Personality Disorders Axis II in DSM-IV consists of personality disorders, an area of psychopathology in which psychoanalytic thinking makes perhaps its most significant contribution to contemporary psychiatry. Personality disorders are long-standing modes of thinking, feeling, and relating to others that are deeply ingrained within the patient. The major features of personality disorders are often *ego-syntonic*, meaning that they are not subjectively experienced by the patient as foreign or distressing in the way neurotic symptoms are. However, personality disorders do create problems for those who must relate to the patient. In many cases those with Axis II disorders do not even seek treatment until the interpersonal and social consequences of their character traits create so much concern that they feel the need to change.

Persons who suffer from personality disorders have generally resolved intrapsychic conflict through the formation of stable defensive patterns that result in severe inhibitions in work and play or that allow for partial gratification of instinctual wishes under certain conditions. The term *character neurosis* is used to describe higher-level personality disorders, such as those of a predominantly obsessive-compulsive or hysterical nature. In those conditions, discrete neurotic symptoms are absent, but certain defensive patterns and cognitive styles pervade the entire personality. Some lower-level personality disorders, such as borderline and antisocial conditions, may involve deficit, as well as certain conflict, and may manifest themselves in certain characteristic ego weaknesses, particularly in the areas of frustration tolerance, drive regulation, object relations, and affective control.

Paranoid Personality Disorder Persons suffering from paranoid personality disorder have rigid, pervasive cognitive styles involving suspiciousness, hypervigilance,

inability to trust or confide in others, pathological jealousy, and a proneness to be easily slighted. Their intrapsychic world is organized along the lines of the paranoid-schizoid position described by Melanie Klein. Splitting, projection, and projective identification are the typical defense mechanisms by which those patients separate out all badness, hatred, and aggression within themselves and deposit it projectively into others. As a result, those patients maintain a stable equilibrium but live with persecutory anxiety connected to the constant threat of attack or mistreatment by others. Moreover, because of their defensive style, the patients must be hypervigilant at all times and attempt to control others, so that the perceived threat is kept at bay. Low self-esteem and feelings of inferiority and weakness are at the core of paranoia, and the grandiosity often seen in the patients is a compensatory defense to deal with the pain caused by those unacceptable feelings.

Schizoid and Schizotypal Personality Disorders Persons with schizoid and schizotypal personality disorders are often considered misfits who seem to avoid other people. Outwardly, they may appear to prefer isolation to relatedness and show little conflict over their solitary existence. However, psychodynamic treatment of them has demonstrated that their apparent lack of concern for their mode of adjustment may mask considerable confusion and deepening longings for relatedness. From a psychoanalytic perspective, the term *schizoid* refers to a splitting or fragmentation of the self into a myriad of self-representations that produce a sense of identity diffusion. The patients' absence of conviction about who they are and what they want may cause schizoid persons to feel paralyzed and to withdraw from attempting interpersonal relatedness. Many have also experienced thoroughgoing frustration as children regarding their ability to get their emotional needs met by others, so they attempt to be self-sufficient to avoid the pain of repeated rejections and of disappointments in others. They may feel that their neediness is so voracious that it would destroy others or drain them of all they have to give. Alternatively, they may fear that they will be consumed or smothered by those from whom they seek emotional sustenance. Hence, many feel caught in a schizoid compromise in which they adjust to a solitary existence as a way of dealing with the twin fears of driving others away by their neediness and of being consumed by the demands of others.

Borderline Personality Disorder Although the borderline concept has been around for many years, the work of Otto Kernberg from his ego psychological-object relations perspective in the 1960s provided the first comprehensive psychodynamic understanding of the condition. He used the term *borderline personality organization* to describe a cluster of characteristics typical of a group of patients who appear to have a mixture of both neurotic and psychotic symptoms. Kernberg's structural analysis of that level of ego organization include the following four elements:

1. Nonspecific manifestations of ego weakness, including poor anxiety tolerance, poor impulse control, and poorly developed subliminatory channels
2. A shift toward primary process thinking, particularly under the pressure of strong affects or in unstructured situations, such as projective psychological testing
3. A pattern of specific defensive operations, including splitting, projective identification, primitive idealization, denial, omnipotence, and devaluation
4. Pathological internalized object relations based on splitting, so that representations of self and others are alternatingly all good or all bad.

Although Kernberg's psychodynamic conceptualization applies to most patients with borderline personality disorder, it was developed as a level of *ego organization* that also encompasses other personality disorders. Kernberg subsumed narcissistic, schizoid, antisocial, paranoid, and lower-level histrionic (infantile) personality disorders under the umbrella of borderline personality organization.

Kernberg also linked the cause and the pathogenesis of borderline personality disorder to a specific developmental arrest during the rapprochement subphase delineated by Mahler and her colleagues. Because those patients can distinguish self from object, Kernberg thought that they had fully traversed the symbiotic phase but had not been able to successfully negotiate separation-individuation. In Kernberg's view, something goes wrong during the rapprochement subphase of development, so that borderline patients never get over the fear that maternal figures will abandon them. He postulated that either a disturbance in the mother's emotional availability or an inborn excess of aggression in the child (or perhaps a combination of both) results in the developmental arrest. As a consequence, the children grow up with chronic anxiety about being abandoned by significant people in their lives. Similarly, they are never able to integrate positive and negative aspects of self-representations and object representations and to internalize well-rounded and complex internal images of the mother to provide object constancy.

Gerald Adler, by contrast, has approached borderline personality disorder from a deficit or insufficiency model that is influenced by self-psychological theories. He understood the borderline patient to be one who grew up in an environment where selfobject needs were not satisfied. Hence, the patients continue to search for selfobjects as adults because they have not developed a holding-soothing introject. Whereas Kernberg viewed the borderline patient as suffering from a predominance of hostile introjects, Adler regarded those same patients as suffering from an absence of introjects, so that they are prone to fragmentations of the self when others do not provide selfobject functions for them. Adler referred to that fear of self-disintegration as *annihilation panic*.

In recent years a considerable body of research has documented an extensive history of childhood trauma in many patients with borderline personality disorder. Approximately 50 percent have experienced incest or other forms of childhood sexual abuse that is etiologically relevant to the disorder; others have experienced physical and verbal abuse as well. Like other patients with a history of early trauma, abused borderline personality disorder patients may reenact characteristic patterns of object relatedness involving abuser-victim paradigms. In addition, the horrific histories of childhood trauma may stir up countertransference needs to rescue in the clinician treating the patient. Finally, the fact of abusive figures in childhood allows the clinician to empathize with the borderline personality disorder patient's need to perceive treaters as “bad objects” who are assumed to be untrustworthy.

Narcissistic Personality Disorder The two major psychodynamic theories of narcissistic personality disorder are those of Kohut and Kernberg. Kohut's theory of the cause and pathogenesis was discussed under the heading of “Self Psychology.” Kohut's view is that narcissistic patients are developmentally arrested because of parental failures of empathy in response to the child's phase-appropriate needs for idealization, mirroring, and twinship experiences. Those children then grow up treating others as though they exist only to gratify their narcissistic needs. Persons who are expected to fill selfobject functions for narcissistic persons are usually alienated by the self-centered nature of the relationship and reject the narcissistically disordered person. Hence, a patient with narcissistic personality disorder goes through life suffering repeated fragmentations of the self in response to the failure of others to fulfill those selfobject needs.

Kernberg offered a different psychodynamic formulation of narcissistic personality disorder. He saw a person with the disorder as essentially similar to a person with borderline personality disorder in that they both operate from the same level of personality organization. The corresponding defensive operations and pathological internal object relations are also present. Kernberg differentiated a narcissistic patient from a borderline patient on the basis of the presence in the narcissistic patient of an integrated but pathologically grandiose self. He conceptualized the grandiose self as being a defensive structure in narcissistic personality disorder that denies dependency on others. Kernberg saw the grandiose self as a fusion of the real self, the ideal object, and the ideal self. In other words, a narcissistic patient maintains an illusion of self-sufficiency through the grandiose self-image.

Kernberg further differentiated narcissistic personality disorder from borderline personality disorder by the presence of higher-level ego functioning in patients with narcissistic personality disorder. Narcissistic patients look much the same from day to day because their self-representation is more continuous than the alternating self-representations of the patient with borderline personality disorder.

Kohut discussed the libidinal and selfobject needs of narcissistic patients, but Kernberg stressed the underlying envy and aggression in patients with narcissistic personality disorder. Because of excessive aggression from either constitutional or environmental sources, narcissistic patients are seen as suffering from chronic intense envy that leads them to destroy and spoil the positive aspects of others whom they envy. Kohut thought that envy does not play a central role in causing narcissistic personality disorder and that aggression is secondary to narcissistic injury, rather than primary, as Kernberg argued. Although Kohut postulated that idealization, commonly seen in narcissistic patients, is a normal developmental need, Kernberg conceptualized idealization as defensive against underlying contempt, rage, and envy.

Antisocial Personality Disorder Of all the Axis II conditions, antisocial personality disorder is the one most clearly linked to biological underpinnings. Twin studies suggest that genetic factors are influential, neuropsychological testing demonstrates the presence of organically based cognitive impairment, and measures of autonomic indicators suggest that antisocial patients are autonomically hyporeactive. The normal attachment process of the infant to the mother may be compromised by those innate constitutional factors. In addition, patients with antisocial personality disorder frequently report a history of abuse or neglect by parental figures. Some authors believe that antisocial personality disorder is psychodynamically related to narcissistic personality disorder. Therefore, a pathological grandiose self is often a key feature of persons with antisocial tendencies. However, such patients differ from narcissistic patients in the nature of the parental introject. Typically, antisocial persons have internalized a cruel, malevolent parental figure, instead of the ideal object that is internalized by those with narcissistic personality disorder. Moreover, the antisocial person never really becomes sensitive to other people as separate persons with needs and feelings of their own. Those major impairments in the internalization process result in a person with no moral conscience. The only trace of superego development may be the presence of sadistic superego precursors. The only value system, if one can call it that, in patients with antisocial personality disorder is the exercise of power and destructiveness over others. Every relationship is approached as an opportunity for exploitation and cruelty. The absence of superego development in those patients makes them extraordinarily difficult or impossible to treat.

Histrionic Personality Disorder Histrionic personality disorder is best conceptualized as a continuum between a lower-level orally fixated histrionic patient on one

end and a higher-level hysterical patient with a phallic fixation on the other end. A female patient at the lower end of the continuum typically turns to her father for maternal nurturance that she feels she did not receive from her mother. She learns that dramatic affective displays are required to capture the attention of her father and other men. Genital sexual relations may be characterized by primitive oral neediness. She then discovers that sexual behavior is rarely satisfying because she is searching for a maternal breast and is receiving a penis instead, an unconscious fantasy known as the *breast-penis equation*.

At the higher end of the continuum, a hysterical female patient has typically been more successful in receiving maternal nurturance than was the female patient at the lower end. However, the hysterical woman is unable to relinquish her libidinal attachment to her father and grows up with an incompletely resolved oedipal situation. She idealizes her father as a man who has no equal. She finds herself in triangular relationships throughout her life, in rivalrous situations with other women for the affections of a man who may be forbidden or unattainable. The hysterical woman frequently chooses romantic partners who are already married or otherwise inappropriate as a way of assuring herself that she will not have to give up her attachment to her father. Because repression is a primary defense used by a patient with hysterical personality disorder, the attachment is often entirely unconscious, and only through psychoanalysis or psychotherapy does she become aware of her tendency to repeat the oedipal drama throughout her adult life.

Although hysterical personality disorder is commonly associated with women, male patients may also meet the diagnostic criteria. The dynamics of such cases is remarkably similar to those found in female patients. The histrionic male patient turns to his father for maternal nurturance. In the absence of an motionally available father, the boy child may either show a hypermasculine flight from concerns about feminine identification with the mother or show a passive effeminate identity in direct identification with his mother. At the higher end of the continuum, the male patient with hysterical personality disorder remains attached to his mother in an incompletely resolved oedipal situation, much like his female counterpart. He may find that the women he meets are disappointing because they never measure up to his mother, or he may choose a celibate or isolated life-style to maintain his unconscious attachment to his mother.

Obsessive-Compulsive Personality Disorder The early papers on the obsessive-compulsive character emphasize regression to an anal fixation in response to castration anxiety encountered in the oedipal phase. The anal traits associated with the character pattern include parsimony, excessive orderliness, and stubbornness. Much like patients with symptomatic obsessive-compulsive neurosis, anally fixated characters were viewed as victims of a harsh superego that is prone to be punitive in response to sexual and aggressive wishes.

As psychoanalytic theory has shifted more and more in the direction of the vicissitudes of object relations, the literature on obsessive-compulsive personality disorder has focused less on anal character traits and more on difficulties in self-esteem, management of dependency and anger, cognitive style, and problems with intimacy. Self-doubt is a common trait of obsessive-compulsive patients, and psychoanalytic treatment frequently reveals the entrenched conviction that they were not loved or valued by their parents. Intense anger directed at the parents and dependent longings are frequently defended against through reaction formation and isolation of affect.

Patients with obsessive-compulsive personality disorder also reveal perfectionistic strivings that are designed to transcend such unacceptable feelings as rage and dependency. They often feel that, if they could just do enough, they will finally win the parental approval that they missed in childhood. Intimacy presents a risk to obsessive-compulsive patients because they fear that their dependent yearnings and angry resentment will be triggered and then get out of control. Most patients with obsessive-compulsive personality disorder prefer work to the unpredictable intimacy of personal relationships. Spouses and significant others often complain that their obsessive-compulsive loved ones are too controlling and lack spontaneity in marriage and other close relationships.

Avoidant Personality Disorder Although it has been controversial because of its overlap with other personality disorders, avoidant personality disorder can be linked to the psychoanalytic tradition of identifying character neuroses that evolved from studying symptomatic neuroses. Avoidant personality disorder can be viewed as a characterological version of phobic neurosis. Persons with avoidant personality disorder are extremely shy and fear social situations in which they may experience humiliation or embarrassment. Although social phobias involve specific situations, the threat in avoidant personality disorder is far more generalized.

The defensive posture of shyness or avoidance typically protects against anticipated rejection, failure, humiliation, and embarrassment. Shame is often a key affective experience for patients with avoidant personality disorder. Psychodynamic exploration reveals that close relationships and social situations are avoided because of the fear that personal inadequacies will be obvious to everyone. Avoidant patients feel that they can never measure up to their own internal standard of performance. Hence, they experience a form of stage fright in interpersonal situations. Some research suggests a genetic-constitutional basis for shyness, but environmental experiences of ridicule or rejection seem to be necessary to produce the full characterological manifestations of avoidant personality disorder.

Dependent Personality Disorder Persons with dependent personality disorder often reveal family backgrounds characterized by overinvolved parents. Messages are given to the children that autonomy within the family is potentially dangerous. Loyalty to and dependency on the family are rewarded. Classical psychoanalytic explanations involving oral-stage fixation are no longer viewed as pertinent to the pathogenesis of dependent personality disorder because the stage specificity of that hypothesis is a dubious proposition. Persons who are extremely dependent have generally experienced parental messages about the dangers of separation throughout the entirety of childhood, a pervasive pattern that is not linked to one particular stage of development. Psychodynamic exploration of patients with dependent personality disorder has also shown that dependency may mask considerable hostility and aggression.

PSYCHOANALYTIC THINKING IN CONTEMPORARY PSYCHIATRY

A detailed discussion of formal psychoanalytic treatment is included in Section 30.1, Psychoanalysis and Psychoanalytic Psychotherapy. However, there are many useful applications of psychoanalytic thinking in contemporary psychiatric treatment that will be considered here. Psychodynamic and biological approaches often work synergistically in treatment settings. Despite the either-or polarization of the biological and psychodynamic orientations in some quarters, psychodynamic psychiatry is not inherently antibiological, and an integrated approach has much to offer.

For psychiatry to avoid the twin pitfalls of becoming either mindless or brainless, clinicians must acknowledge the complex relations between neurophysiological and psychosocial factors in the cause and the pathogenesis of psychiatric disorders. To say that a chemical imbalance, for example, is the cause of a disorder is reductionistic. Neurophysiological or biochemical processes in the brain are mediating mechanisms rather than causal agents. The subjective meaning of the information perceived from the environment sets the biological processes in motion.

The interface between psychological trauma and brain functioning has been amply documented in primate research. Squirrel monkeys who are removed from their mothers undergo dramatic physiological changes, some of which become permanent if the separations are repeated. Among the physiological changes produced by early separation are persistently elevated plasma cortisol, lasting alterations in the sensitivity of noradrenergic receptors, permanent changes in the sensitivity and the number of brain opiate receptors, changes in adrenal gland catecholamine-synthesizing enzymes, and changes in hypothalamic serotonin secretion. Moreover, the psychoanalytic idea that environmental insults may cause varying degrees of psychological damage, depending on the specific developmental phase during which they occur, received some support from the primate research. In one series of experiments, isolating infant monkeys from their mothers resulted in a more serious effect if the separation occurred at 90 days than if it occurred at either 60 or 120 days; perhaps the difference is related to a link between certain forms of bonding behavior and myelinization of the nervous system.

An enormous body of research since the late 1980s has amply documented the phenomenon of neural plasticity. The brain is not a static structure. It undergoes structural and functional changes almost daily. Studies on rats and marine snails have demonstrated that the number of synapses per neuron increases when learning takes place in interaction with the environment. By analogy, psychotherapy inevitably must work by altering the brain. Studies using positron emission tomography scans have demonstrated that patients with obsessive-compulsive disorder undergo similar brain changes, regardless of whether the treatment is cognitive-behavior therapy or medication.

Research has also proven convincingly that genes are far from static. Stressors from the environment appear to regulate gene expression in ways that have profound influence on the presence or absence of psychopathology. In disorders like major depressive disorder, genetic factors appear to alter an individual's susceptibility to react to environmental and psychological stressors with a depressive episode. Similarly, positive environmental influences may help an individual to overcome a problematic genetic diathesis. For example, primate studies have found that approximately 20 percent of rhesus monkeys have an innate, genetically based temperament characterized by marked social anxiety. However, when these monkeys are reared by especially nurturant mothers in the monkey colony, they overcome this genetic disadvantage and rise to the top of the social hierarchy. The fact that biological and psychosocial factors are inextricably tied together in the etiology of mental illness suggests that a combination of psychotherapeutic and psychopharmacological interventions may be the optimal treatment in many cases.

Finally, to say that psychiatric disorders have strong biological underpinnings is not devoid of meaning. Illnesses are elaborated psychologically by patients who

suffer from them, and clinicians must incorporate questions of meaning into an overall diagnostic understanding and treatment plan.

A 29-year-old single man with a 10-year history of obsessive-compulsive disorder was admitted to a psychiatric hospital. He had been housebound for the preceding 8 years because his obsessional thoughts and compulsive rituals had become incapacitating. The patient's mother had retired from her career so that she could be at home with the patient and accommodate his demands for cleanliness.

The patient lived in constant fear of contamination. Specifically, he worried that he might have semen on his hands that would impregnate women. He washed his hands compulsively to make sure that his fears would not come to fruition. He demanded that his mother be with him virtually every hour of the day. She did not enter the shower with him, nor did she sleep with him, but she helped him dress because he feared his clothes would become contaminated with germs if he touched them. The patient insisted on a complex 58-step ritual when his mother prepared his meals. If she made a small deviation from the ritual, he insisted that she throw out all the food she had prepared and start from scratch. She had wasted thousands of dollars each year in her efforts to conform to the rituals demanded by her son. The patient ordered his father to stay away from the house, lest the father bring in germs from the outside world. The father complied by staying in a separate part of the house, where he rarely had contact with his son.

The patient's early childhood had been basically unremarkable from a developmental perspective, but he did recall a vivid and frightening event when he was 5 years old. He remembered seeing his mother crying out for him to rescue her after his father had grabbed her by the breasts. He remembered trying to stop his father but could not succeed in getting him away from his mother.

By the time the patient had turned 19, he had been severely compromised by obsessive-compulsive symptoms and had been to many psychiatrists. Each time, he refused to return after one appointment. One psychiatrist had managed to obtain the patient's agreement to take clomipramine (Anafranil). However, the patient refused to take the medication after the first dose and subsequently suffered ill-defined adverse effects.

The patient was finally admitted to a hospital because he was completely incapacitated by his symptoms. On admission, his hospital psychiatrist asked him why he was seeking treatment. The patient responded, “I'm determined to be dependent—I mean, independent.” The doctor noted that he initially had said “dependent” and asked, “Is there perhaps a part of you that would like to be dependent?” The patient replied, “You mean on my mother?” The psychiatrist responded that he was sure the patient would know better than he. The patient then thought about his situation momentarily and observed, “Well, she does take pretty good care of me.” He went on to say that his mother also made him nervous when she dressed him. The patient speculated that “there was something sexual about that.”

After a week of hospitalization, the patient became less anxious and less controlled by his symptoms. He was able to touch doorknobs without fearing that he would contract germs, and he could even touch magazines that others had read. He also spent less time washing his hands than he had before admission to the hospital. Those improvements occurred without the assistance of clomipramine or other medication. The patient said he was less anxious because he was away from his mother and did not need to worry about the sexual aspects of her dressing him.

Psychodynamic-Biological Interface The interface between the psychodynamic and the biological is illustrated by the above clinical vignette. Obsessive-compulsive disorder is a condition that is biologically based to a large extent. Patients with the disorder have a smaller caudate nucleus volume than do healthy control persons. Monozygotic twins have a higher rate of concordance for the disorder than do their dizygotic counterparts. Also, patients with obsessive-compulsive disorder manifest virtually no response to a placebo.

Nevertheless, in the case of the above patient, the obsessive-compulsive symptoms were rich in psychological meaning. The patient's symptoms reflected the psychoanalytic concept known as *compromise formation:* they contained both the direct expression of an underlying wish and a defense against that wish. The patient's obsessional thoughts and compulsive rituals defended against his sexual wishes for his mother by causing him to spend every waking moment in hand-washing rituals and other activities. However, these symbolic rituals also produced a situation in which his mother showered attention on him, even to the point of dressing him, while his father stayed in another part of the house. For all practical purposes the patient had created a symbolic oedipal victory; he had successfully stolen his mother away from his father. His resistance to taking clomipramine can be understood as a refusal to give up his triumphant position with his mother. His oedipal victory also created guilt and anxiety, which led to increased reliance on the rituals and obsessions. The hospitalization removed him from the anxiety-producing situation at home; therefore, his symptoms were not necessary to deal with his anxiety.

An analogy from a common elementary school demonstration is useful in explicating the relation between the biological and the psychodynamic. If iron filings are placed on a sheet of paper with a magnet underneath, the filings line up in formation on the surface and follow the movement of the magnet as it glides beneath the paper. Similarly, psychodynamic themes often appropriate the powerful magnetlike biological forces in the brain for their own purposes. The obsessive-compulsive patient's unconscious wishes and his defenses against them appropriated the neurophysiologically driven obsessive-compulsive symptoms and used them as a vehicle for the expression of his wishes and defenses.

Noncompliance Noncompliance with pharmacotherapeutic regimens is an everyday problem in contemporary psychiatry. The psychodynamic concepts of resistance and transference may be extraordinarily useful in understanding noncompliance. In the case of the obsessive-compulsive patient above, the psychoanalytically informed understanding of his resistance to taking medication was essential to his successful treatment, which ultimately involved medication and therapeutic work with the family. The patient's slip of the tongue made him aware for the first time that any improvement in his symptoms would threaten his privileged position with his mother.

The psychodynamic understanding of the patient's obsessive-compulsive symptoms illustrates an important distinction within dynamic psychiatry, namely, the difference between causation and meaning. The obsessive-compulsive symptoms may be caused by biological forces, but they are imbued with meaning by the unconscious of the patient. Similarly, only one fourth of persons who witness a traumatic event develop symptoms of posttraumatic stress disorder. Although there may be genetic vulnerability in some cases, one can also speculate that particular forms of trauma have specific unconscious meanings to certain persons that may contribute to their becoming symptomatic.

SUGGESTED CROSS-REFERENCES

The psychoanalytic perspective is relevant to virtually every chapter of this book. Of particular interest are the discussion of Erik Erikson in Section 6.2, other psychodynamic schools in Section 6.3, approaches derived from psychology and philosophy in Section 6.4, psychodynamic to neurodynamic theories and individual psychotherapy of schizophrenia in Section 12.6 and Section 12.10, psychodynamic etiology and psychological treatments of mood disorders in Section 14.5 and Section 14.9 anxiety disorders in Chapter 15, personality disorders in Chapter 24, psychoanalysis and psychoanalytic psychotherapy in Section 30.1, evaluation of psychotherapy in Section 30.11, and psychotherapy with the elderly in Section 51.4i.

6.2 ERIK H. ERIKSON

DORIAN S. NEWTON, PH.D. AND PETER M. NEWTON, PH.D.

Erik Erikson was a psychoanalyst who created an original and highly influential theory of psychological development and crisis occurring in periods that extended across the entire life cycle. His theory grew out of his work first as a teacher, then as a child psychoanalyst, next as an anthropological field worker, and finally as a biographer. Rather than starting within the nervous system of the individual as Freud had done, Erikson focused upon the boundary between the child and the environment, then graphed the evolution of the maturing ego's relations with an expanding social world. Erikson identified dilemmas or polarities in the ego's relations with the family and larger social institutions at nodal points in early, middle, and late adulthood, as well as during the years of most rapid development in childhood.

Of Erikson's many works, three are already firmly established as classics. *Childhood and Society* set forth his theory of the life cycle. *Young Man Luther*, reconstructed and analyzed the developmental crisis of identity in a very young man and its creative resolution in his 30s. *Gandhi's Truth* showed the coming together of authentic identity and calling in a man at midlife. In his psychological biographies of these world historical leaders, Erikson demonstrated the interrelations between individual psychodynamics and development on the one hand and social structure and history on the other, gracefully avoiding a reductionism in either a psychodynamic or sociological direction. Erikson showed in complex, intricate detail how great leaders solve the problem of their own identity by creating solutions for crises in their culture.

