buffer zone. Inside this buffer zone, you are free to use your memory in a selective manner. You can choose those people, places and circumstances that give you a profound sense of satisfaction and accomplishment, while letting everything else fade away. When you choose to come out of the trance state, give yourself a posthypnotic suggestion to maintain your protective buffer zone and allow calmness and serenity to stay within you. When you are out of the formal trance state you can continue to feel calm and serene.” Within hours of learning this technique and sharing her experiences with the therapist, she was sitting up in bed and enthusiastically requesting food. Follow-up sessions reviewed the self-hypnosis strategies and reinforced her feelings of control, vitality, and sense of meaning. Her improvements in mood continued, and she became an active participant in her own care.

A hospitalized 61-year-old woman with metastatic breast cancer (previously assessed as moderately hypnotizable—induction score of 11) had become almost totally immobile, was suffering with severe edema, and was struggling to breathe with the help of an oxygen mask. With little ability to focus her own attention, a simple and directive approach was used. The therapist used her voice as a metronome to influence the breath rhythm of the patient. The words “calm” and “easy,” timed with the patient's exhalations, were used as direct suggestions to enable the patient to breathe without gasping for air. Suggestions were then given: “Allow the bed to work with you as your partner in care. It can hold you safely and securely from underneath while your mind is free to travel through time and space in whatever direction increases your sense of well-being. You can feel the love of your family and friends all around you, giving you additional support, comfort, and strength.” Staff and family members were taught to repeat these suggestions to the patient. The benefits were twofold: the caregivers felt they had something to contribute, and the patient was comforted in the dying process.

Hypnosis has proved helpful in the consultation setting for problems including needle phobias, appetite loss, treatment refusal, respiratory problems, acute and chronic pain, preparation for surgery and invasive diagnostic procedures, and nausea and vomiting related to chemotherapy. In other specialties, interventions with hypnosis helped resolve phantom limb pain, fear of anesthesia, elevated heart rate and blood pressure, and somatoform disorders. In one well-described case by Joseph Dane, with 8-year follow-up, a patient with multiple sclerosis was treated using hypnosis and experienced return to ambulatory status within 2 weeks after beginning the use of hypnosis. She had reduced pain, balance problems, and diplopia, and her improvement persisted.

Surgical Preparation Three approaches selected on the basis of the patient's hypnotizability are useful in using hypnosis to help patients prepare for surgery. Those who test low in hypnotizability prefer to focus predominantly on the specific physiological benefits of less bodily tension and concrete outcome, those who test in the midrange of hypnotizability require more attention to the emotional component of their response to the up-coming procedure, and those who test at the high end of hypnotizability do best with minimal details and firm, clear, simple directions on how to conduct themselves.

Most patients accept that learning to minimize fear, anxiety, and anger reduces their state of physiological arousal. The general principles are to teach patients to enter their own trance state and focus on (1) allowing and welcoming the skilled medical team to do what they know best; (2) choosing images, metaphors, and body language (floating, muscles soft, thoughts of being someplace safe and secure); (3) suggestions on how they want their body to react before, during, and after surgery; and (4) the benefits of the treatment for psychophysiological functioning. In some cases, it is desirable to decrease or eliminate anesthesia. Suggestions are then geared to images and instructions to produce imagined numbness.

Side Effects of Chemotherapy The use of hypnosis to alleviate nausea and vomiting associated with chemotherapy has been reported in the literature for more than 20 years. There are three major facets to target:

1. The anxiety component—patients are taught to enter a hypnotic state and use their imagination to produce generalized relaxation
2. Conditioned responses to hospital cues—patients are to enter hypnosis and entertain suggestions to create comfortable responses to specific environmental cues
3. Physiological responses to the chemotherapy agent—patients are taught to enter hypnosis and focus on suggestions to reverse the usual peristaltic activity that leads to vomiting; it is useful to reframe the chemotherapeutic substance as the person's agent of care and to create a therapeutic relationship that emphasizes self-mastery

The therapist's manner should encourage patients to define themselves as collaborative participants in treatment with a focus on a commitment to living rather than on sickness and death.

The highly hypnotizable patient can frequently control nausea and vomiting by hallucinating the taste of orange or mint and dissociating from negative environmental cues; the midrange patient will benefit from guidance to contain emotions (e.g., the screen technique); and the low hypnotizable patient will benefit from distraction, frequently needing help selecting memories or imaginative projections with sufficient interest to encourage absorption. Patients in each of the three categories need additional help to manage negative cues from friends, family, and hospital staff as well as guidance in creating a secure support system at home, at work, and in their place of treatment. A growing body of data supports the clinical observations of the authors that hypnotic interventions reduce nausea and vomiting.

Pain Although one of the best-established therapeutic effects of hypnosis is analgesia, this technique is underused for analgesia. Since the mid-nineteenth century hypnosis has been known to be effective in controlling even severe surgical pain. Hypnosis seems to work through three primary mechanisms: muscle relaxation, perceptual alteration, and cognitive distraction. Pain is often accompanied by reactive muscle tension. Patients frequently splint the part of their body that hurts. Yet because muscle tension can by itself cause pain in normal tissue and because traction on a painful part of the body can generate more pain, techniques that induce greater physical relaxation can reduce pain in the body. Thus, the first step after patients enter a state of hypnosis is to have them concentrate on an image that connotes physical relaxation such as floating or lightness. This often produces physical relaxation and reduces pain.

The second major component of hypnotic analgesia is perceptual alteration. Patients can be taught to imagine that the affected body part is numb. This is especially useful for extremely hypnotizable individuals who can, for example, relive an experience of dental anesthesia and reproduce the drug-induced sensations of numbness in their cheek, which they can then transfer to the painful part of their body. Some can also simply switch off perception of the pain with surprising effectiveness. More commonly, subjects can substitute a different sensation for the painful one. Temperature metaphors are often especially useful, which is not surprising given the fact that pain and temperature sensations are part of the same sensory system, the lateral spinothalamic tract. Thus imagining that an affected body part is cooler or warmer using an image of dipping it in ice water or heating it in the sun often helps patients transform pain signals. Some patients prefer to imagine that the pain is a substance with dimensions that can be moved or can flow out of the body as if it were a viscous liquid. Others like to imagine that they can step outside their body, for example, to visit another room in the house. The use of hypnosis to enhance involvement in imagery that reduces the pain and related anxiety provides direct and indirect benefits to many pain patients and those with other medically related difficulties.

Less-hypnotizable individuals often do better with distraction techniques that help them focus on competing sensations in another part of the body. Painful stimuli tend to attract, indeed coerce, attention to them. It is possible to use hypnosis to help even low hypnotizable subjects to acknowledge the pain but maintain focus on sensations in other parts of their bodies, often coupled with various anxiety-control techniques.

A 34-year-old patient with Hodgkin's disease had been put on meperidine (Demerol) to control abdominal pain. The patient was referred for self-hypnosis to manage the pain to maintain a clear sensorium. After the hypnotic induction, the patient was given the following hypnotic suggestions: “As you imagine yourself floating, make it more vivid by imagining you are floating in an icy stream or lake. Make it so icy, that as you imagine the water getting colder and colder, you feel an imaginary tingling numbness coming from the cold water into your body. This tingling numbness serves as a protective coating around your abdomen, so you learn to filter the hurt out of the pain. Practice this exercise every 1 to 2 hours—and each time give yourself a posthypnotic signal to retain this feeling of numbness, even when you are out of the formal trance state. As you retain this imaginary numbness, you can begin to extend it so it stays with you around the clock. By constantly making this commitment to impose numbness, even though you know the pain is there, you feel the numbness more than the pain.” This patient developed an ability to function without Demerol.

One of the primary goals is to teach the patient to stop fighting the pain, decreasing psychophysiological tension and discomfort while simultaneously increasing mastery and control with imagined tingling numbness. Thus patients learn to modulate the pain perception and the attention they pay to it by filtering the hurt out of the pain. The heightened awareness of the trance state provides the patient with a powerful tool to respond to signals that have been coming from the body upward to the brain and, through training, practice, and personal choice, influence signals from the brain downward to the body. In trance, imagined activity is heightened, maximizing selective mind-body effects.

Before introducing an induction technique and therapeutic strategy, the clinician first makes the distinction between acute and chronic pain. In the acute situation of trauma, injury, or physical insult, the person may have already entered a spontaneous trance state that maximizes hypnotic responsiveness. Motivation to receive help and comfort creates a powerful transference. In the acute situation, direct suggestions tend to produce immediate results, even with low hypnotizable persons who in other circumstances prefer explanations and collegial discussions. In an acute medical emergency, the most immediate need of the patient is to turn control over to an expert in caring for the problem at hand.

A 34-year-old woman was referred for hypnosis when she was hospitalized for the delivery of her fifth child. She was reliving memories of four extremely painful deliveries and had expressed a desire to kill herself rather than try and live through a fifth delivery. Using the eye roll sign as an emergency indicator, she was identified as potentially highly hypnotizable. She rapidly went into trance as evidenced by stabilization of her blood pressure, heart rate, and respiratory function. Within minutes, she accepted the following suggestions: “Imagine yourself in the delivery room, letting yourself float outside your body, able to watch the delivery. By being outside your body, you have the freedom to come and go as you please, but you always maintain the right to pay attention to the delivery of your child. You have the freedom to participate in every way you wish, but there is no need to feel any of the physical sensations that would cause discomfort. You can respond to verbal cues from the medical team to help you know when to push and when to rest. You do your part, the team does their part, and you can experience the joy of the arrival of your child without any unnecessary discomfort.” The patient readily accepted these instructions and was able to give birth to a healthy baby girl without any further undue stress or complications.

For chronic pain, assessment includes the impact on lifestyle, relationships, ability to maintain previous levels of activity, issues of secondary gain-loss, and prognosis. The success of the hypnotic intervention correlates with the degree of patient motivation, the ability of the therapist to formulate an acceptable rationale, and how well the therapeutic strategy matches the personality style and hypnotic capacity.

As with any pain treatment technique, including analgesic medications, hypnosis is more effective when used early in the pain cycle, before the central pain response component has developed and the pain has become so overwhelming it impairs concentration. Patients should be encouraged to use this technique early and often because it is simple and effective and has no adverse effects. A randomized trial comparing group therapy plus hypnosis with routine medical care demonstrated that metastatic breast cancer patients taught hypnosis had half the pain experienced by the control group at 1-year follow-up. In a randomized trial in interventional radiology, hypnosis was shown by Elvira Lang and colleagues to produce better analgesia than patient-controlled analgesia with midazolam (Versed) and fentanyl (Duragesic), producing less anxiety, fewer adverse effects, less cardiovascular instability, and fewer procedural interruptions.

Hypnosis is especially effective in comforting children who are in pain. Several good studies have shown greater efficacy than placebo attention control in randomized trials. This is likely because children as a group are more hypnotizable than adults. Their imaginative capacities are so intense that separate relaxation exercises are usually unnecessary. Children naturally relax when they mobilize their imagination during the sensory alteration component of hypnotic analgesia.

Recent research indicates cortical effects of hypnotic analgesia exercises, which include reduced ERP amplitude in response to somatosensory stimuli and reduced activity in the anterior cingulate gyrus. Thus hypnotic alteration of nociception seems to involve cortical modulation of pain perception. In other words, the strain in pain lies mainly in the brain.

Anxiety Disorders Anxiety disorders are among the most widely prevalent psychiatric disturbances, affecting approximately 15 percent of the population. Anxiety can be understood as a state of hyperarousal experienced as both emotional and psychosomatic discomfort. Patients often describe their anxiety in physical terms, such as palpitations, GI discomfort, chest pain, sweating, and motor restlessness. Hypnosis can be a helpful adjunctive tool for treating anxiety disorders because of its ability to help patients control their physical reaction to anxiety-provoking stimuli, thereby dissociating somatic response from psychological distress. This enables them to attend to the stimuli long enough to restructure their point of view and achieve a sense of mastery.

Most strategies for the treatment of anxiety disorders that use hypnosis combine instructed physical relaxation with a restructuring of cognition, using imagery coupled with physical relaxation. As in the treatment of anxiety disorders by systematic desensitization or progressive muscle relaxation, patients are instructed to maintain a physical sense of relaxation (e.g., using an image of floating) while at the same time picturing the anxiety-producing stimulus. The relaxation instruction must use an image that connotes reduced somatic tension, such as “floating” or “lightness,” rather than a direct instruction to “relax.” This latter, more-cognitive term may actually induce more anxiety, arousing concerns about adequate performance, while by contrast, affiliation with a somatic metaphor usually produces some reduction in tension. Unlike systematic desensitization, hypnosis can be used to produce a physically relaxed state quite rapidly without going through a series of graded muscle relaxation and imagery steps. Also unlike systematic desensitization, the coupling of relaxation to a fearful stimulus does not require the development or working through of a hierarchy.

A typical self-hypnosis induction can be quite rapid. For example, a patient can be told: Now just get as comfortable as you can. There are many ways to enter a state of self-hypnosis. One simple but useful method is to count to yourself from one to three. On one, do one thing: look up. On two, do two things: slowly close your eyes and take a deep breath. On three, do three things: let your eyes relax but keep them closed, let your breath out, and let your body float. Then let one hand or the other float up into the air like a buoyant balloon. This is your signal to yourself and to me that you are ready to concentrate.

Initially, the use of hypnosis in the session can help demonstrate to patients that they have more control over somatic responsiveness than they had imagined. It is often useful to begin by teaching patients to create a place in their “mind's eye” where they feel safe and secure. On occasion, it helps subjects to learn how to project their image onto an imaginary screen. Later they can learn to manipulate the screen by either making it bigger or smaller, having the screen being nearer or farther away, as needed.

> Just allow your body to float, as if you were floating in a bath, a lake, or a hot tub. Enjoy this sense of floating lightness. Now, picture in your mind's eye an imaginary screen. It might be a movie screen, a television screen, or a piece of clear blue sky. First picture a pleasant scene, somewhere you enjoy being.
>
> Allow the patient to experience this state for a minute or two, then inquire about the experience:
>
> With your eyes closed and remaining in this state of concentration, describe how your body is feeling right now. What image are you picturing?
>
> After receiving the answers, add:
>
> Notice how you can use your store of memories and fantasies to help yourself and your body feel better.

One method to help patients shift gears and restructure their relationship to thoughts and feelings is the screen technique. The patient is told: “You can enter the trance state by permitting your body to float. By permitting your body to float, your mind is free to concentrate on an imaginary screen in front of you. While in trance you have the power to teach your body to maintain the physical sensation of floating and, at the same time, use the imaginary screen to become the director, script writer, actor, organizer, and balancer of your own thoughts and feelings. First, let the central part of the screen serve as a receiving screen for all your thoughts and

feelings. Now imagine a split screen on the right for your creative thoughts and a split screen on the left (the sinister side) for your worry thoughts. Place your thoughts and feelings of anxiety, fear, and worry on the left; place your creative thoughts, feelings, and visions of refuge on the right. After all, you are more than worries and fears. You are now learning to use your mind as a psychological zoom lens, with the right to revisit any worries and fears, if you wish—you don't have to fight them. By putting your thoughts and feelings on an imaginary screen and learning to let your body float, your body is no longer a battleground for your emotions."

For insomnia, the initial concept is the screen technique (see above) with an additional emphasis on switching from sympathetic to parasympathetic function. The patient is told: "Muscle tension is an enemy of sleep. The autonomic nervous system has a day and a night shift. Muscle tension is a barrier that impairs the transition. By feeling a sense of floating while projecting your thoughts onto the screen, tension dissolves, allowing the day shift to yield to the night shift to let sleep come like a welcome friend."

Patients may also use the trance state as a means of facing their concerns more directly. They can be taught to use the screen technique on their own. They can achieve this by placing an image of an upcoming performance or fearful situation on one side of the screen; on the other side, testing out various strategies for mastering the situation. The screen becomes a brainstorming and problem-solving technique that allows them to face anxiety-provoking situations more directly, but seeing them from a different perspective. This helps them move from a passive to an active coping mode, not merely avoiding but responding to the feared stimulus, by acknowledging and working out responses to it while managing somatic reaction to the anxiety.

Other approaches using hypnosis have included instructing patients in a trance to imagine that they are literally somewhere else, away from the fearful stimulus, thus separating themselves from the anxiety-producing experience. Positive reinforcement, or ego-strengthening techniques, have also been used; for example, giving hypnotic instructions to patients suggesting that their capacity to master the situation and their response to it will improve. There is little reason to use uncovering techniques seeking to link the complaint of anxiety to some early traumatic experience in cases of phobia or generalized anxiety disorders. This is different though in cases of posttraumatic stress disorder, where more work may be needed to confront the traumatic experience.

Treatment for performance anxiety, generalized anxiety, and insomnia follows the restructuring approach. Instead of fighting against fear, conflicts, stressful events, or problems, patients focus on physical sensations and learn to distance themselves from the issues, to develop a sense of freedom, clarity of thought, and relief.

Phobias The underlying challenge of a phobic response (irrational fear) is to clarify the confusion between a possibility and a probability. Distinctions are made between anticipatory anxiety for likely and unlikely events, with additional differentiation between useful, protective fear and unnecessary, maladaptive fear. With these clarifications, the therapeutic strategy is to teach the patient to focus on what one is for rather than the fear of what one is against. This provides the momentum for rapid change.

For flying phobia, a prevalent clinical condition, the patient is asked to consider the difference in safety probabilities between an amateur pilot and a professionally licensed pilot on a commercial plane. Anticipatory anxiety is described as a healthy response to mobilize one's resources for a new phase of action. Patients are taught that if they interpret anticipatory anxiety as panic they are perverting a natural resource. Patients are then taught to focus on the many instruments that have been developed to act as an extension of the body. "For example, a hammer is an extension of your hand; a bicycle is an extension of your legs; an airplane is an extension of your arms. When you choose to fly on a scheduled airplane, in one direct move, you can accept the pilot as your agent, and through this choice you are rationally controlling the plane. By choosing to allocate the technology to someone with the proper skills and training, the control is still yours." Patients are taught a self-hypnosis exercise in which they concentrate on floating with the plane, using the pilot as their agent of control.

OUTCOME A number of studies demonstrate the utility of hypnosis in the treatment of anxiety and phobias. A study by the first author and colleagues with 178 patients treated with a single session of self-hypnosis for flying phobia indicated that 52 percent were either improved or cured at 7-year follow-up. There has been considerable interest in hypnosis as an adjunct to dental procedures and in the treatment of dental phobia. The success of hypnotic techniques has created a new interest in teaching the usefulness of hypnotically assisted dental work in dental schools across the country. Similarly, hypnotic techniques have been successfully used to assist phobic patients undergoing a number of medico/surgical and diagnostic procedures, thus diminishing the need for excessive anesthesia or antianxiety medication, improving compliance, and eliminating trauma to patients. Hypnosis may be especially helpful as an adjunctive tool for treating these anxiety disorders because of the ability of the hypnotized person to control somatic response.

Posttraumatic Stress Disorder The most distressing thing about a traumatic event is the sense of absolute helplessness that it engenders. This helplessness is reenacted in both acute and posttraumatic stress disorder through loss of control over the state of mind in the aftermath of trauma, with spontaneous dissociative states, startle reactions, or intrusive recollections of the event. Having regained control of their bodies, many trauma victims feel they have lost control over their minds as they are subjected to nightmares, flashbacks, and intrusive memories. The therapist can be contaminated with association to the trauma. Such patients may tend to identify the therapist with the assailant and feel that the therapy amounts to reinflicting the trauma. The process of the therapy, especially when a technique such as hypnosis is used, must be structured so that it enhances patients' sense of control. This approach can allow patients to integrate the image of themselves as victims with the ongoing, more-global image of themselves as persons coping effectively with severe stress, making the repressed material conscious and therefore less powerful, and enabling them to establish a new, more congruent self-image, absorbing the loss into the ongoing flow of their lives. The psychotherapy of posttraumatic stress disorder contains elements of desensitization, in which reexposure to the traumatic stimulus may gradually deprive it of some of its emotional power. Indeed, the use of hypnosis in the psychotherapy of trauma was initially thought to be limited to abreaction, based on Freud's cathartic method. The idea was that some intense affect associated with the traumatic event needed to be released and that simple repetition of the memory of the event with its associated emotion in the trance state would discharge the energy producing the symptoms. However, it became clear to Freud that conscious, cognitive work must be done on the material for it to be successfully worked through. Indeed, it is now clear that cognitive restructuring of the meaning of the traumatic event coupled with a continued sense of being cared about by the therapist enhances the effect of hypnosis in psychotherapy.

Treatment using hypnosis involves not merely abreaction of trauma, but working through it by assisting with the management of uncomfortable affect, enhancing patients' control over it, and enabling them to cognitively restructure its meaning. Catharsis is a beginning but not an end in itself, and it can lead to retraumatization if not accompanied by support in managing affective response, control over the accessing of traumatic memories, and help in working them through. F. Lindemann's grief work model is useful. Observations of normal grief after trauma have led to recognition that a certain amount of emotional discomfort and physical restlessness and hyperarousal is a natural and indeed necessary part of acknowledging, bearing, and putting traumatic memories into perspective. This is often facilitated by using a hypnotic imagery technique, the split screen, in which patients are asked to picture some aspect of the trauma on one side of the screen, bearing the associated uncomfortable affect, and then picture on the other side of the screen something they did for self-protection or to aid others. In this way the traumatic memory is acknowledged but restructured to encompass efforts at mastery as well as the experience of helplessness.

Hypnosis can be used to provide controlled access to the dissociated or repressed memories of the traumatic experience and then help patients restructure their memories of the events. The unusual characteristics of the hypnotic state provide reassurance that the distress associated with the traumatic memories can to some extent be put aside when the hypnotic state is ended. Also, the dissociation typical of hypnosis can be used to separate psychological from somatic distress. Patients can then find a condensation image that symbolizes some aspect of the trauma. It is often helpful to have them do this on an imaginary screen, giving them some sense of distance from the event. It is also useful to divide the screen in half, having the patient picture on one side some aspect of the event (e.g., a rape victim's image of the assailant) and on the other side of the screen, some self-protective action (e.g., struggling with the assailant, talking with him, running away). This lets the patients restructure their view of the assault, facing it, but not simply in the familiar terms of the humiliation, pain, and fear with which it was initially associated. Victims can better acknowledge their helplessness when they also recognize their efforts to protect themselves. Bereaved individuals can picture themselves at the graveside on one side of the screen and at an earlier moment of joy with the deceased on the other side. They can then be taught to practice a self-hypnosis exercise in which they grieve and work through traumatic memories while enhancing their sense of control over the process.

PRINCIPLES OF PSYCHOTHERAPY WITH HYPNOSIS The principles of psychotherapy for acute and posttraumatic stress disorder using hypnosis can be summarized with the following eight Cs:

Confrontation. The patient should confront the traumatic events directly rather than attribute the symptoms to some long-standing family or personality problem.

Confession. The therapist should help trauma survivors discuss deeds or emotions that are embarrassing to them and at times repugnant to the therapist. It is important to help these patients distinguish between inappropriate guilt and real remorse. Such patients may well be telling the therapist about aspects of the traumatic event that they have discussed with no one else.

Consolation. The intensity of traumatic experiences requires an actively consoling approach from therapists, lest they be perceived as being judgmental or as inflicting

rather than treating trauma-induced emotional pain. Appropriate expressions of sympathy and concern can be helpful in acknowledging and diffusing this common traumatic transference reaction.

Condensation. An image that condenses a crucial aspect of the traumatic experience should be found. This representation can make the overwhelming aspects of the trauma more manageable by putting it in concrete, symbolic form. Furthermore, it can facilitate restructuring of the experience by joining previously disparate images; for example, linking the pain associated with the death of a friend in combat with the happiness experienced during some earlier shared time. This allows patients to alter the pain of the loss by attending to positive aspects of the lost relationship that remain in memory as well as negative ones.

Consciousness. Previously dissociated traumatic memories should be made conscious in a gradual manner that does not overwhelm the patient.

Concentration. The intense, focused concentration characteristic of the hypnotic state should be used to reinforce the boundaries of the traumatic experience and the painful affect associated with it. Directing sharply defined attention toward the loss also implies that when the hypnotic state is ended, attention can be shifted away from the traumatic experience. This counters the common fear of “opening Pandora's box,” and unleashing feelings not easily contained.

Control. Because the most painful aspect of severe trauma is the absolute sense of helplessness, the loss of control over one's body and the course of events, the process by which the therapeutic intervention is conducted must enhance the patient's sense of control over the traumatic memories. Structure the experience so that patients are given the opportunity to stop working through when they feel they have had enough, can remember as much from the hypnosis as they care to, and feel they are in charge of the self-hypnosis experience. They should learn to use it on their own as a self-hypnosis exercise as well as with the therapist. Such procedures help patients imbue traumatic memories with a greater sense of control and mastery.

Congruence. The goal is to help patients integrate dissociated or repressed traumatic material into conscious awareness in such a way that they can tolerate experiencing the memories as part of their continuous life history. In this way the traumatic past is not incompatible with their present xperience. Patients should emerge from therapy having reviewed not only what was done to them but what they did to protect themselves, not only what they lost, but what they had valued and why.

OUTCOME There are numerous clinical reports of the effectiveness of hypnosis as an adjunct to treatment of posttraumatic stress disorder but few controlled studies of the efficacy of hypnosis in treating this disorder. However, one controlled study by D. Brom and colleagues of 112 subjects with posttraumatic stress disorder demonstrated that psychotherapy with hypnosis was superior to a control condition and was equivalent to both psychodynamic therapy and systematic desensitization. Hypnosis was particularly effective in reducing intrusion rather than avoidance symptoms.

Dissociative Disorders Dissociation is best understood as part of a continuum of phenomena involving ongoing fragmentation and coalescence of conscious and unconscious associations. The ongoing process of dissociation and reassociation leads to a variety of patterned integrations of emotional and cognitive material that previously existed as fragments of information.