Erikson's developmental ideas are illustrated here as applied to his own life and work, primarily during youth and middle age. Some terms used here, such as *life structure*, the developmental phase of “becoming one's own man,” and “the mid-life transition” come from Erikson's student, Daniel Levinson, who, building upon his teacher's work became a leading psychosocial theorist of the life cycle.

LIFE AND WORK

Erik Homburger Erikson was born on June 15, 1902, in Karlsruhe Germany, an old capital of a Lutheran principality. His father was Protestant and his mother Jewish. His parents, both Danish, had separated before his birth; his mother was visiting friends in Germany when the baby was born. She stayed in Karlsruhe and a few years later married her child's pediatrician, a well-to-do Jewish doctor, Theodor Homburger, in whose house young Erik grew up. During an alienated adolescence the tall, blond boy found himself regarded as a gentile in his father's Jewish milieu and as a Jew at school. He remembered his mother as sad, bookish, and artistic; his adoptive father as professionally respected; and both as loving. The boy's adoption by his stepfather was the formative occasion of what became a lifelong pattern of getting himself adopted by kind men. His last name remained Homburger until he was 37, when he changed it to Erikson.

Erikson attended the *Humanistiche Gymnasium* in Karlsruhe where he studied Greek, Latin, philosophy, literature, and science. By the age of 18 he had the educational attainments of all but a few American college graduates and a stronger base than many. His primary interest was art; impatient with formal study and possessed by a restlessness he never lost, Erikson chose not to go to a university, preferring to travel about the countryside reading, drawing, and making wood carvings. Back home after a year, he tried formal art study, first in Karlsruhe and then in Munich with some success but in neither case with decisive commitment.

This sort of wandering about was not uncommon among German youth of the period, so Erikson was permitted, as his biographer Robert Coles sagely wrote, “to go through his own years of discontent and confusion without being especially singled out and thereby forced to defend behavior often best granted the limits of its own momentum.” Erikson was having what he would later term a *psychosocial moratorium*; in so doing, he was also mitigating the asperities of an *identity crisis*. At about age 21 Erikson went to live in Florence where he continued his art studies informally. There he enjoyed the friendship of his old *Gymnasium* chum Peter Blos, a writer who later became a famous American child psychoanalyst.

Becoming a Child Psychoanalyst Back in Karlsruhe Erikson felt ready to make art teaching the central component of his first adult life structure. When Erikson was 24 or 25 years of age, Peter Blos invited him to become a faculty member in a progressive grammar school in Vienna, where Blos taught language and science. Erikson's difficult transition from adolescence to early adulthood was over. The year was 1927; Sigmund Freud was 71, and his youngest child, Anna, an educator and psychoanalyst, had started a psychoanalytically enlightened school for children with an American friend named Dorothy Burlingham. Erikson joined Blos and later recalled Blos's determination to turn him into a disciplined worker: “To make a teacher of me... the highly disciplined Peter first had to teach me to keep regular work hours, a task which was initiated every morning, no matter what time of year, by a cold shower, then the preferred shock treatment for identity confusion.”

Before long, Erikson found himself not only a teacher of children but also an *analysand*, what is now called a *candidate*, at the Vienna Psychoanalytic Institute, in treatment with Anna Freud. Any sort of psychoanalytic approach to treating or educating children was then a radical idea, even an approach as cautious as Freud's. Both educationally and clinically, the Freuds' group was sufficiently deviant such that a person with Erikson's diverse identity was able to fit in. There was in 1927 a *configurational affinity* between Erikson's personal history and the history of psychoanalysis as a profession. Still there was the worry: What was a fledgling artist without a university education to do among those high-powered theorists and intellectuals at the Vienna Psychoanalytic Institute?

Erikson recalled this epiphanic exchange with his analyst, Anna Freud: “When I declared once more that I could not see a place for my artistic inclinations in such high intellectual endeavors, she said quietly: ‘You might help to make them see.’" Dreams had been Freud's royal road to the unconscious; observing children's play (and later, anthropological field studies in the role of participant observer) would be Erikson's path to understanding the ego and its development. Looking back, Erikson thought that it was Anna Freud's “simple mandate” that enabled him to succeed in combining the artistic and the theoretical in *Childhood and Society*.

Erikson remained in Vienna for 6 years, until 1933. In those years between the ages of 25 and 31, he continued as a novice adult to develop the skills and meanings of occupation in his life structure. He turned his artist's eye from the observation of nature to the analysis of children; he learned about psychoanalysis by studying children's play and his own free associations as a patient, and he learned fundamental clinical skills in the supervised treatment of others. He formed mentor relationships with Freud and Heinz Hartmann, and a more distant, admiring-inspirational relationship with Anna Freud's sick, aging, but still-productive father.

During his own late adulthood Sigmund Freud had moved beyond clinical problems more narrowly conceived to problems of the ego, society, and history in works such as *Beyond the Pleasure Principle* (written at age 64), *Group Psychology and the Analysis of the Ego* (at 65), and *The Ego and the Id* (at 66); during Erikson's years in Vienna, Freud was working on *The Future of An Illusion* (at 71) and *Civilization and Its Discontents* (at 73). Erikson seemed to identify with both Freuds, internalizing them as mentors, and they provided him with a strong, inner basis for a lifetime of psychoanalytic treatment and psychosocial research.

Equally important, during those years Erikson succeeded in committing himself to what was be the other central component of his life structure. In Vienna, he met his wife, Joan Serson, an American woman with a Masters' degree in sociology, who had a special interest in modern dance and psychoanalysis. They married, and Serson joined the faculty of Burlingham's school as an English teacher. Serson's unusual combination of interests and skills—education, psychoanalysis, and sociology—coupled with her ability as a writer, gave Erikson a skilled co-worker for a lifetime of intellectual work. Several articles were co-authored, Joan Erikson helped with most of the others, and the endowed chair at Harvard that was named after Erikson carried both their first names.

With the birth of their sons, Kai and Jon, Erikson had by 31 become a husband, a father, and a child psychoanalyst. He had come a long way from the aimless youth of his early 20s. His first adult life structure was fully formed, and he was productively engaged in the stage of ego development that he later characterized by the polarity *intimacy versus isolation*. He continued to work on that ego stage, but changes were now required in the life structure that Erikson had begun to build at 25.

Emigrating to America By 1933 the Fascist menace in Europe was growing. When Erikson graduated that year from the Vienna Psychoanalytic Institute, the Eriksons prepared to leave. They considered repatriating to Denmark but encountered sufficient annoying difficulties to allow them to justify a real emigration. Home for Erikson was always a fortuitously adoptive one, and so he allowed chance, in the form of a serendipitous meeting with Freud's disciple Hanns Sachs, to settle his

future. Sachs enthusiastically invited him to come to Boston and in 1933 the Eriksons moved to Boston. At 31, Erikson became the city's first child psychoanalyst and a member of the faculty of the Harvard Medical School. With a new home and a new profession as a professor, Erikson was, in his age 30 transition, revising the life structure that he had created in his mid-20s. At Harvard Erikson joined the group of personality researchers working under the leadership of Henry Murray, who was Director of the Harvard Psychological Clinic.

Murray's book *Explorations in Personality: A Clinical and Experimental Study of Fifty Men of College Age* was published in 1938. It is one of the few integrative masterpieces in American psychology—experimental and biographical, psychological and sociological, Freudian and Jungian, developmental and diagnostic—and it provided a luminous example of studying persons both in their origins and in their purposes. Murray's example proved seminal when Erikson later turned his hand to the biographical study of the world historical figures Sigmund Freud, Martin Luther, and Mohandas Gandhi.

Listed on the title page of Murray's book, among other research associates, was “Erik Homburger.” The next year, at age 37, during a developmental phase that Levinson called “becoming one's own man,” Homburger renamed himself Erikson, retaining Homburger as his middle name. With characteristically bold creativity, Erikson solved the problem of his paternity by adopting himself.

Psychoanalytic Anthropology In 1936 Erikson hit the road again, this time to the Institute of Human Relations of the department of psychiatry at Yale University. The interdisciplinary work of the institute further shaped Erikson's interest in cross-cultural research, and in 1938 he joined a colleague on a research expedition to the Sioux Indians in South Dakota. On the Pine Ridge reservation, he observed children and child-rearing practices and interviewed adults, resulting in his paper, “Observations on Sioux Education,” published in 1939. In the same year the peregrinating Eriksons moved to California, where he joined the faculty at the University of California at Berkeley. He remained there for a decade, the longest period in one place since his pre-adulthood years in Karlsruhe. This was the culminating period of his early adulthood, a time to realize the promise and reap the rewards of youth. At Berkeley he became his own man, visible first in the outward signs of changing his name and later in refusing to sign the university's loyalty oath of anti-Communist purity. Most important, during those 10 years, from 37 to 47, Erikson wrote his masterwork, *Childhood and Society* and began his career as a biographer.

At Berkeley Erikson continued his cross-cultural research, this time with the Yurok Indians of northern California. He also lent his research skills to the war effort in articles on submarine habitation and the interrogation of prisoners of war. He continued to do the research begun at Burlingham's experimental school on children's play. But at age 40, as Erikson was entering his mid-life transition, he was becoming more biographical and more interested in the adult years of the life cycle. Like others who manage to continue developing, he found a way to pursue his development *through* the strictures of exigent reality. World War II was under way and Erikson was deeply concerned about it. After his initial narrowly framed attempts at scholarly patriotism, he began writing his first psychobiographical essays on Adolph Hitler and the psychosocial dynamics of his appeal to young Germans—“Hitler's Imagery and German Youth” was published in 1942.

Midlife Transition The primary developmental task at midlife is to terminate the existing life structure, revise one's dream, and initiate a new life structure suitable for middle age. *Childhood and Society* was the creative product of Erikson's midlife transition. He had intended it to be a contribution to the psychiatric education of clinicians from various disciplines, but the book outgrew its author's intentions and found its way into every corner of the academy and beyond.

Erikson began work on the book when he was 42 and largely completed work on it by 46. Published in 1950, it is at once a product of early research, a prospectus of what was to come, and an initial integration of both. In it he presented clinical cases in which individual psychodynamics, society, and history are interwoven with a skill not seen before or since; analyses of children's play and development in various cultures; a theoretical sketch of the entire human life cycle; pieces on the problem of identity; and biographical essays on Adolf Hitler and the Russian writer Maxim Gorky.

As in Karl Abraham's and Freud's psychosexual stages, most of Erikson's stages in ego development occur in childhood and adolescence. Unlike the Abraham-Freud conception, however, Erikson's stages are *psychosocial*, describing crucial steps in the maturing ego's relations with the social world rather than a biological unfolding of neurophysiological capacities for excitation. Also, whereas Freud's developmental theory falls back on itself after adolescence, Erikson's continued with characterizations of developmental tasks during youth, middle age, and old age.

Erikson's emphasis, like Freud's, was both cross-cultural and universal. Erikson's eight stages are ineluctable parts of the human life cycle, yet each person goes through them in distinct ways that are determined by culture, concrete circumstance, and personality. With *Childhood and Society*, Erikson became and remained an *ego psychologist*, shifting the traditional psychoanalytic focus on the drives to adaptation and growth. In so doing, he was furthering the work of his analyst-mentor, Anna Freud, who in 1936 had written ego psychology's basic theoretical treatise, *The Ego and the Mechanisms of Defense*.

Erikson's conceptualization of psychosocial development took as its model the *epigenetic principle* of organismic growth in utero. In Erikson's view psychosocial growth occurs in phases, with individual aspects of development proceeding according to a predetermined time table. Each phase has its own time of quiescence and critical ascendancy, and each is dependent on the proper development of the other phases in the proper sequence. Work on any particular phase, Erikson theorized, is never complete and old developmental conflicts can be activated by critical life events.

Erikson's theory of the life cycle is the centerpiece of his contribution. Although the richness and complexity of Erikson's conception of life cycle development does not lend itself well to schematic presentation, the following chart is consistent with his theory.

Eight Stages of the Life Cycle Erikson's conception of the eight stages of ego development across the life cycle is the centerpiece of his life's work and he elaborated the conception throughout his subsequent writings (Table 6.2-1). The eight stages represent points along a continuum of development in which physical, cognitive, instinctual, and sexual changes combine to trigger an internal crisis whose resolution results in either psychosocial regression or growth and the development of specific *virtues*. In *Insight and Responsibility* Erikson defined virtue as “inherent strength,” as in the active quality of a medicine or a liquor. He wrote in *Identity:Youth and Crisis* that “crisis” refers not to a “threat of catastrophe, but to a turning point, a crucial period of increased vulnerability and heightened potential, and therefore, the ontogenetic source of generational strength and maladjustment.”

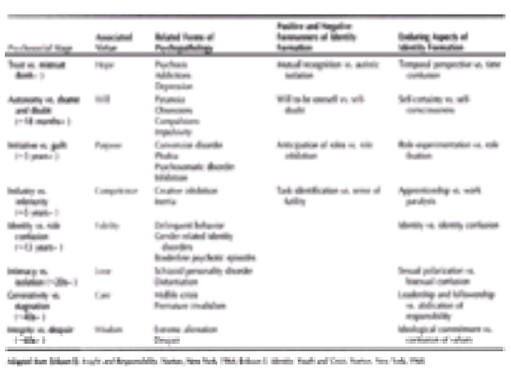

Table 6.2-1 Erikson's Psychosocial Stages

Trust Versus Mistrust (Birth to About 18 Months) In *Identity: Youth and Crisis*, Erikson noted that the infant “lives through and loves with” its mouth. Indeed, the mouth forms the basis of its first *mode* or pattern of behavior, that of incorporation. The infant is taking the world in through the mouth, eyes, ears, and sense of touch. The baby is learning a cultural modality that Erikson termed *to get*, that is, to receive what is offered and elicit what is desired. As the infant's teeth develop and it discovers the pleasure of biting, it enters the second oral stage, the active-incorporative mode. The infant is no longer passively receptive to stimuli; it reaches out for sensation and grasps at its surroundings. The social modality shifts to that of *taking and holding on* to things.

The infant's development of basic trust in the world stems from its earliest experiences with its mother or primary caretaker. In *Childhood and Society* Erikson asserts that trust depends not on “absolute quantities of food or demonstrations of love, but rather on the quality of maternal relationship.” A baby whose mother is able to anticipate and respond to its needs in a consistent and timely manner despite its oral aggression will learn to tolerate the inevitable moments of frustration and deprivation. The defense mechanisms of introjection and projection will provide the infant with the means to internalize pleasure and externalize pain such that

“consistency, continuity, and sameness of experience provide a rudimentary sense of ego identity.” Trust will predominate over mistrust, and hope will crystallize. For Erikson, the element of society corresponding to this stage of ego identity is religion, as both are founded upon “trust born of care.”

In keeping with his emphasis on the epigenetic character of psychosocial change, Erikson conceived of many forms of psychopathology as examples of what he termed *aggravated development crisis*, development that, having gone awry at one point, affects subsequent psychosocial change. A person who, as a result of severe disturbances in the earliest dyadic relationships, fails to develop a basic sense of trust or the virtue of hope may be predisposed as an adult to the profound withdrawal and regression characteristic of schizophrenia. Erikson hypothesized that the depressed patient's experience of being empty and of being no good is an outgrowth of a developmental derailment that causes oral pessimism to predominate. Addictions may also be traced to the mode of oral incorporation.

Autonomy Versus Shame and Doubt (About 18 Months to About 3 Years) In the development of speech and sphincter and muscular control, the toddler practices the social modalities of *holding on and letting go*, and experiences the first stirrings of the virtue that Erikson termed *will*. Much depends on the amount and the type of control exercised by adults over the child. Control that is exerted too rigidly or too early defeats the toddler's attempts to develop its own internal controls, and regression or false progression results. Parental control that fails to protect the toddler from the consequences of his or her own lack of self-control or judgment can be equally disastrous to the child's development of a healthy sense of autonomy. In *Identity: Youth and Crisis*, Erikson asserted: “This stage, therefore, becomes decisive for the ratio between loving good will and hateful self-insistence, between cooperation and willfulness, and between self-expression and compulsive self-restraint or meek compliance.”

Where that ratio is favorable, the child will develop an appropriate sense of autonomy and the capacity to “have and to hold”; where it is unfavorable, doubt and shame will undermine free will. According to Erikson, the principle of law and order has at its roots this early preoccupation with the protection and regulation of will. In *Childhood and Society*, he concluded, “[T]he sense of autonomy fostered in the child and modified as life progresses, serves (and is served by) the preservation in economic and political life of a sense of justice.”

An individual who becomes fixated at the transition between the development of hope and autonomous will, with its residue of mistrust and doubt, may develop paranoic fears of persecution. When psychosocial development is derailed in the second stage, other forms of pathology may emerge. The perfectionism, inflexibility, and stinginess of the person with an obsessive-compulsive personality disorder may stem from conflicting tendencies to hold on and to let go. The ruminative and ritualistic behavior of the person who suffers from an obsessive-compulsive disorder may be an outcome of the triumph of doubt over autonomy and the subsequent development of a primitively harsh conscience.

Initiative Versus Guilt (About 3 Years to About 5 Years) The child's increasing mastery of locomotor and language skills expands its participation in the outside world and stimulates omnipotent fantasies of wider exploration and conquest. Here the youngster's mode of participation is active and intrusive; its social modality is that of *being on the make*. The intrusiveness is manifested in the child's fervent curiosity and genital preoccupations, competitiveness, and physical aggression. The Oedipus complex is in ascendance as the child competes with the same-sex parent for the fantasied possession of the other parent. In *Identity: Youth and Crisis*, Erikson wrote that “[j]ealousy and rivalry... now come to a climax in a final contest for a favored position with one of the parents: the inevitable and necessary failure leads to guilt and anxiety.”

Guilt over the drive for conquest and anxiety over the anticipated punishment are both assuaged in the child through repression of the forbidden wishes and the development of a superego to regulate its initiative. This conscience, the faculty of self-observation, self-regulation, and self-punishment, is an internalized version of parental and societal authority. Initially the conscience is harsh and uncompromising; however, it constitutes the foundation for the subsequent development of morality. Having renounced oedipal ambitions, the child begins to look outside the family for arenas in which it can compete with less conflict and guilt. This is the stage that highlights the child's expanding initiative and forms the basis for the subsequent development of realistic ambition and the virtue of *purpose*. As Erikson noted in *Childhood and Society*, “[T]he ‘oedipal' stage... sets the direction toward the possible and the tangible which permits the dreams of early childhood to be attached to the goals of an active adult life.” Toward this end, social institutions provide the youngster with an economic ethos in the form of adult heroes who begin to take the place of their storybook counterparts.

When there has been an inadequate resolution of the conflict between initiative and guilt the individual may ultimately develop a conversion disorder, inhibition, or phobia. Those who overcompensate for the conflict by driving themselves too hard may experience so much stress as to produce psychosomatic symptoms.

Industry Versus Inferiority (About 5 Years to About 13 Years) With the onset of latency, the child discovers the pleasures of production. He or she develops industry by learning new skills and takes pride in the things made. Erikson wrote in *Childhood and Society* that the child's “ego boundaries include his tools and skills: the work principle... teaches him the pleasure of work completion by steady attention and persevering diligence.” Across cultures, this is a time when the child receives systematic instruction and learns the fundamentals of technology as they pertain to the use of basic utensils and tools. As children work they identify with their teachers and imagine themselves in various occupational roles.

If the child is unprepared for this stage of psychosocial development, either through insufficient resolution of previous stages or by current interference, the child may develop a sense of inferiority and inadequacy. In the form of teachers and other role models, society becomes crucially important in the child's ability to overcome that sense of inferiority and to achieve the virtue known as *competence*. In *Identity: Youth and Crisis*, Erikson noted: “[T]his is socially a most decisive stage. Since industry involves doing things beside and with others, a first sense of division of labor and of differential opportunity, that is, a sense of the technological ethos of a culture, develops at this time.”

The pathological outcome of a poorly navigated stage of industry versus inferiority is less well defined than in previous stages, but it may concern the emergence of a conformist immersion into the world of production in which creativity is stifled and identity is subsumed under the worker's role.

Identity Versus Role Confusion (About 13 Years to About 21 Years) With the onset of puberty and its myriad social and physiological changes, the adolescent becomes preoccupied with the question of identity. Erikson noted in *Childhood and Society* that youth are now “primarily concerned with what they appear to be in the eyes of others as compared to what they feel they are, and with the question of how to connect the roles and skills cultivated earlier with the occupational prototypes of the day.” Childhood roles and fantasies are no longer appropriate, yet the adolescent is far from equipped to become an adult. In *Childhood and Society* Erikson writes that the integration that occurs in the formation of ego identity encompasses far more than the summation of childhood identifications. “It is the accrued experience of the ego's ability to integrate these identifications with the vicissitudes of the libido, with the aptitudes developed out of endowment, and with the opportunities offered in social roles.”

The formation of cliques and the intolerance of individual differences are ways in which the young person attempts to ward off a sense of identity loss. Falling in love, a process by which the adolescent may clarify a sense of identity by projecting a diffused self-image onto the partner and seeing it gradually assume a more distinctive shape, and an overidentification with idealized figures are means by which the adolescent seeks self-definition. With the attainment of a more sharply focused identity, the youth develops the virtue of *fidelity*—a faithfulness not only to the nascent self-definition but to an ideology that provides a version of self-in-world. As Erikson, Joan Erikson, and Helen Kivnick wrote in *Vital Involvement in Old Age:* “[F]idelity is the ability to sustain loyalties freely pledged in spite of the inevitable contradictions of value systems. It is the cornerstone of identity and receives inspiration from confirming ideologies and affirming companionships.” Role confusion ensues when the youth is unable to formulate a sense of identity and belonging. Erikson held that delinquency, gender-related identity disorders, and borderline psychotic episodes can result from such confusion.

Intimacy Versus Isolation (About 21 Years to About 40 Years) Freud's famous response to the question of what a normal person should be able to do well, “Lieben und arbeiten” (to love and to work), is one that Erikson often cited in his discussion of this psychosocial stage, and it emphasizes the importance he placed on the virtue of *love* within a balanced identity. Erikson asserted in *Identity:Youth and Crisis* that Freud's use of the term *love* referred to “the generosity of intimacy as well as genital love; when he said love and work, he meant a general work productiveness which would not preoccupy the individual to the extent that he might lose his right or capacity to be a sexual and a loving being.”

Intimacy in the young adult is closely tied to fidelity; it is the ability to make and honor commitments to concrete affiliations and partnerships even when that requires sacrifice and compromise. The person who cannot tolerate the fear of ego loss arising out of experiences of self-abandonment (e.g., sexual orgasm, moments of intensity in friendships, aggression, inspiration, and intuition) is apt to become deeply isolated and self-absorbed. *Distantiation*, an awkward term coined by Erikson to mean “the readiness to repudiate, isolate, and, if necessary, destroy those forces and people whose essence seems dangerous to one's own,” is the pathological outcome of conflicts surrounding intimacy and, in the absence of an ethical sense where intimate, competitive, and combative relationships are differentiated, forms

the basis for various forms of prejudice, persecution, and psychopathology.

Erikson's separation of the psychosocial task of achieving identity from that of achieving intimacy, and his assertion that substantial progress on the former task must precede development on the latter have engendered much criticism and debate. Critics have argued that Erikson's emphasis on separation and occupationally based identity formation fails to take into account the importance for women of continued attachment and the formation of an identity based on relationships.

Generativity Versus Stagnation (About 40 Years to About 60 Years) Erikson asserted in *Identity: Youth and Crisis* that "[g]enerativity... is primarily the concern for establishing and guiding the next generation." The term *generativity* applies not so much to rearing and teaching one's offspring as to a protective concern for all the generations and for social institutions. It encompasses productivity and creativity as well. Having previously achieved the capacity to form intimate relationships, the person now broadens the investment of ego and libidinal energy to include groups, organizations, and society. *Care* is the virtue that coalesces at this stage. In *Childhood and Society* Erikson emphasized the importance to the mature person of feeling needed. "[M]aturity needs guidance as well as encouragement from what has been produced and must be taken care of." Through generative behavior the individual is able to pass on knowledge and skills while obtaining a measure of satisfaction in having achieved a role with senior authority and responsibility in the tribe.

When people are unable to develop true generativity, they may settle for pseudo-engagement in occupation. Often such people restrict their focus to the technical aspects of their roles at which they may be now have become highly skilled, eschewing larger responsibility for the organization or profession. This failure of generativity can lead to profound personal stagnation, masked by a variety of escapisms, such as alcohol and drug abuse, and sexual and other infidelities. Mid-life crisis or premature invalidism (physical and psychological) may occur. In this case, pathology appears not only in middle-aged persons but also in the organizations that depend upon them for leadership. Thus, the failure to develop at mid-life can lead to sick, withered, or destructive organizations that spread the effects of failed generativity throughout society; examples of such failures have become so common as to constitute a defining feature of modernity.

Integrity Versus Despair (About 60 Years to Death) In *Identity: Youth and Crisis*, Erikson defined integrity as "the acceptance of one's one and only life cycle and of the people who have become significant to it as something that had to be and that, by necessity, permitted of no substitutions." From the vantage point of this stage of psychosocial development, the individual relinquishes the wish that important people in his life had been different and is able to love in a more meaningful way—one that reflects an acceptance of responsibility for one's own life. The individual in possession of the virtue of *wisdom* and a sense of integrity has room to tolerate the proximity of death and to achieve what Erikson termed in *Identity: Youth and Crisis* a "detached yet active concern with life."

Erikson underlined the social context for this final stage of growth. In *Childhood and Society*, he wrote, "The style of integrity developed by his culture or civilization thus becomes the 'patrimony' of his soul... In such final consolidation, death loses its sting."

When the attempt to attain integrity has failed, the individual may become deeply disgusted with the external world, and contemptuous of persons as well as institutions. Erikson wrote in *Childhood and Society* that such disgust masks a fear of death and a sense of despair that "time is now short, too short for the attempt to start another life and to try out alternate roads to integrity." Looking back on the Eight Ages of Man, he noted the relation between adult integrity and infantile trust, "[H]ealthy children will not fear life if their elders have integrity enough not to fear death."