Dissociation of identity (dissociative identity disorder), memory (dissociative amnesia and fugue), or consciousness (depersonalization disorder, dissociative trance disorder) result in an array of symptoms that affect intrapsychic and interpersonal functioning. A central feature of the dissociative disorders is a loss of conscious access to some parts of experience, even though the individual always maintains some connection to a main psychological orientation and an underlying intentionality.

An important development in the modern understanding of dissociative disorders is the establishment of a clear link between trauma and dissociation. While the role of traumatic stress in eliciting dissociative symptoms was a part of Janet's early thinking as well as Freud's, recent work has examined in more detail the proximate role of trauma in eliciting dissociative symptoms. However, not enough critical data has been studied to establish a causative relation among trauma, its timing, its intensity, and its meaning in the emergence of subsequent dissociative disorders. Secondary gain and malingering are critical factors that cannot be ignored in the genesis and maintenance of these syndromes. Often the Axis II diagnosis provides the most significant elements of the clinical picture.

It is important to note the differential diagnosis between pathological dissociation, which is the primary result of an interaction between stressful events and high hypnotizability, and psychosis which is the result of a internal cognitive break, which is associated with low or no hypnotizability. Edward Frischholz and colleagues have found that patients with dissociative disorders have a mean eye roll sign of 3.38 (on a 0 to 4 scale) and have high scores on the Hypnotic Induction Profile, while patients with schizophrenia have a mean eye roll sign of 1.73 and have low scores on the Hypnotic Induction Profile. The difference in both hypnotic capacity and responsivity between these two diagnoses makes the use of formal hypnosis (including testing) a primary aspect in the diagnosis and treatment of dissociative disorders but not in the treatment of schizophrenia. In dissociative disorders, whether the dissociations are spontaneous or conscious, they are always potentially reversible.

Symptomatology and Treatment Dissociative disorders involve a failure in the customary integration of identity, memory, or consciousness. Loss of access to parts of experience to consciousness can intensify many preexisting problems. Formal hypnotic inductions with appropriate treatment strategies are used to teach an individual to access dissociated feelings and memories and to control dissociative process. Conceptualizing dissociative identity disorder as a chronic posttraumatic stress disorder, the psychotherapeutic strategy also involves working through traumatic memories.

To the extent that psychosocial stress triggers dissociation, resolution of that stress can help resolve and reduce the likelihood of further symptoms. Highly hypnotizable individuals who have difficulty asserting their own point of view in difficult interpersonal relationships or who may be dealing with severe situational stressors are prone to extreme dissociative symptoms. Psychotherapy can assist such individuals to recognize and modify their tendency to uncritical compliance with others and their extreme sensitivity to rejection and disapproval.

Memory Retrieval Since memory loss in dissociative disorders is often complex, its retrieval is an integral part of the psychotherapeutic process. In general, recall of recent trauma is more feasible and more accurate than recall of remote trauma. The therapeutic strategy is designed to use memory recall to counter the dissociative fragmentation and to work toward integration.

Patients with dissociative disorders can be helped with a psychotherapeutic approach that facilitates conscious control of dissociated memories and behavior previously experienced as automatic and unwilled. Clinicians must stay alert to the extreme malleability and the uncritical acceptance of new information by the highly hypnotizable person. Excessive exploration may further increase disintegration, leading to confusion or retraumatization. The goal is to garner only the most relevant data that will enable the patient to establish more effective control for present and future living.

Outcome While there are no controlled trials of the efficacy of hypnosis in treating dissociative disorders, the clinical literature indicates that it is highly useful. A recent survey of 305 clinicians indicated that individual psychotherapy facilitated by hypnosis twice a week was the primary treatment for dissociative identity disorder patients, with anxiolytics and antidepressants being used as secondary adjunctive tools.

HYPNOSIS IN FORENSIC PSYCHIATRY

Recent controversies surrounding the so-called false memory syndrome have aroused concern about the use of hypnosis in the clinical setting and have raised questions about the validity of the material recovered by the use of hypnosis. Hypnosis had been used not infrequently to refresh recollection of witnesses and victims of crimes. Despite concern that hypnosis inevitably contaminates memory, the research literature on hypnosis and memory indicates that hypnosis affects belief more than content. Any memory retrieval technique that increases the production of memories may lower the response criterion (i.e., the willingness of a subject to report a thought as a memory). Thus the mere act of trying harder to remember something about an event can always convert thoughts, fantasies, or leading questions into memories. Any special effects of hypnosis may be more feared because they have been more thoroughly examined. Despite these concerns, there are examples of the use of hypnosis in the forensic setting which led to correct new recall. A well-known example is the case involving the driver of a hijacked school bus in Chowchilla, California. Under hypnosis, the bus driver was able to recall the license plate on the car driven by the kidnappers. This information, not available to consciousness prior to hypnotic intervention, led to the arrest and conviction of the criminals.

No memory, whether retrieved with or without the use of hypnosis, can be determined to be true without independent confirmation. However, the courts have become especially concerned about possible contamination of memory by hypnosis. As a result, judges are increasingly unwilling to admit the testimony of a person hypnotized while testifying and recently have also begun to exclude testimony of witnesses who have previously been hypnotized about the event in question. This

dilemma is confounded by the fact that motivated or emotionally charged persons, particularly those with midrange to high hypnotizability, can shift into a spontaneous trance state while trying to recall an event without a formal hypnotic induction. These concerns are based on fears of confabulation and “concreting.” In some circumstances, hypnotized individuals can make up information and believe their newly created story is real. In the phenomenon of concreting subjects emerge from hypnosis with an enhanced conviction that their memories are correct. This makes witnesses appear more convincing to a jury than they really are about the facts. Indeed several states (e.g., New Jersey and New York) restrict the testimony of victims or witnesses who have used hypnosis to refresh their recollection. The reason for the courts' objection to the use of hypnosis is a combination of real and exaggerated dangers of hypnosis. After much legal battle, some courts now allow witnesses to testify after the use of hypnosis provided certain guidelines are followed that relate primarily to the training and independence of the professional doing the hypnotic interrogation and the electronic recording of the entire process.

Therapists treating trauma or crime victims must be aware that the use of hypnosis may compromise a witness's ability to testify in court. If civil or criminal legal issues are pending, it is advisable to ask the patient to discuss the situation with their personal attorney or the district attorney and obtain written consent for the use of hypnosis from both the attorney and the patient. If hypnosis is to be used and there will be subsequent legal involvement of the patient, all contact with the patient should be electronically recorded, preferably on videotape. Because hypnosis involves a suspension of critical judgment and thus a state of heightened suggestibility or responsivity to social cues, the interview must be conducted with a minimum of inserted information. To avoid the risk of contaminating the subject's memories the authors recommend using open-ended questions such as “what happens next?” rather than “how did he sexually abuse you?”

Hypnosis should never be used to replace standard investigative work. Hypnosis is most likely to be worth the risk when traumatic amnesia exists for the events of a crime or when all other avenues of exploration have been exhausted.

Hypnosis is a state of mind and brain that involves intensity of focus, dissociation, and heightened responsiveness to social cues. It is a measurable trait not equally shared, and differences in hypnotizability reflect developmental stages, the presence or absence of psychopathology, and personality style. It is a highly useful adjunctive tool in the management of somatic symptoms such as pain, habit control, and anxiety disorders. It is also useful in the treatment of posttraumatic and dissociative disorders. Fears about its effects are generally due to misinformation, and given its favorable risk/benefit profile, hypnosis deserves more general application in psychiatry and the rest of medicine.

SUGGESTED CROSS-REFERENCES

The biology of memory is discussed in Section 3.4 and psychoanalysis in Section 6.1. Anxiety disorders are the subject of Chapter 15 and dissociative disorders are presented in Chapter 18. Chapter 25 discusses psychological factors affecting a medical condition. Evaluation of psychotherapy is discussed in Section 30.11.

30.4 GROUP PSYCHOTHERAPY, COMBINED INDIVIDUAL AND GROUP PSYCHOTHERAPY

ANNE ALONSO, PH.D.

People thrive best in a community that values their participation and protects their dignity. The stresses that impinge on individuals are defined in part by their biology, family dynamics, and culture. The interplay of these factors shapes how people live and work with others, and how they feel about themselves is also in part shaped by how others experience them and respond to them.

Today's culture has many fewer stable and dependable sources of community and fewer stable and long-lasting ties with institutions or with individuals; thus the individual is left without many of the historically dependable sources of identity. On these shifting sands, individuals must somehow achieve adequate individuation from their immediate family and learn how to manage intimacy with yesterday's stranger.

The integration of mind, body, and social context is vulnerable to assault from problems in any one of these dimensions. When problems occur, people suffer and seek our help for their suffering. Group psychotherapy offers the opportunity for purposefully created, closely observed, and skillfully guided interpersonal interaction, which can positively influence the countless varieties of human distress and malfunction. Distorted perceptions of others, insufficient communication, inadequately discharged affects, stereotyped behaviors, impulsive actions, and alienation can all be addressed and modified within the therapeutic group.

HISTORY

Early Beginnings Group psychotherapy originated in America in 1905 and was first conducted by an internist, Joseph H. Pratt, who led groups composed of tubercular patients. His groups bore remarkable similarity to those currently offered by cognitive-behaviorists and self-help groups to alleviate the distress caused by commonly shared physical or psychological problems. In 1919 L. Cody Marsh applied the group method of treatment to institutionalized mental patients. About the same time E. W. Lazell used group methods in treating psychiatric patients. In 1925 Trigant Burrow coined the term *group analysis* and conducted group therapy for noninstitutionalized patients. In the early 1930s Louis Wender introduced the notion of the group as a re-created family, applied psychoanalytic concepts to group therapy, and began the use of combined therapy. Paul Schilder, one of Wender's contemporaries, elaborated on Wender's approach and encouraged the use of free association.

Coming of Age Samuel Slavson, an engineer by profession, founded the American Group Psychotherapy Association in 1948 and is regarded as having had the most influence on the development of American group psychotherapy. He referred to his method as analytic group psychotherapy and concentrated on the individual in the group, rather than on the group itself. His greatest contribution is acknowledged to be the development of group psychotherapy with children. During the 1930s and 1940s Alexander Wolf actively applied the principles of psychoanalysis to groups of adults. In contrast to Slavson, Wolf believed that in analytic group psychotherapy, the psychoanalytic work was as deep as in the individual psychoanalytic setting and could even be more profound. It remained for current research to buttress Wolf's claims about the effectiveness of group psychotherapy.

European Influence Group psychotherapy also created interest in Europe. The Romanian psychiatrist Jacob L. Moreno (1898–1974), primarily identified with psychodrama borrowed from his experience with the Stegreiftheater (Theater of Spontaneity) in Vienna. Thus his introduction of group psychotherapy in 1910 included role-playing and role-training methods. Moreno may have coined the term *group therapy* in 1931. Although he never formally conducted group psychotherapy, Sigmund Freud called attention to group psychology in *Group Psychology and Analysis of the Ego,* published in 1921, Freud's insights into group formation and transference reactions form the underpinnings of modern psychoanalytically oriented group psychotherapy. Alfred Adler's major contribution to group psychotherapy was his explanation of the processes that account for the therapeutic influence of the group; in particular, he examined the relation of the group to the individual and the individual to the group. Kurt Lewin introduced his field theory concepts, emphasizing that the group differs from the simple sum of its parts. Lewin coined the term *group dynamics* in 1939 and is considered the pioneer of viewing the group as a whole.

Impact of the British School In England, group therapy evolved largely as a result of the pressure to treat a large number of psychiatric casualties during World War II. Wilfred R. Bion, an analysand of Melanie Klein's, offered the hypothesis that the group has a separate mental life, with its own dynamics and complex emotional states, which he termed *basic assumption cultures*. His basic assumptions paralleled Klein's stages of infant development. Bion is best known for his work with the *group as a whole*, and his ideas have gained immense popularity in the United States. Henry Ezriel in 1950 and John D. Sutherland in 1952 were also active in group therapy, emphasizing the “here-and-now” and “then-and-there” perspectives. Ezriel is also credited as the first person to describe the transferences between the members themselves and between the members and the group as a whole.

Mainstream Group Theories and Therapies in the United States The field of group therapy has incorporated the historic influences into a solid clinical modality articulated by the stellar work of a number of theorists in the United States and their followers. Helen Durkin in 1964 integrated principles of systems theory with group dynamics into the field of group therapy. Along with Durkin, Henrietta Glatzer became a prime force in the application of psychodynamic principles to group psychotherapy. She is known primarily for the concept of “the working alliance.” “She used the concept to emphasize the importance of the member-to-member interaction as a principal component of the working alliance in therapy groups.” Saul Scheidlinger's prolific output set the stage for a broad-based view of group development, including concepts such as the “mother-group” and the regressive pull in groups that activates early childhood patterns.

The wisdom of the early theorists and the visionary quality of their insight about group treatment is reflected and revitalized in the work that many clinicians are applying to current problems of epidemic proportion such as breast cancer and acquired immune deficiency syndrome (AIDS).

THEORETICAL ISSUES

While group therapy was originally based on psychoanalytic principles, a broad range of theories now informs the practice of group psychotherapy.

Psychodynamic Theorists Most current analytic theorists define the psychodynamic umbrella as consisting of four major branches: classical theory, object relations theory, ego psychology, and self psychology. In addition, the analytic umbrella covers interpersonal theory, humanistic-existential theories, and feminist-analytic thought.

Classical Analytic The classical analytic emphasis on libido and aggression finds expression in the unconscious forces that propel the group as a whole along its epigenetic trajectory. In this model the group develops along the same epigenetic trajectory as the individual, namely oral, anal, phallic, and genital imperatives dictating the movement from early to mature group stages.

Object Relations Object relations theory finds in groups a natural environment for the projections of internal part-objects onto the other people in the room (members and leader) and the gradual reintrojections of the split-off aspects of the self within the containment of the group envelope.

Ego Psychology Anna Freud's interest in ego defenses by which an individual copes with potentially devastating anxiety influences a host of group interventions

having to do with recovery from physical or mental illness.

Self Psychology Self psychologists recognize the mirroring and empathic possibilities among committed members who can serve as selfobject functions for one another. All of the analytic group therapies rely on interpretation of resistances, defenses, and the multiple transferences that occur between members, between member and leader, and to the group as a whole.

Related Analytic Theorists Sullivanians and other interpersonalists such as Irvin Yalom stress the healing that comes from the real relationships among the members, and the feminists see in groups the opportunity to inspect the impact of gender on environment and vice versa. Existentialists depend on the group to explore, verify, and accept the individual's personal myth and intentionality in the world as they contribute to the individual's self authenticity.

Nonanalytic Theorists In addition to the psychodynamic theorists who have dominated the field of group therapy, a host of other theoreticians have contributed to the field of group psychotherapy. Some of them include the cognitive-behaviorists, the gestalt theorists, transactional analysts, and the redecision therapists.

Cognitive-Behavioral Theorists Cognitive-behaviorists see in the group model the opportunity to rethink old cognitive schemas and to question some of the prior cognitive distortions. Behavioral clinicians address social and psychiatric problems within a testable conceptual framework; thus the social influence that occurs in groups has a pivotal role in altering maladaptive responses by the use of modeling and reinforcement of new behaviors.

Gestalt Theorists Many of the theories that developed in the 1960s and 1970s used group models. The theory of gestalt therapy is defined by two central ideas: first, that the proper focus of psychology is the experiential present moment and second, that it is only possible to know the self in relation to other things in the interactive field. Gestalt theory as developed by Fritz Perls, Paul Goodman, and others from the Cleveland Gestalt Institute, brought the field theory of Kurt Lewin and Kurt Goldstein to bear on patients' attempts to integrate action, affect, and cognition. While working with an individual protagonist within the group, these thinkers used the whole group as a supportive container and reactor to the protagonist's clinical development. In gestalt theory the focus is on organizing the accumulation of past experience into the present reality of the person. Thus, the balance between figure and ground (or content and process) is the direction toward health.

Transactional Analysis Transactional analysis divides personality into three phenomenological components or ego states, colloquially termed *parent, adult,* and *child*. Eric Berne developed a group therapy approach that understands social behavior in terms of strokes or transactions exchanged by people in maladaptive patterns called games.

The redecision school of transactional analysis focuses on “ego state patterns” that may be thought of as character patterns, as expressed in the individual's relationship with others; these clinicians seek to resolve maladaptive early life decisions through contracts for change. Eugene Kerfoot and John Gladfelter describe redecision methods in a brief group therapy format and concern themselves with training models.

Self-Help Groups Alongside group therapy offered by the professional community, a large array of self-help groups have emerged and flourished. The first of these was Alcoholics Anonymous, which became a model for many other problem-specific support groups led by their own members. These groups have become a major source of recovery and cure and illustrate the value of community and group cohesion for managing a range of human distress. In particular, they focus on compulsive problems, such as addictions of all sorts, self-mutilation, and gambling.

All of the modalities listed above share certain curative factors. Table 30.4-1 contains a comprehensive listing of the range of therapeutic factors in group therapy.

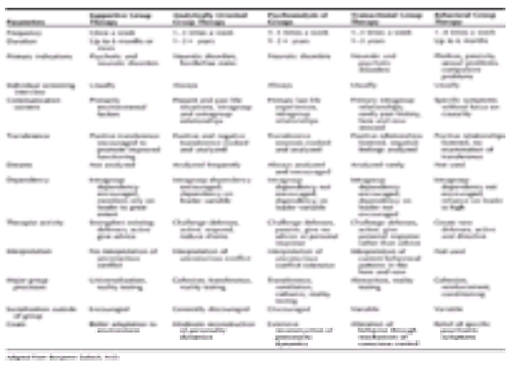

Table 30.4-1 Comparison of Different Types of Group Psychotherapy

THERAPEUTIC FACTORS

Whatever the model, group therapy rests on the assumptions that there are healing factors that emerge and operate in all groups and that some of these can be brought into play to allow the individuals in the group to grow and develop beyond the constrictions in life that brought them into treatment. While some group theorists rely on a cluster of factors relevant to their models of the mind and of pathology, all use some of the whole group of therapeutic factors identified in Table 30.4-2.

Table 30.4-2 Twenty Therapeutic Factors in Group Psychotherapy

It follows that the analysts will probably rely on the recapitulation of the family of origin, and on the way the transferences develop relative to those early family experiences; the cognitive behaviorists will exploit the factors that most rely on examining and clarifying schemas of more or less adaptive cognitions, to offer a simple example. At the same time, all of the theories rely on some universal and powerful factors that cut across all models.

Universal Healing Factors Going from the specific theories and their concepts of clinical change, processes common to all groups move the group on its developmental trajectory and enable the members to use the therapeutic factors delineated above. In what ways are groups therapeutic, and what promotes the healing forces in a group?

Cohesion Primary among universal healing factors is cohesion, which can be defined as a sense of belonging to a stable and accepting group, that relates to the attractiveness of the group to its members. The sense of we-ness seems to allow patients a high level of self-disclosure, to accept one another, to form meaningful

relationships, and to be supportive despite the obvious interpersonal difficulties experienced in the process. As these problems are worked through in the group, the gains in self-awareness and empathy toward others carry over into relationships outside the group, as do all alterations in the dyadic treatments.

Managing Shame Clinicians frequently worry about the shaming aspects of the disclosure that are part and parcel of the work in the group. It is true that going public with one's problems can be a daunting goal. If individuals in the group can manage to do so, paradoxically shame is reduced, patients begin to understand that they are part of the human condition and not subhuman or suprahuman, and development can resume. The group therapist sets the stage for the work of the group by developing a climate that is respectful and avoids undue shaming of any one member by underscoring the universal quality of all human pain and by encouraging frankness and empathic confrontation of the members by one another.

Amplification and Contagion Some of the earlier writers such as G. LeBon and W. MacDougall understood the effectiveness of the intragroup processes along with the dimensions of contagion and amplification. *Amplification* is a process whereby the individual's dimly felt or secretly held problems are spoken by another member or members in the group as centers for their own concern. The constrained members then have their affects amplified and universalized by hearing them as belonging to others in the group and feel a deepening awareness of the troublesome affects that can now be approached in the accepting community of group colleagues. Another factor is that of contagion. At its worst, of course, this is what turns a group into a mob, as has been seen all too often in history. But at its finest, it is a process that enables individuals to rise beyond their solitary life and that makes the group more powerful than the sum of its parts. Some examples of benevolent groups helping in times of natural disasters come to mind. Together with cohesion and the management of shame, these constitute the four fundamental cornerstones by which group treatment affects its members. All four basic curative processes (cohesion, shame reduction, amplification, and contagion) rest on the basic assumptions first mentioned, namely, that all people want to belong and to fit into a community. The power of that force propels each person beyond the constraints of personal inhibitions or cultural habits to achieve that sense of we-ness with the group.

A group of patients have been meeting in a large general hospital for a number of years. These are very distressed people who live isolated lives and exist on the bare margin of society. Most have been hospitalized; some many times. Still, they attend the group as faithfully as they can. When they do make it to the meetings, they speak of the agonizing effort it took to get them out of their cocoons and into the room, but they also say such things as “I set my week by this group.” The wish to join the group “family” can override the schizoidal defenses that so compromise their lives. Notably, the sense of family and community serves to keep these patients out of the hospital and able to function more or less autonomously.

SETTING THERAPEUTIC GOALS

Planning and Organizing a Group Before approaching the concrete work of planning and organizing a psychotherapy group, the goals of the group must be clearly understood and developed by the leader. These in turn depend on the setting, the population, the time available for treatment, and the training and capacity of the leader or leaders. Therapy groups can be organized with the following goals in mind:

1. Character change
2. Supporting homogeneous patient populations
3. Targeting certain symptoms
4. Reestablishing premorbid levels of functioning

The goal of the group informs the structure, membership, duration, and leadership of the group. Also derived from this decision is a rational group contract that can provide a focus to help contain the members of the group. These variables together become the context for the work. For example, if the group is an outpatient, open-ended group with the goal of character change and the resolution of life-long disabling patterns of feelings and behaviors, the contextual factors will differ from those of a group that is organized on an in-patient unit.

Character Change Character difficulties are tenacious for all human beings, from the healthiest neurotic to the most regressed patient that is treated. For all persons character problems are:

1. Outside the patient's awareness
2. Syntonic and perceived as “who I am” when brought into awareness
3. Resistant to change even when the patient wants to make a change
4. Repeated compulsively until worked through; that is, they are robbed of some of their power with each experience of successful change to better alternatives
5. Difficult to change without strong motivation to overcome psychological inertia

The neurotic patient finds intrapsychic conflicts emerging in the interpersonal field of the group and makes use of the group's curative factors to overcome the resistances to newer intimacies. Some of the earlier literature on group treatment expressed doubts about the appropriateness of this “uncovering” kind of group for sicker patients. More recently, group theorists have argued that in fact the distributed transferences in the group seem to mitigate an overly threatening regression for such patients. Character problems have a tenacity that is difficult to reorganize in a brief treatment. Instead the process requires frequent regressions in the service of the ego and attempts to work through the same characterologic habits again and again. At the same time, brief analytic group models have been used to address sectors of the personality difficulties to good effect.

Supporting Targeted Patient Populations Since the time that Pratt offered his “classes” for tubercular patients at the Massachusetts General Hospital in 1905, people have come together to commiserate with one another around common problems, to share information, and to learn how to deal with the impact of those problems on their lives. Groups have been organized around medical illnesses such as cancer, diabetes, and AIDS; around psychological problems such as bereavement; and around psychosocial sequelae of trauma such as war or natural disasters. The goal of such groups is to provide support and information embedded in a socially accepting environment with persons who can really understand what one another is going through. The treatment may emerge from cognitivebehavioral principles, psychodynamic principles, or psychoeducational ones. Frequently these groups are time limited, and members often join at the same time and terminate together. The problems addressed in these groups are found in a broad variety of patients from the very healthy to the more distressed and cut across other demographic variables such as age and culture. Research indicates that involvement in these groups can have remarkably positive effects on extending survival and quality of life for the severely ill patient such as women with end-stage breast cancer.

Targeting Certain Symptoms Group treatment may target specific symptoms. This approach to psychopathology is congruent with categorical nosological systems such as the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). Diagnosis here is seen as symptomatic rather than developmental, and the treatment goal is to alleviate the symptoms. For example, patients with eating disorders or specific phobias are clustered in groups that promote skills for self-monitoring and for replacing the automatic symptom with a more adaptive set of behaviors and cognitions. These groups again may include members from a broad range of intrapsychic development, which is not the primary focus of the group. At the same time, some people who work successfully in these groups may want to continue the work of personality change in open-ended dynamic groups when the symptom is relieved.

Reestablishing Premorbid Levels of Functioning People in acute and immediate distress may find support in groups that have reestablishment of a person's equilibrium as their main goal. Patients who have suffered a breakdown of their lives and have needed to be hospitalized can use groups within the inpatient or partial hospitalization setting. These groups focus primarily on restructuring the patient's sensorium, managing the acute distress, and planning for a return to the community. These patients also need help in dealing with the shameful consequences of hospitalization and the sometimes elusive process of establishing outpatient treatment to support them upon discharge. A benevolent inpatient or partial hospital group experience is of special value in the latter problem, since affordable treatment will be primarily offered in group therapy for the foreseeable future.

TECHNIQUES

Developing the Group Contract All groups need a contract, or a set of agreements about process, content, and goals. The more explicit this contract is in the mind of the leader, the more a prospective patient can feel a full partnership in the decision to join a particular group. The contract provides a structure and lends meaning that advances the work of the group and provides the safe, predictable maturational environment for each member's progress. Nonetheless, each aspect of the group agreement will probably generate internal resistances that are part and parcel of all human change. The specificity of the agreements allows each person a baseline from which to examine and overcome these resistances. The agreement or contract needs to be congruent with the kind of group the leader will conduct, taking into account the multiple variables explored above.

Sample Contract An open-ended psychodynamic group may organize around the following contract in which each member agrees to:

- Attend all meetings for the whole time. Regularity of attendance keeps each member in the process and helps the group cohere, without having to worry about consistency of the participants.
- Be responsible for the fee. Groups offer a rare opportunity to deal with the management of money in a public arena. To that end, a discussion of the fee in the group can be most helpful.
- Put into words the problems, feelings, and thoughts that bedevil them. Safety in a group is preserved by an agreement to express feelings in words rather than in acts, but a major advantage is also the value of sublimating in language what is heretofore felt remotely or is out of awareness.
- Keep the relationships primarily therapeutic, not social. While this is not a universally accepted aspect of group agreements, most psychodynamic leaders try to avoid siphoning the conflicts by segregating certain interactions from the whole group. Some will ask that the members bring to the group interactions that may have occurred among them in outside meetings.
- Protect the identities of the other group members. Confidentiality is crucial in the exposed setting of the therapy group. Members may want to discuss what happened in their group, but the identity of the other members must be protected if the group is to meet its goals.
- Stay until they have finished what they came to do. In the course of the group, people typically become aware of the work needed to overcome the problems that brought them into treatment. In psychodynamic groups, this is less well defined than in groups that are symptom focused, and it must be continually assessed by the individual, the group, and the leader.
- When they think the time has come, they allow the other members of the group to participate in the decision to terminate. Learning to collaborate with important others is a major advantage to working in a group. Thus, allowing others' opinions to influence, but not dictate, one's decisions is a major accomplishment.
- Leave enough time to say good-bye. For many, saying good-bye has historically been so painful that it has been avoided or shortened to formulaic rituals. Taking the time to say good-bye to the group is another chance to symbolically say good-bye to other loves and other homes.

Selecting Patients The question of who should be treated in a group is as elusive as the question of who should be treated in psychotherapy. Perhaps a more salient question is that of therapeutic fit for a particular group.

Indications A psychodynamic group in which early developmental conflicts and relationships are assumed to interfere with the here-and-now of the patient's life should be reasonably homogeneous for the level of ego development and heterogeneous in every other regard. Mixing persons of different genders, cultures, and ages can be extremely useful so long as they emerge from a similar developmental spectrum. The differences among them can then be addressed and exploited to the advantage of the group members. However, when patients diverge sharply in levels of ego development, group cohesion and universality are compromised. For example, a group of patients who all experience severe anxieties about loss consequent to serious abandonment throughout their lives will work together in a group. On the other hand, mixing two or three such patients in a group of persons who are conflicted about intimacy and sustained relationships may well result in two subgroups that lack easy empathic rapport with the other's internal dilemmas. The specific symptom or population designation of other groups defines patient selection.

Contraindications Some patients cannot make good use of group therapy without former clinical intervention. For example, an actively manic patient may be more overstimulated than helped in a group. Another category of patients who frequently are referred to groups are severely schizoidal persons who have really never developed any kind of sustained human relationship. Placing these patients in a group overrides their capacity and may set them up for early failure. Acutely disturbed patients may need and deserve individual attention prior to entry into an ongoing therapy group. In all of these cases prior treatment—psychopharmacological, individual supportive therapy, or both—may enable the patient eventually to make good use of group therapy.

Preparing Patients for the Group Both anecdotal and empirical evidence indicates that investing significant time in preparing a patient for group therapy improves the chances of a successful entry into a group. In addition to the usual history taking, it is helpful to examine patients' fantasies and biases about groups and to collect the history of their participation in all kinds of groups such as family, school, sports, work, and friendships. This is the time to discuss the group agreements and the rationale that underlies them and to elicit the patient's collaboration in the enterprise by making as much information available as possible. Patients are helped by knowing how the group works, what the leader's role might be, and what they might expect for themselves.

WHAT HAPPENS IN GROUP THERAPY?

Basic Early Group Experience A major advantage in all psychotherapy groups is that patients enter a group and promptly “have” their problems instead of just talking about them. In attempting to get to know the other members of the group to feel a sense of belonging, people inevitably experience the emergence of the very conflicts that brought them to treatment in the first place. Thus, the phobic patient may find it difficult to come to the meetings, and the very needy patient may find that time sharing feels intolerable.

Most people enter therapy groups feeling that their problems are uniquely shameful and that their pathology sets them apart from competent human beings. Group members come to recognize that their problems are more similar than different from those of others in the group. As members increasingly feel accepted and cared about in the group, cohesion and universality promote the beginning of the therapeutic work for each patient.

Psychodynamic Group Therapy The fundamental principles of all psychodynamic treatment rest on eliciting and interpreting the transference and providing an opportunity to remember, repeat, and work through difficult experiences and introjects. It is assumed that these conflicts are primarily unconscious and that the unconscious is made conscious through the interpretation of the transference and replacement of the old bad objects with new good objects. In terms of ego psychology, archaic defenses are brought to light and interpreted so that new and more adaptive defenses may develop. Self psychology would suggest that the group serves as a self-object that offers a mirroring environment that can help each individual cope with empathic disappointments and emerge with a more cohesive sense of self.

Developmental Trajectory of a Group Bion and others since have been interested in mapping out the expected developmental trajectory of a therapy group and the expectable stages that evolve during that development. While numerous models have been offered, variations of the model set forth by Bion offer a clarifying way to understand the needs of the members in the early-, middle-, and late-stage group and to anticipate the developmental imperatives attendant to each stage. Since this is an epigenetic model, it applies most clearly to psychodynamic groups, but it may also be used to think about what happens in any group given the stage of engagement and the relative health and pathology of its members.

Group theorists have relied on certain developmental principles to organize and map out the trajectory of a group. Table 30.4-3 illustrates some of the developmental maps.

Early	Middle	Mature
Imperatives		
Establishing trust and dependency	Dealing with conflict: fight/flight	Establishing intimacy
Requisite processes		
1. Developing mourning	1. Splitting, projection, and projective identification	1. Increased capacity for empathy
2. Protection from undue humiliation	2. Reworking characterological problems	2. Capacity for concern
3. Nurturance	3. Managing interpersonal distance	3. Revisiting unresolved grief generated by healthy group termination
4. Early cohesion	4. Reworking guilt-ridden aspects of self	4. Hope and creativity increase
5. True cohesion	5. Moving from external to internal locus of control	5. Termination accompanied by sadness, excitement, and renewed vitality

Table 30.4-3 Trajectory of Group Development

STAGE 1 The developmental chart represents the ideal group development, in which early cohesion is established by a clear sense of meaning, often imbedded in

the group agreements. As the leader encourages a sense of respect, the members feel protected from undue humiliation or assault and can begin to experience nurturance from the group. The leader's group-as-a-whole interventions aid in this awareness of universality. It is common in the early group for members to say to a virtual stranger, “Why, we are really alike. I know exactly what you mean!” The early group senses that the power of the group is greater than the sum of its parts, and the group can proceed to the next stage of development.

STAGE 2 As the group begins to feel too much like a tight little island, relief from the fantasy of merger may come in the way of a split in which negative transference is directed at the leader. If the leader can welcome this development of the terrible 2s stage, the group can move on to the work of dealing with dissent, difference, and the resolution of archaic characterological ways of struggling with disappointment and bias. This is the stage of projective identifications and external locus of control, where the impulse to flee is most prevalent.

Projective Identification Recent theorists have emphasized the value and ubiquitousness of a primitive defense initially defined by Klein. Projective identification has come to be seen as one of the most powerful curative forces in a therapy group that provides the opportunity for each member to temporarily disown the more noxious aspects of the self by eliciting them in another. That other is a willing participant in this process, in exchange for similar favors. For example, a couple may be locked together in an illusion that one person is vulnerable and ill while the other person is only strong, helpful, and long-suffering. Each member in a sense is disowning the half of the self that is now invested in the other. In a sense this is a form of transiently psychotic transference in which the other is perceived as the container of badness and an impediment to one's growth and well-being. Each unconsciously splits off that unacceptable part of the self, thereby reducing each person's anxiety. In a therapy group, this illusion is difficult to maintain, since other competing attachments and perspectives from the members and the leader challenge the tenacity of the split. At best, this allows the work of analysis to proceed until persons are ready to reown the split-off parts of their personalities. This process of oscillating projections and introjections promotes increasing reintegration that smoothes the way for resolution of unconscious conflicts and neurotic traits.

Transference distortions give way to clearer relatedness with others in the here-and-now. The individual is now available for true intimacy with a separate though related other.

> Mr. R. and Ms. G. were members of a group that was deeply locked in fight-flight stages of development. Week after week, Mr. R. would rail at Ms. G. for whining instead of getting a job and, indeed, a life. She would typically burst into tears and finally threatened to leave the group if Mr. R. stayed in the group. This cycle was repeated so many times that the other members finally pointed out that for all they hated each other, they seemed unable to avoid locking horns week after week instead of dealing with other more sympathetic partners in the group. Eventually they called a truce and felt bereft, to their great surprise. Slowly they grew to know and recognize in each other what had been heretofore split off and denied in the self.

Over time, as group members reown their projections in the ensuing relatedness among members, their differences seem less threatening and actually come to represent a chance for expansion of the capacity to empathize with others without requiring that they be identical to the self.

STAGE 3 The mature group is characterized by a mutual concern among the members. As the members begin to accept the concept of good enough to replace the demands of perfection for self or others, intimacy is now possible in new measure. Usually, a member terminates at this stage, and that departure is an opportunity for all to revisit the areas of unresolved grief in their own lives. The movement from melancholia to greater completion of mourning results, as always, in a renewed sense of hope and increased creativity. Terminations are accompanied by a combination of sadness, excitement, and renewed vitality.

Resistance to Change The scenario above is idealized. In fact, many impediments arise in a group, which take the form of avoidance, resistance, and even early dropouts. However motivated, change is painful for all persons and it mobilizes the defenses in the service of maintaining the status quo, as the familiar devil we know. People mobilize their defenses and demonstrate their symptoms in the group. In the era of categorical diagnostic systems, it is difficult to remember that symptoms are compromise solutions to deeper problems, by which patients have tried to avoid being overwhelmed over the course of their lives. What has come to be called acting-out, with all its imbedded judgment, is nothing more than an opportunity to help patients in the group develop a deepening awareness of the cost of the archaic solution, as members confront each other while empathizing with the tempting solution of replacing words or feelings with distracting action. The pull to continue to feel cohesive with the peers in the group motivates the patient to tolerate the challenges and to seek new ways of dealing with difficult feelings and impulses.

Transference in Groups The standard target for psychoanalytic group treatment is the reawakening of early neurotic and characterological problems in the transference that emerges in the clinical hour. The emergence of repressed and avoided conflicts is facilitated by the multiplicity of transference targets and the powerful impact of the above-mentioned curative factors. As transferences develop from member to member, from member to leader, and from member to the group as a whole, people reexperience some of their earliest conflicts.

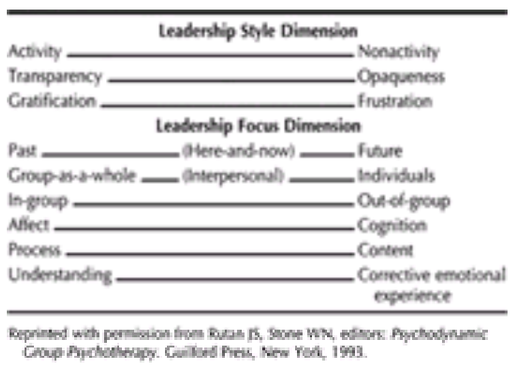
Defenses as Adaptation Resistance emerges and can be explored to illuminate the underlying defensive structure of each individual. With increasing safety, members regress to earlier defensive modes and arrive at increasing insight into the underlying personality dilemmas. These can then be experienced and analyzed in the group, by both the other members and the leader. Initially this process can feel shaming and threatening in a number of dimensions. However, with each event all members become more deeply aware of their own projections and displacements and can gradually reown those split-off parts of the self. When this happens the splits that had depleted the ego are healed, and psychic energy is made available for the conscious goals of the ego.

Self-Help Groups The emergent self-help movement has generated groups that differ from the above in a number of ways. Self-help groups are egalitarian and leaderless, focused on the principles of universality and unconditional positive regard, and open-ended and variable in their membership. Their goal is not necessarily to promote interaction among members; indeed, most discourage the kind of interpersonal discourse commonly found in the group therapies described above. The common enemy is the disease, and the common bond joins the members in resistance to succumbing to the ravages of that disease.

The Role of the Leader in The Group Before the group begins, the leader must make several decisions that have major implications for the whole enterprise. Beyond the obvious focus on the kind, duration, and theoretical underpinnings, the leader must then decide on matters of:

1. Membership
2. Logistics, such as place, time, and fees
3. Whether to work alone, or with a cotherapist
4. Whether patients will be treated in group therapy alone or in some combination of group therapy, individual therapy, pharmacotherapy, or self-help group
5. Managing records and protecting confidentiality

In addition to the logistical decisions listed above, the leader's stance must be consistent with the goals of the group. Leaders of a psychodynamic open-ended group are probably more likely to sit back and allow the group associations to lead the way for the group's work while they comment, like a critic at a concert. On the other hand, this stance makes little sense for the leader of a cognitive-behavioral group, who will be engaged in conducting desensitization exercises and providing cognitive restructuring, including homework exercises to meet the goals of that therapeutic endeavor. The range of clinical stances related to leader and group variables is illustrated in Table 30.4-4.



Leadership Style Dimension		
Activity		Nonactivity
Transparency		Opaqueness
Gratification		Frustration
Leadership Focus Dimension		
Past	(Here-and-now)	Future
Group-as-a-whole	(Interpersonal)	Individuals
In-group		Out-of-group
Affect		Cognition
Process		Content
Understanding		Corrective emotional experience

Table 30.4-4 Leader Dimensions of the Group Therapist

Authority and Group Leadership A group leader must exercise authority about all the above factors if the group is to be safe and containing for its members. Whether a member who is difficult in the group stays or leaves or whether a new member enters must not be left to a vote, no more than it is in a family. The privilege and burden of administrative and matters of inclusion and exclusion is a serious responsibility of the group leader as is the question of single or cotherapy leadership. The leader is not a member of the group, despite the ambivalent entreaties of the members to bring the leader into the group, any more than the group is a democracy. The clearer the leader is about the boundaries, the safer are the members to indulge all the fantasies of wanting to corrupt the process or overcome the leader's authority.

> Dr. R.'s group had recently been decimated by the premature departure of a very difficult patient who, it turned out, had also been attending another group at the same time and decided to go with “the better one.” The group was furious and told her so, but she left after citing their anger as proof of the inferiority of the group and the leader. The following week, the group learned that Mr. T., a long-standing and much loved member, had cancer and would have to be away periodically for treatments. The group was adamant that the leader should not fill the departed patient's chair, and in fact they voted to make the group a six-member group, challenging the leader to deal with his distress in the group as well, if indeed he was not a “cold fish.” He resisted their entreaties and at the same time remained empathic toward their wishes. Eventually, he did introduce a new member who settled in nicely, and the group proceeded. Had the leader succumbed to the break in the group frame, this group would have felt deeply threatened and ineptly held.

The fiduciary responsibilities of the leader are better maintained to the extent that the leader exercises restraint and relative neutrality in the sense of nonjudgmental listening and responding to the patient's struggles. By remaining warm and neutral, the leader can listen nonjudgmentally to all aspects of the whole group's impulses and resistance, without taking sides or carrying the burden of somehow policing the group and deciding which are good feelings and interactions and which are not.

Incorruptibility of the Leader In the therapy group, as in any therapeutic work, the leader must remain as pure as Caesar's wife. No dual roles, no overly familiar incursions into the members' personal lives (nor theirs into the leader's), and no special fee arrangements that are not in the awareness of the group can be tolerated without damaging the integrity of the group boundaries. In short, all group business that cannot be conducted in the group ought not to be conducted at all. Refusal to hold secret any extragroup contacts sets a fine model that says the group is the safe therapeutic agent.

Question of Cotherapy As in many clinical decisions, the question of leading alone or with a colleague depends in part on the model, in part on the context and setting, in part on the availability of an appropriate cotherapist, and the system's support, administrative and otherwise, for committing two professionals to the same task at the same time. Inpatient or partial hospitalization groups tend to meet several times a week, and for those groups, cotherapy is a useful way to ensure continuity of leadership. On the other hand, some analytic group leaders avoid cotherapy because of the splitting of the patient-to-leader transferences. There are no rigid rules, but certain caveats must be observed.

Cotherapists work best when:

1. They are truly cotherapists, of relatively equal status and experience. When a student and a supervisor work together, it is useful to acknowledge this reality.
2. They share a common theory base.
3. They are willing to dedicate an hour or so per week to working out their collaborative problems and their perceptions of the group.
4. They are comfortable in sharing the fee.

Failure to observe these agreements may leave the patients low on the priority list of therapeutic concern while the cotherapy pair compete or otherwise undercut one another. On the more positive side, when cotherapy works well, both clinicians and patients have the advantage of two professional heads and hearts working in concert for the benefit of all.

Benefits for the Group Leader Groups can function as a hall of mirrors, reflecting some aspects of each member including those that are out of awareness. Benefits that accrue to the members from this expansion of self-awareness also accrue to the leader. If knowledge is power and psychological knowledge empowers the individual to lead a better life, then the knowledge of self can increase the leader's personal and professional depth as well. It remains a truism that it is always a race between the patient and the therapist as to who cures whom first. This is eight times truer in a cohesive and well-functioning group. The leader of a group is in a position to develop vicariously each time a member works through another of the universal dilemmas that make up the human experience. In the same vein, the not-so-central role of the leader in a group can be a wholesome and humbling reminder of the innate capacity of the patients to find healing in themselves and in one another, thereby mitigating godlike fantasies in the group toward the leader, and in leaders toward themselves.

Stumbling Blocks for the Group Leader Given the clear clinical advantages of leading therapy groups in the fiscal climate of the late 1990s, it is intriguing to wonder why the option remains difficult for many clinicians. On closer scrutiny, however, a number of potentially daunting reasons can explain this reluctance. Some have to do with the leadership process itself, others concern training for conducting groups, and still others relate to the context of clinicians, and whether they can gather enough referrals to sustain a group practice. The countertransferential pulls on the leader are geometrically increased in a group, just as the power of the multiple transferences have a major impact on the members.

WITHIN THE GROUP The group leader's mistakes are always open to the scrutiny of the whole group. When the members are encouraged to be honest and critical toward one another, the leaders can hardly do less about their personal or professional gaffes.

> Dr. X. announced to her group that they had about 5 minutes left today. The members pointed out that in fact there were 35 minutes left to the session. Dr. X. had nowhere to hide and needed to explore, in the group and later with her consultants, what had led her to want to curtail the session. She came to realize that the group was deeply involved in matters of grief that were currently relevant to her own life and that she had suppressed during the meeting. She then needed to find ways to say some of this to the group without generating a situation in which they felt they needed to care for the leader before they could go back to expecting care for their own concerns.

HELPLESSNESS Confronted with the sense of despair that may be resonating in several members of a troubled group, leaders may find themselves feeling helpless and of little use to the group. For example, some abbreviated treatments mandated for seriously disturbed patients may challenge any clinician's hope and optimism. If the group leader is also personally threatened by rescue fantasies, the group can only amplify the sense of clinical futility.

A group leader is always the target of a set of transferences, whether or not the work is psychodynamic and whether or not the group focuses consciously on managing and interpreting the transferences. It may be more challenging to avoid taking personally the cumulative mistrust, anger, or idealization for that matter, especially at times in the leader's life when loved ones are missing or when work is a source of difficulty. The pull of the group cohesion is powerful, and it is not uncommon for leaders to look at a departing, well-functioning group and wish that they were a member of that group, rather than the leader.

Another set of internal problems arise when the therapist needs to feel in control of the treatment situation. The dyadic model allows at least the fantasy of the therapist being in control, whereas in the group, especially an open-ended psychodynamic group, the members and the group as a whole move the process along, while the leader accompanies and shepherds it, at most.

Inadequacy of Training In most training programs, group training remains minimal, the common assumption being that clinical training is somehow generic and what works for individual therapy will serve as well for group treatment. This failure to take seriously a whole body of theory and research can leave the clinician at sea about how to even think about initiating a group, let alone learning how to manage impasses when they occur.

In fact, many training programs have curtailed or even eliminated the experience group for their trainees that gives them a taste for group process. Indeed, in some cases the training group may be conducted in ways that traumatize rather than support the trainees; when that happens the likelihood of trainees moving on to conduct their own groups is low.

Since most clinicians still enter individual treatment first for their own problems and self-awareness, the stage is set early for perceiving group therapy as second-rate treatment. At the same time they experience the pressures from the work environment to care for their patients in groups, which tends to generate anxiety and

disparage the modality, with little good experience on which to base those judgments.

Opportunities for Further Training The whole field of mental health has so expanded that typically, even the best training programs afford far too little time to learn to be an expert in anything. Across the United States and in other countries as well, training programs have sprung up that provide full postgraduate training, and some meet the criteria for membership in the National Registry for the Certification of Group Therapists. Affiliates of the American Group Psychotherapy Association typically offer training opportunities, as do other continuing education centers, some free standing and some affiliated with teaching hospitals. Given the parsimony of group treatment and the pressures on the mental health dollar, such training can more than pay for itself in many dimensions, both professionally and financially.

Work Context Leaders of therapy groups need to ensure enough referrals to keep the groups populated, with enough confidence to remain calm in the face of real or fantasied departure of one or more members. Thus, the need to join organizations that acknowledge the clinician as a competent group therapist or otherwise place the group in the awareness of potential patients and referrers is of paramount importance. In addition, it is most useful to meet regularly with a group of like-minded colleagues who will help each clinician stay invested in the difficult early stages of group formation.

GROUP THERAPY COMBINED WITH INDIVIDUAL THERAPY

Occasionally, patients are treated in simultaneous individual and group therapy, either by the same therapist or by two different ones. This option is useful for a variety of patients.

Overintellectualized Patient For some patients, insight becomes a way to avoid feeling. When it does, placing these patients in a therapy group lets them see how they interact with others who offer feedback and affective resonance.

> Mr. N. was referred for group treatment by his analyst, who felt the analysis was stalled. Indeed, Mr. N. appeared to know himself quite well, at least intellectually. In the group, he presented a seamless “case history” of himself, retelling a tragic childhood with calm and equanimity. One of the other patients began to weep as he spoke, recognizing similarities in her own life. Another expressed doubt about how cool Mr. N. was when presenting apparently very private material to a group of strangers and doubted that he was affectively present in the narrative. Mr. N. was at first startled, then reacted by assuming that they had not yet worked through their feelings as he had. The group gently confronted him with this assumption, and eventually he became more in touch with his intense affect, which had been blunted in the dyadic transference lock with his analyst. Both treatments proceeded successfully to a happy termination.

Patients who Cannot Tolerate the Dyadic Transference of Individual Treatment Dyadic treatment can threaten the fragile ego boundaries of patients who are either very needy or who are overstimulated by the apparent promises of the individual work. These patients often flee treatment or regress to terrifying actions that can be life threatening in near psychotic levels of transference. Adding group therapy can distribute the transferences across all the members of the group and the group leader and may enable the individual and the group treatment to proceed more safely and more productively.

> Ms. B. was referred to group treatment after her fifth serious suicide attempt; each of these had occurred during the absence of her individual therapist. She came to the group most reluctantly, fearful that she was going to be dropped off in the group and abandoned. She viewed the group leader with much distrust but found two or three members of the group who could empathize with her plight, many of whom had also suffered similar self-destructive incidents and could help her move away from taking action. Her presence in the group was stormy and embattled for years, finally ending with her becoming a strong proponent of group treatment. Notably, she was never hospitalized after joining the group. Finally, she concluded her individual work and remained in the group with the full agreement of both therapists.

Collaboration Between the Two Therapists In the case of Ms. B., it was crucial that the two therapists collaborate by frequent phone calls and by avoiding her many attempts to split them. This was possible because they had a similar level of experience and shared a parallel view of her strength and pathology. When two therapists do not agree or do not respect one another's work, patients are potentially at great risk of harm to themselves or at least in a stalemate of iatrogenic origin.

Combined Treatment With the Same Therapist Patients are sometimes seen both in individual and group therapy with the same therapist. This treatment plan has many advantages and, as always, some costs.

It is illuminating to deal with the intrapsychic dimensions of a patient in the individual hour and then observe this patient express those internal dilemmas and live them out in interactions with members of the group. For example, mild and extremely gentle individual patients might startle their therapists by launching an aggressive attack on one or more members of the group when the shy facade is challenged.

For some patients, however, sharing the therapist's attention can be so distressing that the work of therapy is stalled. It may be far better for that patient to be referred to another leader's group or to defer group treatment to a more secure time.

Boundaries in Combined Treatment Clinicians struggle with how much to preserve the privacy of what they know about the patient from the dyadic hour when the patient enters the group and how much to disclose. While there are no hard and fast rules here, what matters is consistency and the prior agreement with the patient about this matter. Many clinicians opt to protect the information while urging the patient to bring the problems into the group. One major exception is the case where the group or one of its members is at risk; as usual, the rules of confidentiality are suspended when there is any threat to the safety of any of the participants. It is useful to agree that all treaters will be in regular contact with one another to work for the patient's advantage.

LEGAL AND ETHICAL ISSUES

Confidentiality and the Leader The group leader is bound by the usual rules of confidentiality in the group as in any other clinical encounter with the patient. With the exception of a threat to a person or persons, this confidentiality holds and is usually elaborated in the code of ethics of the therapist's professional organization. The same obtains for any conduct of the therapist that violates the code of ethics relative to sexual or other extraprofessional contact with a patient.

Confidentiality and Group Members The bigger challenge is confidentiality among members. Aside from stressing the importance of protecting the identities of patients in the group, the leader can do little to ensure compliance, nor is it against the law for members to break confidentiality. Group therapists worry about whether the group can become a pool of witnesses in the case of a subpoena. Some states extend the same protection to the members that they do to the leader (namely, the patient-therapist privilege), but this has not been tested and may not apply with all professionals across the disciplines.