Implications for Psychotherapists Erikson's belief that psychosocial development continues throughout the life cycle led him to caution psychotherapists against a theoretical reductionism in which symptomatic behavior is viewed as being the result of a traumatic past and in which insufficient attention is paid to contemporary conflicts in the ego's relations with the world. A psychotherapy informed by Eriksonian principles emphasizes not only interpretations based on reconstruction, but also an analysis of the patient's struggles with current developmental tasks. When patients' resolutions of previous psychosocial stages have been so faulty as to seriously compromise their adult development, they have the opportunity to rework early development through the relationship with the therapist. For example, the psychotherapeutic treatment of the individual who suffers a schizophrenic break in young adulthood initially revolves around the painstaking establishment of a sense of basic trust between the patient and the therapist. However, the treatment eventually has to consider contemporary obstacles to building a sense of identity in work and intimacy in relations with others.

Psychotherapy is an intervention, sometimes an entire chapter, in the ongoing biography of the patient. The treatment uses new developmental energies to redirect the patient whose psychosocial development has been blocked. By dint of temperament, education, and conscientious self-analysis the therapist may be prepared to identify and promote a variety of directions that subsequent development may take, avoiding a countertransference rigidity that could further inhibit the patient's growth. As Erikson noted in *Identity: Youth and Crisis*, the object of psychotherapy is not to head off future conflict but to assist the patient in emerging from each crisis "with an increased sense of inner unity, with an increase of good judgment, and an increase in the capacity 'to do well' according to his own standards and to the standards of those who are significant to him."

Becoming a Biographer of Youth In 1949, as *Childhood and Society* was going to press, Erikson's stand on the University of California loyalty oath had rendered his position at the university untenable. News of his availability spread east, and other institutions vied to capitalize on Berkeley's mistake. Erikson was well known at the Menninger Clinic in Topeka, Kansas, where he had lectured, so when Robert Knight left Menninger to become the director of the Austen Riggs Center in Stockbridge, Massachusetts, he took Erikson with him. The Austen Riggs Center was devoted to psychoanalytic research and to the treatment of severely disturbed adolescents and young adults—Erikson had been happily adopted once again.

Erikson stayed at Austen Riggs from 1950 to 1960, from age 48 to 58, when he returned to the faculty of Harvard University. During those years, Erikson completed the transition to biographer, forming more fully the approach foreshadowed in his incomplete essays on Hitler, Gorky, and George Bernard Shaw. The transition was not easy; Coles describes that time as constituting a second "identity crisis." Having completed the mid-life transition and having left the era of early adulthood, Erikson faced the difficult developmental task in his late 40s and early 50s of forming and revising a life structure for middle age. He had been a clinician and a theorist of youth; he was now old enough to enact the program promised in *Childhood and Society* and to become a biographer and theorist of the whole life cycle. However, before he wrote *Young Man Luther*, he once again returned to Freud and the origins of his own professional identity. The way to the future was through the past.

In his early 50s Erikson wrote three biographical essays on Freud: "The Dream Specimen of Psychoanalysis," "Freud's 'The Origins of Psychoanalysis,'" and "The First Psychoanalyst." These essays all concern themselves with the crisis Freud suffered during his own mid-life transition as he struggled to leave neuropathology and to define a new professional identity as a psychoanalyst. Strengthened by that reexamination of Freud's successful transition (and perhaps having reassured himself of Freud's blessing), Erikson began writing one of the genuine masterworks of psychoanalysis, *Young Man Luther*.

As always, Erikson's clinical work and observations enriched his theorizing about the life cycle. He acknowledged his debt to Austen Riggs and the Western Psychiatric Institute at the University of Pittsburgh in his preface to *Young Man Luther*. His work there had allowed him to "study the afflictions of young patients as variations on one theme, namely, a *life crisis*, aggravated in patients, yet in some form normal for all youth. I could identify those acute *life tasks* that would bring young people to a state of tension in which some would become patients."

However, Erikson would neither make Martin Luther a patient nor reify the psychopathology of the young people who were his patients. Instead, he asserted that comparisons between Martin Luther and his patients were "not restricted to psychiatric diagnosis... but... oriented toward those moments when young patients, like young beings anywhere, prove resourceful and insightful beyond all professional and personal expectation. We will concentrate on the powers of recovery inherent in the young ego."

Working with the young patients at Riggs helped Erikson hone his understanding of identity formation. As he later put it in "The Problem of Ego Identity," [I]dentity... is gradually established by successive ego syntheses and re-syntheses throughout childhood. It is a configuration gradually integrating constitutional givens, idiosyncractic libidinal needs, favored capacities, significant identifications, effective defenses, successful subliminations, and consistent roles."

These "ego syntheses and re-syntheses" were about to receive great attention as Erikson attempted his biography of Luther. But to do that work, Erikson the biographer had to move further away from his own professional origins as a child psychoanalyst. He had criticized psychoanalysis for its *originology*, which he defined as the belief that something has been explained by finding an analogy to its earliest manifestations. Yet his own conception of the life cycle, with most of its stages occurring within the pre-adult era, left him still heavily rooted in childhood. In his study of Luther, Erikson was trying to understand a *life*, not just a personality; from that perspective, childhood and adolescence had to be introductory rather than the story itself.

Seeing that a child-centered view was not adequate for the tasks of biography, without either formally changing the imbalance in his theory or neglecting childhood

determinants, Erikson deftly devoted the greatest attention to an explication of development in the adult years. So successful was he in interrelating Luther's adult problems with those of his early development that *Young Man Luther* provided the seminal inspiration for the next generation of life-cycle investigators. Some of those investigators formally redressed in their own theories the originological bias vestigial in Erikson's theories.

In Luther's early or mid-20s, according to some of his contemporaries, the young monk had fallen to the floor of the choir of his monastery in a fit and shouted, “Ich bin's nit!” or “Non Sum!” “It isn't me,” or “I am not.” Erikson's task as a psychological biographer was to explain how Luther got from the identity crisis of his 20s to nailing his 95 theses to the door of the church in Wittenberg at the age of 32. Yet *Young Man Luther* is also, as it is subtitled, “a study in psychoanalysis and history.” Since it is not a psychoanalysis of history, some nonreductionist connecting concepts between the individual and the collectivity were needed. One of Erikson's connecting concepts was *ideology*, which he defined as “an unconscious tendency underlying religious and scientific as well as political thought: the tendency at a given time to make facts amenable to ideas, and ideas to facts, in order to create a world image convincing enough to support the collective and the individual sense of identity.”

Luther had personal and psychiatric problems, but in his defiance of Catholic orthodoxy he created a new religious ideology that not only supported his own identity but the identities of emerging generations of Europeans as well. “Ich bin's nit” expressed the young monk's identity crisis as he found himself “fatally over-committed” to what he was not, a young man authentically embarking on a future as an orthodox Catholic priest. “In some periods of history,” Erikson asserted, “and in some phases of his life cycle, man needs... a new ideological orientation as surely and as sorely as he must have air and food.” As such a man, Luther commanded Erikson's “sympathy and empathy” as he “faced the problems of human *existence* in the most forward terms of his era.”

The reception of the book cemented Erikson's international reputation, initially won by *Childhood and Society*, as the leader in original, humane thought about psychological development. In no other biography have the dynamics of individual conflict and development been so seamlessly interwoven with those of society and history. With *Young Man Luther*, Erikson in his late 50s ascended from the first rank of developmental psychoanalysts to that of a cultural seer.

Becoming a Biographer of Middle Age As Erikson moved through the transition from middle to old age he abandoned clinical work with patients to turn his attention fully to the study of the life cycle and the survival of the species. His emphasis, emergent in *Young Man Luther* and implicit in all his earlier work, was on the ego virtues that permit a person to live in a constructively critical relationship with the social institutions of his time. Earlier, Erikson had described the stages in the development of the ego across the life cycle. In 1964 he wrote more about the ego virtues in *Insight and Responsibility*. He was getting ready amidst the American moral and political crises of the mid-1960s to embark on his last major work, a study of the great moral leader Mohandas Gandhi. In the end, he dedicated it, *in memoriam*, to Martin Luther King, Jr.

Young Man Luther had been a story of personal choice and historical change wrought by a young man establishing and revising a first adult identity and life structure. In his mid-60s Erikson had gained sufficient perspective on the life cycle to analyze a case of decisive crisis and change in a man who was going through a mid-life transition and solving it by creating a vital life structure for middle age. Gandhi did that, as he himself put it, by realizing “his vocation in life,” leading *satyagraha* truth force campaigns in his nation, in his family, and in his own soul. Gandhi was entering the stage of the life cycle in which Erikson's ego polarity of *generativity versus stagnation* becomes active; from his developmental work on this polarity, Gandhi was learning the ego virtue of *care*.

Erikson saw that Gandhi, like Luther, was both a leader and a “religious actualist.” As a leader, he succeeded in articulating inner concerns in a way that struck a collective cord. Self-rule and home rule were inextricably combined in Gandhi's program. He would have endorsed in his own terms, Erikson believed, Luther's assertions, “Christ comes today; God's way is what makes us move; we must always be reborn, renewed, regenerated; to do enough means nothing else than always to begin again.”

Gandhi had begun and successfully completed his political novitiate as an Oxford-trained barrister in South Africa during his 20s and 30s. By his late 30s, he had developed passive resistance as a political strategy to defeat the Black Act, a law that required all Indians in the Transvaal to register with the government and to carry identification papers on their persons. At 40, Gandhi staked out his claim for leadership in his Indian Home Rule Manifesto, and during the next few years of his midlife transition he developed the device of the Satyagraha campaign, culminating in the Great March of striking mine workers in South Africa when he was 44.

When Gandhi returned to India in 1915 at the age of 45, he did so, Erikson wrote, “like a man who knew the nature and the extent of India's calamity and that of his own fundamental mission.” As a mature, middle-aged man, he was, in Erikson's view, a person who has determined what “he does and does not *care for*” as well as “what he *will* and *can* take *care of*. He takes as his baseline what he irreducibly *is* and reaches out for what only he can, and therefore, *must* do.”

What Gandhi had to do was lead a labor strike at the mill in Ahmedabad and the next year, at age 50, a national strike for independence from Great Britain. Erikson contended that Gandhi's emergence at that time as the “father of his country” underlined “the fact that the middle span of life is under the dominance of the universal human need and strength which I have come to subsume under the term *generativity*.” Erikson refers here not merely to the generativity that a parent at 20 or 30 may feel for a child. Erikson's concept of generativity in often mistakenly taken to apply to the child-rearing work of young adults. Instead, he is describing the protective concern for the generations and their retarding-facilitating social institutions, whose leadership is the essential responsibility of the middle-aged individual.

In the early 1970s Erikson returned to the San Francisco Bay Area to live and begin again. The Eriksons relocated to Cambridge, Massachusetts, some 10 years later. In 1981 the Eriksons and psychologist Helen Kivnick undertook an intensive study of 29 octogenarian parents of children whose lives had been meticulously scrutinized in the Guidance Study begun in 1928 at the Institute of Human Development at the University of California at Berkeley. The results of their research were published in *Vital Involvement in Old Age*.

In this work, Erikson, Erikson, and Kivnick revisit the eight stages of psychosocial development and their attendant virtues or strengths. They emphasize the opportunities that exist at the end of life to integrate “maturing forms of hope, will, purpose, competence, fidelity, love, and care into a comprehensive sense of wisdom.” A successful integration results from a final reworking of the earlier polarities of basic trust versus mistrust; autonomy versus shame and doubt; initiative versus guilt; industry versus inferiority; identity versus confusion; intimacy versus isolation; generativity versus self-absorption; and integrity versus despair. The authors use the term *vital involvement* to identify an involvement with the environment characterized by “actuality” and “mutuality.” The elder who is able to maintain a vital involvement with his world—no matter how small its scope—is better able to tolerate the depredations of aging: the loss of sensory acuity, physical mobility, and stamina; changes in intimate relationships as children marry and move away, and friends and partners sicken and die; the loss of social status, financial security, and sources of pride in professional competence; and the realization that relatively little time remains.

Developed in infancy, hope is the basis upon which the senescent individual attempts to integrate faith in the universe and the relative predictability of its laws, with a realistic mistrust about that which is unpredictable and unreliable. The elder may experience a need to affirm a basic faith—in religion or nature—and to understand more deeply his own place in a generational progression.

Late in life the individual must struggle to redefine a sphere of autonomy even as he becomes increasingly dependent upon others. Living independently, residing in familiar surroundings, and following established routines can be crucial symbols of autonomy and the means by which signs of impairment (e.g., a walker) may be accepted without undue shame. An individual's lifelong experience of autonomy influences his or her capacity to adjust to restrictions upon freedom. The ability to allow others to help supports the generative impulses of younger adults and reinforces for both the sense of a generational cycle.

The polarities of initiative versus guilt, first evident in the youngster's exploration and play and subsequently in adult work and recreation, must be balanced anew in old age. With the passage of time the person faces a diminution of opportunities for the exercise of initiative, and must regret those instances where he or she failed to act decisively or with sufficient concern for others. Successful adaptation to the limitations of old age must draw upon the strength of purposefulness developed in childhood and tempered by maturity.

With the natural decline in physical strength and sensory acuity, the senescent individual increasingly depends upon a lifelong sense of effectiveness. External rewards are usually not as numerous as they were in young adulthood or middle age. The feeling of competence and mastery must be sustained internally. An old person may cope with growing physical limitations by changing the criteria for a sense of accomplishment, pursuing new hobbies or modifying old ones, developing new avenues of involvement with former professions, or living vicariously through the accomplishments of children and grandchildren.

Old age provides the individual with the chance to review a lifetime of beliefs, to come to terms with choices made and opportunities lost, and to make and act upon any final commitments, which now most clearly reflect what Erikson termed “the ‘I' in the totality of life.” In striking a final balance between identity and identity confusion, the elder concerns himself with both an external image and a personal image. The external image is the way the individual may expect to be remembered;

the personal image reconciles the sense of who he or she has been with an evolving sense of who he or she may yet become. Identification with the successes of younger generations and satisfaction in one's own part in the transmission of values helps the senescent to stave off feelings of insignificance or obsolescence in the face of technological and sociological changes.

The sense of love that can emerge at the end of life is one that is built upon a foundation of love, expressed and unexpressed, throughout the life cycle. A new balance may be forged between intimacy and isolation in the face of decline. Intimate relationships may be recast in more positive terms; reminiscences provide the elder with the opportunity to draw upon and reintegrate earlier experiences of tenderness and sexuality.

In order to reconcile feelings of integrity and despair, the individual must make peace with previous choices, acknowledging what was gained and lost and accepting that it is too late to change. Relationships and values may be reviewed with more room to consider alternate points of view. In balancing the dispositions toward generativity and stagnation, the elderly person may be able to build upon years of experience as a parent, worker, and creatively productive person from middle age, which themselves were shaped by childhood experiences of caring or its absence. Grandparenthood offers another chance at generativity and a way to undertake it more robustly and less ambivalently. Erikson coined the term “grand-generativity” to distinguish the generativity of old age in which the person, freed from the direct responsibility for family, institution, and community, is better able to incorporate care for the present with concern for the future. Such concern may be expressed through advice or financial assistance to family members or on a larger scale, through commitment to religious beliefs, political involvement, or community action. Grand-generativity contributes to a feeling of immortality: in caring for the younger generation and allowing oneself to be taken care of, the senescent secures a personal place in a generational history.

The “joint reflections on old age” contained in the book are an effort to elucidate the psychosocial process of vital involvement and to extend Erikson's observations to the outer limits of the life cycle. The book also brought Erikson back full circle to his professional beginnings—having made almost 40 years earlier, play observations on the Guidance Study children.

SUGGESTED CROSS-REFERENCES

Sigmund Freud's theories are discussed most fully in Section 6.1. Other theories of personality and psychopathology are discussed in Chapter 6.3 and Chapter 6.4. Schizophrenia is discussed in Chapter 12, personality disorders in Chapter 24, and psychosomatic disorders in Chapter 25. Normal child development and adolescent development are discussed in Section 32.2 and Section 32.3, respectively, adulthood is discussed in Chapter 50, normal human sexuality in Section 19.1, and normal aging in Section 51.2c. Psychoanalysis and psychoanalytic psychotherapy are discussed in Section 30.1. Another perspective on Erikson's work is given in Section 30.9.

6.3 OTHER PSYCHODYNAMIC SCHOOLS

PAUL C. MOHL, M.D. AND MYRON F. WEINER, M.D.

The 11 men and women presented in this chapter—Adolf Meyer, Alfred Adler, Carl G. Jung, Sandor Rado, Otto Rank, Karen Horney, Franz Alexander, Harry Stack Sullivan, Wilhelm Reich, Erich Fromm, and Eric Berne—made their contributions in the early and middle years of the twentieth century. At that time with knowledge of the neurosciences still very primitive, the ethos of psychiatry was to use clinical observation to search for an overarching theory that would encompass not only psychopathology, but all of human behavior. None of these individuals doubted that mind has a physical basis but they all were aware of Sigmund Freud's woeful failure to develop a theory of how experience, thoughts, and feelings are transduced to and from material states. Because of this, they were forced to stand back from the physical organism and view humans strictly as psychological entities. Many doubted that biology would ever be capable of explaining human experience and respected philosophical positions of the time buttressed their opinion. Some neurologists, psychiatrists, psychologists, cognitive scientists, and computer scientists still adhere to this position.

For reasons that are complicated and not always clear, despite the availability of improving phenomenologically based nosological systems, the bias of all psychological theories of personality and psychopathology was to blur the distinction between diagnostic entities and emphasize the common elements of different psychopathologies. Carl Jung stated that with each new patient he had to abandon all theory and listen afresh. Reductionistic neurobiology was considered almost inhumane in its efforts to explain the complexities of human behavior and experience. The understanding of what it is to be human and humane has evolved, as has the understanding of what is and is not scientific. The scientific method involves observation, hypothesis-formation, hypothesis-testing, and coming to conclusions and all these individuals were scientists in that sense. They approached their clinical experience with open-minded rigor and discipline. The proof of their theories was that they fit the observations. These individuals were skeptical observers who were willing to adjust their theories if the observations failed to confirm them; their major flaw is that they overexplained mental phenomena in psychological terms.

This section addresses the contributions of 11 individuals to the present view of normal personality development, psychopathology, and the treatment of mental illnesses and minor emotional disorders. Their greatest contribution is their effort to make mental and emotional disturbances understandable as psychological phenomena. They were able to do so in large measure because of their involvement with psychoanalysis, whose basic credo is that there are laws and principles that govern mental phenomena just as there are laws that describe the physical world. Each theorist anticipated certain aspects of modern psychoanalytic theory (e.g., object relations, self psychology). The primacy of the instincts and of the Oedipal conflict in Freud's thought left many of these thinkers with the sense that something was missing. Their solutions and explanations often leave the modern psychiatrist with the very same sense. However, their struggles toward theories based on the relevance of the interpersonal world, self-esteem, and the first year of life contributed enormously to the broadening focus of psychodynamic theorizing.

All these theorists except Meyer had had experience with or trained in psychoanalysis. Alfred Adler, Fromm, Horney, Jung, Rank, Reich, Rado and Alexander had strong personal involvements with Freud. Jung was Freud's first apparent heir. Except for Rank and Fromm, all were physicians. They all had unique, strong personalities that led to schools of therapy developing around them, partly of their own devising and partly based on the needs of their followers. The best-known schools are Jung's analytic psychology, Adler's individual psychology, and Berne's transactional analysis. These theories developed and the treatment techniques based on them are widely divergent, yet each theory often began with a critique of some aspect of Freud's theories and then built a psychological edifice to correct his errors. Often, the shared foundations were not acknowledged.

The divergence of these theories and techniques and their success as explanations and treatments suggest that each is useful in some contexts and that none is applicable in every context. In attempting to employ any or all of these theories or techniques it is necessary to ask, as psychotherapy research now asks, what theory or technique is useful with what patient under what circumstance and in the hands of what therapist. In order to illustrate the different understandings and therapeutic approaches of each theorist, the following case will be used as a basis for formulation according to each theorist.

Mr. A. was a 26-year-old white male who had a history of bipolar I disorder. He was brought in for treatment after failing to complete the last required course for his advanced degree, and being arrested for disturbing the peace. He had consistently lied to his family about where he stood with his course work and about having skipped an examination that would have qualified him to use his professional degree. He had also not told them that he had been using marijuana almost daily for a number of years and occasionally used hallucinogens. His arrest for disorderly conduct had been for swimming naked in an apartment complex in the middle of the night, while under the influence of hallucinogens.

Mr. A.'s use of marijuana had begun early in college, but became daily during graduate school. He was diagnosed as having bipolar I disorder early in his senior year at college after a clear episode of mania. His mood disorder was well controlled on lithium (Eskalith). During graduate school he was episodically compliant with medications, preferring to try to maintain a state of hypomania. He saw a psychiatrist every 3 to 6 months for medication checks. During his 4 years in graduate school he had two clear episodes of depression and was begun on sertraline (Zoloft), 100 mg a day with questionable benefit. Mr. A. believed that he could be a great writer. He spent most of his time reading and trying to write. He dreamed of going to New York city and becoming part of a group of avant-garde writers that would parallel the Algonquin Club of the 1930s or the beat poets of the late 1940s. This aspiration and his marijuana abuse predated his development of bipolar I disorder. He attended class episodically, nonetheless performing adequately. His last class had no final examination, but required a paper. He planned to write this paper in the form of a play, involving a dialogue between two thinkers from different times and cultures. His professor was very excited about this idea, but Mr. A. kept postponing the task until he was forced to extend his schooling by a year. His other major interest during this time involved growing and photographing flowers.

Mr. A. was born and raised in a large city. His father had been very successful in commercial real estate, and his mother, after raising the children, used the substantial real estate holdings she inherited from her father to set up a business to manage them. Most of the money was placed in a trust for the patient and his siblings. His mother had total financial control of the trusts and doled out the proceeds to the children as they needed them. There was no family history of any psychiatric disorders.

The patient described his mother as very loving and caring, but to the point of being intrusive and controlling. For example, the mother arranged the initial treatment, but then was angry that the psychiatrist had not called her regularly to report on her adult son's progress. She was also critical of various aspects of the treatment as reported to her by her son. The patient's two older siblings had attended prestigious colleges and graduate schools, but had returned home to work in the mother's real estate management company. The 30-year-old sister was living in the parents' home. The 35-year-old brother had lived at home for a time, but then moved out to a location a few blocks away. There was a younger brother, still in college, who also smoked marijuana excessively. He had tried to minimize the patient's problems to the family, and tried to protect the patient, who desperately had not wanted to return home. Of note is that none of the children were married, although the two older ones had each had a couple of serious relationships.

The children seemed to regard the mother with affectionate amusement and bemusement. The father was seen as a very caring but not demonstrative man who put much energy into keeping the mother from becoming too upset and encouraged the children to do the same. The children often wanted to provoke the mother for her judgemental, detail-oriented intrusiveness. The father would discourage them, but occasionally found their provocations amusing.

The family viewed itself as very close, with strong values oriented towards community service and family loyalty. The family belonged to a religious community, but expressed their involvement primarily in social service and social action volunteer work, accompanied by very generous financial contributions.

The patient had been a very successful debater in high school and recalled his development as very positive, but provided few details. He tended to place himself in the role of the outsider, an observer of humanity, which he saw as consonant with the role of writer. He was proud to have bipolar I disorder, and tried to regulate his medications so that he would be hypomanic much of the time, seeing this as enhancing his creativity. He viewed his use of marijuana in the same vein. One of the most distressing aspects to him of his depressive episodes was that marijuana no longer created a feeling of well-being, but made him feel worse. His current depressive episode involved no neurovegetative symptoms. Rather, he presented as flat, numb, apathetic, ashamed, anhedonic, and anergic. He was particularly ashamed of being back in his hometown and of living with his parents.

The patient ostensibly understood and accepted his illness well and had read much about it. However, the family had responded to the information, “With proper treatment bipolars can live normal lives,” as meaning that the information should be kept secret so that he should be treated normally. Mr. A., on the other hand, was very open with friends at graduate school about his illness and his pride in it and the creativity he associated with it.

The patient had two longstanding recurrent dreams. One involved him flying. The narrative line varied but the flying theme recurred. Often he had other magical powers in his dreams such as the ability to heal, to not be killed by bullets, to save the world or some group of people from mortal danger, and so on. The other recurrent dream was of a hotel lobby. The dreams regularly began with him entering a hotel lobby to meet a group of people, accompanied by a feeling of dread.

ADOLF MEYER

Meyer (1866–1950) emigrated to the United States after having trained as a neuropathologist in Switzerland (Fig. 6.3-1). Not interested in metapsychology, he espoused a commonsense psychobiological methodology for the study of mental disorder, emphasizing the interrelationship of symptoms and individual psychological and biological functioning. His approach to the study of personality was biographical. He attempted to bring psychiatric patients and their treatment out of isolated state hospitals and into communities, and was also a strong advocate of social action for mental health. He began his career as a clinically oriented state hospital pathologist, becomming the second head of the Pathological Institute (later, the New York Psychiatric Institute, whose affiliation with the Columbia College of Physicians and Surgeons he created). He later became the President of the American Psychiatric Association and had a 32-year tenure as Chairman of Psychiatry at Johns Hopkins. His major social contribution was helping to found the National Committee on Mental Hygiene.

FIGURE 6.3-1 Adolf Meyer. (Courtesy of National Library of Medicine, Bethesda, MD.)

Psychobiology Despite his background as a neuropathologist, which was common among European psychiatrists of his generation, Meyer strongly opposed the Kraepelinian view of mental illness as having a predetermined course based on phenomenologically identified syndromes. Instead, he believed that individuals' habitual reaction patterns made them more susceptible to specific types of breakdown. Meyer used biographical study, strongly encouraging psychiatrists to take a thorough, detailed, life history of the patient to understand each individual's reaction patterns. He saw development as lifelong, thus viewing the data from adolescence onward as equally important as that from childhood in understanding the patient's narrative.

He observed reaction patterns, attempted to predict the conditions under which they might occur, and tested and validated methods for their modification. He acknowledged the contributions of Freud and Jung but thought they were too narrow. A thoroughgoing pragmatist, he preferred common sense to metapsychological constructs as the means to understand and deal with psychopathology.