RESEARCH AND EVALUATION

Group therapy research has tended to focus on outcome and prediction. More recently, measures have been developed that seek to relate the patient's sense of belonging and feeling valued in the group with the effectiveness of the treatment. Studies continue to support the importance of group cohesion on group effectiveness, and feeling valued is seen as a statement of cohesion. The research literature indicates greater confidence in the efficacy of group treatment, showing no appreciable difference between individual, group, or pharmacotherapy. But these studies remain problematic, given the problems that bedevil most social science research: it is difficult to control therapist differences, and attempts to do so by providing manuals for intervention become different models than those in real life. The nonspecific factors are elusive, but they still seem to indicate that patients progress when they feel cared about, when the leader is warm and somewhat structured, when the match with colleagues in the group is appropriate, and when the goal and direction of the group are clear and consistent.

Researchers have tended to move beyond the question of do groups work to a finer look at how they work, in what circumstances, and for whom. Proper and careful screening and otherwise preparing a patient to enter a group results in a greater chance of success in entering and staying. As stated earlier, groups in which the members are at about the same level of ego development do better than groups with a large disparity of ego development levels. Short-term, focused groups are more successful if leaders have structured agendas and time boundaries and if the patients are more homogeneous in regard to the problem being addressed.

Research instruments are proving useful for measuring patient satisfaction and self-reports of increased well-being. The Clinical Outcome Results battery developed by the American Group Psychotherapy Association is but one example and it uses such measures as the Symptom Checklist 90-Revised (SCL-90-R), the Social

Adjustment Scale Self Report (SAS-SR), the Multiple Affect Adjective Check List-Revised (MAACL-R) and the Global Assessment Scale (GAS). More recently, measures such as the Structured Analysis of Social Behavior and the Group Climate Questionnaire (GCQ) have been used extensively by MacKenzie and others working with patients in structured, time-limited groups.

A major shortcoming in group therapy research stems from the pragmatics of conducting research over a long time, with more amorphous goals. Thus, most data are derived from research on time-limited groups, usually within the cognitive-behavioral or interpersonal model. While those findings are important, they have limited applicability to the more open-ended dynamic models of group treatment. That research remains to be enlarged.

CONSULTATION AND SUPERVISION FOR GROUP THERAPY

It is often difficult for group leaders to ask for help, as it is difficult for most professional helpers, especially beyond the formal training years. But failure to find help in group leadership can expand the strain on the leader exponentially, given the number of people in the consultation room and the multiplicity of counter-transference vectors. A well-running group can look deceptively autonomous of the leader's impact, but the leader's calmness and full attention is the platform on which the group grows. Occasional consultations, ongoing peer supervision, or both, are safe, judicious practices. It also allows leaders to take advantage of their affiliative needs, to avoid using the patient group for dealing with the loneliness of the well-functioning group leader.

SUGGESTED CROSS-REFERENCES

Additional discussion of the conceptual models used in group psychotherapy appears in Chapter 6 on theories of psychoanalysis and on other psychodynamic schools and on approaches derived from psychology and philosophy. More information about the clinical application of those models is located in Section 30.1 on psychoanalysis and psychoanalytic psychotherapy, Section 30.2 on behavior therapy, Section 30.6 on cognitive therapy, and Section 30.8 on brief psychotherapy. Further elaboration about psychiatric emergencies is found in Chapter 29. Detailed descriptions and backgrounds about the special patient populations and self-help groups are in Chapter 11 on substance-related disorders, Chapter 12 on schizophrenia, Section 13.2 on delusional disorders, Chapter 14 on mood disorders, Chapter 15 on anxiety disorders, and Chapter 16 on somatoform disorders. Elaboration about other population groups for which group therapy has been used can be found in Chapter 25 on psychological factors affecting medical condition (psychosomatic disorders), Chapter 24 on personality disorders, Section 51.2c on the psychological aspects of aging, Section 51.3 on the psychiatric disorders of late life, and Section 51.4l on group therapy with the elderly.

30.5 FAMILY THERAPY AND COUPLE THERAPY

ALAN S. GURMAN, PH.D. AND JAY L. LEBOW, PH.D.

Family and couple therapy is a rubric that subsumes a large number of therapeutic forms, varying widely in their theoretical foundations, structure and process, and treatment aims. Family-couple therapy has been defined as “any psychotherapeutic endeavor that explicitly focuses on altering the interactions between or among family members and seeks to improve the functioning of the family as an amount, or its subsystems, and/or the functioning of individual members of the family.” These family and couple therapies have been used in the treatment of disordered individuals as well as dysfunctional relationships, across all developmental levels, and with a broad range of family structures. *Couple therapy* has recently come to replace the more familiar and limiting term *marital therapy* because of its emphasis on the link and bond between two people, without the associated judgmental tone of social value implied by the more traditional term. Although couple therapy is generally viewed as a subtype of family therapy, the majority of influential clinical theoreticians in the family realm have in fact infrequently focused on the treatment of conflictual couples' marriages.

Table 30.5-1 presents the major approaches to family and couple therapy in terms of central concepts, typical goals, and commonly used strategies and techniques and offers brief comments on each method's current status. While the schools of family and couple therapy are at times subdivided into problem-solving and transgenerational types, there has been so much cross-fertilization among them since the late 1980s that such distinctions are now more apparent than real. Also, there is significant historical and conceptual overlap among many of these thirteen approaches. Nonetheless, each therapy approach holds a unique place in the broader field. Some family and couple therapy methods involve logical extensions of therapeutic work with individuals whereas others clearly either have anti-individual therapy origins, or at least arose outside traditional treatment settings. Family and couple therapy approaches are at least as varied as individual approaches in terms of such central organizing principles as length, temporal focus, intrapersonal versus interpersonal emphasis, typical goals, and views on the role and stance of the therapist. In addition, highly specialized family and couple intervention methods have been developed for clinical populations with a wide range of common presenting problems, for example, infidelity, divorce and remarriage, abuse and violence, sexual dysfunction, and chronic illness.

Table 30.5-1 Major Approaches to Family and Couple Therapy

HISTORY

Contemporary family and couple therapy has varied historical roots, including the fields of group dynamics, family life education, gynecological medicine, sexology, social casework, and psychoanalysis. Couple or marital therapy traces its roots rather independently to the earlier marriage counseling tradition, spearheaded in the late 1920s and 1930s by such famous clinics as the Marriage Council of Philadelphia, the Marriage Consultation Center in New York, the American Institute of Family Relations in Los Angeles, and the Marriage Guidance Council centers in the United Kingdom. Emerging in the next two decades were the *collaborative* (two therapists) and *concurrent* (same therapist) husband-and-wife psychoanalysis and the more radical *conjoint marital therapy* (the partners meet with the same therapist together). Such inclusion of spouses in treatment showed the earliest recognition that problematic family interaction patterns maintain what is purportedly individual psychopathology, and that intervention with symptomatic individuals is often inadequate to the therapeutic task.

The major accelerant of the dominant theories of modern family therapy, however, was the rapid and independent emergence in the late 1940s and 1950s of clinical and research interest in the multigenerational transmission and reinforcement processes involved in various psychiatric disturbances, especially psychoses and schizophrenia. Nathan Ackerman and Salvador Minuchin's groundbreaking family work with child- and adolescent-focused problems began in the same general period, and Ivan Boszyormenyi-Nagy and James Framo brought the ideas of intergenerational psychodynamics to the forefront. Although a large number of the early family therapy pioneers were psychiatrists, innovators from other professions were also highly visible in this rapidly growing field, for example, John Bell and Framo (clinical psychology), Haley (communications), and Virginia Satir (social work). Even anthropological (Gregory Bateson) and hypnotherapeutic (Milton Erickson) perspectives helped to establish the early foundations of the family therapy movement. Interestingly, a great deal of early conceptual work in family therapy occurred in clinical research settings. Regardless of substantive focus or work context, however, what all the first-generation family therapists had in common were a passionate questioning of the dominant individual models (primarily psychoanalytic) of problem development, maintenance, and treatment, and an assertion of the explanatory power of thinking in terms of circular versus linear causality. The conceptual fervor that characterized such systemic truth-seeking was often associated with a rather close-minded dismissal of extant views of mental health intervention.

The 1960s saw several groundbreaking professional conferences in the field and the founding of what were to become influential training institutes. The first family therapy journal, *Family Process*, was inaugurated in 1962, opening a new era for the field by giving it a home journal whose board of directors and editorial board included almost all the luminaries of the day.

The 1970s was a period of major expansion in the field, both conceptually and organizationally. By this time, the vast majority of currently influential approaches to family and couple therapy had become established in a variety of training centers, both free-standing and university-based. Schools of therapy proliferated, and some of the energy that had previously been put into the conceptual battle with mainstream mental health perspectives was redirected across scholastic lines. Organizationally, two major events in American family and couple therapy took place. In 1978, the American Association of Marriage and Family Counselors (AAMFC), formerly the American Association of Marriage Counselors, changed its name to the American Association for Marriage and Family Therapy (AAMFT) and soon became the official accrediting and credentialing body in the field. In 1978 the American Family Therapy Association, now American Family Therapy Academy (AFTA), was founded by most of the early pioneers in the field and originally consisted of many senior clinicians and researchers.

The 1980s and 1990s have witnessed four major patterns of continuing interest and influence in the field of family and couple therapy. First, there has been an extraordinary explosion in the professional literature, with the appearance annually of dozens of new books, and the creation of more than three dozen journals spanning all five continents and published in almost a dozen different languages. Second, research activity has rapidly evolved due in part to the growth of family psychology, focusing a good deal on comparative treatment outcome studies and the treatment of diagnosable psychiatric disorders as well as explicitly relational difficulties. Third, the field has begun to embrace a variety of perspectives on relational functioning, such as those based in feminism and multiculturalism, that have broadened the conceptual and perceptual lenses of the human condition beyond those typically set forth by the dominant and traditional mental health points of view. Also, having established a pervasive footing throughout the world of psychotherapy, the field of family and couple therapy has become increasingly integrative. This integration movement, which followed a parallel movement in the domain of individual psychotherapy, has brought together purportedly incompatible theories of family or couple interaction and intervention and has coordinated interventions at multiple levels of behavior and experience, for example, intrapsychic, interpersonal, and

biological. In these ways the field has become more consistently and genuinely systemic and contextual.

Theoretical Issues The defining and distinguishing conceptual characteristics of family-couple therapists, regardless of their theoretical allegiances (Table 30.5-1) is their emphasis on the context in which clinically relevant behavior occurs. While more strident family therapy theoreticians and clinicians may restrict their vision to the realm of human interaction, an ecumenical attitude is more typical of systemically oriented clinicians. As a result, intrapsychic processes (especially conscious and preconscious) of individuals are not seen as beyond the purview of family-oriented therapists, and clinically relevant biological phenomena are seen as factors that are potentially as relevant to treatment as any others in the given clinical case. In contrast to the conceptual extremism that has at times characterized some leaders in the family and couple field, the arbitrary punctuation of understanding human experience is not consonant with effective and responsible systems-oriented psychotherapy.

Family Systems Theory Much of the newer orientation to a family systems view of clinical problem formation and treatment derives from a mixture of ideas from *general systems theory* (the study of the relationships between and among interacting components of a system that exists over time) and *cybernetics* (the study of systemic regulatory mechanisms that operate via feedback loops). A third major orienting perspective in family systems theory is that of *family development* (the family life cycle). The first two of these frameworks did not originate in the study of human behavior per se, and so are typically used metaphorically in discussing clinical events and processes. More human-level theories, especially those emphasizing psychodynamic and social learning principles, have also had a pervasive influence on the field.

CLINICAL IMPLICATIONS OF FAMILY SYSTEMS THEORY Family systems thinking is *antireductionistic* (wholeness, organization). The notion that the whole is greater than the sum of its parts (*nonsummativity*) implies the inappropriateness of trying to understand individuals (e.g., symptoms, problems, behavior) apart from their relational situation. Thus, “crazy,” “maladaptive,” or “dysfunctional” behavior often makes sense when viewed contextually within the framework of the social (family) system at hand. As a result, the role of the identified (or index) patient in the family can be varied. One member's difficulties may regulate problematic underlying family patterns, may itself be a major source of stress on the family, or may be a consequence of relationship conflict. Moreover, since there is no objective truth that best describes any clinical situation (“the map is not the territory”), multiple vantage points are valued (*constructivism*). Direct observation of family and couple interaction by the therapist is therefore complementary to patient reports. Although individual psychotherapy within a family systems perspective is certainly done, the preferred clinical mode of interviewing and intervening is with all (sub) “systems of import.”

Family life is viewed as a continuous balanced (*homeostatic*) process of adaptive change (*morphogenesis*) and maintenance of stability (*morphostasis*). To maintain its organizational identity, the structure of this social system must be flexible (*open system*) yet predictable (e.g., hierarchies, boundaries), so that the most salient requirements of the group family roles are satisfied. *Normality* and *pathology* are relativistic concepts in family systems thinking, and are contingent upon particular cultural practices and beliefs and the requirements of both individuals and other family units (*subsystems*) at different and relatively predictable stages of development (*family life cycle*).

In family systems thinking, focusing on the current organization of the family is often though not always viewed as a sufficient data base with which to intervene (“the system is its own best explanation”). Since it is assumed that an individual and a family or couple may have traveled a variety of etiological routes to the same point (*equifinality*), history-taking during the assessment phase of therapy is often minimal, and exploration of the past is not a dominant facet of many courses of family and couple therapy (although some methods do emphasize such investigation— Table 30.5-1). “What?” questions are as likely as “why?” questions. Family members and others may unwittingly reinforce the very problematic patterns that are of concern (collusion, quid pro quo, family rules) and the therapist's strategic and technical options are increased because change in any one part of the system may lead to change in other parts (feedback loops, circular causality). The essential intervention principle derived from family systems thinking is to place primary effort into blocking, disrupting, and replacing repeated sequences of interaction that maintain the clinical problems of interest, whether of an individual or relationship nature.

Techniques As is true of individual psychotherapy, the field of family and couple therapy includes an extraordinary array of both disparate and overlapping strategies and techniques. This vast landscape of clinical approaches can be addressed in two complementary ways. First, the variety of salient ideas and methods is sampled, and then descriptions are offered of typical or modal styles of clinical practice. Four aspects of the therapeutic experience are considered in this manner: the structure and composition of therapy, the role of the therapist, goal-setting and assessment, and specific clinical techniques.

Structure and Composition of Therapy In family therapy the question of who participates produces many answers. On the patient or client side, the complainant or “customer” (who may or may not be a patient in psychiatric or diagnostic terms) is always included. And while the patient (note that one may not be designated when a relationship is “the patient”) is typically present, this is not always the case, for example, a child-focused family treatment may regularly exclude the child from sessions with the parents that are focused on parenting skills, marital conflict, and other areas of concern. Family therapy may be conducted with one patient or client present (e.g., Bowen family systems therapy, Mental Research Institute brief therapy), may be limited to the nuclear family (e.g., behavioral, psychoanalytic), or may even be transgenerational (e.g., structural, symbolic-experimental): combined therapies (e.g., individual and family) are more common than is reflected in the literature. In everyday practice those included (other than the therapist) are whoever is thought to constitute the *systems of import,* which sustain the problem or may help to resolve it; the problem is usually operationally defined as the “minimum sufficient network” to be likely to achieve the desired therapeutic goals. Relevant systems may include nonfamily members such as other health care providers, school teachers, and representatives of various community agencies.

Most family therapy is conducted by a single therapist, though co-therapy (especially of one male and one female therapist) is somewhat common in training centers, and is even preferred in some family therapy approaches (e.g., contextual, symbolic-experiential). Moreover, therapeutic teams of several clinicians, usually comprised of the actual treating therapist and some number of colleague observer-consultants (behind a one-way mirror), are highly valued in certain models (e.g., Milan systemic, strategic, structural), especially in training institutes.

The length of family therapy ranges from ideal courses of fewer than ten visits (e.g., Mental Research Institute brief therapy, solution-focused) to up to dozens of visits (e.g., Bowen family systems) or even hundreds (e.g., psychoanalytic) over several years. Family therapy is generally quite brief by traditional standards of length in individual therapy, even when it is not explicitly time-limited (which is not the usual case), with most family and couple therapy lasting 10 to 20 sessions over a period of less than 6 months. Family therapy is typically conducted in private offices and clinics but not uncommonly takes place on hospital wards and even in family homes.

Role of the Therapist The therapist's role in family and couple therapy varies along several dimensions, most noticeably in terms of emotional closeness or distance to the family or couple. Three gross categories of the therapist's emotional proximity can be discerned: the educator-coach, the perturbator, and the healer. These fundamental relational stances vary as a function, for example, of the degree to which therapists intentionally and systematically uses his or her “self” (e.g., by self-disclosure of fantasy material, personal or countertransfertential reactions, or factual information), and explicitly addresses the nature and meaning of the therapist-family member relationship (e.g., transference analysis). The therapist as educator-coach (e.g., behavioral, Bowen Family Systems, Psychoeducational) sees him/herself as possessing expert, professional knowledge about human relationships and change processes, and attempts to impart such knowledge to the couple and families with whom he or she works as a basis for inducing change. The family therapist as perturbator (e.g., Mental Research Institute brief therapy, narrative, strategic, solution-focused) possesses expert understanding of problematic family processes, but tends to use this awareness from an outside stance to induce change in the family system without giving family members information, concepts, or methods they can take away from therapy for future use. The family therapist as healer (experiential-humanistic, psychoanalytic, transgenerational) places special value on the transformative power of personal relationships.

Despite such a divergence of views on the stance of the family therapist, it is widely agreed that a working therapeutic alliance is essential for effective therapy even though such a collaborative relationship is established in different ways in different therapeutic approaches. In everyday practice it is also often the case that therapeutic alliances need to be established in different ways with different family members, for example, one may respond well to empathic understanding from the therapist, whereas another may not begin to form a working alliance unless the therapist offers guidance and concrete suggestions. The therapist needs to track recurrent family and couple interaction patterns that maintain relational or symptomatic problems without inflexibly siding with any individual or other subsystem against others, although temporarily taking sides to unbalance fixed relational structures is often necessary.

Assessment and Goal-Setting Predictably, different family theoretical orientations emphasize different treatment goals, and thus involve different assessment foci. Since all family and couple therapies are concerned with interactional problem-maintaining cycles, the issue raised earlier about who should be included in ongoing treatment should always be assessed early. It is not unusual for initial assessment to include people who may be discharged from most or all of ongoing treatment, especially in child- or adolescent–focused cases. Marital therapy cases less commonly involve multiple generations, although family-of-origin sessions with the partners' parents are a possibility, and the partners' children are occasionally included, for example, if parenting problems coexist with couple problems.

ASSESSMENT METHODS The methods of family therapy assessment vary. Self-report paper-and-pencil methods are commonly used in behavior therapy for standardized measures (e.g., child behavior checklists) and for case-specific monitoring related to particular patient or family treatment aims (e.g., establishing

baseline measures of the frequency of problem behavior). Couple therapists not infrequently also use self-report inventories to help assess overall marital satisfaction as well as common areas of couple conflict. Genograms are often used in multigenerationally oriented methods to help the clinician and the family discern cross-generational patterns of maladaptive functioning. Finally, direct observational methods involving various microanalytic coding schema are occasionally used, especially in academic settings, but are too labor intensive to be used regularly in clinical practice.

The clinical interview is the major vehicle for assessment. It is often difficult for even a reasonably sophisticated observer to identify the theoretical orientation of family therapists during the opening stage of therapy in that therapists' interventions are often less discrepant than their conceptualizations of what they experience and observe. Nonetheless, therapists of different theoretical schools can be rather reliably differentiated in terms of the levels of assessment upon which they focus. Two such levels may be identified: the unit level, and the experiential level. The *unit level* is the composition of the psychosocial unit of evaluative interest. The individual (identified patient or others), the marriage or couple, the parental subsystem, the sibling subsystem, the whole family, and the family-plus-nonnuclear family social entities (e.g., grandparental subsystem, school system) may all be given careful attention. More psychodynamic, experiential-humanistic, and intergenerationally inclined therapists tend to be interested in assessing the potential treatment planning role (even if only by reference, rather than face-to-face) of a larger number of units whereas more pragmatic orientations focused on resolution of presenting problems (e.g., behavioral, psychoeducational, strategic) tend to assess a less complex array of these units. The *experiential level* refers to the level of organization at which assessment occurs (e.g., molecular, biological, unconscious, conscious, interpersonal, transpersonal). Therapists also differ on the related dimension of past versus present centeredness. The more pragmatic therapists (who focus more on presenting problems and teachable therapeutic techniques such as Behavioral, Psychoeducational, Mental Research Institute brief therapy, strategic, and structural tend to show little to no significant interest in either unconscious psychological processes or the family's or its individual members' past. More aesthetically oriented therapists (e.g., psychoanalytic, contextual, humanistic, symbolic-experiential), by contrast, who tend to espouse a more relationship-based style of intervention in which the “real” problem is believed initially to be hidden are more attuned to psychological events that are not so immediate. Indeed, such therapists' assessments tend to emphasize inference whereas the more pragmatic therapists' assessments tend to emphasize observation.

GOAL-SETTING Different theoretical orientations to family and couple therapy will emphasize different types of typical goals (Table 30.5-1) in line with their differing views of symptom-formation and symptom-maintenance and the role of the therapist. Most family- and couple-oriented therapists endorse many or most of the following goals, regardless of the particular nature of the presenting problem: (1) reduction of psychiatric symptoms, or when such symptoms are not present or dominant, reduction of other presenting problem behavior or experience, especially in relation to interactional patterns that maintain the problem(s); (2) increased family and couple resourcefulness, for example, improved communication, problem-solving and conflict resolution skill, enhanced coping skill and adaptability; (3) improvement in the fulfillment of individual psychological needs for attachment, cohesion, and intimacy; increased trust and equitability; enhanced capacity to foster the development of individual family members; (4) increased family ability to interact effectively with important larger social systems; and (5) increased awareness and understanding of how couples' and families' patterns of interaction influence the group's everyday effectiveness in living as well as how such patterns affect and are affected by the psychological health and satisfaction of individuals.

Within some influential approaches to family therapy (e.g., Bowen family systems, contextual, symbolic experiential), certain goals are considered virtually universal, that is they are relevant in all cases regardless of differences between families or couples. In several other widely practiced approaches (e.g., Mental Research Institute brief therapy, strategic, narrative, solution-focused) such universal treatment aims are almost never invoked, as each clinical case is viewed as a sort of unique experiment. In the former case symptoms and presenting problems are often seen as signs of and metaphors for dysfunction elsewhere in the family system whereas in the latter such difficulties and concerns tend to be taken more or less at face value.

The treatment goals largely involve the *ultimate goals* of treatment, that is, desired end-states. In addition, a variety of *mediating goals* arise in the various family therapy approaches. *Mediating* goals are of a shorter-term nature and include change in psychological processes that an individual, couple, or family must undergo in order to reach their own or their therapist's treatment objectives. These are sometimes referred to as process goals. Common forms of such mediating or process goals are achievement of interactional (dyadic) or genetic (multigenerational) insight; the teaching of various interpersonal skills, for example, communication and problem-solving; and the disruption of interlocking pathologies or blocking of rigid symptom- or problem-maintaining patterns of behavior to allow opportunities to experiment with more adaptive responses. Mediating goals may also be more abstract and are not necessarily made explicit to families by the therapist.

Finally, it is important to appreciate that treatment goals are not always explicitly negotiated in family or other methods of therapy. Mediating goals in a wide variety of approaches are particularly unlikely to be discussed between the family and therapist, and ultimate goals also vary in the degree of overt, concrete discussion they receive across the more than one dozen influential methods of family and couple therapy.

Techniques of Family and Couple Therapy The techniques of family and couple therapy cast at least as broad a net as those of individual psychotherapy. While there are well over a dozen discernibly separate schools of family and couples therapy (Table 30.5-1), there is a good deal of overlap within several subgroups of them because of some common origins (e.g., Mental Research Institute brief therapy, strategic therapy, solution-focused, Milan systemic). Moreover, since the 1980s there has been a strong movement within the field toward combining elements of different methods, which has led to the increased borrowing of techniques across scholastic lines. Some of this borrowing has been in the form of technical eclecticism, that is using techniques presumed to be relevant and effective without regard to the originating theories' basic assumptions or the contradictions therein contained. Other borrowing has grown out of the search for the so-called common ingredients of effective therapy, and has shown considerable attention to matters of conceptual clarity and coherence. In addition, the general practice of family and couple therapy has become increasingly comprehensive and less doctrinaire, for example, in the use of individual therapy plus couple therapy, couple therapy plus (child-focused) family therapy, and other methods. Moreover, the field's early disdain for psychiatric and psychodiagnostic perspectives and practices has largely eroded as clinicians increasingly coordinate the use of psychopharmacological agents with flexible psychosocial treatment plans.

Therapeutic Techniques A representative sample of treatment techniques in the field of family and couple therapy is shown in Table 30.5-2.

Techniques Focused on In-Session Experience (Orientation)	Techniques Focused on Out-of-Session Experience (Orientation)
Circular questioning (Milan systemic)	Communication training (behavioral)
Communication training (behavioral)	Family management skills (psychoeducational)
Family sculpting (experiential)	Letters, therapeutic (narrative)
Family reconstruction (Satir model)	Ordeal prescription (strategic)
Genogram construction (Bowen family systems)	Paradoxical injunctions (Mental Research Institute)
Interpretation of unconscious processes (psychoanalytic)	Parent management training (behavioral)
Positive connotation (Milan systemic)	Problem-solving training (behavioral)
Problem-solving training (behavioral)	Pretending, prescription of (strategic)
Reframing (strategic)	Rituals, prescription of (Milan systemic) (e.g., invariant prescription)
Scaling, miracle, and exceptions questions (solution-focused)	Task assignment (behavioral, structural)
Teaching the emotional functioning of systems (Bowen family systems)	

Table 30.5-2 Representative Treatment Techniques Across the Range of Family-Couple Therapies

Therapeutic techniques are created and used to draw upon a theory's presumed mechanisms of change, that is, those causal processes by which clinically relevant change occurs. In addition, each therapy approach refers to a *dominant site of change,* which is a biopsychosocial space in which the clinically most salient change is believed to occur.

Table 30.5-2 reveals that behavior change is the dominant mode of change induction in family and couples therapy in contrast to insight and reflection. *Behavior-change techniques* refer to any therapeutic techniques that are called upon to modify observable behavior, whether at the level of the individual, the dyad, or the whole family whereas insight-oriented techniques refer to those that lead to change in awareness or perhaps affective experience without any automatic change in overt behavior. In contrast to much traditional individual psychotherapy in which insight is generally assumed to precede therapeutic change, in most family and couples therapy the opposite sequence is generally preferred. In addition, family therapists are usually more bi-directional in their thinking, that is, they believe that change can be initiated in any domain of psychosocial organization. For pragmatic reasons, however, initial change is more often sought at the interactional, public level of experience.

Table 30.5-2 distinguishes between family and couples therapy techniques that focus on in-session versus out-of-session experience. The wide use of techniques that emphasize patients' experiences away from the consultation room reflects family therapists' respect for the healing power of families and their understanding that

change that endures and generalizes to everyday life is not achieved primarily in the substitutive relationship between therapists and their patients, but between and among family members in their natural environment. What is especially striking about the centrality of out-of-session techniques in family and couple therapy is that it also reflects the modal family therapist's view that the dominant site of action in therapy change is within the family or couple relationship.

Therapeutic techniques in family and couples therapy are dominated by those focused on cognitive dimensions of experience, such as meaning and attribution, and those that focus on action. The former, the more cognitive of these techniques, may emphasize a therapist's attempts to change meaning, to discover meaning, or to cocreate meaning. Such efforts, can range from the cognitive-behavioral therapist's attempts to persuade family members that their partners general inexpressiveness reflects not a lack of love but rather internal discomfort with intimate conversation to the strategic therapist's positive reframing of such inexpressiveness as an understandable attempt to maintain a tolerable level of affective arousal in a marriage to a highly expressive mate, even with the unfortunate self-sacrifice that it requires. Some meaning-oriented interventions in family and couple therapy assume that the therapist's meaning is “correct” and that these interventions reflect a knowable reality and psychological truth (e.g., behavioral, Bowen family systems, psychoanalytic) whereas others are markedly different and believe that since there is no knowable external reality, all of therapy involves the making of meanings (“co-construction of reality”) rather than their discovery (e.g., Narrative, Solution-Focused, Strategic). For these latter approaches truth is pragmatic, that is it is a meaning or explanatory framework that leads to clinically relevant change but is not presumed to reflect any knowable truth.

Action-oriented techniques can be further meaningfully divided into those that assume that family members already have the requisite behaviors in their repertoire, and those that assume that family members presently lack such skills or knowledge. In learning theory terms, this is the important distinction between problems of performance and problems of acquisition. Action-oriented techniques involve either therapeutic directives or skill training. Directives can involve either in-session or out-of-session (often referred to as “homework tasks”) actions, for example, asking a father to not allow his 8-year-old daughter to divert his attention when he seems uncomfortable with his wife's assertiveness toward him, or assigning the couple the task of seeing to it that their noncompliant child goes to bed at an appropriate predetermined time so that they are guaranteed “couple time” together several evenings per week. The same couple may also need specific training in communication and problem-solving skills in order to carry out the out-of-therapy assignment.

Don and Kris, the 44-year-old parents of three children ages 19, 17, and 12, began contact with the therapist during Don's week-long hospitalization because of his intensifying depression and increased use of anxiolytics. Although he had had two brief psychiatric hospitalizations in his 20s and early 30s Don had generally functioned quite well for several years. But over the preceding several months, he had become easily fatigued, generally pessimistic and irritable, and “clingy.”

These symptoms, among others, seemed to have arisen as Kris became increasingly less involved with Don's life. Kris, the eldest of three siblings, had a long history of self-sacrifice, originating in her family of origin, in which she was the “parentified child” of an alcoholic father and a passive, depression-prone mother. Although her father's alcohol problem had largely abated over the previous decade, the marriage between Kris' parents had never progressed much beyond becoming a “pseudo-civil, polite but distant” relationship. They had retired to the Sun Belt, hoping the change would allow them to “start over,” but Kris' mother had become increasingly depressed of late as marital conflicts became more frequent.

Kris had recently become extremely involved in her parents' difficulties, especially as her mother's confidante, and less involved in her own family's life. In addition to this loss, Don, a generally avoidant man, felt more and more isolated from meaningful relationships, now that his 19-year-old son was away at college, and his 17-year-old son was “never around.” Don was very dependent upon and angry at Kris, but feared voicing his concerns about their disconnected lives. This dilemma was reminiscent of his relationship to his father, who had essentially abandoned the family when Don was 7 years old.

Over the next 5 months couples therapy addressed problematic patterns at several levels. Structural interventions included dislodging Kris from her therapist-like role with her parents, in part by helping her to help her parents identify a skilled couples therapist for them to see in their new location and by supporting her in setting and keeping appropriate boundaries in her conversations with her mother.

Cognitively oriented work on Kris' guilt about putting her own needs higher on her priority list, for example, for connectedness to her husband and children, occurred in the sessions, aided by bibliotherapy and other homework assignments. Don's normal adult attachment needs were validated, and he was also encouraged to explore new peer relationships in his community. A good deal of therapy time was devoted to communication and problem-solving training. In this, Don had to address his anxiety about assertiveness and fear of conflict and abandonment, and Kris had to address her anxiety-guilt about “saying no” and expressing her own needs.

Clinical Issues

Indications There are two overarching sets of indications for family and couple therapy: those that involve the therapist's mindset and those based on empirical validation or support. With regard to the former, it has been said that the indications for family therapy are to be found in the therapist. That is, just as behavior therapy is not equivalent to the practice of systematic desensitization, family therapy is not merely a collection of interpersonal techniques. It is a therapeutic collage of ideas about both family and individual stability and change, the evaluation and maintenance of psychopathology and problems-in-living, and relational ethics. Family therapy might better be called systemically sensitive therapy and in this sense reflects a basic world view as much as clinical treatment methodology. For therapists thus inclined, all clinical problems involve salient interactional components and so some kind of family or interpersonally functionally significant others' involvement in therapy is always called for even in the systemically aware treatment of an individual.

Although there are some likely contraindications to family and couple therapy, there is now an impressive array of common clinical disorders and problems for which various family or couple treatment methods have been empirically demonstrated to be effective. In a few cases, family interventions are probably even the treatment of choice. These disorders span both adult and child adolescent difficulties.

ADULT DISORDERS *Schizophrenia* Research has demonstrated unequivocally the effectiveness of a range of psychoeducational and behavioral treatment methods that teach family members about schizophrenia, and emphasize the reduction of expressed emotion and the enhancement of skills for coping with stress. These psychosocial methods are used in conjunction with medication. Some of them include multiple-family group therapy and all include interpersonal skills training. The inclusion of even a few family sessions often has powerful posthospitalization effects on both symptoms and recidivism, with rehospitalization rates regularly reduced by over 50 percent. Moreover, these psychoeducational approaches appear to be enormously cost-effective as compared to standard care. This body of evidence supports a handful of particular family intervention models, and the practice of dramatic, affect-arousing, and symbolically interpretive styles of work with these families, once fashionable in some influential quarters of the family field, is no longer empirically warranted.

Mood Disorders Psychoeducational methods have recently shown promise in the family treatment of bipolar I disorder as well as schizophrenia. Among the adult mood disorders, however, major depressive disorder has been the most responsive to certain systems-oriented therapeutic approaches. Specifically, behavioral marital therapy has been compared to individual cognitive therapy, the individual therapy treatment of choice for major depressive disorder. Both therapies lead to significant improvement in depression, but only behavioral marital therapy leads to an increase in marital satisfaction, attributable to its communication-skill and problem-solving skill components. It has been found that (1) couple therapy is not an effective treatment for depressed persons whose marriages are not in serious distress; (2) treating major depressive disorder with individual therapy does not help to resolve marital difficulties; and (3) individual therapy for depressed women who see their marital conflict leading to their depression may actually increase marital discord. Given the central role of relationship problems in predicting the relapse of depression in married women, the research offers strong support for behavioral marital therapy for women who are both depressed and maritally distressed.

Substance Abuse Earlier major outcome studies of structural family therapy for opiate addicts showed that this approach retained the users and their families in treatment longer than standard interventions, led to a decrease in drug use and related behavior problems, and increased social functioning. More recent studies favor family therapy over individual therapy and show family therapy to be a cost-effective adjunct to methadone maintenance. In the realm of adult alcoholism, a number of models of family involvement have been shown to have strong positive effects in terms of helping to motivate alcoholic individuals to enter treatment. On the other hand, the long-term outcomes (over a year) for the main rehabilitation phase have been only marginally more positive than individual alcoholism treatment (which itself is not especially effective).

Anxiety Disorders The inclusion of the spouse of the patient with agoraphobia in therapy sessions, often called spouse-involved treatment (not marital therapy), appears to lead consistently to lower dropout rates and more reliable practicing of exposure. In addition, spouse involvement in cases that are accompanied by marital distress may help to reduce marital tension, which in turn may make symptomatic spouses less anxious overall.

Marital Discord Troubled marriages (there have been no treatment studies of dissatisfied nonmarried heterosexual or same-sex couples) not only bode poorly for recovery from certain individual psychiatric disorders, but are also emotionally painful and stress-inducing in themselves. Since as many as 40 to 50 percent of the reasons for adults seeking mental health services may involve marital dissatisfaction, marital conflict constitutes a significant public health concern, despite the psychiatric status of marital discord as a mere other condition that may be a focus of clinical attention. There is compelling evidence that conjoint methods of marital therapy are the only validated approaches to date, and no individually oriented treatment methods have been shown to be effective. Thus far, three distinct methods have received either promising or very substantial empirical support. Emotionally focused therapy, grounded in attachment theory and espousing an experiential style, has shown considerable promise in several studies. Insight-oriented marital therapy, a psychodynamic method that emphasizes dealing with conflictual emotional processes both within and between marital partners, has been found to be very helpful at both the conclusion of therapy and at long-term follow-up. Finally, Behavioral Marital Therapy is by far the most frequently investigated couple therapy approach. Findings from about three dozen studies reveal it to have the largest effect size of all couple treatments. The central change-promoting treatment components of this method are behavioral exchange and communication and problem-solving skills training, recently enhanced by attribution-shifting and empathy-based acceptance training.

Sexual Dysfunction Although sex therapists generally do not travel in the same professional circles as family and couple therapists, there is every reason to consider sex therapy as a bona fide systemic therapy approach because of its conjoint nature. Drawing upon learning theory principles used in behavioral exposure therapies and communication training approaches, among others, conjoint couples sex therapy is well established as the treatment of choice for such common sexual dysfunction as premature ejaculation, vaginismus, primary female orgasmic disorder, and secondary erectile dysfunction. On the other hand, ejaculatory inhibition, primary erectile disorder, secondary orgasmic dysfunction, and problems of inhibited sexual desire are not so effectively dealt with by conjoint therapy.

CHILD AND ADOLESCENT DISORDERS ***Childhood Conduct Disorders*** Behavioral Parent Training (also known as parent management training or social learning family therapy) has a long history of demonstrated effectiveness in helping parents deal with aggressive and oppositional children and preadolescents. The intervention model (which typically excludes the child from treatment sessions) places central emphasis on learning–theory-based contingency management procedures, in which parents are taught essential parenting skills for providing appropriate consequences for desirable and undesirable child behaviors. In addition, effective parent training appears to lead to increased marital satisfaction (which in turn probably leads to greater parental unity, which leads to better enforcement of consequences).

Delinquency and Substance Abuse Three types of family therapy have been shown to be as effective as and at times more effective than standard care or individual psychotherapy in the treatment of acting-out adolescents, including those involved in drug abuse. These therapies are Functional Family Therapy, a variant of Behavioral Family Therapy; multisystemic therapy, an approach that targets an array of social systems (e.g., schools, per groups) in addition to the nuclear family; and a modified version of structural therapy. These highly structured treatments actively engage clinically relevant systems, enhance communication skills, and set clear behavioral and generational limits. They consistently yield positive clinical changes in recidivism, substance use, and impulse-control disorders, in addition to fostering higher rates of case retention than traditional forms of mental health intervention.

Other Indications In addition to the empirically justified indication for one or more forms of family and couple therapy, systems-oriented therapy is also commonplace in many other clinical situations. Dealing with the process of marital separation and divorce, addressing the complexities of remarriage and stepfamily life, crises of mid-life adaptation, extramarital affairs, crosscultural transitions, and chronic nonpsychiatric conflict constitute a large share of a family therapist's clinical practice, with or without an attendant diagnosable psychiatric disorder in one or more family members.

Contraindications There are no absolute contraindications to the use of family therapy, although clinical experience suggests caution in certain common circumstances. A therapist's lack of training in family therapy and a disinclination to view psychopathology and psychotherapy interpersonally and systemically are probable contraindications. Training in individual psychotherapy alone does not prepare adequate conceptual and technical therapist skills for engaging in family and couples therapy. Moreover, a conceptual bias toward intrapsychic experience may lead to a reductionistic, noninteractional focus and perhaps inevitably to a side-taking and blaming posture.

Some patient characteristics may be relative contraindications to family and couple therapy. Patients who refuse to divulge material essential to the harmony and smooth functioning of marriage and family living may thereby impose artificial limits on the success of treatment. A serious lack of commitment to a marital or couple relationship is probably a counterindication for systems therapy. A separated or divorced marital status does not preclude systems-oriented intervention, but directs it toward a style and focus of therapy attuned to the couple's relationship status, that is, one in which issues of individual adjustment and development may be as central as those of the family unit. In addition, the presence of ongoing family violence or sexual abuse is believed by many practitioners to preclude conjoint family or couple therapy because of the possibility of uncontrollable affective arousal during and especially outside of treatment sessions. Moreover, the courts typically remove alleged offenders from the family home, and legally allowed contact between the offender and the alleged victim may be limited to meetings with mental health professionals. Such common restrictions usually preclude clinically meaningful change in family structural-interactional terms, as the emphasis is often put on preventing continuing abuse, healing from the trauma of the disclosure of the relational betrayal, and restructuring the family-minus-offender in terms of its everyday functioning. Offenders are usually ordered into individual or specialized offender-group therapy and are regularly reintegrated into the family therapy much later on.

Finally, certain patient characteristics that have traditionally been seen as relative contraindications for uncovering individual psychotherapy seem not especially salient in the family therapy context, that is, age, intelligence, verbal ability, and psychological-mindedness, unless the therapy itself involves a long-term insight-oriented approach.

Limitations The main limitation in the practice of family and couple therapy is that systemically oriented treatment is not the sole treatment of choice for certain kinds of psychiatric and psychological disorders and problems, although it may deserve to play an adjunctive role. For some problems alternative treatments are clearly called for and are reliably effective even without family involvement, for example, individual behavioral treatment of many adult anxiety disorders.

Another limitation on family and couple therapy is involved when one or more family members resist genuine involvement, for example out of fear of being blamed for family difficulties or being exposed in some manner. The skilled family therapist must come prepared to cope with such possibilities.

Complications and Ethical Issues Complications in the practice of family therapy arise most often in terms of maintaining confidentiality, obtaining adequate diagnostic information, and receiving payment for professional services.

In conjoint family therapy confidentiality between or among family members does not exist. When individual family members seek to reveal to the therapist outside the conjoint sessions material that is of a confidential nature, anti-therapeutic side-taking could occur. Moreover, unlike therapists, family members are in no way legally bound to maintain confidentiality about other family members with people outside the family. These concerns, although probably not widespread, may certainly limit some patients' therapeutic involvement and raise sensitive strategic dilemmas for therapists.

Since a great many family and couples therapists focus mostly on those aspects of family life that seem essential for resolving presenting problems, and because most family and couple therapy is of relatively short duration, the therapist may not become aware of individuals' psychiatric histories, parts of which could be pertinent to the current course of treatment. Even in the most problem-centered, present-centered of treatments, it is always appropriate to carry out a brief exploration of potentially relevant psychiatric material, including the symptom or problem, and treatment histories of family members other than the identified patient or the member in whose name professional fees are submitted for payment. Doing so is not inherently inconsistent with interactionally focused treatment because such information, especially if it refers to current conditions, may set limits on the amount or rate of change possible via an interactionally based treatment approach.

A potential complication encountered with unfortunate frequency in family therapy is that what may be reasonably considered an appropriate treatment, or even the treatment of choice, may not allow therapist reimbursement or may require therapists to force-fit standard diagnostic criteria to one or more family members. Ironically, although the ascendance of managed-care–based health delivery systems has generally constrained psychotherapists' decision-making options, some managed-care arrangements, for example, the closed panel health maintenance organization, have actually expanded family therapists' treatment planning alternatives in that the professional service providers are the insurers and because managed-care organizations favor clinical methods that are problem focused and relatively brief.

Ethically, family therapists seem to face two major recurrent issues. The first involves the dilemma of whether to adhere strictly to “the systems perspective” even when the clinical situation suggests that a more linear, noninteractional point of view is not only arguable, but perhaps even the only ethical one to adopt in terms of likely clinical effectiveness. The best interests of patients must always supercede the best interests of therapists' conceptual frameworks.

There is an inherent tension in many family and couple therapy cases between balancing the best interests of individual family members with those of the group as a whole. For example, helping a family minimize its pain in the process of a divorce hardly fosters family cohesion, although it may reduce individual suffering and foster individual growth on certain members' parts while simultaneously increasing the stress felt by other individuals. Even when major overhauling of the basic family structure is not at issue, it is regularly a challenge of some proportion to therapists who must seem to support the treatment goals of two (or more) family members whose individual treatment goals appear to be largely antithetical, for example, a wife wants her husband to assume more household responsibilities as she returns to school or the workforce while her husband insists on maintaining his “freedom” to spend a significant amount of time in activities outside the home, arguing that they help him “relax” in the face of very stressful job or career conditions.

Emerging Issues and Trends Family therapy began to a significant degree as a clinical and conceptual movement in rebellion against the dominant belief systems in the mental health professions, as was true of behavior therapy. As the twentieth century closes, both these iconoclastic clinical forces have become assimilated into the mainstream of mental health treatment and training. Most family therapies have moved away from earlier radical systemic positions that endorsed allowing in multiple vantage points but arbitrarily excluded certain views. Thus, adopting a nonlinear explanatory framework, for example, is no longer believed to be antithetical to attributing and accepting responsibility for one's own actions, as in the case of marital and family violence.

As the concepts and practices of family therapy have penetrated the traditional mental health professions, more integrative therapies have evolved. These integrative approaches draw together varied theoretical orientations (e.g., psychodynamic and behavioral) and foster combined clinical practice at several levels of biopsychosocial organization (e.g., individual, family, larger systems). Just as the biological and the psychosocial are being addressed together, so is there a trend toward returning the psyche to the system by attending to levels of organization within the individual in concert with levels of multiperson systems.

There is also an increasing push toward developing and refining more specific variants of family and couple treatment for application to specific kinds of cases, such as particular diagnostic groups (e.g., psychoeducational programs for schizophrenia, cognitive-behavioral couple therapy for depression, and multisystemic treatment for adolescent delinquency). As family therapy has become a mainstay of the dominant mental health professions, it has adopted some of the world views and operations of those domains, including the operationalization and manualization of therapies. Although this trend may appear to some observers to narrow the scope and purview of family therapy, it has moved clinical theorizing in practice in quite the opposite, broadening, direction. Thus, gender and culture have received increasing attention as essential forces to be attended to in clinical practice. Contrary to the uniformity myth identified in the late 1960s by psychotherapy researchers, contemporary family therapy does not assume that the same treatment will be appropriate across different patient groups.

Finally, although certain commonly used family therapy approaches have shown very impressive treatment results, other historically influential approaches lag far behind in demonstrating rather than merely asserting their effectiveness. Thus, there is virtually no empirical evidence of the effectiveness of Bowen family systems therapy, symbolic-experiential therapy, Milan systemic therapy, Mental Research Institute brief therapy, or contextual therapy. Similarly, some recently popular approaches have yet to amass any compelling evidence of positive treatment outcome, for example, narrative therapy and solution-focused therapy. The family and couples approaches that have presented a reasonable body of empirical support for their methods (e.g., cognitive-behavioral marital therapy, psychoeducational family therapy, functional family therapy, emotionally focused couple therapy, behavioral parent training, insight-oriented marital therapy, and structural therapy) have evolved largely within academic settings and are thus more connected to an empirical, hypothesis-testing tradition. Nonetheless, other influential approaches are not likely to be sustained or to expand their influence if they remain too far outside the mainstream of mental health practice and do not become accountable for their effectiveness.

SUGGESTED CROSS-REFERENCES

Psychosocial treatments for mood disorders are presented in Section 14.9. Psychosocial treatment of schizophrenia is discussed in Section 12.9. Substance abuse and substance-related disorders are discussed in Chapter 11. Relational problems are covered in Chapter 26. Sexual dysfunctions are presented in Section 19.1a. Behavior therapy is covered in Section 30.2 and cognitive therapy in Section 30.6. Family therapy with children is further discussed in Section 48.5 and interventions and consultations with families of the elderly in Section 51.4k.

30.6 COGNITIVE THERAPY

A. JOHN RUSH, M.D., AND AARON T. BECK, M.D.

Cognitive therapy is based on a theory of psychopathology that draws on concepts from cognitive and social psychology as well as from information-processing and psychoanalytic theory. Therapeutic principles and techniques are derived partly from both these theoretical frameworks and from clinical empirical investigations. Cognitive theory posits that the way individuals interpret experience determines how they feel and behave. For example, if persons view situations as dangerous, they experience anxiety and want to escape. The four basic emotions of sadness, elation, anxiety, and anger, respectively, are evoked by perceptions of loss, gain, danger, and wrongdoing by others.

Biased information processing causes distorted interpretations in the form of verbal or pictorial cognitions as well as cognitive deficits. Examples of such biases include incorrectly evaluating specific life situations as hostile or dangerous. Cognitive deficits are represented by failing to generate adequate strategies to solve problems.

Specific psychiatric disorders are associated with characteristic cognitive biases that result from and contribute to impaired corrective function of higher-level cognitive processes. In depression, for example, patients see themselves, their experiences, and their futures in negatively biased ways, which in turn sustains or magnifies depressive symptomatology.

Cognitive therapy employs specific treatment strategies to correct these habitual thinking errors found in different psychopathological states. Treatment employs a combination of verbal interventions and behavior modification techniques designed to help patients identify their dysfunctional cognitions, test whether they are based on logic and reality, and correct the distorted conceptualizations and dysfunctional beliefs that underlie their dysfunctional thinking. A wide range of therapeutic techniques consistent with the cognitive model of psychopathology may be used. The therapy itself is active, structured, time limited, and focused on current problems. As patients begin to think and act more realistically, their symptoms and behavior improve.

Cognitive therapy has been used successfully in the treatment of depressive disorders, anxiety disorders (e.g., phobias, panic disorder, obsessive-compulsive disorder) eating disorders, substance abuse, and personality disorders; as well as a number of psychophysiological disorders. Cognitive therapy may be used in individual, group, couple, and family formats. Recently, adaptations for treatment of the elderly, depressed children and adolescents, and patients with bipolar I disorder or schizophrenia have been prepared. Finally, cognitive techniques have been specified and evaluated to increase patients' compliance to medication regimens.

HISTORY

The phenomenological approach to psychology, psychoanalytic psychology, and cognitive psychology has contributed to the theoretical foundations of cognitive therapy as formulated by Aaron T. Beck. The concept that individuals' views of themselves and their personal world determine behavior is derived originally from the Greek stoic philosophers. The philosophical emphasis on conscious subjective experience stems from the works of Immanuel Kant, Martin Heidegger, and Edmund Husserl. The theories of these phenomenologists were made operational by psychologists such as Alfred Adler, Otto Rank, and Karen Horney, who were influenced by them. Many of the basic theoretical or therapeutic concepts of cognitive therapy can be found in their writings. Adler, for example, emphasized both the importance of understanding patients within the framework of their own conscious experience and the need to determine in therapy the conscious meaning that patients attach to their experiences.

The structural theory and depth psychology of Sigmund Freud contributed the theory of hierarchical structuring of cognition into primary and secondary processes and the concept that symptoms and affect are based upon “pathogenic ideas.” The major contributions of cognitive psychologists include George Kelly's concept of “personal constructs” as a determinant of behavior and the cognitive theories of emotion formulated by Magda Arnold and Richard Lazarus.

The emphasis of cognitive therapy on finding solutions to conscious, definable, here-and-now problems has been paralleled by rational-emotive therapy, developed by Albert Ellis. The therapeutic style of gentle questioning and unconditional acceptance owes much to the client-oriented therapy of Carl Rogers. The procedure of developing common themes across the patient's emotional reactions to diverse experiences is related to the neopsychoanalytic approach of Leon Saul. The behavior therapy movement contributed several crucial therapeutic strategies: the structuring of the interview, preparing agendas for individual sessions, setting goals, eliciting feedback, operationalizing the procedures, testing hypotheses, formulating and testing problem-solving techniques, and assigning homework. Finally, the empirical thrust of cognitive therapy has been influenced by the work of cognitively oriented writers such as Albert Bandura, Jerome Frank, Marvin Goldfried, Arnold Lazarus, Michael Mahoney, Donald Meichenbaum, and G. Terence Wilson.

MODEL OF PSYCHOPATHOLOGY

Relation of Cognition to Emotions The basic cognitive themes can be derived from the examination of four basic emotions. Thus, sadness is evoked when there is a perception of *loss*—a defeat or deprivation—frequently in the form of unfulfilled or disconfirmed positive expectations or the disruption of a valued personal relationship. The usual consequence is to withdraw the investment in the particular source of disappointment. Elation, in contrast, follows from a perceived gain and thus is likely to reinforce activity toward achieving a goal.