Meyer believed that through a basic tendency toward integration, multiple biological, social and psychological forces contribute to personality development. The vulnerable person uses poorly planned, ill-suited means of adaptation. Meyer used the biographical approach as a practical guide to elicit information about personality development, to organize the information, and to check and reevaluate the information obtained under different circumstances. His clinical examination assessed each patient's life history; physical, neurological, genetic and social status; and the relationship between those factors and personality factors. A diagnosis and an individual treatment plan were based on this assessment.

Treatment The aim of psychobiological therapy was to help individuals make the best possible adaptation to changing environmental circumstances. It began with the development of a collaborative relationship. Out of the collaborative relationship came *distributive analysis*, an examination of the factors in patients' lives that contributed to their adjustment or lack thereof, and concluded with *distributive synthesis*; helping patients to understand themselves and to develop better coping skills. The first step in distributive analysis is the patient's own exposition of the presenting problem. Assets and liabilities are then determined by eliciting the life history in terms of the memories that are immediately available and those that are later fleshed out by reconstructing past experiences.

Treatment is initiated by focusing on patients' assets. It involves psychological, chemical, physical, and environmental measures as needed. In more severe cases, attention is paid first to patients' sleep habits, nutrition, and daily routines because these must be normalized before psychological work can be done. Patients are helped to describe their difficulties in detail. In addition to eliciting complaints or worries, patients are asked what eases or worsens their complaints and what significance they attach to their symptoms and concerns. In doing this, the therapist attempts to use the patient's own language and concepts to communicate suggestions and advice.

Meyer did not pay attention to unconscious mechanisms, but focused on patients' functioning in reality. Both present-day and long-term adaptive patterns are considered. Therapeutic sessions proceeded from immediate, obvious problems in the present to longer-term issues and historical data. With guidance, patients investigate their own personality problems, ascertain the origin of their conflicts and work to develop more useful behavior patterns. Meyer called this *habit training*, a term he may or may not have borrowed from behavioral tradition. When unhealthy adaptive patterns are modified, proper adjustment and personal satisfaction result.

Meyerians would focus first on the adequate treatment of Mr. A.'s mental illness. Because he is still dependent on his parents, they would be included in the treatment plan and might be seen separately by a social worker. Both Mr. A. and his parents would be told that failure to control the symptoms of his mental illness could cost him his life and any satisfaction that he might derive from it. Mr. A.'s mood swings would be stabilized on an appropriate medication and he would be observed closely for restoration of normal sleeping and eating habits. He would be asked to discontinue his habit of marijuana use because of its tendency to aggravate the symptoms of his mental illness and its clouding of the assessment of treatment efficacy. Random urine screening might be recommended. Mr. A. would be helped to develop a daily schedule including time for work, social interaction, and recreation. He would not be encouraged to return to school because of his tendency to use school as an escape from responsibility. He would be encouraged to develop his photography as a hobby after a period of stable work performance. Later, he would begin the distributive analysis phase of his treatment, and would be asked to reflect on the impact of his bipolar I disorder and his avoidance of responsibility on his life. In the distributive synthesis phase of treatment, he would be helped to realize that his habit of using his hypomania to heighten his enjoyment and his avoidance of responsibility would keep him from achieving independence and the pleasure of attaining any realistic goal. He would be asked to develop a plan for achieving both appropriate independence and for remaining within the family structure. Mr. A.'s parents would be seen periodically for progress reports and to urge them to push Mr. A. toward appropriate self-care, toward making use of his own resources. They might be asked to place Mr. A. on an allowance and to hold him to it strictly to reinforce his accountability for his actions. Over time, his parents would be asked to slowly withdraw financial support and to give Mr. A. more independence. They might be asked to place his inheritance in a trust designed such that he could not impulsively misspend it.

ALFRED ADLER

Adler (1870–1937) was born in Vienna and spent most of his life there (Fig. 6.3-2). A general physician, he became one of the original four members of Freud's circle in 1902. Adler never accepted the primacy of the libido theory, the sexual origin of neurosis, or the importance of infantile wishes. In 1911 he resigned as President of the Vienna Psychoanalytic Society and continued the development of his own socially and interpersonally focused theory of development. He posited a striving for self-esteem through overcoming a sense of inferiority, which he saw as an inevitable presence in the human condition as a result of our extended childhood. He equated psychological health with constructive social consciousness, developing a system that he called *individual psychology* that is still vigorous in many countries. His major social contribution was the establishment of child guidance centers in Vienna that served as a model for the rest of the world.

FIGURE 6.3-2 Alfred Adler (print includes signature). (Courtesy of Alexandra Adler.)

Personality Theory If Meyer's system were captured in a phrase, that phrase would be common sense. Adler's system might be described similarly as *Menschenkenntnis*, which is the concrete, practical knowledge of mankind. Adler saw individuals as unique, unified biological entities, all of whose psychological processes fit together into an individual lifestyle *(lebensstil)*. He also postulated a principle of dynamism, that every individual is future-directed and moves towards a goal. Once the goal is established, the psychic apparatus shapes itself toward attainment of that goal. Life goals are chosen, and are thus subject to change. Changes require modification of memories, dreams, and perceptions to fit the accomplishment of the new goal. Adler also emphasized the interface between individuals and their social environment: the primacy of action in the real world over fantasy. Community-mindedness, acceptance of the need to conform to the legitimate demands of society, is an important precept, but Adler also recognized a dialectic that occurs between individuals and their interpersonal environment, each constantly reacting to and shaping the other. Thus, Adler anticipated some of the modifications of Freud's theories introduced by Heinz Hartmann, as well as some of Sullivan's thinking.

Normal Personality and Adaptation The cornerstone of Adler's personality theory is the concept of moving from a sense of inferiority to a sense of mastery. Early in life everyone has a sense of inferiority resulting from realistic comparison with adults' size and abilities. Moving from this sense of inferiority to a sense of adequacy is the important motivational motif in life. Thus, the ideal person strives for superiority and does so through high social interest and activity; the emotionally handicapped person continues to feel inferior and reinforces that position through lack of striving and social interest.

There are many obstacles to the development of self-esteem and social interest. Prominent among them are poorly developed or “inferior” organs or systems (such as poor eyesight or poor eye-hand coordination), childhood diseases, pampering, and neglect. Physical handicaps and childhood diseases may promote self-centeredness and loss of social interest; birth order is another factor. According to Adler, first-born children, having lost their position of only child, tend not to share and become conservative. Second children change and become social activists. Youngest children feel secure because they have never been displaced. These theoretical thoughts and clinical observations by Adler anticipated recent psychological research on the importance of birth order in human behavior.

Theory of Psychopathology Emotional disorders result from mistaken lifestyles that are subject to change by will and by self-understanding. Individuals subject to emotional disorders have false ideas about themselves and the world and inappropriate goals that lead them away from constructive social interest. Individuals with a pampered lifestyle, for example, expect and demand from others, avoid responsibility, and blame others for their failures, but they feel incompetent and insecure because their well-being depends on pressing others into service. If life poses no challenge, a mistaken life style may have no consequences. When a mistaken lifestyle is ineffective, symptoms develop that protect self-esteem while helping the individual to avoid dealing realistically with the problem being confronted. The difference between *neurosis* and *psychosis*, is that neurotic individuals maintain social interest, but are blocked from life goals by symptoms, while psychotic

individuals lose social interest and retreat into their own world.

Psychotherapy Because his theory emphasized the mismatch of lifestyles with the demands of the real world, Adler focused on blocks to living productively in the real world, not on exploring unconscious conflict. His aim was to point out mistaken self-views and mistaken views of the world and then, by mobilizing will, make the needed changes, including a change in life goals.

Therapeutic Process Starting with three sessions per week and tapering off to once a week, a positive relationship with patients is established, used to lead patients to awareness of their lifestyle, how it is discordant with the demands of social reality, and ways in which it may be reoriented. Instead of striving for goals of no social value that falsely raise self-esteem, they are pushed to work toward ameliorating their own situation. Having become aware of the obstacles they have placed in their own path and of the consequences of these self-defeating behaviors, they are now helped to develop constructive interests in themselves and others. As they become less self-engaged, they find themselves better accepted by others, which reinforces their constructive efforts. Persons who have dedicated themselves to symbolically defeating others learn to cooperate and advance toward useful goals. Any endeavor in which patients can develop real competence is encouraged, whether social, work, artistic, or musical.

Patients are encouraged to remove the concrete obstacles to developing a useful lifestyle, including reading instruction for slow readers or contact lenses for persons self-conscious about their appearance. Early recollections, birth order, dreams, daydreams, and present-day interactions are all used to help patients see the inappropriateness or falseness of their ideas and life goals. Actual life events or memories of events are less important than individuals' reactions to those events or memories. Because memories are likely to be retrospective falsifications justifying an erroneous lifestyle, there is little need to verify them. There is also no need to look for latent content in dreams; they are merely an expression of present-day concerns. Nor is it necessary that therapists' interpretations be correct because they need only to help patients build a useful conception of themselves and the world. This perspective anticipated what has come to be called the *hermeneutic approach to psychotherapy*.

Several of Adler's techniques, including *reframing* and *paradoxical communication*; now enjoy wide popularity. Reframing is viewing the same data from a different point of view. Indecision, for example, was reframed from a product of mixed feelings to a wish to maintain the status quo. Failure to act keeps everything the same, which is the self-fulfilling prophecy of the discouraged person. Following this reframing statement, patients would be pushed to act constructively. Paradoxical communication is instructing patients to do the opposite of what the therapist wishes them to do. In dealing with an indecisive person, for example, Adler might caution against doing anything rash. Adler also paid attention to the impact of his patients on their environment and recognized that individuals do much to create their own interpersonal world. In response to complaints about being treated unfairly by others, Adler would ask patients how they dealt with the persons about whom they complained. Above all, Adler treated his patients as rational and as able to learn more productive ways of living. In his emphasis on practical, constructive solutions, misconstrued goals, and misperceived views of the world and the self, Adler also anticipated important elements of cognitive therapy.

As seen from the Adlerian point of view, Mr. A. has developed a mistaken lifestyle and an inappropriate life goal. He maintains himself in fantasy as a writer while failing at the accomplishments that would enable him to become a writer. Thus, he has been attempting to make the normal step of moving from inferiority to mastery in fantasy instead of through realistic achievement. Blocks to his development include pampering and his concomitant denial and abuse of his bipolar I disorder, the latter representing his organ inferiority. He has lost the social interest he had earlier in life and become extremely self-centered, unconcerned with others or with the consequences of his actions. He has used drugs and hypomania to avoid the pain of defeat. An Adlerian therapist would encourage Mr. A. to develop a realistic self-view. He has a mental illness that requires lifelong treatment. Grandiose dreams and intoxication with drugs cannot substitute for accomplishments in the real world and will always lead to defeat. He would be asked to set and to strive to accomplish small, realistic goals for himself, such as holding a steady job while enjoying photography as a hobby. His mental illness would be reframed as a challenge to his creativity and his use of marijuana as an obstacle to mobilizing his creativity. He might initially be encouraged to accept his dependency on his family and later, as he stabilizes, to reduce his dependency on his family as a means to heighten his self-esteem and to make a transition into adulthood. He would be encouraged to join the Depressive and Manic Depressive Association or other available support and educational groups as a means to better understand and accept his illness, to develop a social conscience, to stimulate his altruism. His dream about flying would be interpreted as his wish to achieve mastery, his dream about the hotel lobby would be recast his awareness that he has been trying to substitute fantasy for reality.

CARL JUNG

Jung (1875–1961) was a lifelong resident of Switzerland (Fig. 6.3-3). He trained in psychiatry under Eugen Bleuler at the Burgholzli Mental Hospital in Zurich and was strongly involved with Freud and the psychoanalytic movement from 1906 to 1914, when he resigned as president of the International Psychoanalytic Association. Following a “creative illness” that lasted from 1914 to 1918, Jung became an advocate of active introspection as the means to intrapsychic change. This episode and Jung's subsequent interpretation of it as well as that of his disciples has formed the focus of much of the recent controversy about him and his ideas. Although Jung rejected Freud's notion of libido as sexual energy and the Oedipus complex as a universal developmental stage, he believed not only in the unconscious mind, but in a shared racial and species unconscious. Jung, an intuitive introvert, was not interested in the practical aspects of living in the world; his focus was instead on individuation through becoming aware of the unconscious.

FIGURE 6.3-3 Carl Gustav Jung (print includes signature). (National Library of Medicine, Bethesda, MD.)

Personality Theory Jung developed an elaborate metapsychology that was every bit as detailed and formalized as Freud's. In addition, his theories most clearly identify most of the important fault lines in classical psychoanalysis. His construct of the psychic apparatus (Fig. 6.3-4) differed from the Freudian structure of ego, superego, id, and ego ideal. Below an outer rim of consciousness is the personal unconscious, which contains the complexes. Contained within the personal unconscious and connected to the complexes are the archetypes, the elements of the self, which in turn connect to the surface of the personality as the ego.

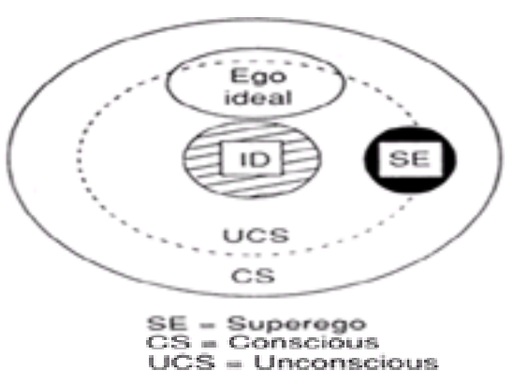

FIGURE 6.3-4 The Freudian topology of the psychic apparatus.

Complexes Complexes are groups of unconscious ideas associated with particular emotionally toned events or experiences. Jung inferred them from his early word-association studies, when he noted that certain words provoked intense reactions or produced less reaction than would be expected. Complexes are built around genetically determined intrinsic psychic structures known as *archetypes*. Complexes are also reinforced by environmental events and by selective attention or inattention and are thus self-perpetuating. They are endowed with psychic energy from their affective tone: positive, negative, mild, or strong. The more intense the complex, the greater the emotion, imagery, and tendency to action. Complexes are often stimulated by interactions with others. A father complex can be stimulated by a person who symbolizes a father (such as an older friend) or by a stimulus such as music or art that evokes father memories. The complex, formerly dormant in the unconscious, comes to the fore and tends to dominate consciousness and to displace other complexes, which then sink into the unconscious. As the father-related external stimuli diminish, the father complex, including what was thought, felt, and expressed during its ascendancy also ebbs. This is a very different model of the dynamic unconscious from Freud's. The boundary between the conscious and unconscious is far more permeable, and there is no emphasis on forces that maintain ideas and feelings in one place or another. Movement between conscious and unconscious experience is triggered by experience. Similarly, Jung's conceptualization of interpersonal boundaries was far more permeable than Freud's; Jung also placed much more emphasis on nonverbal stimulation (music, art, spiritual life) in this process than did Freud, who was the archetypal Enlightenment rationalist.

Some complexes are more conscious, better developed and more ego-syntonic; others are less conscious, poorly developed, and ego-alien. The latter are projected onto the environment, especially by the immature psyche of children, and from this, projective and introjective processes evolve. One person may introject and identify with a complex being projected by another person. Thus, therapists may become psychologically infected by their patients. It is also possible to project a complex that is not integrated within one-self onto another person and then develop a relationship with that projected complex. One can envision an interpersonal environment charged with projected complexes potentially available for introjection, thus offering endless potential for psychic mutation in an interpersonal field. Thus, for Jung, the psychological boundaries between individuals was far less clear than they were for Freud or Adler. Jung also had a parallel appreciation for the process of projective identification that Melanie Klein was developing at about the same time.

In another insight that paralleled Klein's observations, an important aspect of complexes is their bipolarity. Each complex has a positive and negative pole, such as good father and bad father or rewarding father and punishing father. One pole of a complex can be projected onto another person, who in turns acts on it in a relationship. In this way, the theory of complexes is a theory of interpersonal as well as intrapsychic relationships.

In Jungian theory, the ego is also a complex. It serves the same function as the Freudian ego, controlling conscious life and bridging the intrapsychic and external world. The other complexes that also make up the psyche may align with or be in opposition to the ego. For example, emotionally charged primitive complexes have a great tendency to become autonomous and may behave like partial personalities that oppose or control the ego. These personalities appear as images in dreams, as hallucinations, and as separate personalities in dissociative identity disorder. They also appear in seances when mediums bring forth so-called personalities from the dead. For Jung, this phenomenon also explained animism and states of possession. Jung had a great interest in mystical experience, which Freud saw as the persistence of infantile, magical thinking, primary process, or wish-fulfillment—this is another of the clear divisions in their thinking. For Freud and Freudians the world is a harsh, demanding place that forces one to give up primitive wishes for magical experiences. For Jung and Jungians magic is alive and well in the inner world, and is to be embraced.

Archetypes Complexes are connected to structures embedded more deeply in the psychic apparatus, the archetypes. Complexes, the more superficial aspect of the complex-archetype continuum, are related to events, feelings and memories from individual lives. They are the means by which archetypes express themselves in the personal psyche. Archetypes are the inherited capacity to initiate and carry out behaviors typical of all human beings, regardless of race or culture, such as nurturing and accepting nurturance; being aggressive or dealing with aggression by others. These predispositions are analogous to the organization of the cerebral cortex into the anlage for perception of visual or auditory stimuli that become the capacity to see and hear, but that require stimulation for their development. Just as vision cannot develop without visual input during physiologically critical stages, so archetypes require interactional stimulation for their elaboration into complexes. Thus, the human infant's psyche is not amorphous energy awaiting organization by the environment; it is instead a complex and organized set of potentials whose fulfillment and expression depend on the appropriate environmental stimuli. There are as many archetypes as there are prototypic human situations.

The mother complex-archetype illustrates the interrelationship of complex and archetype. All humans are born with a poorly formed but relatively clear model of an all-nurturing caretaker, which Jung referred to as the *earth mother archetype*. The mother complex emerges from this based on experiences with mothers or mother-surrogates: their attitudes, personalities, and relationship to the particular individual. The mother archetype is found in dreams or fantasies, often as a huge woman or an animal with many breasts. The motif of a many-breasted animal, found in many cultures, is that of unlimited nurturance.

Unconscious The Jungian unconscious has two layers, the more superficial being the *personal unconscious*, and the deeper layer the *collective unconscious*. The complexes exist in the personal unconscious, the archetypes in the collective unconscious or *objective psyche*. The personal unconscious is the equivalent of the Freudian unconscious, a repository of what has been repressed. The collective unconscious is the residue of what has been learned in humankind's evolution and ancestral past, much as human deoxyribonucleic acid (DNA) is an aggregate of the past. In this portion of the psyche reside instincts, potential for creativity, and the spiritual heritage of mankind. The potent synthesis of Darwinian natural selection theories with Mendelian genetics, which has had such a profound impact on all of biology, occurred in the 1920s. It is not clear whether Jung was aware of this intellectual thrust, but his understanding of the collective unconscious and of the archetypes is remarkably consonant in form if not in detail with the modern understanding of hereditary and developmental neurobiology as applied by cognitive science.

The psyche, like all other living systems, attempts to stay in balance. Jung's term for homeostasis in the relationship of conscious to unconscious life is the *law of compensation*. For any conscious attitude or experience that is overly intense, there is an unconscious compensation. A person experiencing neglect might fantasize or dream about a huge, many-breasted mother. When interpreting dreams, Jung would ask himself what conscious attitude the dream compensated for.

Symbols Although Jung accepted that certain symbols are universal, he suggested that in dealing with patients it is wisest to view symbols as expressions of content not yet consciously recognized or conceptually formulated. A tall, cylindrical object might symbolize a penis, but it could also stand for creativity or healing. Symbols are often attempts to unite and strike a balance between images from the collective unconscious with the personal unconscious. A tall, cylindrical object that symbolizes a penis in the personal unconscious might symbolize the phallic principle of creativity or fertility in the collective unconscious.

Personality Structure At the center of the conscious personality is the complex called the *ego*. Several universal complexes attend the ego. The *persona* (named after the mask worn by ancient Greek actors), or public personality, mediates between the ego and the real world. The *shadow*, a reverse image of the persona, contains traits that are unacceptable to the persona, whether they are positive or negative. A brave persona, for example, has its fearful shadow. The archetype of the shadow is the enemy or feared intruder. The *anima* is a residue of all the experiences of woman in a man's psychic heritage; the *animus*, the residue of all the experiences of man in a woman's psychic heritage. The anima or animus connects the ego to the inner world of the psyche and is projected onto others in day-to-day or intimate relationships. When connected with the shadow, a man, for example, might see attributes of woman as undesirable, and might experience guilt encountering such qualities in himself.

SELF The *self* is the archetype of the ego; it is the innate potential for wholeness, an unconscious ordering principle directing overall psychic life that gives rise to the ego, which compromises with and is partly shaped by external reality. In Jungian metapsychology, the unconscious gives rise to integration, order and individuation. The self appears from the unconscious in dreams, fantasies, and altered states of consciousness to give direction. In the first half of life, the ego attempts to identify with the self and to appropriate the power of the self in the service of the ego's growth and differentiation. During this time the ego may become inflated with an unrealistic sense of power: the arrogance of youth. If cut off from the self, there may be a sense of alienation and depression.

INDIVIDUATION In the second half of life the ego begins to attend more to the self than to the conscious realm of life. Jung called this developmental process *individuation*, the drive for individuals to become unique and to fulfill the spiritual propensities common to all humanity. Often, this process requires withdrawing from earlier identities and conventional definitions of success and seeking new paths. This change often has the paradoxical effect of leading to broader and more mature relationships in addition to greater creativity.

PSYCHOLOGICAL TYPES Jung's theory of psychological types has three axes (Fig. 6.3-5). The *extroversion-introversion* polarity refers to the two basic types of object relatedness. Extroverts are oriented to others and to the world of consciousness. Their energy flows outward first, then inward. Introverts are oriented to their inner world, their energy flowing first inward and then to outer reality. Introverts might therefore be seen as selfish and unadaptable because they attend first to their inner world and then determine how the outer world can fit them. Extreme extroverts, on the other hand, can seem insensitive to themselves and to the inner lives of

others.

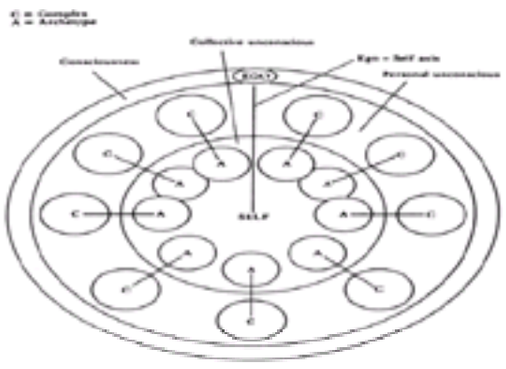

FIGURE 6.3-5 The Jungian psychic apparatus. (Reprinted with permission from Stevens A: *On Jung*. Routledge, London, 1990.)

The *sensation-intuition* polarity concerns perception. The perceptive type that Jung called sensation-oriented is stimulus-bound and attuned to the specifics of here-and-now reality. The intuitive type blurs the details but apprehends the overall picture. The sensation type comes to understand a situation by assembling the details; the intuitive type grasps the overall situation before attempting to assimilate its parts. The sensation type sees the trees first, the intuitive type sees the forest first.

The polarity of *thinking* and *feeling* deals with information processing and judgment. In the thinking mode, data is evaluated according to logical principle. Feeling, at the opposite pole, is making judgments through nonlogical processes having to do with values and understanding relationships. In social relationships, the thinking type would deal with people according to their social rank or according to the tradition of etiquette; a feeling type would deal with others in terms of their present social relationship or perceived emotional state.

Each individual has a preferred mode on each of these three polarities. By placing an individual on each of the three axes indicated in Figure 6.3-6 each individual can be identified as a type. An extroverted-sensation-thinking type is oriented to the real world, tends to perceive details, and organizes them into a logical structure. An introverted-intuition-feeling type is self-oriented, grasps situations as a whole, and is sensitive to their emotional implications.

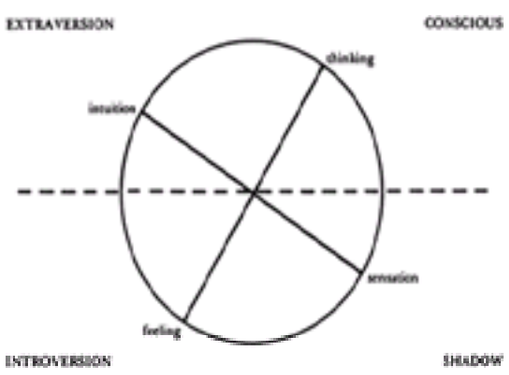

FIGURE 6.3-6 The three personality axes: extraversion-introversion, thinking-feeling, and intuition-sensation. (Reprinted with permission from Stevens A: *On Jung*. Routledge, London, 1990.)

Everyone's psyche contains all of the types. However, each person has a superior set of functions: types that are evolved from early life and that are shaped strongly by constitutional factors. In the second half of life, adults who continue the process of individuation attempt to integrate or broaden and deepen their understanding of their inferior functions. Thinking types become more aware of feelings, sensation types allow themselves to rely more on intuition, and extroverts become more interested in their own inner lives. The Myer-Briggs Type Indicator, a simple paper-and-pencil test consisting of about 40 questions, reliably places individuals on these dimensions. It has become a very popular instrument among pop psychology, management consulting, counseling, and self-improvement organizations for quickly identifying the qualities of individual participants. The typology may be the most widely known and accepted aspect of Jung's theories, although it is often used independently of its original context.

Psychopathology When another complex becomes incompatible with the ego complex, anxiety is experienced. To contain the anxiety, the incompatible complex splits off from the ego and moves unconsciously against the ego or other complexes identified with the ego. This splitting enables individuals to live out the two incompatible complexes, one more ego-identified and the other more ego-alien. The latter is often experienced as being inflicted by the outer world (“I am being mistreated” rather than “I have inner conflict”). This splitting and dissociation of consciousness is particularly evident in hysteria and is an especially good explanation of the phenomenon of multiple personalities (dissociative identity disorder). Within the psyche, ego or part personalities or complexes operate along with shadow personalities that are antithetical to them. In addition, the anima and animus and archetypal images of the self that attempt to integrate and to control the chaos. The various personalities that appear in dissociative identity disorder are manifestations of the complexes and the self.