In contrast to sadness and gladness, which relate to positive goals, anxiety and anger are usually responses to threats to the self or valued attachments. Anxiety is evoked when persons are concerned about their vulnerability—for example, to being hurt, killed, or devalued—and are consequently impelled to withdraw or to appease. Anger focuses on the offensive qualities of the threat, with the behavioral consequence of aggressive self-defense or counterattack.

Cognition and Psychiatric Disorders The cognitive and emotional concomitants of the psychopathological syndromes can be viewed as exaggerated, persistent forms of the kind of normal emotional and behavioral reactions described above. Thus, in depression, sadness and withdrawal of interest in previous goals are intensified and prolonged beyond the usual sense of defeat or deprivation of normal reactions. In anxiety disorders, a generalized and intensified sense of vulnerability to a wide variety of threats stimulates anxiety and avoidance.

Each of the disorders is characterized by idiosyncratic beliefs about the self or others that distinguish them from the other disorders. Panic disorder, for example, is characterized by a catastrophic misinterpretation of bodily sensations or mental experiences. In obsessions the content revolves around a warning or doubt: the compulsion is prompted by an urge to dispel the danger through a repetitive act (Table 30.6-1).

Disorder	Idiosyncratic Cognitive Content
Depressive disorders	Negative view of self, experience, and future
Hypomanic or manic episodes	Inflated view of self, experience, and future
Suicidal behavior	Hopelessness and debased self-concept
Generalized anxiety disorder	Fear of physical or psychological danger
Phobia	Fear of danger in specific, avoidable situations
Panic disorder	Fear of immediate physical or mental disaster
Paranoid state	View of others as biased, manipulative, and devious
Conversion disorder	Concept of motor or sensory abnormality
Obsessive-compulsive disorder	Continual thoughts about safety; repetitive acts to ward off threat
Anorexia nervosa or bulimia nervosa	Fear of being fat and unattractive
Hypochondriasis	Concern about serious insidious medical disorder

Table 30.6-1 Cognitive Profile of Psychiatric Disorders

In delusional disorder, the perception of being mistreated is generalized and leads to anger and an inclination to counterattack. The specific cognitive profile of each disorder provides the framework for specific cognitive interventions.

Each of the personality disorders is characterized by a set of dysfunctional beliefs. The dependent personality, for example, is driven by beliefs such as “I cannot function without somebody to lean on.” The avoidant personality is motivated by beliefs such as “If people are aware of my performance, they will be critical and rejecting.” The beliefs of the histrionic personality disorder center around the theme, “I need to entertain people in order to be accepted.”

Cognitive Processing Both normal and pathological emotions are mediated by primitive cognitive processes (analogous to Freud's primary processing). These processes support conceptualization of situations that are global and relatively crude, while higher levels of cognitive processing (analogous to Freud's concept of secondary process) are more refined and, when the latter function properly, provide reality testing and correction of the global, primal conceptualizations. In psychopathological states, however, these higher-level cognitive functions are impaired and lead to extreme levels of anger, anxiety, elation, or sadness in an ever-widening range of inappropriate situations. That is, malfunctioning secondary process thinking leaves primary responses unmodulated in full-blown psychiatric disorders.

Although these pathological and psychological processes clarify the role of cognitive mechanisms in the development of depression, anxiety, and other disorders, they do not address the issue of causality. The ultimate causes of these disorders are not necessarily found in the cognitive structures or processes even though cognitive therapy may be an effective intervention. Causes are best understood in terms of the interaction of innate biological, developmental, and environmental factors.

In the various disorders certain dysfunctional beliefs relevant to helplessness, danger, and unlovability play an important role in information processing. Embedded in cognitive structures *(schemas),* these dysfunctional beliefs mold the individual's thinking and contribute to the cognitive errors typical of psychopathology.

Logical Errors in Thinking *Arbitrary inference* is the process of drawing a conclusion in the absence of evidence supporting it or even in the face of evidence to the contrary. *Selective abstraction* refers to focusing on a detail taken out of context, ignoring other, more salient, features of the situation, and conceptualizing the whole experience on the basis of this element. *Overgeneralization* refers to drawing a general conclusion across all situations on the basis of a single incident. *Magnification* and *minimization* represent distorted evaluations of the relative importance of particular events. *Personalization* describes the tendency to relate external events to oneself when there is no basis for making such a connection. *Dichotomous thinking* occurs when the patient tends to make interpretations on an either-or, black-or-white basis (Table 30.6-2).

Arbitrary inference	Selective abstraction
Overgeneralization	Magnification and minimization
Personalization	Dichotomous thinking

Table 30.6-2 Cognitive Distortions in Psychopathology

PRINCIPLES OF THERAPY

Therapeutic Relationship As in other therapies, the therapist-patient relationship is important in cognitive therapy and provides the medium for improvement. Therapists function as guides to enable their patients to acquire the understanding that will help them to cope better with their problems—the process of guided discovery—and also as catalysts to promote the kind of corrective experiences outside of therapy that will enhance the patients' adaptive skills. The style of the therapist in manifesting genuine warmth and nonjudgmental acceptance is similar to that of the client-centered or Rogerian therapist. In contrast to Rogerian and psychoanalytic therapists, however, the cognitive therapist plays an active role in helping to pinpoint present problems, focusing on important areas, proposing and rehearsing specific cognitive and behavioral techniques, planning homework assignments, and re-evaluating the experiences during therapy.

Most of the therapist's verbal statements are in the form of questions, reflecting the basic empirical orientation and the immediate goal of converting the patient's closed belief system into an open system. The therapist actively engages the patient in working out the agenda for each session and elicits feedback from the patient regarding the therapist's suggestions and behavior during the session. Although an attempt is made to maintain an optimal level of warmth and rapport during the therapy, this effort includes the uncovering of patients' negative reactions to the therapist and resistance to assignments. Transference reactions are often valuable in demonstrating to patients their interpersonal distortions. Similarly, resistance is dealt with in terms of the underlying dysfunctional beliefs.

Because the standard duration of cognitive therapy for depression is 15 to 20 visits over a 12-week period, there is considerable pressure on both patient and therapist to make the best possible use of the available time. Thus, a substantial effort is made to induce patients to carry out homework assignments designed to help them recognize and respond to negative cognitions, master the cognitive and behavioral skills learned during the sessions, and to test dysfunctional beliefs about themselves and others. This time-limited format requires that patients rather readily form and maintain the therapeutic alliance. Patients for whom formation of the alliance is troublesome (e.g., patients with borderline personality disorder) are generally unsuitable for this time-limited structure and will require much longer treatment. Panic and generalized anxiety disorders often improve in ten sessions or less.

The proximal goal is to promote behavioral activation, cognitive restructuring, which involves modification of the patient's systematic bias in interpreting personal life experiences and making future predictions. In sum, cognitive therapy is a learning experience in which the therapist plays an active role in helping the patient to uncover and modify cognitive distortions and dysfunctional beliefs.

Case Conceptualization To prepare a treatment plan, a tentative conceptualization of the case is needed. Ideally, this formulation includes an understanding of the person's idiosyncratic dysfunctional beliefs, specific vulnerabilities, and how the particular stresses impinge upon these vulnerabilities to activate the present symptoms. Most patients have dysfunctional core beliefs, such as “I am helpless” or “I am unlovable,” upon which dysfunctional disorder-specific (idiosyncratic) beliefs

are superimposed—such as “If I don't have love, I am nothing” (depression) or “A disaster could occur at any time” (anxiety disorder).

Each personality disorder is also characterized by a specific set of dysfunctional beliefs. The cross-sectional analysis delineates the dysfunctional core beliefs and idiosyncratic beliefs and the dysfunctional strategies developed by the patient in reaction to these beliefs (e.g., the excessive attachments of the dependent personality in response to beliefs of helplessness or unlovability).

Case formulation rests on both a historical and prospective evaluation of the pattern of symptom exacerbation in relation to situations and the patient's conceptualization of them. By searching for common denominators among symptoms, the patient's views of diverse situations and the underlying cognitive pattern can be identified.

A woman was handicapped by fears of elevators, tunnels, hills, closed spaces, riding in open automobiles, flying in an airplane, swimming, walking fast, running, strong winds, and hot muggy days. A careful review of these problems revealed that the common denominator was a fear of suffocation—she had the idiosyncratic belief that she could suffocate in one of these situations in which there could conceivably be a deficit of air: stalled elevators, tunnels, closed car, and closed spaces. Her expectation of riding in an open car was that the “wind would be swept out of my mouth.” Fear of riding in an airplane was expressed in a fantasy of a leakage or a sudden drop of oxygen occurring. Initially, treatment consisted of inducing the patient to pay more attention to her respiratory cues. As she began to realize that she felt a tightening of her chest muscles and a sense of suffocation even when she only thought about being in one of these situations, she began to recognize that her fears originated in her imagination and did not represent realistic dangers.

STRUCTURE OF THERAPY PROGRAM

Behavioral Techniques These are prominently used at the beginning of therapy with profoundly depressed patients who have a limited capacity for introspection and abstraction needed to identify and evaluate automatic thoughts or assumptions. Often, the first step is to obtain baseline information by asking patients to complete the Daily Schedule of Activities form. This report forms the basis by which the therapist and patient design and schedule homework that can vary substantially depending on the phase of therapy. Because a significant part of the positive effect of cognitive therapy results from the patients' application of the principles outside the therapy session, it is important to help patients structure their days and weeks such that the impact of the therapy is maximized.

Initially, therapist and patient agree on scheduling activities that help to mobilize the patient and counteract the inertia often present, especially in depression. Because most patients need to proceed in small steps, a graded-task assignment is developed to enable them to have progressively greater success experiences without overextending themselves. Typical behavioral techniques are listed in Table 30.6-3.

Behavioral Techniques	Cognitive Techniques
Mastery and pleasure ratings	Identifying automatic thoughts
Activity scheduling	Testing and correcting automatic thoughts
Graded task assignment	Reattribution techniques
Behavioral rehearsal	Identifying and testing imperatives—“shoulds”
Role-playing	Cognitive rehearsal through imagery
Testing dysfunctional beliefs	Imaginal recreation of pathogenic events

Table 30.6-3 Behavioral and Cognitive Techniques

The more severely retarded patients, and particularly those who are hospitalized, may have a wide variety of negative thoughts regarding the activities, such as “I won't be able to do it,” “I would feel silly,” or “It won't do any good.” These cognitions are “grist for the mill” and can be formulated as predictions or hypotheses that the patient can then test as part of the graded task assignment.

Cognitive Techniques When the patient is already active, more purely cognitive procedures may be used. The patients track their automatic thoughts, particularly when they precede or accompany a negative feeling. An automatic thought occurs spontaneously, is very rapid, and represents an immediate interpretation of a situation. A depressed patient, for example, on seeing a lose friend had the automatic thought, “She won't want to talk to me.” These patients are asked to fill out the Daily Record of Dysfunctional Thoughts and are trained to give reasonable or rational responses to their negative automatic thoughts.

During the course of cognitive therapy the therapist and patient review the relationship between the automatic thoughts and an objective description of a disturbing event. Logical errors are identified and more realistic interpretations of the event are considered, thereby correcting the automatic thoughts.

Reality testing of automatic thoughts and assumptions is carried out by treating the belief or thought as a hypothesis to be tested; for example, discussion of its validity with the therapist using information already provided by the patient in prior sessions or through prior homework assignments. Alternatively, the therapist and patient may design a homework assignment (“experiment”) to more directly test the notion in question by gathering new evidence.

As therapy progresses, attention is focused on the patient's underlying beliefs, such as “If I'm not successful, then I am a failure” or “If somebody doesn't like me, it means I'm socially undesirable.” These beliefs are re-evaluated in the same way as automatic thoughts; namely, in terms of the evidence supporting them, the logical basis on which they rest, and empirical testing.

Automatic Thoughts Most people are unaware that automatic thoughts precede unpleasant feelings or automatic inhibitions. These thoughts occur rapidly, are at the fringe of awareness, and include both specific verbal ideas and images. With some training, however, patients increase their awareness of these thoughts and are able to pinpoint them with a high degree of regularity. It is possible to perceive a thought, focus on it, and evaluate it just as it is possible to identify and reflect on a sensation, such as pain.

Automatic thoughts are distinguished from the ordinary flow of thoughts observed in reflective thinking or free association. For a specific form of psychopathology, a large proportion of automatic thoughts reflect the idiosyncratic cognitive theme specific to the syndrome (Table 30.6-1). Although these thoughts are often very rapid and generally are at the fringe of consciousness, they may be identified retrospectively because they generally precede some emotion such as anger, sadness, or anxiety: the content of the automatic thought is consistent with that emotion. These thoughts are generally plausible to the patient, who takes it for granted that they are accurate. Finally, they have an imperative quality such that they recur even though the person tries to block them out.

In therapy, patients learn to identify their automatic thoughts and their reactions to them. Patients may report, for example, a number of circumstances in which they feel unaccountably upset. Usually, a gap may be identified between the stimulus situation and the emotional response to it. An excessive or inappropriate emotional response becomes more comprehensible when patients recollect the thought that occurred during this gap. Albert Ellis has referred to the sequence as the ABC sequence. *A* is the activating stimulus or event and *C* is the excessive inappropriate response. *B* is the blank in the patient's mind that must be filled by identifying the fringe automatic thought.

Depressed and anxious patients predictably interpret many situations in systematically biased ways, even though more plausible interpretations are available. When asked to reflect on alternative explanations, patients may realize that their initial interpretations are erroneous or rest on unlikely inferences. They may then be able to recognize that they tailored the facts to fit their performed negative conclusions. When one compares what actually appened in a particular situation with the patient's automatic thoughts in that situation, a number of logical errors are often apparent (Table 30.6-2).

Cognitively oriented techniques (Table 30.6-3) are applied as patients become less symptomatic and thereby become more objective about themselves and their thinking. As patients are able to view their thoughts objectively, these thoughts become hypotheses that are amenable to experimental testing and revision using

cognitive techniques. They thereby unravel, clarify, and modify the meanings they have assigned to upsetting events. Cognitive techniques, such as identifying automatic thoughts, recognizing and correcting cognitive distortions, and identifying broad beliefs and assumptions that underlie the dysfunctional thoughts, are used to clarify patients' problems.

Through a process of collaborative empiricism, the therapist and patient may produce shifts in thinking to a more realistic level. Structural changes may be achieved through the analysis of basic beliefs and imperatives that have governed the person's responses. Structural change extends beyond modifying the cognitive errors associated with the specific syndrome to changing the underlying organization of beliefs and assumptions that misclassify events as threatening or upsetting.

Homework The design of appropriate homework assignments to test specific dysfunctional notions requires ingenuity on the part of the therapist. For instance, many persons with anxiety or depression believe that their behavior is consistently being scrutinized and judged adversely by other people. They view themselves as vulnerable, rejected, and ridiculed. These patients may believe that if they deviate even slightly from conventional expectations or from their usual rather restricted roles, other people will notice and disapprove. Homework assignments consist not only of completing the various forms mentioned previously but also of testing these kinds of dysfunctional beliefs.

APPLICATION TO SPECIFIC CONDITIONS

Cognitive therapy has been applied to a variety of psychopathological conditions (nonpsychotic major depressive disorder, generalized anxiety disorder, panic disorders or phobias, obesity, alcohol or other substance use disorders, chronic pain). Different techniques may be used depending on the cognitive profile of the disorder, the phase of therapy, and the specific cognitive formulations of a given case.

Depression

Cognitive Triad Depression entails the activation of three major cognitive patterns that lead to individual patients viewing themselves, their experiences, and their future in negative biased ways (“the cognitive triad”). The first component consists of patients' negative concept of themselves, present in nearly all depressed patients. They regard themselves as deficient, helpless, or unlovable, and they tend to attribute their unpleasant experiences to their presumed physical, mental, or moral defects. In their opinion, they are undesirable and worthless because of their presumed defects, and they tend to reject themselves because of them. Furthermore, they may regard themselves as lacking in those attributes that they consider to be essential for the attainment of happiness or contentment.

The second component is the patients' predominantly negative interpretations of day-to-day and past experiences. They tend to see their personal world as exorbitantly demanding, as presenting insuperable obstacles to achieving their life goals, or as being devoid of pleasure or gratification. The third component, a negative view of the future, is present in nearly all depressions. Depressed patients anticipate that their current troubles will continue indefinitely and they see a future life of unremitting hardship, deprivation, and frustration.

Motivational and behavioral symptoms of depression are derived from, maintained, or exacerbated by negative cognitive patterns. Paralysis of the will results from the depressed patients' pessimism and hopelessness. Expecting their efforts to end in failure, they are reluctant to commit themselves to any goal, and their activity level drops. Believing they cannot affect the outcome of various situations, they experience a desire to avoid such situations. Suicidal wishes are an extreme expression of the desire to escape from problems that appear to be uncontrollable, interminable, and unbearable.

Regarding themselves as inept and undesirable, patients tend to overestimate the difficulty of normal tasks in life and expect things to turn out badly. They may unnecessarily seek help from others (increased dependency). Similarly, indecisiveness may derive from patients' beliefs that they are incapable of making the right decision. Even the subjective loss of energy, easy fatigability, and inertia seem to be derived from the negative expectancies.

Predisposition The cognitive model posits that certain individuals are predisposed to depression because of beliefs developed early in their lives. These beliefs are shaped by personal experiences, and stem from identification with significant others and from their perceptions of attitudes of other people toward them. Once a particular basic belief is formed, it may influence subsequent concept formations and if it persists, it is incorporated into an enduring cognitive structure or schema.

Although latent or inactive at given times, schemas are activated by particular situations analogous to those early experiences that shaped the development of the schema. When these schemas are activated, depression may develop. For instance, if a person had lost a parent during childhood, the disruption of a close interpersonal adulthood relationship may activate the concept of irreversible loss implanted by earlier experiences. Other types of precipitating events include not performing as expected on an examination, being demoted, acquiring a disease, or encountering serious difficulties or frustrations in meeting important life goals. Depressions do not always occur in relation to specific stress situations, but may be reactions to a series of traumatic experiences.

Although such events may be painful to the average person, they would not produce depression unless the person was especially sensitive to the situation because the specific predisposition was embedded in an underlying schema or belief. When such traumas are encountered, depression-prone persons experience a negative shift in their views of every aspect of their lives. As the depression deepens, their thinking is increasingly saturated with typical depressive themes, regardless of the immediate situation until they gradually lose their ability to view their negative thoughts objectively.

The activation of these schemas interferes with the capacity for objective appraisal of all events, thoughts, and emotions and reasoning is impaired. Systematic cognitive errors (e.g., arbitrary interpretation and selective abstraction) occur as dysfunctional schemas and become more activated. The patient becomes less and less objective in evaluating current situations.

The patients' cognitive and emotional responses themselves further serve to reinforce these negative views. As the unpleasant life situation activates cognitive schemas related to defeat or deprivation, negative expectancies and self-blame ensue. These in turn produce sadness, apathy, loneliness, and reduced performance. The emotions and inertia are interpreted as yet another sign of loss or failure—“I'm feeling bad, so things must be bad”—which further reinforces negative attitudes. Automatic thoughts evolve from these schemas.

Ms. M., a 68-year-old widowed mother of three, was self-referred for the chief complaint of “I am depressed,” following her husband's death. The current depressive episode had lasted 6 months and included a marked weight loss, anorexia, insomnia, easy fatigability, reduced capacity for enjoyment, social withdrawal, suicidal ideation, guilt, and difficulty concentrating. Her mood seemed reactive to daily stresses and events.

Stressors around the onset of the current episode included a gallbladder operation 3 months prior to the onset, and a visit to her daughter's house, during which the patient learned her daughter and son-in-law might be transferred out of state due to his position with a major corporation. Treatment of the current depressive episode with three different antidepressant drugs led only to a partial response.

Basically, four techniques were used to change cognition during twice-weekly cognitive therapy over a 6-week period.

Step 1 The first step consisted of scheduling activities each hour of each day and asking the patient to record the relative degree of mastery and pleasure experienced with each. This exercise provided a basis for examining how the patient evaluated herself with respect to different activities. Activities that she appeared to underrate for mastery and pleasure formed the basis for eliciting negative automatic thoughts associated with each activity. For example, she cleaned her living room and kitchen, but rated her sense of mastery as 0. Her thoughts at the time were: “Babs (her daughter) won't be here anymore” and “I used to enjoy this and now I hate it.”

Step 2 In addition to the thoughts collected through schedule-keeping (step 1), a number of other cognitions were collected using the Dysfunctional Thought Record. The patient was asked to record the events, her depressed or upsetting feelings, and the associated thinking in each instance when she felt a drop in her mood. The cognitive errors of overgeneralization and selective abstraction were identified and corrected by having the patient practice answering her automatic thoughts using a notebook and tape recorder.

Step 3 The thoughts collected in Steps 1 and 2 contained the theme of “Without Babs I have nothing.” This dysfunctional belief was logically refuted with several pieces of evidence provided by the patient herself. First, she was shown that in her 68 years, her daughter had been around for only 24 of them, yet the other 44 years had been very rewarding. Secondly, her daughter had not been home much of the time since she had attended college and then worked; yet, during the period that her daughter had been away, the patient continued to enjoy and participate meaningfully in a variety of activities.

Finally, the patient's own list of activities for the previous several weeks provided data that revealed to the patient that she had initially enjoyed and felt satisfied about volunteer work in a hospital, church social gatherings, and shopping when Babs was not around at all. So in fact without her daughter the patient still experienced substantial degrees of pleasure and mastery. Ms. M. came to see that although interaction with her daughter had provided a great deal of enjoyment and satisfaction, there was no hard evidence that without her daughter her life was meaningless.

Step 4 Finally, alternatives for maintaining contact with her daughter by phone, letter, or audiorecording were explored. Thus, even if her daughter did move out of state, some contact time nearly equivalent to the rather modest time during which the patient and her daughter had interacted after her daughter's marriage might be feasible. As the patient explored these alternatives, she began to see that her daughter had developed her own life. While her daughter might have to move away with her husband, the daughter was not disappearing altogether. Further, the potential move could be viewed as a testimony to the patient's successful completion of the mothering role.

The patient responded rather rapidly so that her depression ratings had normalized by the ninth session. Nine months following termination, the patient reported doing volunteer work, experiencing no symptoms of the syndrome of depression and scored a 0 on the Beck Depression Inventory (BDI).

Ms. M. initially recorded her activities and rated them for the sense of mastery and pleasure associated with each. This technique not only helped her to become objective about her present day-to-day activities, but also helped to elicit thoughts that occurred in specific situations that led her to devalue herself. Her preoccupation with the anticipated loss of her daughter became apparent. In addition, evidence was accrued that later was used to refute one of the themes in her thinking—namely, that without her daughter, nothing was worthwhile.

Suicidal Behavior Suicidal behavior has specific cognitive, motivational, and behavioral features that lead to particular cognitive techniques. Suicidal individuals evince high levels of hopelessness—the greater the hopelessness, the more likely it is that patients will commit suicide and their thinking often has a rigid all-or-none quality that precludes objective problem-solving. Hopelessness further impairs poor problem-solving; conversely, the difficulties in coping with life situations independently contribute to suicidal potential.

When suicidal individuals are unable to generate alternative solutions to solve current problems (i.e., their accustomed way of dealing with a problem does not work), they seem unable to think of alternatives to rectify the situation. Thus, much of therapy is devoted to problem-solving techniques, such as defining the problem, generating alternative ways of solving the problem, and implementing alternative solutions.

In treating suicidal patients it is important to promote a good relationship from the beginning and to establish bridges from one therapy session to the next so as to discourage suicide attempts between sessions. The therapist immediately focuses on the patients' hopelessness and applies a variety of cognitive techniques to increase the patient's objectivity about current dilemmas. The therapist teaches patients to identify and change their all-or-nothing thinking style, thereby opening up alternative solutions previously not considered.

Suicidal patients seem to operate according to certain specific beliefs, such as “If my girlfriend doesn't respond to me, it means she doesn't like me and I will always be alone.” By addressing both the hopelessness and the rigid self-defeating beliefs, the therapist helps patients to recognize a variety of alternative solutions to life's problems (i.e., suicide to escape these problems is not necessary).

COGNITIVE MODEL OF ANXIETY DISORDERS

Various anxiety syndromes may be considered as expressions of a malfunction of normal survival mechanisms. As in depression, the various symptoms are the manifestation of the operation of the specified systems: cognitive, affective, behavioral, motivational, and physiological. The basic mechanism for coping with a threat is the same for the anxious patient as for the normal person. The difference between the two is that the anxious patient's perception of danger is either incorrect or excessive and is based on incorrect or inaccurate false premises whereas the normal response to threat involves a reasonably accurate assessment of the possibility of harm.

Although normal persons may incorrectly identify situations as dangerous (and thereby become immobilized to deal with them), this misinterpretation is readily amenable to objective reappraisal following which the response returns to a baseline level. The anxious patient, in contrast, consistently misperceives danger and is relatively insensitive to cues indicative of safety. Moreover, the patient's capacity for objective reappraisal becomes impaired.

The thinking of patients with clinical anxiety revolves around the notion of danger and how it should be dealt with. When contemplating a problematic or ambiguous situation, anxious patients automatically anticipate the most negative consequences. Although it may be adaptive under some circumstances to anticipate the worst possible case, patients with clinical anxiety are consistently fixated on anticipating extreme outcomes and therefore are overprepared to deal with physical or social threats.

The cognitive appraisal of danger triggers (1) the emotional component, (2) the motor components specifically designed for coping with a threat (e.g., fight, flight, freeze, or faint), and (3) the physiological components (i.e., activation of the autonomic nervous system), which facilitates the action of the specific motor component. Anxiety symptoms reflect the subjective experience of the specific systems: nervousness (affective); muscular tension (motor); wish to flee (motivational); inhibition of speech and movement (behavioral); and multiple fears and inhibition of memory and selective thinking (cognitive).

Subjective Anxiety Subjective anxiety prods an organism to take protective action in response to perceived danger. The immediate response to danger (e.g., freezing), occurs almost instantaneously. However, anxiety also impels the person to select an appropriate strategy after appraising the dangerous situation. Subjective anxiety generally increases as one approaches a dangerous situation and decreases as one withdraws. Thus, subjective anxiety reinforces the motivation to reduce the danger by withdrawing. Furthermore, anxiety also stimulates the person to mobilize active coping mechanisms to reduce the danger.

When anxiety is continuous yet without objective threat, as in the anxiety disorders, it may be incorrectly attributed to ongoing situations perceived as dangerous. When a person incorrectly conceives of problematic situations as dangerous, there is no opportunity to develop or apply coping skills because there is no objective danger for which the coping is appropriate.

Autonomic activity facilitates the motor activity through regulating blood supply, metabolism, and temperature control (e.g., through sweating). A person manifests the same type of physical response in response to a psychosocial threat—for instance, negative evaluation by a superior—as to a physical threat (e.g., being injured or killed). The same autonomic-motor pattern, such as defensive stiffening that is manifested by sweating and pulse and blood pressure changes, occurs in response to either type of threat. Inhibition of action (muscular rigidity, blocking, and muteness) is expressed in tonic immobility associated with sympathetic dominance. Demobilization (muscular flaccidity and loss of postural control) is embodied in atonic immobility associated with parasympathetic dominance. Muscular and vocal inhibition reflects the impulse for self-protection and self-regulation.

This mechanism involved in anxiety disorders is counterproductive in the usual situation of psychosocial threat. A person with test anxiety or public speaking anxiety becomes fixated on the ultimate disaster (e.g., failing or being rejected). Thoughts of failure or rejection, although extraneous to the immediate performance task, are central to the danger and are consequently enhanced. Concentration, planning, and recall regarding the task are extraneous to the danger and are thus blocked.

Cognitive Therapy For intensely anxious patients a cognitive groundwork must be laid before any behavioral tasks are introduced. Patients are given a framework to integrate the experiences aimed at correcting their exaggerated fears. Thus, patients who have strong fears and inhibitions relevant to asserting themselves would be encouraged to explore all the presumed catastrophic occurrences that would result from unsuccessful self-assertion. They could then weigh the magnitude of pain resulting from a reversal and compare it with the potential gain from self-assertion.

In depression, the main thrust is towards disconfirming a strong belief, such as “I can't do anything” or “Nothing brings me pleasure.” A single disconfirming experience (e.g., in which patients do something they expected to fail at) can substantially undermine this belief. In contrast, in anxiety a series of positive outcomes do not in themselves prove that a negative outcome might not occur at another time. Thus, the initial work with anxiety patients consists of reducing the catastrophizing regarding the importance of a negative outcome and teaching patients coping techniques in order to improve the chances of positive outcomes and to learn how to deal with negative outcomes should they occur.

Many anxious individuals view their anxiety as being constantly at a high level, but typically, anxiety occurs in waves. Self-monitoring anxiety symptoms helps patients to recognize that anxiety has a beginning, a peak, and then tapers off, and that they are able to handle it successfully. Thus, when in an anxiety-provoking situation, the person merely has to “wait it out” until the wave of anxiety passes.

In the early stages various imagery techniques are helpful. Patients can be encouraged to “live through” a frightening situation by imagining that it is occurring right in the therapist's office (*cognitive rehearsal*). Patients can then be asked to imagine the worst and best possible outcomes. This technique gives them greater perspective of the feared situation and constitutes a learning experience in itself.

After preliminary cognitive restructuring using Socratic questioning, reevaluation of anticipated catastrophes, and imagery techniques, patients are encouraged to try out what they have learned in actual threatening situations. These tasks are assigned in a graded way so patients are only gradually exposed to threatening situations. In these situations they continue to monitor automatic thoughts, and when possible, to re-evaluate them.

Panic Disorder The treatment of panic disorder focuses on the patient's tendency to make catastrophic misinterpretations about bodily sensations or mental experiences. The first one or two sessions are devoted to determining the precise nature of the patients' symptoms and how they misinterpret them. Careful attention is paid to the specific automatic thoughts that occur during the panic attack, the situation in which the panic attack is likely to occur, and the prodromal symptoms of the attack. By the third session the patient is generally ready to consider a different interpretation of the cause of the symptoms leading to the panic attack (*reattribution*).

It is usually possible to produce a mild panic-like attack through hyperventilation, exercise, use of imagery, or other stimuli, depending on the specific case. Patients are also taught distraction techniques to demonstrate to them that panic attacks are controllable. Following this, patients are encouraged to enter situations in which panic attacks can occur and to apply the techniques or rational restructuring based on what they have learned. It is often desirable for patients to go through at least one more panic attack from beginning to end, but without using rational responses or distractions to convince them that the panic attack in itself does not constitute a serious danger.

Obsessive-Compulsive Disorder Initial treatment focuses on increasing patients' awareness of automatic thoughts and images at the time of urges to carry out compulsive acts (e.g., handwashing or checking). These cognitions often portray the extent of patients' fears that motivate these redundant activities. In most cases individuals respond to these catastrophic ideations (or images) as though there is a high probability of their occurring. Thus, decatastrophizing methods are important. It is also crucial to steer the patient to recognize the excessive sense of responsibility in thoughts such as “If I don't do these compulsions and something bad happens, it would be my fault” or “It is my responsibility to protect my own life and those of my family.”

Typical behavioral methods include *response prevention,* in which the patient is prevented from engaging in the compulsive rituals; *exposure,* in which patients are exposed to threatening material (e.g., a pile of dirty towels). These behavioral methods are used to elicit the patient's thinking and images. By testing the reality of these thoughts and images, patients are able to cognitively restructure their unrealistic fears of some disaster.

Obsessions without compulsive behavior are sometimes more difficult to treat. The therapist focuses not only on the obsessional thought, for example, “bloody vagina” or “God is dead,” but on the self-evaluative cognitions that follow the thought, such as “I must be going mad” or “I'm God.” The therapist demonstrates that attempts by the patient to neutralize or suppress the offensive thought only increases its intensity. The patient is encouraged to allow these thoughts to occur and the therapist may attempt to desensitize patients by having them listen to taped recordings of the verbal thoughts.

Paranoid States To treat paranoid states, a strong collaborative alliance with the patient is essential and the patient must trust the therapist. In applying cognitive methods, the therapist must be aware that some of the patient's beliefs may be so highly charged that they are better left unexplored until a later date.

Initial interventions entail having patients monitor their automatic thoughts regarding other people's presumed biases towards them, with subsequent encouragement to look for alternative explanations for others' presumed noxious behavior. Next, certain basic beliefs, such as “I can't trust anybody” or “Everybody is out to get me,” can be subjected to a logical and empirical analysis. The therapist should be alert to finding at least a single episode that can disconfirm an absolute statement (e.g., “Everybody mistreats me”) since a single disconfirmation, if accepted by the patient, can help to undermine the absolute nature of such thoughts.

Decatastrophizing methods are also useful to demonstrate to patients that the consequences of being mistreated, abused, or persecuted are not necessarily as bad as they think. Further, it is important to have the patients learn that by attaching too much value to certain rules they impose on others (such as that other people must show deference towards them), they are continually setting themselves up for feeling infringed upon.

Somatoform Disorders Cognitive therapists occasionally see patients with a somatoform disorder, often after some type of traumatic physical episode that the patient believes caused damage to the brain, the spinal cord, the nerves, or some other part of the body. The therapist can devise the cognitive formulation for the particular patient by pinpointing exactly what the patient thinks has happened, the patient's theory as to what damage was caused, and the particular symptom presumably caused by that damage. The therapist can then reeducate the patient about the improbability of a real physical problem and can give the patient a reattributing type of explanation for the symptom.

Eating Disorders Anorexia nervosa and bulimia nervosa are characterized by a constellation of maladaptive beliefs that generally revolve around a few central assumptions, such as, “My weight and shape determine whether I am worthwhile or socially acceptable.” Associated with these assumptions are beliefs such as “I will look ugly if I gain more weight,” “If I don't starve myself, I will let go completely and become enormous,” “The only thing in my life that I can control is my weight.”

For the most part therapists initially give graded task assignments to attempt increased food intake (anorexia) or decreased binge eating, purges, and vomiting (bulimia). Fairly rapidly, however, discussion focuses on specific faulty beliefs regarding eating and its effect on body weight, the importance of appearance, and the patient's insistence on self-control. As therapy progresses, the cognitive analysis spreads to various other dysfunctional beliefs such as the patient's negative

self-concept (helpless, unlovable, undesirable), hypersensitivity to control by others, and wishes for approval.

Personality Disorders A complete elaboration of cognitive therapy of the personality disorders has been published. The focus of treatment is directed toward formulating the patient's basic beliefs (e.g., “Since I am helpless, I need to have a stronger person available at all times”) and demonstrating how those beliefs feed into the patient's dysfunctional behavior.

In contrast to the treatment of Axis I disorders, treatment of Axis II disorder requires a long period of therapeutic work—often 1 or more years. Also, there is a greater therapeutic focus on transference issues, exploring childhood patterns and even revivifying pathogenic childhood experiences, an increasing convergence with psychodynamic therapy. The major difference remains that the cognitive therapist is more active and directive, the therapeutic sessions are more structured, the content is based on conscious rather than unconscious or repressed memories, on exploring and testing cognitive distortions and basic beliefs, and patients are expected to carry out homework assignments.

M.K., a 40-year-old, hard-driving director of a research institute, was admitted because of a major depressive episode and generalized anxiety disorder. During the depressive episode, he had strong beliefs such as “I am worthless,” “I am useless,” and “I am a burden to my family.” With therapy for the acute depressive episode, these ideas were transformed into testable hypotheses about himself. Through Socratic questioning, application of logic, and empirical testing, the patient was able to regard these notions as testable beliefs rather than as reality. The cognitive interventions effectively contradicted his notions and, as these beliefs were attenuated, his depressive and anxious symptoms dissipated. Both patient and therapist recognized, however, that his personality problems (a mixture of compulsive and narcissistic features), led him to overemphasize achievement, productivity, efficiency, and perfection.

While initially regarding these beliefs as normal, healthy, and adaptive, M.K. came to see himself as being driven by these beliefs. When these traits were translated into beliefs, he began to see how dysfunctional they were. For him to understand and gain perspective on these beliefs, the therapist explored their origin during the developmental period of his life. M.K. began to see that these ideas were not based on rational decision-making, but rather they were imprinted on him by his parents.

The patient, an only child, saw his father as tough, demanding, and having very high expectations for him. The patient observed his father withdraw approval from him when he did not perform extremely well in school, and he observed his mother criticize his father for his supposed inadequacies. As a child, M.K. learned, “I must do extremely well to be accepted or else I risk others' disapproval and withdrawal of their respect and caring.” At times, for example when his best friend was promoted ahead of him, he had the thought “I'm inadequate.”

The patient coped with the painful beliefs of inadequacy and fear of rejection by developing and living up to extremely high standards, crystallized in a cluster of beliefs: “I must be the best at everything I do. It isn't enough to excel at one thing. If I have the potential in any area, I must live up to that potential in each of these areas.” For many years he fulfilled his professional potential as a biochemical researcher. This success strengthened his belief that “I can and should excel at everything now and in the future.”

Problems inherent in this belief, however, included tremendous personal sacrifice for overvaluing professional achievements. He had no time to “stop and smell the roses,” to nurture his wife and children, to appreciate the joys of nature, or to replenish himself physically and emotionally. He suffered from chronic anxiety, sleep problems, psychosomatic symptoms, and he was unable to increase his scientific achievements over a long period of time. External factors interfered with achievement: increased administrative demands, scarcer funding, changes in the attitude of faculty who wished to go elsewhere, and increased requirements from a new president. His time and energy were finite, yet the external factors over which he had no control continued to escalate. He could not accept these real limitations on his high-level productivity; instead, he blamed himself—“I'm inadequate.”

He developed anxiety symptoms when he perceived that he might not have the resources to cope with situations in which achievement was at risk. He was vulnerable to depression when he was forced to take time out due to overwork. When anxious, he felt as if he was on a tightrope, fearing that with one misstep, he would fall all the way down. When depressed he saw himself as being inadequate and a failure. “If I were really adequate, I could continue to achieve. Since I can't achieve to the same level as previously, it means I'm inadequate.”

Therapy consisted of delineating and then modifying these dysfunctional beliefs. The therapist explored with him his perfectionistic, dichotomized view of success, “Either I live up to my potential in all areas or I've failed,” whereby one misstep felt fatal to him. He believed he had to continuously drive himself to stay at the top because even one step below the top was equal to failure in his mind. In addition, he was hypersensitive to and became either anxious or irritated at perceived obstacles to smooth functioning: signs of physical or emotional illness in himself, a secretary's mistake, the tardiness of others' reports; in short, anything that could interfere with his achieving optimally.

The therapist helped the patient to fashion more functional beliefs: (1) “It is rewarding to succeed highly, but lesser success is rewarding also and has no bearing on my adequacy or inadequacy. I am adequate no matter what;” (2) “Scientific achievement is important but not vital;” (3) “What is vital is a reasonable mix of achievement; emotional and physical well-being; an enriching family and social life; joy in recreation, relaxation, and nature; and spiritual and personal growth;” and (4) “It is impossible for anyone to achieve this vital balance if any one area is overvalued.”

Therapy extended over the course of 1 year. The patient's dysfunctional attitudes gradually attenuated and new attitudes were incorporated. He continued to have a few brief spells of anxiety and depression but without full-blown recurrences of either disorder.

Schizophrenia Four recent well-controlled British studies indicate that cognitive or cognitive-behavioral therapy was more effective than the control groups in the treatment of acute schizophrenia (along with medication and routine hospital care) and also in chronic hospitalized patients with treatment-resistant schizophrenia. In two 18-month follow-up studies of medication-resistant patients with schizophrenia, the cognitive therapy groups showed a significant and continuing improvement on the Brief Psychiatric Rating Scale (BPRS) whereas the control groups were no better at 18 months than at baseline. Further, the cost of the cognitive therapists was offset by reduced service utilization and associated costs during treatment and subsequent follow-up.

Other Applications Cognitive therapeutic methods have been developed for application in a variety of formats, clinical contexts, and use in special populations, including depressed patients seen in primary-care settings, depressed adolescents, and adults with bipolar I disorder. Cognitive therapy has been used successfully in group, family, and couple therapy formats. Cognitive therapy has also been shown to be effective with marital problems. Some of the newer applications of cognitive therapy have been with posttraumatic stress disorders, sexual offenses such as exhibitionism and incest, alcohol abuse, hypertension, and dissociative disorders. In addition, cognitive therapy has recently shown promise in the treatment of smoking cessation. Several studies have shown that cognitive therapy is effective in the treatment of cocaine abuse. One study found that cognitive therapy provided better long-term outcome than clinical management, while the other found that participants in cognitive-behavioral therapy were significantly more likely to achieve abstinence than those who participated in a 12-step facilitation program.

Particularly notable is the development of an interactive, video-based, computer-assisted adaptation of cognitive therapy for depressed patients. This approach does not eliminate the therapist, but does appear to save therapist time and have high patient acceptance.

In sum, cognitive therapy appears to be applicable to an increasingly large number of disorders, formats, populations, and clinical contexts. Age, sex, socioeconomic status, and racial or ethnic background do not appear to be important factors, but the cognitive therapist needs to adapt the theory and principles to the special features associated with specific subgroups, and empirical evaluations of these adaptations must be provided.

OUTCOME STUDIES

Table 30.6-4 summarizes systematically controlled efficacy studies of cognitive therapy for various disorders. The findings have been supportive of cognitive therapy for patients with major depressive, generalized anxiety, panic, and somatoform disorders; heroin dependency; as well as anorexia nervosa, bulimia nervosa, and schizophrenia.

Disorder	Conclusions
Major depressive disorder (outpatients)	Meta-analysis Cognitive therapy >other psychotherapies Cognitive therapy >pharmacotherapy
Generalized anxiety disorder	Cognitive therapy >behavior therapy
Panic disorder	Cognitive therapy >supportive therapy Cognitive therapy >behavior therapy, imipramine (Tofranil)
Hypochondriasis	Cognitive therapy >standard treatment
Inpatient depression	Cognitive behavioral + standard >standard treatment alone
Bulimia nervosa	Cognitive therapy >interpersonal therapy
Heroin dependency	Cognitive therapy + supportive-expressive >methadone group counseling
Schizophrenia	Cognitive therapy >treatment as usual or befriending therapy (all treatments included antipsychotic medications)

Table 30.6-4 Clinical Outcome Studies of Cognitive Therapy

A meta-analysis of studies of cognitive therapy for major depressive disorder showed the superiority of this treatment over pharmacotherapy, behavior therapy, and other forms of psychotherapy. Another finding was that the average rate of relapses across four published studies was around 30 percent in cognitive therapy as compared to in excess of 60 percent in pharmacotherapy (without maintenance).

A report showed that cognitive therapy when combined with standard hospital treatment was more effective than standard hospital treatment (usually involving antidepressant drugs) followed by a period of outpatient therapy. Also, contrary to expectations, cognitive therapy has been found to be as effective in endogenous as in nonendogenous depressed patients. Of particular interest is the finding of an excellent response rate of 81 percent for cognitive therapy for hospitalized patients with depression who received no medication.

Cognitive therapy has been used with all age groups from children through geriatric populations. Several controlled studies have shown it to be at least as effective as antidepressant medication in the treatment of elderly depressed patients.

INDICATIONS

Cognitive therapy can be used to (1) remove or moderate the symptoms of the disorder as a sole treatment or in combination with medication; (2) reduce the likelihood of relapse or recurrence; (3) increase adherence to recommended medication treatment; (4) address specific psychosocial difficulties (e.g., marital discord, low self-esteem) that may either have preceded or been caused by the disorder; or (5) modify underlying beliefs (schemas) that contribute to dysfunctional personality trends or disorders. The indications for cognitive therapy are determined more by patient and therapist variables than by the nature of the disorder.

Patients The ideal patients are psychologically minded; able to recognize and label their emotions; to become aware of their automatic thoughts; and to see the connection between thoughts, feelings, and behaviors. The degree of fit between the patient's own personal notions of psychology and the basic cognitive model is important. Patients who adhere to such popular notions as the relation between stress and psychological disorders and the importance of self-control seem to benefit more from cognitive therapy than those wedded to Freudian concepts such as the unconscious and infantile fixations. High intelligence is not a prerequisite. Motivation for therapy is important but not initially crucial. Some hopeless, unmotivated, or depressed patients become highly motivated once they experience improvement.

Therapists As in any therapy, therapist characteristics are important. The ideal therapists are psychologically minded, versatile, attentive, empathic, and uncritical. They do not bring their own “personal baggage” (such as the need to control or show off) into the therapy session. A high motivation to “rescue” patients may be an asset with very sick patients but may be counterproductive for the less acutely ill. Skill in conducting cognitive therapy is obviously important for successful treatment. Several studies have shown a surprisingly high correlation between therapists' competency and successful outcome. Therapists who are skilled at educating patients about the cognitive nature of their problems and how to resolve them seem to get the best results. At least 1 year of supervised cognitive therapy following training and experience in basic interviewing skills is recommended.

Disorders Systematic data are lacking regarding the utilization of cognitive therapy for severe, psychotic, or melancholic depression, and for depressive episodes in bipolar I disorder. Since medications are of established efficacy in these conditions, cognitive therapy can be used to enhance the effectiveness of medications and has a specific role in promoting adherence to medication and training the patient to cope more successfully with life stressors and to integrate a more adaptive self-concept. Cognitive therapy without medication may be successful even with depressed inpatients who are refractory to medication or in whom medication is medically contraindicated. In view of the limited number of studies, however, cognitive therapy is not recommended as the initial treatment for depressed inpatients.

Most outpatients with either depressive or panic disorders who ultimately respond will do so within 5 to 7 weeks of once- or twice-weekly treatment with cognitive therapy alone, although a few patients have a more gradual response. If a symptom reduction of 50 percent according to a standard rating scale for depression is not achieved in 14 sessions, it might be useful to reconsider the diagnosis and treatment plan.

Maintenance treatment (booster sessions once or twice a month for 6 or 12 months after a course of more intensive once- or twice-weekly acute-phase treatment) may be useful in those with recurrent depressions; however, empirical evaluation of this notion is yet to be completed.

Clinical experience suggests that for those with double depression (recurrent major depressive episodes without full interepisode recovery superimposed on dysthymic disorder), the combination of cognitive therapy and medication may be the optimal choice. Clinical experience also suggests that major depressions that accompany medical disorders respond rapidly to cognitive therapy, especially in those without a history of preexisting psychopathology. For example, patients with their first myocardial infarction, with some forms of cancer, or with physical injuries that require marked psychological readjustments (e.g., blindness, loss of limb) often profit from this approach.

LIMITATIONS

Notwithstanding frequent successes with different individuals, for no obvious reason, some patients do not respond to cognitive therapy. Some with longstanding chronic conditions who have been treated by many professionals without lasting results may not do well in time-limited cognitive therapy. Sometimes an appropriate pharmacological agent added to cognitive therapy will produce a synergistic effect. In refractory cases, transfer to another therapist may be helpful. The therapist should also consider a change of strategy; for example, spending more time on empathic listening and less on exploration or becoming more active and directive. In any event, cognitive therapy is not a panacea even though its success rate is respectable.

Adverse reactions are difficult to differentiate from lack of efficacy. For instance, suicide attempts as well as premature terminations may be evidence of either adverse reactions or lack of efficacy. Some studies suggest that cognitive therapy is associated with lower premature termination rate than antidepressant pharmacotherapy. Perhaps the structured, planned, directive nature of this approach helps retain depressed outpatients in treatment. If so, cognitive therapy might be particularly useful for outpatients of low socioeconomic class, whose dropout rate from psychotherapy is particularly high.

Several limitations to this treatment are suggested by clinical experience. Patients with severely impaired reality testing (e.g., fixed delusions) or impaired reasoning abilities or memory function (e.g., organic brain syndromes) do not appear to respond well to cognitive therapy. However, cognitive methods may have a place even in those conditions if integrated into a total therapeutic regimen.

Despite our attempts to delineate the indications and contraindications for cognitive therapy, the fact remains that it may be difficult to predict outcome in an individual case. To some extent, the application is empirical (i.e., trial and error) for a given case. In some instances of refractory depression, for example, cognitive therapy has been used as a last resort and has been successful. For the most part, however, the professional evaluating a case can reasonably consider cognitive therapy, either alone or in combination with pharmacotherapy, for any of the conditions previously listed for treatment.

SUGGESTED CROSS-REFERENCES

Learning therapy is discussed in Section 3.3, sociology in Section 4.2, psychoanalysis in Chapter 6, other types of psychotherapy in the other sections of this chapter and the biological therapies in Chapter 31.

30.7 INTERPERSONAL PSYCHOTHERAPY

MYRNA M. WEISSMAN, PH.D., AND JOHN C. MARKOWITZ, M.D.

DEFINITION

Interpersonal psychotherapy, a time-limited treatment for major depressive disorder, was developed in the 1970s, defined in a manual, and tested in randomized clinical trials by the late Gerald L. Klerman and collaborators. Its success in research trials has led to its subsequent modification for different age groups, for subtypes of mood and non–mood disorders, and for use as a long-term treatment, in couples and group formats, over the telephone, and in a patient guide. The interpersonal psychotherapy manual has been translated into Italian, German, and Japanese. Having begun as a research intervention, interpersonal psychotherapy is only recently being disseminated among clinicians and in residency training programs. Increasing requests for training have followed the publication of interpersonal psychotherapy efficacy data, the promulgation of practice guidelines that include interpersonal psychotherapy among antidepressant treatments, interest in defined and proved treatments for managed care, and the endorsement of the 1995 *Consumer Guide*. A host of new research applications are also under study.

In 1993 practice guidelines appeared for mental health professionals and primary care practitioners. The two sets of guidelines differ considerably in scope, audience, and level of scientific basis for treatment recommendation. Neither claims to define the standard of care for any individual patient. Each discusses interpersonal psychotherapy as a short-term and maintenance treatment for depression, used alone or in combination with medication. The American Psychiatric Association (APA) *Practice Guideline for Major Depressive Disorder in Adults* describes interpersonal psychotherapy as useful for patients who face conflicts with significant others or who are having difficulty adjusting to a life transition. The clinical practice guidelines for treatment of depression in primary care settings recommended interpersonal psychotherapy for short-term treatment of nonpsychotic depression, to remove symptoms, prevent relapse and recurrence, correct causal psychological problems with secondary symptom resolution, and correct secondary consequences of depression. The guidelines state that medication alone may suffice to prevent relapse or recurrence and maintain remitted recurrent depression. The primary care guidelines describe interpersonal psychotherapy, cognitive-behavioral therapy, and behavior therapy as effective in most cases of mild-to-moderate depression but characterize indications for continuation-phase psychotherapy as unclear.

HISTORY AND THEORETICAL ISSUES

Interpersonal psychotherapy was initially formulated as a time-limited, weekly, outpatient treatment for depressed patients. Based on the ideas of Harry Stack Sullivan and the interpersonal school, interpersonal psychotherapy makes no etiological assumptions but uses the connection between onset of depressive symptoms and current interpersonal problems as a treatment focus. Interpersonal psychotherapy generally deals with current rather than past interpersonal relationships, focusing on the patient's immediate social context. It attempts to intervene in symptom formation and social dysfunction associated with depression rather than addressing enduring aspects of personality, which is difficult to assess during an episode of an Axis I disorder.

The theoretical foundation of interpersonal psychotherapy can be found in the writings of Sigmund Freud on grief and mourning and on attachment theory as developed by John Bowlby, who proposes that humans have an innate tendency to seek attachments. These attachments contribute to the survival of the species and to individual satisfaction. The threat of loss of important attachments creates anxiety and sadness, and frequent threats of such loss may predispose to depression. Attachment theory has stimulated a strong body of empirical research on the relationship between interpersonal relationships and depression. This research includes studies of childhood experiences and later adult depression, studies of the offspring of depressed parents, the childhood of adult depressives, social stress and life events, the role of social supports, lack of intimacy, marital discord and onset of depression.