Extroverts tend to develop hysterical or antisocial traits whereas introverts become dysthymic, anxious, and obsessional. The symptoms are often related to the attempted emergence of inferior functions. Viewed in this way, pathological conditions may contain within them the struggle toward wholeness or health; attempts by inferior functions to become integrated instead of dissociated from consciousness. The integration of these inferior functions often requires emotionally painful rearrangements of conscious thoughts, attitudes, and lifestyle.

The attempted expression of inferior functions need not result in psychopathology. Persons with highly developed thinking functions may find themselves wishing to experience life more fully and may involve themselves in highly emotional extramarital relationships. On exploration, one may find the unresolved loss of a mothering person with the resultant inability to achieve intimacy with a woman. The process of reaching for intimacy is enacted outside the marital relationship because the wife has been assigned the role of the cold, abandoning mother. This is an example of how Jungian theory can arrive at a fairly typical Freudian formulation by a rather different route.

Application Jung suggested that therapy begin with four visits per week and then be spaced out to one or two per week. Present-day Jungian practitioners work with their analysands once a week, face to face. Jung placed great emphasis on the human relationship between analyst and analysand and noted that both parties change in the course of analysis. He defined *transference* as the patient's attempt to develop psychological rapport with the doctor and held that without rapport and object relationship, the technical operations of the analyst were of no value. With its emphasis on reintegration, symbolism, and dreams, Jungian analysis seems well suited to helping educated persons deal with the developmental problems of midlife. Having achieved a professional identity, material success, and established a firm family role, they often begin to ask “Who is the real me?” “What is most meaningful to me?” and “What is my relationship to humankind and human history?” Often given strongly to self-criticism in the service of self-improvement, such individuals may be relieved to find themselves described as trying to become fully themselves instead of as being neurotic. However, the complicated, often blurred intrapsychic relationships described, the interest in mystical experience with its potential shading into magical thinking, and the blurring of boundaries between therapist and patient have made analytic psychology particularly attractive to those who are drawn to or inclined toward cults or exploitative relationships with patients. The break between Freud and Jung, which had for decades been ascribed to Freud's rigidity and authoritarianism, now appears to have had a contribution from Jung: Freud disapproved of a complicated, dependent relationship Jung is believed to have had with a former patient.

Jungians would see Mr. A.'s bipolar I disorder and use of marijuana as having unleashed conflicting archetypes, all attacking the ego complex he had grown up with. This could be seen as an opportunity for Mr. A. to claim a fuller definition of the self. Mr. A.'s aspirations to be a great writer would be taken as potentially healthy and even the content of his psychotic and substance-induced states would be analyzed so as to incorporate their meanings into his ego complex. Mr. A.'s previous psychological type would be described as extroverted, sensation, thinking—an observer of life, but not a full participant. The type emerging in his psychotic and intoxicated states would be described as introverted, feeling, intuitive—the self-absorbed, self-experiencing lover of beauty and ideas. The dreams about flying suggest an expression of the hero archetype; the anxiety dream suggests some emergence of his shadow in association with his aspirations to be a writer. His love of flowers and creativity during his periods of psychosis and intoxication suggests that the shadow is connected to his anima. The task of therapy would be to assist Mr. A. to accept these alien parts of himself and integrate them into his ego complex. Relatively little emphasis would be placed on education or specific treatment of his bipolar I disorder, except insofar as it prevented a good therapeutic alliance. His fantasies, dreams, and psychotic experiences would be investigated, discussed, and analyzed in terms of the psychological functions used and the archetypes expressed. His interpersonal issues with his family would be seen primarily as projections by him of other, unacceptable archetypes that needed identification, analysis, acceptance, and integration. For example, his relationship with his mother would be seen as a projection and fear of the earth mother archetype. The overall goal would be to harness the unleashed unconscious material to allow Mr. A. to pursue his ambitious, creative goals.

SANDOR RADO

Hungarian-born, trained in psychiatry, Rado (1890–1972) emigrated to the United States in 1931 after helping to organize the Hungarian Psychoanalytic Society and being an active member of the Berlin Psychoanalytic Institute (Fig. 6.3-7). In 1945 at Columbia University he was the director of the first psychoanalytic institute within a university medical school. Rado believed that learning, cultural, and parental influences were of greater importance than instinctual factors as causes of emotional or behavioral disorder, but also believed strongly that an underlying genetically determined biochemical abnormality was present in schizophrenia. His work fit in with the development of ego psychology, influenced by Anna Freud, Heinz Hartmann, and David Rappoport.

FIGURE 6.3-7 Sandor Rado. (Courtesy of New York Academy of Medicine.)

Adaptational Psychodynamics Rado viewed the psychic apparatus as an organ of adaptation. Effective adaptation is psychological health. Psychological illness or maladaptive behavior is a failure of this adaptive mechanism. There are hierarchical levels of human mental integration: hedonic, emotional, emotional thought, and unemotional thought. These levels parallel the phylogenetic and ontogenetic evolution of the brain with the gradually increasing influence of the neocortex over the more primitive parts of the brain. The hedonic level is the realm of pain and pleasure. Pain signals impending damage and causes flight. Pleasure indicates benefit and elicits clinging or moving toward. Persistent pain has the secondary effect of reducing self-esteem through a sense of failure; pleasure has the secondary effect of enhancing self-esteem through a sense of success. More than most other psychoanalysts, Rado stayed true to Freud's belief that a neurobiological basis for the psychic apparatus would be discovered. He integrated Walter B. Cannon's theory of emotions with James Papez' identification of the limbic system as the neuroanatomical locus of emotional and hedonic mechanisms. He also anticipated the recognition by modern evolutionary biology and neuropsychology of hedonic mechanisms being the keys to memory.

The emotional level of psychic integration consists of the emergency emotions (e.g., fear, rage) and the tender or welfare emotions (e.g., love, pride). The emergency emotions are responses to real or anticipated pain and result in flight or fight. The welfare emotions are responses to actual or anticipated pleasure or benefit and prepare the organism to embrace the pleasurable stimulus. Rado's observation that ordinary human mental activity is primarily at the hedonic and emotional levels was borne out by George Vaillant's later studies that followed a group of successful college undergraduates into their middle years.

Emotional thought justifies and reinforces the emotions from which it springs and is not reality-based; it corresponds to Freud's primary process. Examples of emotional thought include dreams, fantasies, delusions, and the hallucinations of psychiatric illness. Rational or unemotional thought operates on Freud's reality principle, making it possible to delay action and gratification, to forgo present pleasure for future gain, and to control emotional responses. Rado concluded that much effort is required by ordinary adults to combat emotional thinking, and that the emergency emotions are far stronger than the welfare emotions.

Conscience Conscience is the part of the mature psychic apparatus, operating unconsciously, that rewards good behavior, raising self-esteem, and punishes bad behavior by guilt, thus lowering self-esteem. Unlike Sigmund Freud's conception of the superego, conscience is seen as primarily constructive and adaptive. It facilitates cooperation with others and reduces destructive forms of competition. Although conscience stimulates adaptive behavior, it can also produce pathological behavior.

Anticipating the work of Lawrence Kohlberg on the developmental stages of moral thought in both children and adults, Rado described the development of conscience as originating in the dependent child's wish and need to remain in its parents' good graces. Initially, the child projects its own omnipotent feelings onto the parents. Believing that parents see and know all causes the child to fear punishment that it feels is inescapable. A child who misbehaves experiences guilty fear, which has the positive effect of stimulating expiatory behavior. The child admits wrongdoing and accepts punishment to restore the parents' positive feelings. This relieves the painful guilty fear and restores the child's self-esteem. Pain-dependent or masochistic behavior is a form of expiatory behavior based on guilty fear. Fear motivates the person to seek punishment in advance, which may at times permit satisfaction of a formerly proscribed desire. Although not a complete explanation of masochistic behavior, Rado provided an important link in its understanding.

Both discipline and conscience formation are complicated by the buildup of rage that occurs when the child obeys or submits to its parents. The rage, which is repressed, constantly seeks discharge and is a potentially serious problem for both the individual and society.

Treatment According to Rado, psychological health is a predominance of welfare emotions in a reasonably independent, self-reliant person. Such a person creates a self-reinforcing interpersonal field by stimulating pleasurable feelings in others. By recognizing the interpersonal field within which emotions occur, Rado reflects the influence of Sullivan and Kurt Lewin. The emergency responses are still active, but are released nondestructively through various types of play or constructive activity and through dreaming.

The aim of psychotherapy is to increase the influence of the welfare emotions on behavior and to reduce the influence of the emergency emotions. Patients are encouraged to relinquish the dependency that both causes and results from maladaptive behavior and to become reasonably self-reliant. The past is explored in therapy primarily to increase understanding of the present rather than to reconstruct the past. Rado focused more on examining patients' present-day behavior than on the recovery and analysis of memories and the development of insight based on those reconstructions. He preferred to educate patients directly instead of developing and analyzing the transference, as was done in classical analysis.

Rado would have framed Mr. A.'s difficulties as failures of adaptation to his mental illness and adult life and as a regression to the hedonic level of adaptation in which pleasure is sought and pain avoided. As Mr. A.'s self-esteem was reduced through his failure to face his obligations, he avoided the resultant pain through flight into mania and the use of drugs. Activation of his emergency emotions led him to behave and to fail in ways that provoked punishment. He failed at graduate school and was arrested for disturbing the peace. Rado would have emphasized reducing the self-defeating behaviors that alienated Mr. A. from others and on increasing

behaviors that would result in support and positive input from others. Rado would have encouraged Mr. A. to examine his dependence on his family and to decide if he wanted to continue in this dependent role. Mr. A. would have been helped to uncover his welfare emotions and to relate to his family in a positive way that would allow him to reduce his rage toward his parents for being controlling of him, reduce his acting out against them, and enable him to develop into his own person.

FRANZ ALEXANDER

Alexander (1891–1964) was one of the second generation of psychoanalysts. He was born in Budapest and attended medical school there, graduating in 1912 (Fig. 6.3-8). He conducted research at the Institute for Experimental Pathology in bacteriology until World War I when he practiced clinical microbiology on the Italian front, primarily combating malaria. Following the war he joined the department of psychiatry at the University of Budapest Medical School as a brain researcher. This led to an encounter with Freud's work and in 1919, he became the first student of the Berlin Psychoanalytic Institute. In 1930 Alexander became a visiting professor of psychoanalysis at the University of Chicago and in 1932 founded the Chicago Psychoanalytic Institute. He established the Institute independent of the psychoanalytic societies, leading the Chicago Institute to be one of the most creative sources of psychoanalytic thought. During the same time he began his interest in psychosomatic illnesses, helping to found the journal *Psychosomatic Medicine*. A guiding principle of his work was to make psychoanalysis an integral part of medicine.

FIGURE 6.3-8 Franz Alexander. (Courtesy of Franz Alexander.)

In 1946 Alexander became Professor of Psychoanalysis at the University of Southern California, where he continued his work on psychosomatic medicine and became interested in the interface of learning theory, the psychophysiology of stress, and psychoanalysis.

Theory of Personality Alexander did not develop a unique overarching theory of personality; his contribution was his application of psychoanalytic thought to pathophysiological processes. In this he laid the ground work for the burgeoning fields of psychosomatic medicine, behavioral medicine, and psychophysiology. Alexander created the basis for the biopsychosocial model and studied the mind and body at a time when American psychiatry, despite Freud's original ideas, had become purely psychological in its orientation. In studying and treating many patients with serious physical illness, he was also forced to consider creative modifications of therapeutic technique.

Alexander and his group began by intensively studying, by means of clinical interviews, patients who had one of seven illnesses that had been identified by general practitioners as having strong psychological components. Out of these clinical studies emerged the *specificity hypothesis*, which proposed that certain illnesses are the product of a complex interaction of specific constitutional predispositions, specific unconscious conflicts, and specific types of stressors that activate such conflicts. The group then tested these hypotheses in a series of clinical studies of patient populations. The independent variable was usually the ability of skilled clinicians to predict a patient's illness from disguised case reports. The model he proposed remains the fundamental psychosomatic conceptualization; a variety of illness situations are now studied by controlling for genetic influences while measuring and modifying intrapsychic conflict and external stressors.

In the field of psychotherapy Alexander was one of many who sought to shorten the analytic process. He hypothesized that intellectual insight was not the central curative factor in therapy. Rather, he emphasized the role of corrective emotional experience. This led him to experiment with variations in technique that might facilitate such experiences. This, his most controversial stand, nearly ruptured his relations with the psychoanalytic movement.

Theory of Psychopathology The seven diseases that Alexander studied were peptic ulcer disease, ulcerative colitis, essential hypertension, Grave's disease, neurodermatitis, rheumatoid arthritis, and bronchial asthma. Alexander and his group identified what they believed to be the single, specific core conflict which, in interaction with constitutional predispositions and in the circumstance of a particular stressor, would activate the disease.

The core conflict identified in peptic ulcer disease is hyperindependence as a defense against unacceptable dependency needs. The stressor that would result in an acute attack could be any situation that demanded that the afflicted individual openly acknowledge or ask that dependency needs be met. Ordinarily, patients would use dominance and control to intimidate others into meeting their dependency needs. Thus, Alexander was the first to describe the “little boy” business executive prone to peptic ulcers. The groundwork was laid for John J. Brady's executive monkey experiments. This particular illness model has received more confirmatory evidence than any of the others, especially from a study of army inductees in whom psychological profiles as described by Alexander, in combination with measurements of serum pepsinogen, were extraordinarily successful in predicting the development of duodenal ulcer. It is not clear what the impact of the recent recognition of a specific pathogen means for this particular hypothesis. On the one hand, there is ample evidence that Alexander was right. Perhaps the identified pathogen, *Helico pylori*, is merely the constitutional factor that had previously been thought to be serum pepsinogen concentration, or perhaps Alexander's hypothesis applies to some subgroup of patients with duodenal ulcer. However, today peptic ulcer disease is treated primarily as an infectious ailment.

Alexander's theory of ulcerative colitis also implicated dependency conflicts; however, rage at unmet needs was seen as the defining feature. This rage provokes guilt and the urge to make restitution towards the object of anger by means of gifts of achievements and successes. The model here is clearly the angry child seeking to placate a parent by means of performance. The precipitating event for reactivation of the illness is the perception that the efforts at placation will be unsuccessful. Alexander claimed that this resulted in excess parasympathetic activity, leading to diarrhea. Alexander's own study in which skilled internists and psychiatrists reviewed case descriptions in which each case had one of the seven identified psychosomatic illnesses, and then predicted which illness each patient had, resulted in correct identification of over half of the patients with ulcerative colitis from their dynamics alone—well beyond chance. However, most clinicians now regard George Engel's object-relations based formulation to be the more accurate.

Alexander's hypothesis about essential hypertension focused on inhibited anger and suspiciousness in an outwardly compliant, cooperative individual. A hypertensive patient often goes for long periods with blood pressure under good control and then, seemingly inexplicably, experiences a dramatic rise in blood pressure. Alexander attributed these episodes to incidents when the chronic anger is exacerbated and intense defenses must be used, causing chronic sympathetic, fight-or flight activation. Several psychophysiological studies have suggested that this theory has some validity at least in terms of short-term changes in the blood pressure of a subset of hypertensives. Labile hypertensive patients appear to fit this model best.

The proposed specific conflict for rheumatoid arthritis postulates conflicts over rebellion against overprotective parents. A compromise formation in which the conflict is discharged via physical activity, especially sports, works for a time, but the anger eventually is expressed in self-sacrifice designed to control others. Failure of this pattern results in increased ambivalent tension, directly expressed via muscular contractions that lead to joint degeneration. A remarkable amount of confirmatory evidence for this constellation appeared in a series of psychological test studies; however, more recent research has failed to replicate much of this and has implicated more general stress issues, life change, and psychoneuroimmunological mechanisms.

Alexander proposed that the wheeze of bronchial asthma represented a symbolic cry. The specific conflict, according to him, was the wish for protection versus the fear of envelopment. This conflict leads to sensitization to separation issues, which become the events that provoke the suppressed cry of the asthma attack. In recent years it has become clear that the population with asthma is far more heterogeneous both psychologically and physiologically (in terms of vulnerability to allergens) than was recognized in Alexander's time. The role of a vicious physiological-psychological cycle in which asthma stimulates panic, which in turn triggers pathological pulmonary psychophysiological responses, has been a focus of more recent research.

Although the role of conflicts in neurodermatitis remains widely accepted by clinicians, the specific conflict proposed by Alexander, that early deprivation leads to wishes for closeness that are opposed by a fear of it, is no longer accepted. Finally, Grave's disease (thyrotoxicosis) is no longer widely accepted as a psychosomatic illness. Alexander's hypothesis was that premature responsibility led to a martyr-like denial of dependency.

Treatment The specificity hypothesis led Alexander to focus his psychotherapeutic efforts in a way that other analysts of his time did not. He reasoned that if he could help patients to resolve their core conflict without necessarily addressing other parts of the personality structure, the medical illness would improve. Indeed, he published numerous case studies suggesting just this kind of success. In addition, he was among the first to question the value of intellectual insight as the curative agent in psychotherapy. He proposed that a corrective emotional experience is the central agent of change. A corrective emotional experience involved disconfirmation within the transference relationship of previous assumptions and projections.

Thus, Alexander felt justified in introducing a variety of techniques that would initially induce and heighten the emotional experience of the transference, and, subsequently, challenge the underlying unconscious assumptions. These techniques included manipulating the frequency and length of sessions, making direct suggestions about the patient's life, self-conscious alteration of the therapist's behavior according to the patient's conflict and behavior therapy techniques. In many ways this was the most controversial aspect of Alexander's work. Serious questions about the validity of his suppositions and the ethics of his “manipulative stance” were raised. He was impatient with the slow, methodical process of convincing his colleagues, his intellectual energy led him to embark on ever-newer experiments while other analysts were still struggling to digest his previous suggestions. Yet today few would quarrel with the concept that emotional learning is at least as important as intellectual insight in psychotherapeutic success. Alexander's efforts to modify and shorten the analytic process have come closer to the norm in psychiatric practice than in classical analysis.

Ironically, although Alexander's therapeutic innovations seem prescient today, his specificity hypothesis, which was in his time far less controversial, seems simplistic, naive, and forced. He did not have available the sense of how complicated illness causation truly is. The dominant model of the time was infectious diseases: one organism, one illness. In addition, the complexity of social phenomena and stressors was unknown in his time. Yet, Alexander was the first to postulate a multicausal etiology for disease: a specific constitutional defect, a specific conflict, and a specific stressor. He was also the first to study mind-body interactions in a systematic way. Thus, he laid the very basis upon which his own formulations seem so limited today.

In the absence of a clear psychosomatic illness, Alexander would have little to say specifically about Mr. A's dynamics. However, like any good dynamically oriented psychotherapist, he would readily recognize Mr. A's core conflict about dependence-independence. Mr. A would be understood as rebelling against his mother's nurturant control, while secretly desiring to continue basking in it. He has serendipitously found that illicit drugs and his mental illness can be harnessed such that his mother has to rescue him and take over, while he can avoid becoming aware of the conflict. Alexander's unique contribution to Mr. A's case would be to propose that he could be treated with 40 or fewer sessions, focusing exclusively on this conflict (and ignoring others such as oedipal components and issues with his father). Further, Alexander's agenda would be to structure the therapeutic relationship to intensify Mr. A's experiencing of this conflict. He might do this by taking a somewhat intrusive, directive stance, thus creating the opportunity for a rapidly, intense transference around this issue. Alexander might then spread out the sessions to elicit expression of the patient's yearning for that control. The key therapeutic effort would then be to respond constructively to attempts by Mr. A to assert himself appropriately and take over control of his life—for example by learning more about his illness and taking responsibility for his treatment.

WILHELM REICH

Reich (1897–1957) was one of Freud's most controversial disciples; his latter years were marred by mental illness (Fig. 6.3-9) Reich fixed on and elaborated Freud's early, but later discarded view, that neurosis results from the damming up of sexual energy. Blockage of normal orgasm can lead to partial conversion of sexual energy into aggression, but residual tension manifests in the form of characteristic physical tensions that reflect the underlying character armor of each individual. In so doing, Reich laid the groundwork for a psychoanalytic theory of personality. Prior to Reich, the focus was on symptoms and psychopathology. There was occasional mention of “character” in psychoanalytic work, but there was no focus on personality as an entity unto itself. This shift is of great importance because as neurobiology has come to explain more and more Axis I mental disorders it has become clear that psychodynamic theories' enduring strengths involve understanding and treating personality traits and disorders. Together with Anna Freud and Heinz Hartmann, Reich is regarded as the originator of ego psychology.

FIGURE 6.3-9 Wilhelm Reich. (Courtesy of New York Academy of Medicine.)

Personality Theory Reich did not disagree with Freud's notions concerning personality development, including character types based on fixation at specific levels of psychosexual maturation. Reich elaborated the interpersonal and physical behavior of these personality types. Specific behavioral traits constitute *character armor* that defends against internal and external dangers. Character armor is composed of involuntary, repetitive, ego-syntonic behaviors that prevent the emergence of repressed impulses. For instance, the trait of ingratiation frequently defends against hostile impulses, just as the traits of hostility or self-assertion may defend against wishes to be dependent and passive. These traits manifest physically in the voluntary musculature as characteristic postures (clenched jaw or fist, rigid or bowed back) or in excessive stiffness or fluidity of movement. Although Reich's ideas of the behavioral and postural components being central features of character armor are no longer accepted, his ideas successfully transformed the focus of psychodynamic thought from individual wishes defended against by individual defenses, expressed in specific transferential forms into an emphasis on patterns, organization, and intertwining of all of these elements.

Hysterical Character The hysterical character has the least body armoring, hence the most lability of function. Body movements tend to be soft, rolling, and sexually suggestive. These individuals are superficial, excitable, flighty, fearful, highly suggestible, and easily disappointed. Their armor helps to defend against easy sexual arousability by flushing out potential sexual stimuli in the environment and then reacting to them with anger.

Compulsive Character These individuals are tense and restrained, walk stiffly and sit rigidly. They are overconcerned about orderliness, tend to ruminate, and are indecisive and distrusting. They experience a blockage between their thoughts and feelings. Because they have little access to their feelings, they have little ability to prioritize their actions, to make decisions, or to sense others' reactions to them. The compulsive character avoids expression of repressed impulses by rigid overcontrol. Because of this, these individuals are very threatened by trivial changes in routine.

Phallic-Narcissistic Character Phallic-narcissistic persons appear cold, reserved and prickly. They are outspoken, provocative, and seek positions of power. Frustrated at the genital-exhibitionist stage of development, the men are identified with the penis and the women with the fantasy of having a penis. The men have strong erective potency, but little capacity for intimacy; the women actively dominate men.

Masochistic Character Masochistic individuals suffer, complain, and damage and deprecate themselves in ways that provoke and torture others. Reich differed with the analytic interpretation that these persons enjoy suffering. He thought the opposite—that pleasure is painful for the masochist because of an enormous need, excessive guilt, and the resultant low tolerance for love or pleasure. Suffering allows the masochist to then indulge in a certain amount of self-gratification. Sexual intercourse can be enjoyed, for example, if the partner is inconsiderate or if intercourse is accompanied by the fantasy of rape.

Treatment Reich's major contribution was in the realm of treatment. He was the first to recognize the need to deal with character resistances before attempting to

recover repressed material: that interpersonal resistances need to be dealt with before free association is possible. He did this by analyzing patients' character armor—their characteristic behaviors (including tone of voice, posture, and physical movements) in the analytic setting—before proceeding to an analysis of the unconscious. Reich worked face to face with patients and sought to relax their character armor by physical manipulation. This type of therapy, called *vegetotherapy* by Reich, is still practiced by Reich's followers as *bioenergetics*.

A Reichian analyst might have seen Mr. A.'s seeming rebellion against conformity as a defense against his fear of being away from his mother's protection and domination. The Reichian might have pointed out that the more Mr. A. rebelled, the more tightly he was binding himself to his mother. The therapist might also have suggested that the behaviors that seemed so much under Mr. A.'s control were in fact compulsive behaviors; his prolongation of his manic states and use of drugs were being dictated by forces outside of his awareness to protect him from internal and external dangers. Among them, the internal danger of recognizing his rage at his parents for their overprotection and the external danger of failing to deal with a world with which he was poorly equipped to deal. As these behaviors became more ego-alien, the Reichian would have begun a classical analysis of the conflicting unconscious forces involved, including the patient's fear of engulfment by his mother and his wish to be engulfed; fear of his attachment and the wish to be attached, and the harshness of his own superego. The patient's identification with his father as one who superficially placates, but with contempt, would have been explored. The analysis would have included Mr. A.'s dreams. His dream of flying might have been interpreted as his fear that to separate from his mother he would need to become invulnerable to all life's potential injuries, a superman. His lobby dream might have been interpreted as his wish to return to the womb as a defense against the injuries he might experience away from his mother.

OTTO RANK

Rank (1884–1939) was a 21-year-old student when he met Freud (Fig. 6.3-10). Rank later earned a doctorate in psychology and eventually became a peer of Freud's before ultimately breaking with him. Rank saw each person as an artist whose ultimate task is the creation of an individual personality. In Rank's view the neurotic was an *artiste manque*, a person whose strong creative urge was stultified by the negative use of will.

FIGURE 6.3-10 Otto Rank. (Courtesy of New York Academy of Medicine.)

Rankian Dialectic The basis for his break with Freud was Rank's view that the birth trauma was more important than the oedipal conflict. According to Rank, the physical and psychological experience of birth gives rise to a primal anxiety that is dealth with by primal repression. The crucial intrapsychic conflict that occurs in all developmental phases is the conflict between maintaining the primal bliss of attachment and experiencing the excitement and fear associated with separation.

Union stands in contrast to separation; likeness stands in contrast to difference. In adulthood, movement toward another person is possible only if one knows who one is, which can come about only through having experienced separation. Movement toward autonomy is possible only after having established the sense of belonging and self-worth that derive from the experience of fitting in or belonging.