Based on these theoretical and empirical sources, interpersonal psychotherapy assumes a connection between the onset of mood disorders (and perhaps other psychiatric disorders) and the interpersonal context in which they occur. The problem areas on which interpersonal psychotherapy for depression focuses were defined by psychosocial research on depression that suggested that complicated bereavement, role disputes, and role transitions were often associated with depressive episodes, either as precipitant or consequence. The progress of interpersonal psychotherapy has been defined by the sequential adaptation and empirical testing of the approach for particular psychiatric diagnoses.

TECHNIQUES

Phases of Treatment Interpersonal psychotherapy as a short-term treatment has three phases. The first, usually one to three sessions, includes diagnostic evaluation and psychiatric history and sets the framework for the treatment. The therapist reviews symptoms, diagnoses the patient as depressed by standard criteria (e.g., the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-IV]), and gives the patient the sick role. The sick role may excuse the patient from overwhelming social obligations but requires that the patient work in treatment to recover full function. The psychiatric history includes the *interpersonal inventory*, a review of the patient's current social functioning and close relationships, their patterns, and mutual expectations. Changes in relationships proximal to the onset of symptoms are elucidated (e.g., death of a loved one, children leaving home, worsening marital strife, or isolation from a confidant). This review provides a framework for understanding the social and interpersonal context of the onset of depressive symptoms and defines the focus of treatment.

The therapist assesses the need for medication on the basis of symptom severity, past history and response to treatment, and patient preference and then educates the patient about depression by explicitly discussing the diagnosis, including the constellation of symptoms that define major depression and what the patient might expect from treatment. The therapist next links the depressive syndrome to the patient's interpersonal situation within the framework of one of four interpersonal problem areas: (1) grief, (2) interpersonal role disputes, (3) role transitions, or (4) interpersonal deficits.

Strategies In the middle phase, the therapist pursues strategies specific to the chosen interpersonal problem area. For *grief*, defined as complicated bereavement following the death of a loved one, the therapist facilitates mourning and gradually helps the patient find new activities and relationships to compensate for the loss. *Role disputes* are conflicts with a significant other: a spouse, other family members, coworker, or close friend. The therapist helps the patient explore the relationship, the nature of the dispute, and options to resolve it. If these fail, they may conclude that the relationship has reached an impasse and consider ways to change the impasse or to end the relationship. *Role transition* includes change in life status (e.g., the beginning or end of a relationship or career, a move, promotion, retirement, graduation, or diagnosis of a medical illness). Patients learn to deal with the change by recognizing positive and negative aspects of the new role they are assuming and assets and liabilities of the old role it replaces. *Interpersonal deficits*, the fourth interpersonal psychotherapy problem area, defines the patient as lacking social skills, including having problems initiating or sustaining relationships.

Interventions Interpersonal psychotherapy sessions address present here-and-now problems rather than childhood or developmental issues. Sessions open with the question “How have things been since we last met?” This focuses the patient on recent interpersonal events and recent changes in mood, which the therapist attempts to link. Therapists take an active, nonneutral, supportive, and hopeful stance. Important interventions include helping the patient identify desires for resolution of interpersonal problem areas and options for achieving those desires. The therapist emphasizes the need to test new skills and change the interpersonal environment and often uses role playing to help the patient prepare for such life changes. Interpersonal psychotherapy focuses on what happens in the patient's life outside the office rather than on processes such as transference within it.

The final phase of interpersonal psychotherapy, occupying the last few weeks of treatment, supports the patient's sense of independent competence by recognizing and consolidating therapeutic gains. The therapist also helps the atient anticipate and develop ways of identifying and countering depressive symptoms should they

arise in the future.

CLINICAL ISSUES

Indications Indications for interpersonal psychotherapy have been defined by efficacy trials. Interpersonal psychotherapy has been one of the most carefully studied psychotherapies for mood disorders and the only psychotherapy tested in a maintenance treatment study. Its efficacy has been established for various subtypes of nonpsychotic depressive disorders and for bulimia nervosa.

Limitations Interpersonal psychotherapy showed no benefit in two studies of patients with substance abuse. It has not yet been definitively tested for other psychiatric disorders, such as anxiety disorders and borderline personality disorder, although studies are planned or under way.

Complications Interpersonal psychotherapy is an uncomplicated treatment that has met with high levels of patient acceptance and excellent clinical results in most trials. Attrition has been lower than that in competing therapies in several studies. Not all patients benefit from interpersonal psychotherapy, but no particular complications have been reported. Because the treatment is time-limited, nonresponse to interpersonal psychotherapy should lead to reevaluation and prescription of an alternate treatment after 12 to 16 weeks, minimizing the risk of complications.

Contraindications Interpersonal psychotherapy is not intended to be a treatment for delusional depression. It showed no benefit in two studies of patients with opioid dependence and cocaine abuse.

Ms. A., a 29-year-old never-married vice president in a successful business, presented with a 9-month history of depression complicated by panic attacks. She described her involvement in a relationship with her superior at work, which they both desired but which work policy forbade. Her symptoms emerged under the pressure she felt to resolve this situation, from which she saw no way out. Neither she nor her boyfriend Bob wanted to leave their jobs, and neither wanted to end the relationship. Yet exposure of their secret threatened both their jobs.

In this context Ms. A. developed the full spectrum of symptoms of major depressive disorder, with a Hamilton Rating Scale for Depression score of 28 on presentation, including intermittent panic attacks and suicidal ideation without attempts. Her work and mood suffered. She had a family history of depression and alcoholism but had no prior symptoms, and she did not drink. She had been in twice-weekly psychodynamic psychotherapy for 2 years, starting after the breakup of a previous relationship. She felt this therapy had increased her self-understanding but had not helped her symptoms. She had considered but declined to take antidepressant medication, feeling it would not resolve her dilemma.

Although quite depressed, Ms. A. quickly agreed that she was in a depressive episode and was able to relate it to her interpersonal situation. This had some aspects of a role transition—a change in her personal and work roles—but was best characterized as a role dispute with Bob: what did she want to happen, and what options did she have to negotiate its happening? A 12-week time limit was set for treatment. Her interpersonal therapist focused on helping her explore various options. She developed a resume and went to a headhunter to seek new job possibilities, although she was ambivalent at leaving her hard-earned and promising post. Role-playing helped her discuss the situation and its possibilities with her lover. Subsequent encounters with Bob better defined the nature of their agreements and differences.

Simply defining the problem and mobilizing Ms. A. to constructive action yielded an improvement in her mood and a greater sense of mastery of her situation. Interpersonal psychotherapy also helped her to develop interpersonal skills: although Ms. A. was appropriately assertive in her work role, she was far more pliant and submissive in her personal relationships, a problem that emerged in reviewing her interpersonal inventory of past romances. Depressive symptoms steadily subsided, but the turning point came in the sixth week of interpersonal psychotherapy when, after considerable exploration and role-playing in therapy, Ms. A. told her boyfriend that she had decided she could not give up her job; either they would have to end the relationship, or he would have to move. He initially said that his own job came first. But several days later he recanted, saying how much he loved her and that he would try to find a new job himself. Her symptoms resolved. Shortly thereafter, a wonderful prospect appeared for Ms. A. in effect giving her a promotion at a different, related company, and allowing the relationship to continue overtly. She attributed her symptomatic improvement to her newly firm stand, not to the job change. On 6-month follow-up, she remained euthymic without panic attacks and felt she was holding her own in a relationship that was going more smoothly than previous relationships ever had.

Goals of Treatment As illustrated above, interpersonal psychotherapy has two goals: (1) to help the patient solve an interpersonal problem and thereby (2) to alleviate the patient's psychiatric syndrome (e.g., depression).

ETHICAL ISSUES

In encouraging depressed patients to recognize and enact their own goals and wishes, therapists must be careful not to impose their own values (e.g., whether the patient stays in a marriage). Although interpersonal therapists take a relatively relaxed and informal, conversational approach to therapy, they must know appropriate boundaries regarding self-disclosure and focus treatment on benefit for the patient.

RESEARCH AND EVALUATION

Interpersonal psychotherapy has been widely tested in outcome research. The range of this research and its encouraging results indicate the excitement surrounding the treatment.

Acute Treatment of Major Depression The efficacy of interpersonal psychotherapy as a treatment for acute depression was first demonstrated by Klerman, the first author, and colleagues in a four-cell, 16-week randomized trial of interpersonal psychotherapy and amitriptyline (Elavil), alone and in combination, and a nonscheduled control treatment for 81 outpatients with major depressive disorder. There were no significant differences between interpersonal psychotherapy and amitriptyline in symptom reduction by the end of treatment, although the effects of amitriptyline appeared earlier. Each active treatment reduced symptoms more effectively than the nonscheduled control group, and combined amitriptyline-interpersonal psychotherapy was more effective than either active monotherapy. A 1-year naturalistic follow-up found that many patients sustained benefits from the brief interpersonal psychotherapy intervention. Patients who received interpersonal psychotherapy developed significantly better psychosocial functioning, whether or not they received medication. This effect on social function did not occur with amitriptyline alone and had not been evident at the end of the 16-week trial. Many patients from all treatments, however, reported requiring additional treatment over the follow-up year. This suggested that short-term treatment was insufficient for persistent response, a fact now recognized in many studies that include a maintenance phase.

The most ambitious short-term treatment study to-date, the multisite National Institute of Mental Health Treatment of Depression Collaborative Research Program (NIMH TDCRP), randomly assigned 250 depressed outpatients to 16 weeks of imipramine (Tofranil), interpersonal psychotherapy, cognitive-behavioral therapy, or placebo plus clinical management. Most subjects completed at least 15 weeks or 12 treatment sessions. Less-symptomatic patients improved in all treatments, including placebo. Imipramine induced the most rapid response and was most consistently superior to placebo. Interpersonal psychotherapy was comparable to imipramine on several outcome measures and showed a mean outcome superior to that with placebo for the more severely depressed patients. Cognitive-behavioral therapy was not superior to placebo for this group.

A reanalysis of the efficacy data from the NIMH TDCRP by sophisticated statistical techniques ordered treatment efficacy; medication was superior to psychotherapy, and the psychotherapies were superior to placebo, particularly among the symptomatic and impaired patients. This reassessment found cognitive-behavioral therapy to be inferior to interpersonal psychotherapy for patients with Beck Depression scores above approximately 30, which is generally considered the boundary between moderate and severe depression. These findings are consistent with those originally reported, but they sharpen differences between treatments.

An 18-month naturalistic, follow-up study of TDCRP patients found no significant difference in recovery among remitters (defined by the presence of minimal or no symptoms following the end of treatment and sustained during an 18-month follow-up) among the four treatment groups: 30 percent for cognitive-behavioral therapy 26 percent for interpersonal psychotherapy 19 percent for imipramine, and 20 percent for placebo. Among patients who had remitted by the end of the 16-week study, relapse over the 18-month follow-up was 36 percent for cognitive-behavioral therapy 33 percent for interpersonal psychotherapy, 50 percent for imipramine, and 33

percent for placebo. The authors concluded that 16 weeks of specific treatments were insufficient to achieve full and lasting recovery for many patients.

Hoencamp and colleagues are undertaking a study at the Hague in the Netherlands comparing interpersonal psychotherapy and nefazadone (Serzone) alone and in combination, for the acute treatment of major depression.

Continuation and Maintenance Treatment Interpersonal psychotherapy was first developed and tested in an 8-month, six-cell trial in 1974. Today this study would be considered a continuation rather than a maintenance treatment, as the concept of long-term treatment of depression has changed. Acutely depressed outpatient women (*N* = 150) who responded (>50 percent symptom reduction rated by a clinical interviewer) to a 4- to 6-week acute phase of amitriptyline were randomized to receive 8 months of treatment with weekly interpersonal psychotherapy alone, amitriptyline alone, combined interpersonal psychotherapy amitriptyline, interpersonal psychotherapy-placebo alone, or no pill. Randomization to interpersonal psychotherapy or a low contact condition occurred at entry into the continuation phase, whereas randomization to medication, placebo, or no pill occurred at the end of the second month of continuation. Maintenance pharmacotherapy was found to prevent relapse and symptom exacerbation, whereas interpersonal psychotherapy improved social functioning. The effects of interpersonal psychotherapy on social functioning were not apparent for 6 to 8 months. No negative treatment interactions were found, and combined psychotherapy-pharmacotherapy yielded the best outcome.

In the longest maintenance trial, Ellen Frank and colleagues studied 128 outpatients with recurrent depression, defined as a history of at least three acute major depressive episodes, who responded to 12 weeks of combined imipramine and interpersonal psychotherapy for the acute episode and 20 weeks of continuation treatment. Interpersonal psychotherapy was modified for this maintenance trial (interpersonal psychotherapy-M), primarily by emphasizing problems that persist or develop as a consequence of remission. Because of the length of treatment, multiple problem areas were addressed.

Following continuation treatment, patients were randomly assigned to receive 3 years of maintenance in one of five cells: monthly maintenance interpersonal psychotherapy, either (1) alone, (2) combined with imipramine, or (3) combined with placebo, or medication clinic visits for either (4) continuing high-dosage imipramine or (5) placebo, without further psychotherapy. This study was unique in using the highest dosage of medication ever in a maintenance trial (mean, 200 mg a day) and the lowest dose of interpersonal psychotherapy ever (monthly). This is also the only maintenance psychotherapy study of major depressive disorder to date.

Findings showed the highest significant effect for maintenance imipramine in preventing recurrence (survival time) and a modest but significant effect for interpersonal psychotherapy. After 1 year, major depression had recurred in 65 percent of placebo patients, 46 percent of those on interpersonal psychotherapy without imipramine, 17.9 percent of those on imipramine alone, and only 8 percent of those receiving interpersonal psychotherapy-imipramine, a trend supporting the superiority of combined treatment. At 3 years, mean survival without recurrence of depression was 45 weeks on placebo, 74 weeks on interpersonal psychotherapy plus placebo, 82 weeks for interpersonal psychotherapy alone, 124 weeks for imipramine alone, and 131 weeks for interpersonal psychotherapy-imipramine. Survival without recurrence was longer in patients who received interpersonal psychotherapy only than in those who did not (*P* = .043). The authors concluded that imipramine maintenance treatment at a dosage of 200 mg a day effectively prevents recurrence of major depressive episodes in patients with a history of recurrent episodes and that monthly interpersonal psychotherapy lengthens the time between episodes in patients not receiving medication. The 82-week survival time without recurrence with interpersonal psychotherapy alone for patients with a history of recurrence would suffice to protect many women, with recurrent depression, through pregnancy and nursing without medication.

Attempting to determine factors contributing to the efficacy of interpersonal psychotherapy, the investigators found that the quality of interpersonal psychotherapy, as measured by the interpersonal specificity and purity of the sessions (i.e., specific focus on interpersonal themes) but unrelated to the individual clinicians per se, was associated with longer time to recurrence. Audiotapes of therapy sessions were rated blind to the patient's clinical state and time since entry into the study. High specificity and purity of sessions were associated with a delay in recurrence of depression more than four times as long as would have been expected on the basis of the patient's history of recurrences. Patients whose therapy sessions were rated above the median on specificity of interpersonal psychotherapy had a median survival time of almost 2 years, whereas those below relapsed in less than 5 months.

A cost-effectiveness analysis based on this study showed that maintenance medication or interpersonal psychotherapy, either alone or in combination gave better expected lifetime health than placebo as measured by Quality Adjusted Life Years. A similar conclusion was reached comparing combined imipramine and interpersonal psychotherapy to interpersonal psychotherapy alone. In neither case were health care costs reduced.

The first phase of the maintenance trial was short-term–treatment study that used interpersonal psychotherapy for 12 to 24 weeks. Remitters, defined as having a Hamilton Rating Scale for Depression (HAM–D) score of 7 or below were entered into the maintenance study. Patients who failed to remit on interpersonal psychotherapy alone experienced higher levels of somatic anxiety and were more likely to meet diagnostic criteria for life time panic disorder. The authors concluded that concomitant anxiety can adversely affect the outcome of interpersonal psychotherapy for depression.

Nonremitters also had significantly worse subjective sleep quality and other indicators of disturbed sleep.

Further study required to determine whether the efficacy of interpersonal psychotherapy differs in patients receiving newer medications (e.g., selective serotonin reuptake inhibitors). Additional questions, including the effectiveness of more frequent than monthly interpersonal psychotherapy need to be addressed. A study of differing schedules of interpersonal psychotherapy for depressed women is under way in Pittsburgh.

Geriatric Depressed Patients The first use of interpersonal psychotherapy in geriatric depressed patients was not an efficacy study but an addition to a 6-week medication trial, to enhance compliance and to provide some treatment in the placebo control group. Noting that grief and role transition specific to life changes were the prime focus of treatment, the authors suggested interpersonal psychotherapy modifications including more flexible duration of sessions, greater use of practical advice and support (e.g., arranging transportation, calling the physician), and recognition that major role changes may be impractical and detrimental (e.g., divorce at age 75).

One 6-week clinical trial comparing interpersonal psychotherapy and nortriptyline (Aventyl) in 30 geriatric depressed patients showed some advantages for interpersonal psychotherapy, largely because medication adverse effects produced higher attrition in the medication group. Interpersonal psychotherapy was not modified for this study.

Charles Reynolds and colleagues in Pittsburgh conducted a 3-year maintenance study for geriatric patients with recurrent depression using a design similar to the study by Frank and coworkers. Interpersonal psychotherapy was modified for geriatric patients as interpersonal psychotherapy late-life maintenance treatment. During the acute phase, patients received combined nortriptyline and monthly interpersonal psychotherapy. This study then compared interpersonal psychotherapy late-life maintenance treatment alone, nortriptyline alone, interpersonal psychotherapy late-life maintenance treatment plus nortriptyline, interpersonal psychotherapy late-life maintence treatment and placebo, and placebo alone as randomized discontinuation maintenance therapies. The manual has been modified to allow more flexible session length, since elderly patients may not tolerate 50-minute sessions. Some of the authors found that older patients need to address early life relationships in their psychotherapy, distinguishing interpersonal psychotherapy late-life maintence treatment from the typical here-and-now focus of interpersonal psychotherapy. As in the earlier geriatric study, they found that therapists needed to help patients solve practical problems and should share awareness that some problems may not be amenable to resolutions (e.g., existential late-life issues or life-long psychopathology). They found that elderly depressed patients whose sleep quality normalized with early continuation of treatment had an 80 percent chance of remaining well during the first year of maintenance treatment. Response rates were similar in patients receiving nortriptyline or interpersonal psychotherapy. The final results in 187 patients over the age of 59 with recurrent depression found that maintenance treatment with nortriptyline or monthly interpersonal psychotherapy was superior to placebo in preventing or delaying recurrence. Combined treatment using both medication and psychotherapy was the optimal strategy in preserving recovery.

Bereavement-Related Depression A study comparing interpersonal psychotherapy and nortriptyline for short-term treatment of bereavement-related major depression is ongoing in Pittsburgh. The interpersonal psychotherapy modification includes more-detailed information gathering in the initial phase of treatment on the quality of earlier and current relationships and roles and determines available social supports for spousal bereavement. Detailed information on practical quality-of-life issues includes bill payment, financial burden, leisure activities, and children.

Depressed Adolescents Laura Mufson and coworkers modified interpersonal psychotherapy to incorporate adolescent developmental issues, adding as a fifth problem area the single parent family, an interpersonal situation found frequently among their adolescents. Parents are also involved in the initial phase, and their permission is obtained for treatment. Telephone contacts are readily used, and the school is involved when appropriate. In an open trial, 14 patients were significantly

less depressed and had improved functioning after 12 weeks of treatment. At 12 weeks, none met criteria for revised third edition of DSM (DSM-III-R) major depression. A follow-up of 10 patients found that only 1 met criteria for an affective disorder at 1 year. There were no hospitalizations, suicide attempts, or pregnancies, and all remained in school, even though about a third had experienced serious negative life events since completing treatment: violence, physical or sexual abuse, parental psychopathology, or the death of a parent. The small sample of adolescents of low socioeconomic status limits generalizability. A larger, controlled clinical trial recently has been completed and has demonstrated the efficacy of interpersonal psychotherapy in symptom reduction of improving social function.

Depressed Adolescent Mothers Laune Gillies at Clark Institute, Toronto, is completing a pilot study of depressed pregnant adolescents (ages 15 to 19). Thirty patients, all scoring 14 or higher on the Beck Depression Inventory (BDI), were randomly assigned to 12 weekly sessions of arts and crafts, a psychoeducational group, or individual interpersonal psychotherapy. Eleven subjects terminated early, with attrition approximately equal across groups. Results are pending.

Depressed Human Immunodeficiency Virus (HIV)-Positive Patients (IPT-HIV) The second author and coworkers modified interpersonal psychotherapy for depressed HIV patients, emphasizing common issues in this population including concern about illness and death, grief, and role transitions. In a pilot open trial, 21 of the 24 depressed patients responded with symptom reduction. Most patients found brief therapy suitable to their situation, in which time was precious and quick results needed. A 16-week randomized clinical trial has been completed comparing interpersonal psychotherapy with the modified cognitive-behavioral therapy, supportive psychotherapy, and imipramine plus supportive psychotherapy. Treatment of 101 patients showed that while symptoms decreased across therapies, interpersonal psychotherapy and imipramine resulted in differential improvement relative to supportive psychotherapy or cognitive-behavioral therapy. These results resemble outcomes for the more symptomatic patient subgroup in the TDCRP.

Depressed Primary Care Patients H.C. Schulberg and colleagues completed a clinical trial comparing interpersonal psychotherapy with pharmacotherapy for depressed ambulatory medical patients in a primary care setting. The interpersonal psychotherapy manual was not modified, but interpersonal psychotherapy conformed with practices of the primary care center; for example, nurses took vital signs prior to each session. If a patient was medically hospitalized, interpersonal psychotherapy continued in the hospital when possible.

Patients with current major depressive disorder (*N* = 276) were assigned to either interpersonal psychotherapy nortriptyline, or primary care physicians' usual care. They were seen weekly for 16 weeks and monthly thereafter for 4 months in interpersonal psychotherapy. Depressive severity declined more rapidly with either nortriptyline or interpersonal psychotherapy than in usual care. Among treatment completers, approximately 70 percent receiving nortriptyline or interpersonal psychotherapy but only 20 percent in usual care were judged recovered at 8 months. Patients with lifetime comorbid panic disorder had poorer recovery than those with major depressive disorder alone, regardless of treatment. Interestingly, a post hoc analysis found that severely depressed patients (Hamilton Rating Scale for Depression Score ^{3} 20) did equally well on interpersonal psychotherapy and nortriptyline. However, less severely depressed patients responded more rapidly to medication as compared to interpersonal psychotherapy during the first 3 months.

Conjoint Interpersonal Psychotherapy for Depressed Patients With Marital Disputes Since marital conflict, separation, and divorce have been associated with the onset and course of depressive episodes and individual psychotherapy for depressed patients in marital disputes may lead to termination of some marriages, a manual was developed for conjoint therapy of depressed patients with marital disputes. This modified interpersonal psychotherapy focuses on the current marital dispute and involves the spouse in all sessions. Eighteen patients with major depressive disorder linked to the onset or exacerbation of marital disputes were randomly assigned to 16 weeks of individual interpersonal psychotherapy or conjoint interpersonal psychotherapy. Patients in both treatments showed the same reduction in depressive symptoms. Patients in conjoint interpersonal psychotherapy had significantly better marital adjustment, greater marital affection, and better sexual relations than did patients receiving interpersonal psychotherapy alone. These preliminary findings require replication with a larger sample and other control groups.

Antepartum and Postpartum Depression Margaret Spinelli is using interpersonal psychotherapy to treat women with antepartum depression at Columbia University. Examination of this role transition focuses on the pregnant woman's self-evaluation as a parent, physiological changes of pregnancy, and altered relationships with spouse or significant other and other children. A fifth problem area, complicated pregnancy, has been added. Timing and duration of sessions require flexibility because of bed rest, delivery, obstetrical complications, and child care. Young children may be brought to sessions, where postpartum mothers may breast feed. Telephone sessions and hospital visits may be necessary. Spinelli has published results of an open trial and is undertaking a controlled clinical trial comparing interpersonal psychotherapy with didactic parent education groups in depressed pregnant women over a 16 week period of treatment and 6 monthly follow-up sessions.

Scott Stuart and Michael O'Hara have a trial under way comparing interpersonal psychotherapy and a waiting list control for women with postpartum depression. They assess both the mothers' symptom state and interactions with their infant.

Dysthymic Disorder (IPT-D) In a modification of interpersonal psychotherapy for dysthymic disorder, patients are encouraged to reconceptualize what they had seen as their lifelong character flaws as ego-dystonic, chronic mood-dependent symptoms. Contrary to expectation, open treatment found that dysthymic disorder patients with lifelong chronicity had a reduction of depressive symptoms in 16 weekly interpersonal psychotherapy sessions. Markowitz treated 17 pilot subjects; none worsened, and 11 remitted. Medication benefits roughly half of dysthymic patients, but nonresponders may need psychotherapy, and even medication responders may benefit from combined treatment. Based on these pilot results, a comparative study of 16 weeks of modified interpersonal psychotherapy for dysthymic disorder alone, supportive psychotherapy, sertraline plus clinical management, and interpersonal psychotherapy and sertraline, is under way at Cornell Medical Center.

Gina Browne and Meu Steiner at McMaster University in Hamilton, Canada have a 20-month study of approximately 700 dysthymic disorder patients receiving unmodified interpersonal psychotherapy or sertraline alone or in combination for 1 year. Preliminary results at 6 months showed that sertraline (Zoloft) alone had better compliance than interpersonal psychotherapy alone and was equally effective to sertraline plus interpersonal psychotherapy and more effective than interpersonal psychotherapy alone, as measured by symptom reduction. However, patients who received interpersonal psychotherapy either alone or in combination with sertraline had economically important containment of or reduction in expenditures from use of health and social services and lower expenditures for social assistance. One and 2-year follow-up studies are planned to assess the enduring nature of these effects and the impact, if any, on family functioning.