Moving toward union or separation is not an innate biological process but an act of will. In moving toward and engaging with another person, all individuals experience their need for belonging. Moving away from others allows individuals to experience their uniqueness. Maturity is the triumph of will over the forces that inhibit movement both toward and away from others—guilt, death-fear, and life-fear.

Rank saw guilt as the price to be paid for any act of will. Moving toward union causes guilt over being needy; moving away causes the guilt of abandoning another person. Death fear is the fear of losing one's identity by fusing with another person. The weaker one's personal identity, the stronger the death-fear. Life-fear, by contrast, is fear of losing all ties in the process of becoming separate. Every person experiences the cycle of movement from union to separation and back again as part of the life process. This movement takes place at various levels: family, societal, artistic, and spiritual. At each level, there is one or more movement toward union and rebirth. Each person, for example, usually yields to a love experience in which personal differences are set aside to experience unity with another, to experience self-worth, and to be relieved of the sense of difference. The yielding to another ends when the will asserts its separateness and a new affirmation of individuality occurs.

Will, the prime mover in the Rankian dialectic, is an irreducible creative force. It is not solely an agency for the expression of freudian sexual or aggressive impulses, nor is it the will to power in the Adlerian sense. The beginning of will is in the child's “no,” an assertion of what the child will not do. In maturation, will becomes a positive force. Neurotic persons, however, deny will, because of guilt over what they will. They deal with that guilt by using defense mechanisms such as projection and rationalization. Viewed from this perspective, neurotics are strong-willed persons who cannot acknowledge what they will or even that they will. As a result, they cannot use their will constructively in the service of their greatest potential artistic creation, their own personalities.

Treatment Rankian psychotherapy is a here-and-now interaction with the therapist that mobilizes the patient's will and results in a rebirth experience. The treatment, which is time-limited, focuses on the relationship with the therapist. In the therapist-patient relationship are reenacted earlier life struggles, especially struggles involving intimacy. After patients are strengthened through the therapist's acceptance, they begin a process of negative will assertion that is seen as resistance in classical analysis. Rank regarded this negative will assertion as indicative of growth and supported it. Now able to provide self-affirmation on their own, patients free themselves of the therapist and begin to individuate. They overcome the life-fear by living up to their fullest potential. Therapy is not aimed at reconstructing personal history, it is a struggle in the here and now between the therapist as a representative of transference objects and of reality.

The therapeutic process parallels the process of personality growth. At first, the therapeutic relationship recapitulates prototypical early relationships. The first rebirth experience for patients is claiming their own individual personalities and their uniqueness as human beings. The second phase is their discovery of the physical universe and their likeness to it. Later, they claim their distinctness as creators of themselves. With the emergence of the self, individuals unite with ideological, philosophical, and spiritual reality and experience the final birth of the ideal person, a self-fulfilled person who no longer needs to create to justify his or her existence. In Rank's theories the beginning of the shift to what would now be called pregenital issues in psychoanalytic thought can be seen. Very early on, many of Freud's associates sensed that something was missing from the theory. Klein, Rank, and others searched for this understanding in the earliest phases of development. Although rarely cited these days, Rank's work clearly anticipated that of the object relations therapists and the self psychologists.

A Rankian therapist would have seen Mr. A. as attempting to achieve separation from his family of origin, but as lacking the will to achieve real separation. The prolongation of his manic episodes and his use of drugs helped him to avoid the pain of separation and individuation, and his failure to complete graduate school allowed him to maintain his dependence on his family. Initially, the Rankian therapist might have approved of Mr. A.'s attempts to sustain his manic episodes and his marijuana use as a negative assertion of will against his mother's efforts to run his life. The therapist would then have suggested that developing more constructive and positive means might enable Mr. A. to become more free in reality. The Rankian therapist might challenge Mr. A. to develop attachments outside his family and to develop skills to help free himself. Resistance to the development of these skills would have been interpreted as fear of separation and aloneness. Mr. A. would then be encouraged to develop his will in a positive direction; following a path of action that he desired instead of rebelling against a path of action seemingly dictated by others. Finally, Mr. A. would work toward separation from the therapist as a prototypical separation-individuation experience.

KAREN HORNEY

Physician-psychoanalyst Horney (1885–1952), who emphasized the preeminence of social and cultural influences on psychosexual development, focused her attention on the differing psychology of men and women, and explored the vicissitudes of marital relationships (Fig. 6.3-11). She was one of three women whom Freud trained so as to have female analysts who would contribute their unique perspective to the psychoanalytic theory about women; the other two were Anna Freud and Helene Deutsch. Horney's view that repression and sublimation of biological drives are not the primary determinants of personality development led to her removal as an instructor in the New York Psychoanalytic Institute and her founding, in 1941, of the American Psychoanalytic Institute.

FIGURE 6.3-11 Karen Horney. (Courtesy of the Association for the Advancement of Psychoanalysis, New York.)

Personality Theory Horney believed that personality development results from the interaction of biological and psychosocial forces that are unique for each individual. At the core of each personality is an enduring *real self*. Partially equivalent to the Freudian ego and partly to Eric Berne's child ego state, the real self combines choice, will, responsibility, and identity with spontaneity and aliveness. A natural unfolding process of *self-realization* leads to the development of human potential in three basic directions: toward others—to express love and trust, against others—to express healthy opposition, and away from others toward self-sufficiency.

Although conditions during childhood may block psychological development healthy growth is always possible if the internal blockages can be removed. Children whose family situation leads them to feel endangered concentrate on psychological survival, and may do so at the cost of developing stereotyped coping mechanisms. All human beings suffer from *basic anxiety*, which Horney saw as the normal response to the infant's helplessness and separateness. How families respond to this fundamental situation, guided by cultural norms, determines whether individuals spend their lives struggling with basic anxiety or pursuing self-realization.

Horney believed that the attributes of passivity and suffering were not biologically specific to women, as taught by the analysts of her day, and that male and female personalities are in fact culturally determined.

Theory of Neurosis Horney defined neurosis in both intrapsychic and interpersonal terms. She noted that her patients complained, not of the symptomatic neuroses such as phobias and compulsions, but of unhappiness, blockage, lack of fulfillment in their work, and inability to establish or maintain relationships. She saw these individuals as having a complex system of self-perpetuating defensive patterns against basic anxiety—a character neuroses.

Safety Seeking Children move psychologically in three directions to relieve their anxiety, make life safe and predictable, and achieve satisfaction. They seek affection and approval, become hostile, or withdraw. Children eventually employ the coping strategy that best meets their needs, but if only one basic strategy is used children become limited in their coping repertoire and in their experience of themselves and their world. Their sense of safety is tenuous because there is now danger from within, from suppressed or repressed feelings and impulses. Given continued unfavorable environmental conditions, conflicting feelings are driven into the unconscious, and such children are left with a sense of discomfort, anxiety, apprehension, and an insecure sense of self. At this juncture their point of reference is externalized; patterns of behavior rigidify and increasing blockages to growth develop. Horney designates these complex, relatively fixed attitudes toward self and others as neurotic trends.

Character Types Horney's three main character types are based on the predominant mode of relating to others. The *compliant, self-effacing type* results from the defensive operation of clinging to others. These individuals try to curry the favor of others, subordinate themselves to others and are reluctant to disagree for fear of losing favor. The *aggressive, expansive type* results from moving against others, and relies heavily on power and mastery as a means to achieve security. The *detached resigned type* results from moving away from others in an attempt to avoid both dependency and conflict. These are very private individuals who, while refusing to compete openly, see themselves as rising above others.

Supplemental Means to Relieve Inner Tension The overdevelopment of any one of the three basic interpersonal styles suppresses the two others. In a manner analogous to Jung's complexes, repressed impulses continue to be active and to produce conflict. An artificial harmony is achieved by the use of mental mechanisms such as blind spots, compartmentalization, rationalization, and coping techniques such as excessive self-control, arbitrariness, elusiveness, cynicism, and externalization.

Idealized Image As teenagers, individuals who will grow up to be neurotic create an ideal image that, if achieved, promises to end their painful feelings and provide self-fulfillment. The idealized image counterbalances the alienation from their core selves that developing neurotic individuals undergo because the survival techniques they adopted earlier force them to override their genuine wishes, feelings, and thoughts. The idealized image covers over all the contradictions, conceals the defensive nature of their behavior, and restores a sense of wholeness. Energy formerly available for self-realization is now used in efforts to become like the idealized image. For example, an individual who has adopted the strategy of moving toward others and is consequently dependent on others for affection and approval experiences the fear of reasonable self-assertion as saintly humility and considerateness of others.

Because the ideal self is imaginary, neurotic persons are readily bruised by confrontation with reality, and work excessively hard to prove they are in fact their ideal selves. This results in a type of perfectionism that insists on flawless excellence in which “I should” replaces “I want” or “I need.” It also results in the neurotic ambition to be first and in a strong drive for revenge against those perceived as having interfered with their efforts to match the ideal self. This aspect of Horney's theories anticipates some of Heinz Kohut's earliest ideas on the origins of narcissism.

Claims, Shoulds, and Self-Hatred Despite their frequent self-disparagement, neurotic individuals expect to be treated as though they were their ideal selves. These claims to special treatment, when frustrated, produce anger, righteous indignation, and resentment. The “shoulds,” or self-imposed demands that they live up to their idealized selves, are irrational and unrelated to the realities of daily life. They are projected, experienced as demands made by others, and are also demanded of others. This results in neurotic persons being critical of others and very sensitive to criticism themselves.

Self-hatred results when the threat arises that neurotic individuals may be unable to achieve their idealized selves. If support were not needed for the idealized self, claims, shoulds, and self-hatred would not be such an important part of the psychic apparatus.

Neurotic Pride and the Pride System Glorifying aspects of the idealized self, *neurotic pride*, substitute for healthy self-confidence. Thus, when their pride is injured by others, neurotic individuals become enraged and seek to avenge their injury and to conceal their self-deception by achieving a vindictive victory over the offending person. Together with supporting claims and shoulds, neurotic pride and self-hatred form a defensive network or *pride system* that protects the idealized self. Any attempt to reduce elements of the pride system is experienced as an attack on the person. Despite the armoring of their defensive network, such individuals are not at peace because they are in inner conflict with the forces that protect them. The conflict between the forces driving toward healthy self-realization and the pride system is the *central inner conflict*.

There is also conflict within the pride system itself. Neurotic pride and claims are associated with the glorified idealized image; self-hatred and shoulds are associated with the unacceptable aspects of the self. When attempts are made to satisfy both forces simultaneously, conflict arises. Attempts to avoid these conflicts involve

further alienation from the real self.

Alienation Alienation from self is one of the most serious consequences of neurotic development. It results from the combination of repeated denial of external reality and the repression of genuine thought, feelings, and impulses. As the process of alienation continues, neurotic individuals lose touch with the core of their being and can no longer determine or act on what is right for them. Their feelings may range from uncertainty and confusion to inner deadness and emptiness.

Analytic Treatment Horney did not regard adult neurotic persons as recapitulating childhood experiences and thus did not focus on the recovery of childhood memories; she dealt instead with the self-perpetuating neurotic process. She stressed the importance of dreams in analysis and later, the exploration of the patient-analyst relationship. She was one of the earliest analysts to recognize and make constructive use of her own feelings toward patients. To Horney, psychoanalysis was a cooperative venture that enabled patients to free themselves from their neurotic structures and mobilize themselves toward self-realization. The analyst's responsibility was to assist in liberating patients from *blockages*, the forces that impede healthy growth.

Early in therapy, termed the *disillusioning process*, the two types of blockages are identified and examined. The first group of safety-oriented blockages, *protective blockages*, help to avoid the anxiety caused by self-awareness. They include silence, lateness, depreciating the analyst, the use of drugs, and even the use of self-accusation as a means to avoid further exploration.

Positive-value blockages reinforce patients' satisfaction with themselves and support their idealized self. In the disillusioning process the analyst identifies both types of blockages, exposing the protective blockages before exposing the blockages that defend the idealized image. Analyzing the positive-value blockages first would arouse too much fear.

Qualities of the Analyst These qualities, later described by Carl Rogers as therapist-offered conditions, include maturity, belief in constructive conflict resolution, and the ability to communicate hope and respect. Analysts listen, clarify, provide directions and suggest alternative resolutions to conflicts. Horney emphasized the need for the analyst to help move patients out of their alienation and suggested that therapists be flexible, tailoring their interventions to patients' present needs. She did not recommend using the couch or a fixed number of sessions per week.

Therapeutic Process Horney believed that fundamental attitudinal changes were the best means to change self-defeating, self-alienating behaviors. She created a setting in which patients were able to assess themselves as individuals, free to discover and choose personal values that fit with their real self. This type of reorientation begins after the disillusioning phase of treatment. As patients begin to question their present values and their idealizing process abates, they can revise their values and develop more flexible values consonant with their inner self. Dreams are used in all phases of treatment to bring patients into better contact with their real self. As unconscious attempts to solve conflicts, dreams can show constructive forces at work that are not yet discernible in patients' conscious thoughts and behavior.

As patients mobilize their constructive forces, they experience the struggle between the pride system and the real self. In the process they experience uncertainty, psychic pain, and self-hatred. As the central conflict is resolved successfully, patients move into the final phase of treatment: the discovery and use of their real inner self.

From the standpoint of Karen Horney, Mr. A.'s process of self-realization has been blocked in all three directions. He has failed to develop the ability to love and to trust, he expresses opposition in an unhealthy way, and he has made self-defeating moves toward independence. He would be seen as having developed a detached style of relating to others, having substituted hypomania and the use of drugs for real relatedness. He justifies his illness by taking pride in it. His goal of becoming a writer is part of the development of an ideal self that is a detached observer. He supported his ideal self by having fantasies of involvement with other writers, by convincing his professor that he was able to write a play as his term paper, and by procrastination. He has become more and more isolated from his real self by denying the reality of the facts that his mental illness and cannabis abuse posed a danger to him, and that he was failing in school.

A therapist in the Horney tradition would begin by pointing out that Mr. A.'s drug use and his sustaining of manic episodes were blocking his ability to learn about himself, and would work with Mr. A. toward abstinence from substances of abuse and appropriate use of mood-stabilizing agents. The therapist would later begin to point out that Mr. A.'s pride in his manic episodes served the purpose of sustaining a false self of boundless energy and creativity. Mr. A. would be encouraged to decide who he really wanted to be—a writer in fantasy or a persons able to obtain real satisfaction from real accomplishments and real relationships. His dreams would be examined and their themes explored. His omnipotent, messianic dreams would be interpreted as evidence of his ideal self and viewed in the light of reality. His dreams of being exposed would be interpreted as the fear engendered by his ideal self as a means of defending itself against exposure: “If you expose me, you will be embarrassed and humiliated.” Mr. A. would be supported through his fear of humiliation and the pain of realizing that he had been deceiving himself. His self-loathing would be interpreted as the activity of the pride system in defending his ideal self. As he begins to relinquish his ideal self, he will begin to discover and to mobilize his real inner self in directions that might not have been predictable at the beginning of treatment.

ERICH FROMM

Psychoanalyst Fromm (1900–1980) was often thought of as the archetypical neo-Freudian, the leader among those who emphasized that culture and social setting influence an individual's dynamics as much as instincts do (Fig. 6.3-12). Neither physician nor biologist, Fromm a native German received his doctorate in philosophy, sociology, and psychology from the University of Heidelberg in 1922. There he was exposed to a Marxist emphasis on how history shapes societies and how societies in turn, shape individuals according to economic needs. He was trained as a psychoanalyst at the Berlin Psychoanalytic Institute and then founded, with his wife, Frieda Fromm-Reichmann, the Frankfurt Psychoanalytic Institute. In 1933 he immigrated to the United States and in 1949 he moved to Mexico City to found an institute. In 1974 he moved to Switzerland where he died in 1980. As much a social critic as a personality theorist, he was later claimed by the existential and humanistic psychoanalysts. Fromm's intellectual agenda was the integration of Freud's theory of a dynamic unconscious with Karl Marx's theory of history and social criticism.

FIGURE 6.3-12 Erich Fromm. (Courtesy of Erich Fromm.)

Personality Theory For Fromm, two central facts dominate human behavior: the inevitability of separateness and the historical and social moment into which each person is born. He argued that every person struggles to recapture the state of blissful union that existed prenatally. From the moment the baby begins to recognize itself as a separate human being a titanic struggle begins, pitting the desperate anxiety of loneliness against the urge to fully express and actualize oneself, ultimately transcending the self. Most individuals find the loneliness too painful to bear and they suppress their striving for individuation in the service of maintaining the illusion of connectedness. They are socialized by their parents into the roles defined by the society into which they are born. Fromm actually used the term *symbiosis* years before Margaret Mahler used it to describe the universal human yearning for fusion, safety, and security.

Facing aloneness and choosing individuation leads to freedom and a productive life. However, true freedom is too terrifying for many persons who instead construct a series of illusions that engender a feeling of safety and security. They create a pseudoself, think pseudothoughts, and experience pseudofeelings in support of these illusions, thereby cutting themselves off from the fullness of their own inner lives. Fromm saw Freud's theory as a special case of his own more general ideas. The

illusions that Victorian society offered involved sublimation of sexuality and aggression in the service of social respectability. Social respectability, in turn, provided the illusion of acceptance and security. In other places and at other times, different solutions might be offered. Early in World War II, shortly after his escape from Nazi Germany, Fromm wrote about the willingness of people to give up their own freedom to serve an authoritarian society. In the 1950s he wrote of the pursuit of material acquisitions in the service of postwar productivity, leading to self-satisfied conformity. Fromm's most direct application of Marxism was in his hypothesis that individual development has paralleled historical development since the time that humankind freed itself from symbiosis with nature and embarked upon a unique path, evolving inevitably towards the Marxist utopia: the end of history in the universally humane society. However, Fromm departed from other Marxists who saw revolution as the only healthy response to an inevitably repressive society. He believed that even within an imperfect culture, individuals could face their terror, give up their pseudoselves and pseudothoughts, and choose to become themselves—encountering others who had made similar choices with love and mutuality. In order to achieve this, Fromm said four basic human needs must be met: *relatedness, transcendence, identity*, and a *frame of orientation*. Relatedness is the need to feel connected to other humans. Transcendence refers to rising above basic instincts. Identity is the need to feel accepted yet unique. Emphasis on the need for a frame of orientation led Fromm late in his career to an exploration of the constructive and destructive roles that religion may play in individual lives.

Theory of Psychopathology As a social philosopher and critic, Fromm did not really develop a systematic theory of psychopathology. He identified three major mechanisms of retreat from individuation. Some individuals, he said, may seek an authoritarian solution, trying to live through someone or something external to themselves, relying on that for their sense of adequacy. Others may become destructive, attacking anything that confronts them with their separateness and aloneness. Most individuals develop a conformist attitude, warding off the anxiety of experiencing their own intentionality by accepting socially offered thoughts, roles, and attitudes.

These mechanisms result in four different unproductive orientations or characters typical of twentieth-century society: receptive, exploitative, hoarding, and marketing. Fromm's economic perspective on available social roles is made evident here. The *receptive character* often appears to be cooperative and open; however, the primary agenda is to establish a passive relationship with a leader who solves problems magically. *Exploitative characters* are likewise interested in filling themselves up from the outside; however, they aggressively manipulate and usurp whatever will reduce their terror. *Hoarders* collect, store, and close in upon themselves, often being cold and aloof in their efforts to feel secure. *Marketers* treat themselves as a plastic commodity to be manipulated as needed in order to achieve externally validated success.

Treatment Fromm wrote nothing at all on the practice of psychotherapy; therefore, what is known is derived from anecdotal reports by those who studied with him or were treated by him. They report his emphasis on a tender and empathic inquiry into the self-deceptions and illusions created by patients in their efforts to ward off the anxiety of separateness and to maintain some sense of connectedness to significant others. He placed great emphasis on the tendency of unloved children to identify intensely with parental values in order to capture the magical safety they seem to offer. At a time when most psychoanalysts were preoccupied with detailed examinations of the instincts and defenses, Fromm contributed a sense of the range and richness of inner experience that underlies superficial adaptation. He contributed the sense that a new authenticity could be found by those willing to confront the truth about themselves with all its terror of aloneness.

In some respects, Fromm's ideas are uniquely applicable to Mr. A. who is clearly maintaining the illusion of his separateness by conforming to the socially sanctioned role of rebellious artist. His bipolar I disorder becomes an unexpected weapon in his battle with his terror of aloneness. The dread in the hotel lobby dream is probably the closest this fear comes to consciousness. Fromm would gently probe this dream and Mr. A.'s self-image. He would point out the chains created by Mr. A.'s seemingly rebellious independence. The self-destructive quality of the patient's lifestyle would also be confronted and investigated. Ultimately, Mr. A. would have to experience his own loneliness and face his terror of it in order to find true freedom, true intimacy, and an authentic self-definition.

HARRY STACK SULLIVAN

Sullivan (1892–1949) is generally acknowledged as the most original and distinctive American-born theorist in dynamic psychiatry (Fig. 6.3-13). Although rarely acknowledged explicitly since the late 1970s, most American psychiatrists make significant use of concepts and approaches that he developed. For many years the primary theoretical dispute within dynamic psychiatry circles was between the classical Freudians and the Sullivanians (or interpersonal psychoanalysts). When psychiatrists use the terms *parataxic distortion*, apply the concept of self-esteem, consider the importance of preadolescent peer groups in development, or view a patient's behavior as an interpersonal manipulation, they are applying concepts Sullivan first proposed.

FIGURE 6.3-13 Harry Stack Sullivan. (Courtesy of the New York Academy of Medicine.)

Sullivan graduated from medical school in Chicago in 1917. He spent from 1921 to 1930 in the Washington, D.C. area working with schizophrenia patients at St. Elizabeth's and then Sheppard and Enoch Pratt Hospitals where he developed a reputation as a remarkable clinician with an uncanny ability to communicate with floridly psychotic patients. He initiated the first of what would now be called therapeutic communities. Later, he entered private practice in New York, and eventually returned to the Washington area where he was involved in clinical, consulting, and teaching activities. In the 1920s and 1930s he wrote a number of papers on schizophrenia, later collected in *Schizophrenia as a Human Process*. His other books were compiled from his lectures by his students; most were published posthumously, which explains some of the density and seeming disorganization of his written work.

Personality Theory Sullivan rejected the Kraepelinian dogma of his day that dominated psychiatric thinking about schizophrenia. Sullivan would elucidate the meaning of passages of patient speech that Kraepelin presented as nonsensical. In searching for alternative understandings of psychosis he turned initially to Freud, but rejected his theories as increasingly rigid and dogmatic. Thus, he developed his own working theory of personality, psychopathology, and therapy.

Sullivan was very concerned that language could be misleading. He was very wary of self-reifying conceptualizations that led to rigid theories and tried to emphasize the psychiatrist as participant-observer in the clinical situation. By emphasizing this aspect of the role, he sought to keep observations as objective as possible, although he recognized the difficulty this presented in dealing with private emotional experience. What can be observed is the social interaction of patients; thus, he defined personality as the “relatively enduring pattern of interpersonal relations which characterize a human life.” From the outset, his focus was very different from the intrapsychic emphasis of psychoanalysis. By approaching psychopathology in this way, he necessarily created a field theory rather than a structural theory, characterized by temporal and interactive processes. Sullivan defined a “dynamism” as “the relatively enduring pattern of energy transformations,” that is, recurrent interpersonal behavior patterns.

Sullivan's theory is fundamentally one of needs and anxiety. Needs are defined as needs for satisfaction and needs for security. Anxiety occurs when fundamental needs are in danger of not being met and is the primary motivator of human behavior. Needs for satisfaction include physical needs (e.g., air, water, food, warmth, etc.); emotional needs include needs especially for human contact and for expressing one's talents and capacities. Because infants are utterly unable to meet their own needs, interpersonal relationships are a central concern. Decades before Margaret Mahler wrote of a symbiotic stage in infant development, Sullivan spoke of the “empathic linkage” between caretaker and infant, and described the complicated interaction of infants communicating tension and anxiety, arousing anxiety in the caretaker, leading to tender responses to the infant's needs. Failure to meet these needs results in loneliness and anxiety.

Sullivan defined security as the absence of anxiety. Thus, needs for security are defined as the need to avoid, prevent, or reduce anxiety. Because there is no such thing as a perfect mother or parent, anxiety is inevitable and becomes the primary driver for personality development. The self-system is defined by Sullivan as the

dynamism that is responsible for avoiding or reducing anxiety. Sullivan equated the self, identity, or ego with the individual's developed patterns for avoiding the discomforts that arise from the failure of others to meet one's fundamental needs. It exists, like all else, purely within an interpersonal framework. The self-system develops a set of mechanisms, called *security operations*, which effect this goal.

Security operations function within Sullivan's theory much as defense mechanisms do within psychoanalytic theory. The specific security operations, however, were defined interpersonally and Sullivan tried to link them closely to actual observation or experience. Some bore the same labels and definitions as Anna Freud's but Sullivan is best known for three contributions that bore his distinct stamp: apathy, somnolent detachment, and selective inattention. These were drawn from observing the way infants and young children reacted to painful interactions, such as scolding, with their parents.

The self-system accrues from ever-evolving interpersonal experiences, that is, fulfillment of needs for satisfaction as a result of the emphatic linkage with the mother. The most difficult experiences are not necessarily those involving failure to meet the child's needs, but the child's sensing of the caretaker's anxiety in the process of responding to those needs. This arouses anxiety in the child, promotes the need to establish a sense of security, and leads to evolution of the self-system and the development of security operations. The self-system is divided into three parts. The “good me” is a set of images, experiences, and behaviors associated with an unanxious, tender, empathic, and approving on accepting response from the environment. The “bad me” comes to be associated with ideas, actions, and perceptions that provoke anxiety and disapproval from caretakers. Some situations, however, provoke such intense anxiety that they are entirely disavowed and disowned; they become part of the “not me.” Eventually, the empathic linkage becomes unnecessary and the self-system operates autonomously within the individual, developing ever more subtle and complex ways to manage the person's anxiety.

Developmental Theories Sullivan had two theories of development, one cognitive, the other social. He postulated three developmental cognitive modes of experience whose degree of persistence into adulthood would be important in understanding psychopathology. The *prototaxic* mode, characteristic of infancy and early childhood, involves a series of disconnected, brief states experienced as totalities with no temporal relationship. In later life, mystical experiences and schizophrenic fusion represent persistent prototaxic experiences. *Parataxic* experience begins early in childhood as the self-system begins its more independent functioning. It too involves a series of momentary experiences; however, they are now recorded in sequence and with apparent connection to one another. They may be given symbolic meanings, but rules of logic are absent and coincidence plays a major role in how the world is perceived. The self-system uses this mode to seek effective anxiety-reducing behaviors and to repeat them, seeking sameness and predictability. Sullivan used this mode to explain transference, slips of the tongue, and paranoid ideation. The *syntactic* mode of experiencing is based upon the development of language and consensual validation. The world and the self is perceived within rules of logic, temporal sequencing, external validity, and internal consistency. Thinking about oneself as well as others becomes testable and modifiable based upon rigorous analysis of experiences in a variety of different situations. Maturity may be defined as extensive predominance of the syntactic mode of experiencing.

Social development is somewhat based on these evolving cognitive modes. However, disturbed interpersonal relationships may cause persistence of the more primitive (prototaxic or parataxic) ways of experiencing the world. Social development is characterized by the satisfaction needs, which are predominant, and the interpersonal sphere in which these and their resulting security needs are sought to be fulfilled. Each stage is also characterized by the primary “zone of interaction”—bodily areas through which the individual channels needs, anxiety, and relief—in interactions with the environment. These aspects of Sullivan's theory bear a superficial resemblance to Freud's genetic theory; however, Sullivan accorded them far less importance; they are mere conduits when compared to psychoanalytic libido theory.

Infancy spans birth to the onset of language and is characterized by the primary need for bodily contact and tenderness. The prototaxic mode predominates and the primary zones of interaction are oral and, to some extent, anal. Insofar as needs are fulfilled with a minimum of anxiety, the infant experiences euphoria and a sense of well-being. To the extent that some anxiety is commonly present in the caretakers, apathy and somnolent detachment will be regularly used as security operations, persisting into adult life as a basic detached and passive stance. If anxiety and inconsistency are severe, intense experiences of dread will persist, presenting in later life as the eerie, uncanny, bizarrely disruptive internal states seen in individuals with schizophrenia.

Childhood begins with the onset of usable language, continues until the beginning of school, and is characterized by the child's focus on the parents as other from whom praise and acceptance are sought. The primary mode of experience shifts to the parataxic and the most common zone of interaction is anal. The child needs an approving adult audience. This leads to a variety of learning—of language, behavior, self-control, and so on. It can also be observed in a variety of trial-and-error efforts by the child to find what pleases. Gratification leads to an expansive self-system with many facets of life associated with the “good me” and positive self-esteem. Moderate anxiety leads to chronic anxiety, uncertainly, and insecurity. Extreme anxiety results in giving up known successful behavior in favor of self-defeating patterns that fulfill others' expectations.

The juvenile era covers ages 5 to 8. The shift to syntactic cognitive modes begins and the interpersonal focus spreads to the peer group and outside authority figures. Peers and teachers have the opportunity to approve and accept behavior previously frowned upon within the family (e.g., talking dirty with one's friends). Interpersonal cooperation, competition, play, and compromise become the gratifying experiences. Juveniles learn to negotiate their own needs with a legitimate social concern without sacrificing their self-esteem in the process. The risks of excessive anxiety are either too great a need to control and dominate social situations or internalization of restrictive, prejudicial social attitudes.

Preadolescence, ages 8 to 12, marks the child's movement from peer group cooperation and competition based upon rules towards genuine intimacy with a chum. Sullivan saw this phase as a particularly important stage in which the give and take of the special friend could repair and undo distortions that resulted from excessive anxiety at earlier stages. This is the point at which the individual truly moves outside the family and engages in a free give and take with another person unfettered by the same dynamics. During this stage the major shift towards syntactic thinking takes place, although some distortions may persist into adolescence. The preteen years see the initiation of a capacity for attachment, love, and collaboration or their failure to develop in the face of excessive anxiety. Although sexual exploration may be a part of the chum relationship, Sullivan did not see sexuality as a central element in this developmental phase.

Adolescents, beginning at puberty, are seen to have concerns similar to those of preadolescents, except that lust is added to the interpersonal equation. Thus, the same needs for a special sharing relationship persist but shift to the other sex for their outlet, whereupon a major opportunity for learning or severe anxiety begins. As the person faces culturally defined stereotyping, many new opportunities for social experimentation may lead to consolidation of self-esteem or self-ridicule. The struggle to integrate lust with intimacy is accomplished by painful trial and error. If this is completed with the self-system relatively intact, the later years of adolescence are an opportunity to expand the syntactic mode to such areas as a consensual view of interpersonal relations, values and ideals, career decisions, and social concerns.

Theory of Psychopathology Sullivan abhorred diagnostic labeling for being unhelpful, overly restrictive, dehumanizing, and used primarily to impress patients and colleagues. In discussing schizophrenia, he said, “We are all much more simply human than otherwise.” Thus, he sought to understand the fundamental human process within his patients, especially his sickest ones. He saw psychopathology as resulting from excessive anxiety arresting development of the self-system and thereby limiting both opportunities for interpersonal satisfaction and available security operations. He viewed psychiatric patients as struggling to maintain their self-esteem with very limited means. To understand them, the developmental phase at which they operate has to be gauged and the interpersonal needs they express have to be understood.

Sullivan believed that several different factors could play a role in the particular form that these disturbances might take. The level of anxiety at particular developmental stages could lay the groundwork for a developmental arrest. Basic cognitive capacity might play a role in the choice of security operations relied upon or retained. The degree of success achieved interpersonally combined with whatever capacities are used would affect later success. Finally, the chance occurrence of stresses encountered during life was deemed a factor. Thus, Sullivan theorized that anyone might develop schizophrenia, even persons with relatively successful developmental histories, should their chosen defenses fail dramatically and their life stresses mount in the extreme. However, it was more likely that schizophrenia patients would be highly vulnerable along all four dimensions whereas others with greater developmental strengths might become obsessive, hysteroid, schizoid, or paranoid.

Interpersonal Psychotherapy Sullivan emphasized that the psychiatrist is a participant-observer in all interactions with patients. He thought deeply and extensively about the nuances and opportunities involved in this unique situation. By interacting actively with patients, verbal and nonverbal expressions of recurrent interpersonal patterns become apparent. These observations then inform the therapist's further behavior, thereby creating the opportunity for change. This process occurs over seconds and over months and years as the psychotherapy unfolds. Sullivan saw this perspective as an antidote to what he perceived as the wrongheaded emphasis on objective neutrality embodied by the “blank screen” model of psychotherapist behavior. He argued that parataxic distortions emerge in all interactions, not only in the classical analytic situation. This differing view of transference, and of it being a universal human process were among the core debates for

decades between classical analysts and interpersonal analysts.

Sullivan saw therapy as elucidating the patient's interpersonal patterns, exploring their utility in the service of the patient's needs, and considering alternative, more favorable possibilities. Thus, he shared the ego psychologists' understanding that even the sickest behavior was the best adaptation available at a given moment to the patient. He emphasized the experiencing of the distortions, the needs, the patterns, and the potential changes within the ongoing interaction with the therapist. He saw great power in the very entanglement of the therapist with the patient and recognized the ability of a skilled therapist to manage the interpersonal process to reveal patterns and to shape the patient's emotional experience. However, he constantly emphasized and respected the ultimate autonomy of his patients, who could still in the end choose not to reshape their approach to the world.

Sullivan viewed psychotherapy as divided into four distinct stages: inception, reconnaissance, detailed inquiry, and termination. Inception involves the very beginning, often only a part of the first interview, during which the contract and roles are stipulated. Reconnaissance might go on for as many as 10 to 15 sessions, during which the therapist identifies the patient's recurring patterns and assesses their adaptive and maladaptive qualities. The detailed inquiry is a very lengthy process of exploring the patient's thoughts, feelings, and memories; evaluating and re-evaluating data from earlier stages seeking to recognize, clarify, and change persistent parataxic distortions. The recurrent patterns are discussed within the context of the person's developmental history, needs, anxieties, failures, and successes. There is often much ongoing interchange between patient and psychiatrist as feelings and perceptions are validated or questioned within the context of mutual emotional interchange within each session. Termination is a product of the evolving contract and understanding between the patient and therapist and may reflect either extensive or limited goals. Sullivan emphasized the constant reassessing of goals by the therapist and the power of the ongoing negotiation and renegotiation of the therapeutic contract as a means to reveal and change parataxic distortions. The ultimate goal of psychotherapy is to experience as much as possible within the syntactic mode and to broaden the repertoire of the self-system. To the extent that this is achieved, individuals are in a position to become responsible for their ongoing growth through subsequent interpersonal interactions.

Sullivan would see Mr. A. as probably arrested in childhood, when his fear of displeasing his mother led him to give up healthy self-esteem strivings for independence in favor of a distant yet dependent position. He used drugs and psychosis as escapes in order to maintain some degree of self-esteem. His “good me” consists of his debating and his intelligence. His “bad me” is expressed in his rebelliousness whereas the “not me” seems to encompass issues of closeness, independence, and constructive engagement with others and with life's tasks. In therapy, the reconnaissance phase would be extremely important, identifying the moment-to-moment interactions through which Mr. A.'s security operations interfere with his attempts at constructive independence. His bemusement and detachment would be identified, as would his escape into prototaxic thought through drugs and noncompliance with medications. His acceptance of his mother's management of his trust fund would be noted as well. A Sullivanian therapist would actively interact, empathically identifying and confronting Mr. A.'s ways of avoiding authenticity and constructive interaction. Once identified, their meanings would be gently probed as would the feelings associated with them. The terror of displeasing his mother and its effects on Mr. A.'s ongoing interactions with the therapist would be addressed. Interactions would be examined for their consequences, with the assumption that the outcome had bearing on the motivation. Finally, Mr. A. would be encouraged to try out different ways of relating to the therapist as a prelude to restructuring his outside relationships. He would be encouraged to think rationally about his circumstances, to seek a good peer group, develop close friendships, and gradually move away from his near-exclusive focus on his immediate family for all of his interpersonal needs.

ERIC BERNE

Berne (1910–1970) was an American original in both style and substance. He worked in the San Francisco area most of his career, breaking with psychoanalysis in the mid-1950s, but never becoming antianalytic as did many of his followers (Fig. 6.3-14). Like many others, he felt the need to develop briefer treatments than were offered at the time.

FIGURE 6.3-14 Eric Berne. (Courtesy of Wide World Photos.)

A group gathered around him that came to be known as the San Francisco Transactional Analysis seminars. Through weekly discussions of clinical cases and social and political issues, Berne gradually refined his theory. Berne was wry and provocative in his approach to human behavior. His approach contributed much to what would now be called “pop psychology,” although his particular popularity and faddishness has long since faded. Few clinicians now call themselves transactional analysis therapists; nonetheless, Berne's ideas remain useful in grasping hidden agendas in human interactions.

Personality Theory For Berne the primary motivator of all human behavior is the need for “strokes”—attention, recognition, and response from others. Early survival depends on adequate physical contact, stimulation, and nurturance. This need remains strong, but later becomes more symbolic and interpersonal. Children learn rapidly what works within their family and practice it extensively. This led to one of Berne's more widely quoted observations: “Negative strokes are better than no strokes at all.” People evolve ways of interacting with their world to obtain regular strokes in whatever way possible, and in whatever way they have been taught to define a stroke (e.g., sympathy in response to chronic depression may provide such gratifying attention that the depression cannot be given up). So great is the need for regular stroking that blatantly destructive actions persist in the face of insight, recognition, and enduring psychological or physical pain. Like Adler and Sullivan, Berne suggested that hidden social needs motivate human behavior to the extent that, with rare exceptions, there is an interpersonal hidden agenda in all human activity. For Berne the unit of observation was the *transaction*, the short-term process of individuals interacting with each other. He spent much energy analyzing transactions to try to discover patients' definitions of strokes and their preferred mechanism for obtaining them. He noted that most people engage in very predictable, stereotyped, repetitive transactions—the content may vary from situation to situation, but the form tends to be quite rigid. He called these transactions “games,” and his bestseller, *Games People Play*, captured the imagination of the American public in 1964. Some games are harmless, some are socially encouraged, many have destructive elements or at least limit opportunities for more gratifying relationships (intimacy), and some are highly destructive. A common, socially accepted game is cocktail party flirtation, which is ordinarily pleasant and harmless, but depending on the intensity, frequency, and seriousness with which it is played may result in inability to experience intimacy, disrupted marriages, or even physical harm.

Berne divided the human psyche into three primary parts; *child, parent*, and *adult*, with two of those further subdivided (Fig. 6.3-15). He called these *ego states*. An ego state consists of characteristic body language, voice qualities, verbal productions, and affective experience. The Child represents the persistence of childlike experience and expression in all persons. It is divided into the *natural child*, the ego state in which the spontaneity, joy, and intuitive perceptiveness of young children persists in all adults; the *adapted child*, the part that is compliant and cooperative, and the *rebellious child*, the repository of that part of each person prone to fight authority, challenge accepted wisdom, and struggle for autonomy. The *Parent* is the residue of internalized parental messages and injunctions. It is divided into two parts, the *critical parent* and the *nurturing parent*. The Critical Parent bears some resemblance to Freud's superego, embodying rules, values, instruction, criticism, and restrictions. The Nurturing Parent is the internalization of positive caring experience, the memory of loving interactions. The Adult is a purely rational, data-processing element that is objective, calculating, and weighs options and estimates probabilities.

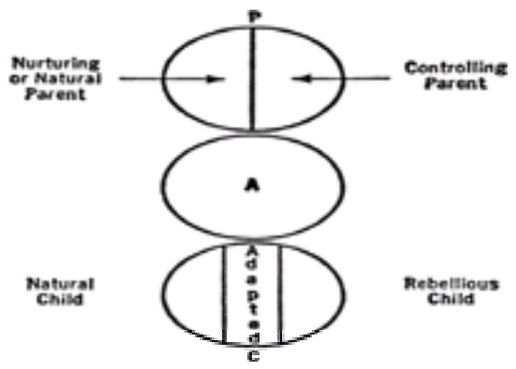

FIGURE 6.3-15 Eric Berne's descriptive model of the personality. (Reprinted with permission from Berne E: *What Do You Say After You Say Hello?* Random House, New York, 1972.)

Mental health is the flexible availability of all ego states with no one predominating. Excess critical parent produces guilt and depression, but insufficient Critical Parent produces sociopathy. Excess nurturing parent produces a narcissistic laziness whereas insufficient Nurturing Parent causes an inability to soothe oneself and to maintain self-esteem. Excess Adult results in a cold, overly rational person, but insufficient adult leaves individuals unable to balance the various internal forces in their lives. Too much natural child may result in irresponsible, behavior but not enough depletes the ability to experience joy in living. An overabundance of rebellious child results in self-destructive battles with no constructive purpose; however, insufficient rebellious child may result in an overly conformist stance. Excess adapted child prevents appropriate striving toward autonomy; insufficient adapted child prevents participation in group or hierarchical efforts.

Berne placed great emphasis on the child's ability to intuit parental messages and instructions, especially those communicated nonverbally and unconsciously. In this way the growing child might encode a conscious verbal instruction in the critical parent (e.g., be strong, be perfect, be smart), while internalizing a more powerful, unconscious message in the child (don't grow up, don't leave me, don't surpass me). Usually, a model for carrying out the instruction is preserved in the adult (be passive, drink alcohol, run around with women, act crazy). Together these make a *script*. Berne emphasized the active role of the child in searching for the messages and in accepting them. This was crucial for him because it emphasized the individual's responsibility in deciding to follow the script, even though this might have occurred at a very young age. The entire basis for psychological change lies within the person's capacity, having once accepted the script, to later reject it. However, Berne was impressed by the force with which individuals would play out the script throughout their lives. Scripts come in all varieties, ranging from the successful to the utterly self-destructive. Thus, for Berne, the business of human living involved carrying out one's script according to the transactions learned as a child.

Theory of Psychopathology Given this view of human nature, Berne's understanding of psychopathology is based on the adaptiveness of a person's games and script, and the capacity for adaptive use of all ego states. Written at a time when American psychiatry rejected phenomenological diagnosis, Berne's theories are difficult to accept. However, he did describe numerous clinical situations and case histories that are familiar to all psychiatrists and he analyzed them according to their scripts. He was very impressed with the role of fantasy and fairy tales in children's development and would often ask patients what their favorite story was as a child. He would then search for the hidden identifications and messages within the story to help discern the patient's script. Insofar as he developed a nosology it lay in the scripts encouraged by culturally sanctioned fairy tales. For example, Cinderella is about a young girl waiting to be rescued by a fairy godmother or a charming prince and unwilling to assert herself against unjust authority. Little Red Riding Hood is about a girl who likes to chat with wolves and gets into trouble trying to please everybody. Men, he found, would identify with the wolf or Prince Charming, and were unable to regard women as real persons.

A separate nosology of games was also developed and catalogued by Berne. Examples from this nosology include cocktail party flirtation (Rapo I), which concludes with the man and woman, having experienced the stroke of feeling attractive and attracted, move on to other conversations, seeking other persons to attract. Rapo II usually ends with a line like, “What kind of girl do you think I am?” and Rapo III ends up with a painful, destructive love affair. Another game is “Why Don't You... Yes, But.” In its mild, socially acceptable form one person presents a problem, successfully enlisting the advice of many others; however, for every proferred solution the person has a ready explanation of why it will not work. The stroke (or payoff) is the attention and the feeling of superiority achieved by defeating others. The second-degree version of this game produces a chronic, helpless depression; the third-degree version may lead to the back wards of a state hospital.

There was no rigid mapping of his nosology of games and of scripts and Berne never claimed that either was exhaustive. They were intended as clinical examples to guide the psychotherapist's thinking in evaluating each patient who would present unique script and transactional issues. Individuals were assessed according to the straightness of their transactions (Were there hidden communications and invitations emanating from different ego states?), the adaptiveness of their scripts, and the predominant ego state and its effects. Thus, Berne might describe a compulsive person as having too much critical parent, or a histrionic person as having too much natural child. In the final analysis, however, he saw his catalogues and nosology as poor substitutes for careful, clinical study of individual patients.

Treatment Having been trained in psychoanalysis, Berne used many psychoanalytic techniques but he applied them very differently from traditional psychoanalytic methods. Much of his clinical work was done in groups with the therapist being very active in confronting and interpreting the interpersonal behavior of the patient. He emphasized the initial contract with the patient and the setting of clear, concrete goals. He encouraged therapists to inquire very early on in therapy, “How will we know when our work is finished?” If a clear and specific answer was not forthcoming, he would inform the patient that therapy had not yet begun. The focus would then be on the patient's difficulty in defining a recognizable endpoint for the work. Berne's approach was heavily informed by the psychoanalytic concept of resistance but he applied it in a very different manner. Berne would examine any treatment goal defined by patients for evidence that it was a way to continue playing games or pursuing scripts more effectively, rather than giving them up entirely.

Like Sullivan, Berne regarded the ongoing interaction between patient and therapist as the key ingredient of psychotherapy. The therapist's job was to interact actively with the patient; recognize the ego states, games, and scripts being enacted; and to counter them using confrontation, interpretation, or various other interpersonal maneuvers that were designed to thwart the enactment and to confront the patient with a choice and an opportunity to relate differently. He emphasized simple direct statements using everyday words to stimulate affective experience and interaction. Commonly, interactions would begin with his inquiry, “What do you want to work on today?” Observers sometimes described his work as individual therapy within a group context because the other patients, who were silent observers, would often respond emotionally to the interaction.

Berne placed great emphasis on the role of individual responsibility for one's life and experience, which he felt had been obscured by the emphasis on psychic determinism. He constantly communicated the opportunity for choosing to continue or discontinue the patterns or habits encouraged as a child. He also showed patients how they invite others to behave in various ways, thereby creating their own interpersonal reality. Health lies in recognizing one's option for deciding which invitations to offer to others and which to accept from others, even though these invitations may be communicated unconsciously and nonverbally.

Mr. A. is clearly playing a very destructive game and living out a particularly unproductive script. The script seems to contain the messages: “Don't ever leave me,” and “Act crazy.” The message: “You must be special” may also exist. The games used might be called “I'm out of control,” “Helpless,” “Artiste,” and “I'm better than you are.” A transactional analyst would place Mr. A. in a group and work with him on these games and scripts. Many such therapists have productively combined Berne's theories with Fritz Perls' empty chair technique. Mr. A. might be asked to carry on imaginary dialogues with his mother, professor, his illness, marijuana, and admired writers of fiction, with Mr. A. assuming both sides of the dialogue. The transactions he employs would be elucidated in this way and he would be invited to recreate the transaction more constructively. His internalization of his mother as an excessively Critical Parent would be identified, and the fantasy dialogues would be used to enable more internalization of both his mother's and father's nurturing qualities, which would contain other script messages such as “grow up” or “be successful.” Similarly, his excess Rebellious Child would be demonstrated and efforts to bring it under more adult control would be made.

In looking at the formulations and treatment plans each of these theorists might propose for Mr. A. significant, even contradictory interpretations become apparent. Commonalities exist but are expressed in different words and concepts. Each of these great thinkers has contributed to the overall understanding of the psychodynamics of psychopathology and treatment.

SUGGESTED CROSS-REFERENCES

Many sections of this textbook refer to the theorists described above. Some are included in Section 55.1 on the history of psychiatry. Others are referred to Section

6.1 on psychoanalysis, Section 6.4 on theories of personality and psychopathology: schools derived from philosophy and psychology, and Section 25.1 on the history and current theoretical concepts in psychosomatic medicine.

6.4 APPROACHES DERIVED FROM PHILOSOPHY AND PSYCHOLOGY

PAUL T. COSTA, JR., PH.D. AND ROBERT R. MCCRAE, PH.D.

Few topics are of more interest to people than people, but an understanding of human nature is not inborn. Children must learn how to interpret others' behaviors and motives, and they do this so well that by adulthood they have acquired the use of hundreds of words to describe themselves and others, and have developed implicit theories of personality. Formal, explicit theories—accounting for the universals of human nature and the reasons for individual differences—have a long intellectual history in philosophy and theology. In the twentieth century the study of personality was undertaken by psychologists, and after an initial period of vigorous but speculative theorizing a body of sound empirical findings has emerged. No single theory of personality is universally accepted today, but there is increasing agreement on the facts that must be explained.

After a sampling of philosophical views of the person, this chapter provides an overview of psychological theories, grouped under the traditional rubrics of behavioral, humanistic, and trait approaches. Because of its importance in contemporary personality research, special attention is given to the trait perspective.

PHILOSOPHY

The recognition of individual differences is probably as old as human culture, but differences in personality were long confounded by differences in status, class, or caste. Individuals from a higher status were assumed to be superior human beings, more sensitive, honorable, and wise. They were endowed with these characteristics either by education, bloodline, or—in the view of Indian philosophy—by moral behavior in a previous life.

Plato The first major account of personality in Western thought was provided by Plato (circa 428–348 BC). In *The Republic*, Plato made extended comparisons between the constitutions of different states and the constitution of the soul. Just as every state must have peasants and artisans, soldiers, and rulers, so each individual has appetites (for food, sex, and so on), passions (for honor and advancement), and reason. The relative strength of these three determines character as well as fitness for a particular place for the individual in society. Intelligent and thoughtful people ought to rule, passionate people should be chosen to defend the state, and dull and spiritless individuals, lacking reason and passion, should be given the menial chores of agriculture and industry.

Plato assumed that these psychological characteristics, like physical strength or musical talent, were largely inborn, but he regarded them as a property of the individual, not the individual's social status. Although he assumed that high-status citizens would normally bear children of the greatest potential, he specifically acknowledged that there would be exceptions, and in his ideal state children of the lower classes would be promoted and those of the higher classes demoted on the basis of their own merit. Here personality would be the basis of the social order, not vice versa. His most radical extension of this idea was to argue that women should be given social equality and allowed to become soldiers and rulers if they possessed the necessary mental and physical qualifications.

One of the recurring questions in personality theory has been the relative importance of nature versus nurture. Trait psychologists—particularly those interested in the study of temperament—have frequently pointed to innate differences in personality whereas behaviorists and psychoanalysts have emphasized the formative influences of the environment and early childhood experiences. Although Plato acknowledged the importance of inborn potential, he was also keenly aware of the influence of education. Much of *The Republic* is devoted to his views on the effects of physical exercise, mental instruction, and poetry and music on the development of personality. Present-day concerns about the influences of television and rock music on children follow in this tradition.

Like most philosophers, Plato was more concerned with understanding virtue and vice than psychopathology, but because he considered vice to be the result of weak or corrupted nature rather than free but evil choice, his discussions of character can be viewed as early descriptions of what might now be viewed as personality disorders. Just as there are better and worse forms of government for states, so there are also better and worse configurations of reason, passion, and appetite. Plato described five types, corresponding to five forms of government. The ideal of mental health, corresponding to government by wise rulers, is one in which reason holds passions and appetites in check. The arrogant and ambitious type has an excess of passion or pride; in the avaricious type there is an excess of appetite. However, in both these types reason still retains some authority; for example, avaricious individuals can control most of their appetites in order to indulge their desire for money. In the fourth, self-indulgent, type, appetites are undisciplined, and in the debauched fifth type (corresponding to a despotic government), reason is completely disregarded, and a clearly psychopathological state is reached: “Thus, when nature or habit or both have combined the traits of drunkenness, lust, and lunacy, then you have the perfect specimen of the despotic man.”

Aristotle Plato's vivid but rough typology was succeeded by Aristotle's (384–322 BC) detailed analysis of human character in the *Nicomachean Ethics*. Courage, temperance, generosity, pride, ambition, irascibility, friendliness, boastfulness, and shame were all defined and distinguished. Aristotle attributed pathological variations on these traits to innate defects or to disease processes: “Among all the excesses of foolishness, cowardice, intemperance and irritability some are bestial, some diseased. If, e.g., someone's natural character makes him afraid of everything, even the noise of a mouse, he is a coward with a bestial sort of cowardice.” Aristotle considered variation within the normal range the result of training and habit, and thus subject to praise or blame.

Aristotle's basic moral precept is the “golden mean.” He argued that extreme standing on either end of a trait dimension should be avoided. Thus, both stinginess and extravagance are vices whereas generosity is a virtue; similarly, vanity and humility represent excessive or insufficient self-esteem. This theory continues to influence some modern notions of psychopathology, in which marked deviation from the norm in either direction is considered pathological. Individuals excessively concerned with social attention may be regarded as having a histrionic personality disorder; those insufficiently concerned with social attachments may have a schizoid disorder.

Aristotle carried conceptual analysis to a level that has seldom been surpassed, distinguishing, for example, between the superficially similar qualities of temperance and self-control: individuals are temperate if they have healthy and moderate impulses that require little control whereas individuals have self-control only if they have immoderate appetites that are nevertheless held in check. Such considerations allowed Aristotle to form rational taxonomies of traits, which anticipate the empirical taxonomies proposed by twentieth-century factor analysts.

Immanuel Kant and Arthur Schopenhauer The last great period of the Western philosophical tradition begun by Plato and Aristotle was inaugurated at the end of the eighteenth century by Immanuel Kant (1724–1804) whose critical philosophy forms a transition between purely rational approaches to human nature and the empirical sciences that followed. One of Kant's last works, *Anthropology from a Pragmatic Point of View*, considered both natural and moral variations in character, and reintroduced the Roman physician Galen's taxonomy of choleric, phlegmatic, sanguine, and melancholic types to modern psychology.

Sciences are usually distinguished from philosophy by their reliance on empirical data, but it should not be imagined that philosophers made no use of experience. On the contrary, like many of the clinicians who offered psychological theories of personality, philosophers based their ideas heavily on their observations of human nature. A striking instance of this is provided by Arthur Schopenhauer (1788–1860), a nineteenth-century follower of Kant whose dark view of the world as a place of purposeless striving had an extraordinary influence on early personality theorists, including Freud and Jung.

One of the central beliefs of Western thought has been that human happiness or misery is the result of external conditions—what we now call “quality of life.” But Schopenhauer's acute observations, reported in *The World as Will and Representation*, led him to propose “the paradoxical but not absurd hypothesis that in every individual the measure of pain essential to him has been determined once and for all by his nature.... His suffering and well-being would not be determined at all from without, but only by... what is called his temperament.”

In support of this view Schopenhauer noted that wealth and power do not make us happy, “for we come across at least as many cheerful faces among the poor as

among the rich.” He also argued that the effects of great misfortunes or successes are short-lived, and that for the most part our evaluations of the external causes of our state of mind are illusory attributions.

> We often see our pain result only from a definite external [cause] and... believe that, if only this were removed, the greatest contentment would necessarily ensue. But this is a delusion.... [The pain] would appear in the form of a hundred little annoyances and worries over things that we now entirely overlook.

Recent scientific research on psychological well-being has confirmed this account in every detail: well-being is chiefly a function of enduring personality dispositions; wealth, social class, and other markers of the objective quality of life are virtually unrelated to subjective happiness; and processes of adaptation quickly return individuals to their own characteristic baseline of happiness after favorable or unfavorable life events. Schopenhauer's observation is also consistent with recent evidence on the heritability and lifelong stability of many mental disorders.

However, reason and insight are not enough. On the basis of his own experience and the examples of history, Schopenhauer also concluded that “man inherits his moral nature, his character, his inclinations, his heart from the father, but the degree, quality, and tendency of his intelligence from the mother”—a conclusion not supported by the findings of modern behavioral genetics. Psychology broke from philosophy over precisely this need to seek empirical verification of hypotheses, but it carried with it concepts and insights accumulated over two millennia of profound thought about human nature.

BEHAVIORAL AND SOCIAL LEARNING APPROACHES

Theories of Personality Behaviorism as a school of psychology grew up in reaction to the prevailing mentalistic model, in which introspection was used to determine the contents and operations of consciousness. John B. Watson (1878–1958) proposed that a scientific psychology should confine itself to an examination of observable behavior and explain all human conduct in terms of stimuli and learned responses. Ivan Pavlov's experiments with conditioned responses offered hope that such a science could be successful, and theorists such as Clark L. Hull (1884–1952) provided elaborate mathematical models of learning.

Radical Behaviorism Certainly the most influential behaviorist, and perhaps the most influential psychologist of the century, was B.F. Skinner (1904–1990). Skinner's basic concept was *operant conditioning*, in which behaviors are a function of the organism's history of reinforcement. The observation that animals can be taught tricks by giving them rewards and punishments is nothing new. However, behaviorists like Skinner refined and systematized this idea, using elegant experimental designs to determine the effects of the amount and schedule of reinforcements, the use of positive and negative rewards, and the difficulty of the discriminations required. Behaviors could be shaped, maintained, or eliminated by the judicious use of these principles.

Skinner was a radical behaviorist, a purist who denied not only the scientific value but even the existence of mind. Further, he avoided any neurophysiological or psychophysiological theorizing, preferring to study the “empty organism.” Individual differences were ignored in understanding basic phenomena and were explained in individuals as being the result of different histories of reinforcement. Even differences between species were neglected: Skinner believed that the pigeon provided an adequate model for the study of learning in all organisms, and he and his followers were in fact able to replicate many of their animal findings using human subjects. Much of Skinner's success can be attributed to his single-minded pursuit of a highly circumscribed set of variables.

Skinner's view of personality was, predictably, a reductionistic one. As he stated in *About Behaviorism:*

> a self or personality is at best a repertoire of behavior imparted by an organized set of contingencies. The behavior a young person acquires in the bosom of his family composes one self; the behavior he acquires in, say, the armed services composes another.

This position is rejected by humanistic psychologists, who attribute more choice and control to the individual, as well as by trait psychologists, who see consistencies of behavior that appear to transcend the consistencies of the reinforcing environment. Many personality psychologists have argued that controlled laboratory experimentation is a poor basis for theories of personality, because individuals play a large role in selecting and shaping their own environments. Skinner's radical behaviorism was rejected or modified by many later learning theorists who acknowledged the power of conditioning but also recognized differences among species and among individuals within a species.

Social Learning Theory One of the most distinctive features of human organisms is their use of speech, which makes possible elaborate thinking and planning as well as complex social interactions. In recent decades learning theorists have increasingly emphasized social and cognitive processes. Among the most important have been Julian Rotter and Albert Bandura both of whom have offered versions of social learning theory.

Rotter's theory proposes that human behavior is guided not only by the actual history of reinforcement, but also by plans, goals, and expectations of success. Individuals will perform a behavior if they believe it is likely to lead to a valued goal, based upon their past experiences in general and in similar situations. Individuals with a history of success are likely to have a generalized expectancy that they can control their lives; they are described as having an *internal locus of control*. At the opposite extreme are those whose prior efforts have been generally unsuccessful; they come to believe that rewards and punishments are a matter of luck or the arbitrary decisions of powerful others. Such individuals are said to have an *external locus of control*. Locus of control has been one of the most popular variables in personality research, employed in numerous studies that generally support Rotter's theory.

Bandura's version of social learning theory also acknowledges the importance of internal cognitive processes. Individuals learn not only on the basis of their own experience, but also through vicarious reinforcement from observing others. Bandura's demonstration of modeling effects in experiments conducted in the 1960s gave scientific legitimacy to the social learning perspective.

Both Rotter's and Bandura's theories are general theories of behavior, not specifically theories of personality. However, for them personality is more than a collection of learned behaviors. The total pattern of experience will lead to a generalized expectation of reinforcement or to a general sense of self-efficacy that can be considered the central individual difference variable. People are to be characterized primarily on the basis of their beliefs in their own ability to control their lives, because these beliefs powerfully determine the effort they make to adapt to their surroundings.

Social-cognitive approaches to personality are among the most influential for current research in personality. These approaches focus on individuals understanding of themselves and how these self-appraisals shape goals, plans, and behaviors. Because of their origins in social learning theory, these theories tend to emphasize the role of the environment, pointing out that an individual's sense of self varies from setting to setting. Because of their ties to social theory, these theories usually explain personality in terms of the effects of social interactions. For example, Hazel Markus has suggested that individuals have a number of *possible selves*—conceptions of what one is or could be—which result from the messages significant others provide. For such theorists, concern has moved beyond the social learning of specific behaviors to the learning of entire identities.

Theories of Psychopathology Psychoanalytic theories of personality grew out of attempts to understand psychopathology, and thus the two are intimately connected. By contrast, behavioral approaches have focused on the general principles by which behavior is acquired and maintained, and psychopathology is usually treated as an area of application. Learning theories have had much more influence on methods of psychotherapy than on theories of psychopathology itself.

Behavioral approaches might suggest two different classes of explanations for psychopathology: psychopathology might be related to the mechanisms of learning or it might be considered the result of learning behaviors that are maladaptive or socially unacceptable.

In the 1950s Hans Eysenck (1916–1997), a psychologist who has figured prominently in both learning and trait schools of personality, proposed that individual differences in the dimension of introversion-extraversion determined the ease with which individuals could acquire conditioned responses, which in turn determined the form of psychopathology to which they were prone. Very introverted individuals, he proposed, were easily conditioned and thus acquired many inhibitions. They were predisposed to the development of depressive, anxious, and obsessive-compulsive disorders. By contrast, extreme extraverts were considered to be resistant to conditioning and were likely to develop hysterical and psychopathic disorders. In later versions of Eysenck's theory, psychopathic disorders were grouped with psychotic disorders and linked to a different dimension of personality, called *psychoticism*.

Most behaviorists have viewed the laws of learning as universal processes and considered psychopathology to be the result of normal learning processes. In the 1920s Irena Shenger-Krestounika taught a dog to discriminate between a circle and an ellipse as a cue for food. When the ellipse was made increasingly circular, the dog's ability to discriminate between them was taxed, and the dog began to struggle, squeal, and bite. Ivan Pavlov dubbed this an “experimental neurosis,” and

proposed that human neuroses might have parallel causes.

Probably the most famous attempt to explain psychopathology in learning theory terms was provided by John Dollard and Neal Miller. Dollard, an anthropologist, and Miller, an experimental psychologist, shared an interest in psychoanalysis. Their goal was to translate psychoanalytic concepts into the more testable terminology of learning theory. Consider, for example, the central psychoanalytic notion of *repression*. Sexual behaviors in the child might be punished by parents, and the child might learn to associate the behaviors with pain. By stimulus generalization even the thought of the behaviors would elicit anxiety, and cognitive processes that blocked these thoughts would lessen anxiety and thus be reinforced. Eventually, the thoughts would be effectively barred from consciousness.

Many behaviorists who did not share Dollard and Miller's enthusiasm for psychoanalysis followed their lead in attempting to explain psychopathology in terms of principles of learning. Phobias in particular were easily explained as conditioned responses reinforced by avoidant behavior. Similarly, compulsions could be understood as a kind of self-reinforcing behavior: each time the compulsive act is performed, the anxiety associated with not performing the act is reduced, increasing the probability that the behavior will be repeated.

Social learning theorists have also noted the self-perpetuating nature of some maladaptive behavior. Individuals who lack a strong sense of self-efficacy in social situations may avoid them. As a consequence, they fail to learn the social skills that would enhance their self-confidence. Self-defeating behaviors, which may appear irrational, can often be understood in terms of the dynamics of learning.

Application of Theory to Therapy Behaviorists have a rather rudimentary view of personality, seeing it as an assemblage of learned behaviors. They also tend to see psychopathology in superficial terms. Psychological maladjustment is considered to be the result of learned behaviors, called *symptoms*, but there is no underlying disorder of which they are symptomatic. Curing the symptoms cures the disorder. At worst, this position is naive and simplistic, equating the patient's presenting problem with the real source of difficulty. At best, however, it focuses attention on a specific problem that can be concretely addressed.

A large number of techniques for behavior modification have been used with considerable success in treating symptoms of psychopathology. Joseph Wolpe developed *systematic desensitization* as a treatment for phobias. Patients were instructed to relax and were then presented with increasingly vivid cues of the phobic object. Eventually they were able to face the object itself without anxiety. A more dramatic technique is *implosive therapy*, in which the individual is confronted directly with the feared object (e.g., a room full of snakes) without an opportunity to escape. Because the object itself is harmless and because avoidant behavior cannot be performed and is, therefore, not reinforced, the phobic reaction is swiftly extinguished.

Therapeutic interventions may be based on eliminating the reinforcements that sustain behavior, on punishments for unwanted behaviors, or on modeling or shaping of more desirable behaviors. Any variable known to affect the acquisition or extinction of behaviors may provide an opportunity for behavior change, and behavioral techniques have been applied to physiological responses as well as to voluntary behaviors through techniques of biofeedback. Behavior therapies have been used extensively in treating phobias, in controlling addictive behavior, in reducing the self-destructive behavior of autistic children, and in improving classroom discipline—for the behaviorist, the distinction between psychopathology and bad behavior is generally unimportant. Behavior therapies are most effective when the problem can be clearly traced to a particular set of behaviors or conditioned responses; they are much less effective in dealing with vague complaints of confusion and distress, although these are frequently the problems the patient presents to the clinician.

HUMANISTIC APPROACHES

Theories of Personality Psychoanalysis and behaviorism are mechanistic theories that trace human behavior and experience to the gratification of instinctual impulses or to the acquisition of learned responses. Many of the most influential personality theorists of the twentieth century have defined themselves in terms of their opposition to these two approaches. Although they vary widely in terms of their explanations of personality, humanistic approaches share a positive evaluation of human nature and emphasize its unique and distinctively human aspects. Personality produces as well as reflects organization, rationality, consistency, future orientation, planfulness, self-expression, cognitive complexity, and adaptability. Human reason and freedom of will, the capacity for growth and change, the need for love and self-transcendence are prized by most humanistic theorists.

Social learning theories might be seen as a humanized form of behaviorism because they recognize the role of complex symbolization and language in human learning. In a similar way, many now-classic humanistic theories were intended as modifications of psychoanalysis. Indeed, the first major psychoanalytic revisionist was Carl Jung, who argued that human beings had spiritual as well as sexual needs. Henry Murray also made major modifications to psychoanalysis in his view of personality. For example, Murray credited the mature ego with much more autonomy than Freud granted it, and he argued that the individual's sense of morality was not fixed by the superego instilled in childhood but could continue to develop into more rational and altruistic forms. Erich Fromm and Karen Horney minimized the instinctual origin of personality development and suggested that culture played a large role in shaping the individual. Erik Erikson proposed stages of psychosocial development to parallel Freud's stages of psychosexual development, emphasizing such distinctly human characteristics as identity, intimacy, and generativity; Erikson also theorized that personality development continued throughout the lifespan, giving encouragement to research on aging and personality.

Gordon Allport Although he is usually classified as a trait psychologist, in his general orientations to theorizing Gordon Allport (1897–1967) was clearly a humanist. For him, man's behavior is proactive, reflecting internal, self-initiating characteristics more than situational forces. In his view, human personality possesses psychological coherence and both momentary (*cross-sectional*) and long-term (*longitudinal*) organization. Allport considered personality functioning to be characteristically rational, organized and influenced by such conscious characteristics as long-range goals, plans of action, and philosophies of life.

Perhaps the most salient and controversial feature of his approach was the extreme emphasis that Allport placed on the uniqueness of the individual personality. Allport viewed the major task of *personology* (or personality psychology) as the understanding and prediction of the individual case. In order to grasp the real personality, personal dispositions must be assessed, which requires intensive study of an individual's past, present, and anticipated future functioning through the use of such techniques as the case history and content analysis of personal documents. In *Becoming: Basic Considerations for a Psychology of Personality*, Allport championed the view that concepts and laws must be developed to fit the individual case; Allport coined the terms *idiographic* and *morphogenic* to symbolize his conviction that “each person is an idiom unto himself, an apparent violation of the syntax of the species.”

Allport was deeply concerned with identifying personality functions, which he discussed under the concept of the *proprium*, the superordinate concept in his system. Propriate functioning not only organized and integrated actions and experience but also provided the impetus to psychological growth. Allport described the functions of the proprium as *sense of body, self-identity, self-esteem, self-extension, rational coping, self-image*, and *propriate striving*. These propriate functions were vital to personality, and although they were ongoing they were by no means considered unchanging. Allport theorized that the propriate functions are modified throughout life, predominantly in the direction of greater differentiation and integration, or growth. The development of selfhood, away from the undifferentiated, opportunistic functioning of infancy and early childhood towards propriate functioning and striving is part of human nature for Allport. Individuals guide or direct their lives by attempting to fulfill their sense of self or proprium. Development continues into adulthood, with increasing signs of maturity and personal lifestyle.

Abraham Maslow Abraham Maslow interpreted personality in motivational terms. The individual's whole life—perceptions, values, strivings, and goals—is focused on the satisfaction of a set of needs, and the needs themselves are arranged in a universal hierarchy. These needs serve an organizing and integrating role in life and are not to be understood as a simple and invariant set of responses to environmental pressures; they organize and create action possibilities and external reality.

At the lowest level of the motivational hierarchy are physiological needs for food, water, sex, and sleep. The second level consists of safety needs—needs for protection and security. The third level consists of needs for love and belongingness, and the fourth for self-respect and esteem from others. Above these lie the higher needs—for beauty, truth, justice, and *self-actualization*, the development of one's full potential as a unique human being.

Individuals live at the lowest level of motivation that is problematic for them. That is, if needs for food and shelter are not routinely met, these needs become the overriding concern in life: the hungry individual will risk danger and social ostracism to find food. Those who have always been well fed, however, learn to take the satisfaction of physiological needs for granted, and their attention is dominated by higher needs. Instead of examining specific behaviors and their reinforcements, Maslow's theory concerns the long-term satisfaction of broad classes of needs, and thus gives a much broader depiction of the individual.

Maslow devoted much of his writing to a characterization of higher needs including self-actualization, a drive to fulfill one's unique potentials. He believed that personality psychology had become obsessed with psychopathology and felt that a corrective emphasis on positive mental health was needed. His biographical studies of such exemplary people as Eleanor Roosevelt and Abraham Lincoln suggested a number of distinctive characteristics of self-actualizers, including accurate perception of reality, creativity, a need for privacy, and the frequent experience of mystical or “peak” experiences. As an exception to his general theory of motivation,

he also noted that such individuals often skip the lower levels and proceed directly to self-actualization. The most creative artists and musicians never seemed to care about poverty or lack of social acceptance.

George Kelly One of the most unconventional theories of personality was offered by George Kelly (1905–1967). It is in some respects a purely cognitive approach, but one with few ties to traditional learning theory. Instead of seeing human beings as organisms that are conditioned by their environment, Kelly argues that they should be seen as scientists trying to make sense of their world. In *The Psychology of Personal Constructs* he states the fundamental postulate of his theory: "A person's processes are psychologically channelized by the ways in which he anticipates events."

The basic unit for understanding personality is the *personal construct*, a schema for classifying and interpreting experiences. For example, an individual might characterize other people in terms of the contrast *strong* versus *weak*. Each new acquaintance would be categorized as either a strong or a weak person, and subsequent interactions with this person would be guided by the original construct. In the course of experience it would probably be necessary to reclassify some individuals initially thought to be strong as weak, and vice versa; more importantly, some people might act in ways that are neither strong nor weak, leading the individual to develop new constructs (say, *friendly* versus *hostile*) that are more useful in predicting other people's behavior.

This rather abstract and bloodless theory is made relevant to psychopathology by Kelly's ingenious reconstruing of some basic emotional reactions. *Anxiety* is defined by him as the awareness that one's construct system is inadequate for construing important events. *Guilt* is the recognition that one's behavior is inconsistent with the ways in which one construes oneself. *Hostility* is viewed as the attempt to force experience to fit one's existing constructs. Such definitions are remote from common sense as well as from clinical notions of anxiety, guilt, and hostility, but that is precisely why they offer the prospect of novel ways of treating them.

Carl Rogers Carl Rogers (1902–1987) is probably the most influential humanistic personality theorist. He articulated a formal theory of personality, pioneered a major school of therapy, *client-centered therapy*, and encouraged rigorous research on his theory and therapy. Rogers held that all organisms tend toward their own actualization—that mental health and personal growth are the natural condition of humankind. Psychopathology is a defensive distortion of this actualization process, and psychotherapy consists of creating conditions in which defense is unnecessary. Given these conditions, patients (or *clients*, as Rogers called them) essentially cure themselves.

Under ideal conditions people's needs, desires, and goals emerge naturally as part of self-actualization and are recognized as part of the self; individuals are fully open to experience. In real life, however, one person's needs and desires often conflict with persons', in particular, children find themselves in conflict with their parents, who are perceived as withholding love when the child (from their perspective) misbehaves. Because love is so essential, children internalize these *conditions of worth* and believe that they are good and worthwhile individuals only when their self is consistent with the ideals imposed by significant others. To maintain their sense of worth, children may distort their experience—this leads to anxiety and to self-defeating behavior.

In some respects Rogers' theory is much like Freud's: both see psychopathology as the result of defensive distortions and see the ideal state as one in which individuals can accept conflicts and deal with them rationally. Rogers is a humanistic theorist because he assumes that human nature is essentially good and that defenses are ultimately unnecessary. For Freud the impulses of the id are eternally primitive and selfish, and their full actualization would be socially catastrophic.

Dan McAdams Since the mid-1980s a number of scholars in the humanities and social sciences have turned their attention to the *life narrative* as a focus of research. These writers argue that the consciousness of self that distinguishes human beings from other animals is not a static list of personal characteristics; it takes the form of a story. In telling their life stories, people explain themselves in the context of their history and their significant relationships. Life narratives are not objective life histories; they are subjective interpretations that give personal meaning to past, present, and future events.

The personality psychologist most closely associated with this perspective is Dan McAdams. McAdams has postulated that personality can be understood on three levels: level 1 consists of *traits*, abstract and enduring tendencies seen in general styles of action and experience; level 2 is defined by *personal concerns*, the goals, plans, and strategies that preoccupy the individual at a certain time and place; and level 3 is the *life narrative*, the story the person tells to himself or herself and to others in an effort to give a sense of unity and purpose to life.

Psychiatrists and psychotherapists have listened to patients' life stories for many decades, usually seeking clues to the origins of current problems. McAdams' approach is different; he wishes to understand the narratives as stories. Stories can be analyzed in terms of such features as narrative tone (e.g., tragic, comic, ironic), imagery, theme (what goals the characters pursue), ideological setting, and nuclear episodes (crises, turning points). From this perspective key life events are not construed as causes of development, but as symbols of identity. A patient's vivid recollection of a childhood humiliation may be important chiefly because it conveys the patient's sense of being a victim to whom fate has always been and always will be unfair.

Much of the scholarship on life narratives has been in a humanistic tradition that eschewed empirical rigor: a narrative reduced to a set of numbers is no longer a narrative. McAdams and his colleagues, however, have begun to conduct psychometric studies on such basic issues as the inter-rater reliability and temporal stability of life story variables. These studies will form the basis for a scientific evaluation of narrative perspectives on personality.

Theories of Psychopathology Humanistic theories of personality tend to emphasize the positive aspects of human nature and discuss maladjustment in terms of failures of and blocks to the full growth and development of the individual. It is of some interest to note that both Rogers and Kelly formulated their theories in the context of counseling students—individuals who presumably had relatively minor maladjustments and considerable personality strengths. The applicability of humanistic theories to patients suffering from schizophrenia or dementia is certainly questionable, but the theories have had a profound effect on routine clinical practice, where clearly diagnosable psychiatric disorders seldom account for all the patient's problems.

Humanistic psychologists differ tremendously in their views of the origins of maladjustment. Rogers pointed to internalized conditions of worth acquired chiefly during childhood. Erich Fromm, who was influenced by Karl Marx, blamed society as a whole for instilling nonproductive orientations in individuals, such as *hoarding* or *marketing* orientations. Kelly said little about the origins of maladjustment, but thought its essence was an ineffective construct system too rigid to be corrected by experience.

Other personality theorists such as Rollo May have been influenced by existential philosophy and have argued that the essential characteristic of human nature is freedom. Freedom, however, implies responsibility, and it is what Fromm called the attempted "escape from freedom" that often leads to psychopathology. In this view, individuals are the ultimate source of their own problems. The debate about responsibility and mental illness continues today, perhaps most conspicuously in questions about whether alcoholism should be considered a disease or a failure of self-discipline.

Application of Theory to Therapy Some humanistic theories of personality—for example, Allport's theory—have had little impact on psychotherapy; others, like Rogers' theory, have been tremendously influential. It is helpful to recall that for decades the dominant form of therapy was psychoanalysis, a process that could take years and in which treatment was focused on dreams, childhood memories, and the ongoing relation with the therapist (*transference*) rather than on the immediate problems of the patient. Many of the standard techniques of contemporary counseling, clinical psychology, and psychiatry rest upon a very different set of assumptions about human nature made scientifically respectable by the work of humanistic psychologists.

Brief psychotherapies often consist of opportunities for individuals to express their feelings and rethink their problems in a supportive atmosphere. The therapist may provide advice and guidance, or at least offer new ways in which patients can think about their problems. This general approach is used by many psychiatrists as an adjunct to medication even to treat serious mental disorders. The process implicitly assumes that individuals, even those requiring psychotherapy, are basically rational and able with some help to solve their own problems; it also assumes that given the right conditions they will move toward mental health: patients are seen as scientists and self-actualizers.

Noting that Freud's "psychoanalytic cure" was based on a conscious understanding of one's life experiences, McAdams has argued that having a satisfying life narrative is a requirement for complete mental health. A good life story has coherence, credibility, a capacity for growth and change, and a generative orientation toward the world. One goal of psychotherapy may be to help patients rewrite their life narratives along these lines. This is a modest but realistic goal. Psychotherapists cannot easily alter patients' personality traits nor can they undo traumatic events of the past, but they may be able to help patients make sense of their dispositions and their life history. Human tragedy can bring great suffering, but in the hands of an artist it can also be the source of great beauty.

The humanistic emphasis on freedom and responsibility has often clashed with the psychiatric tradition of regarding mental disorders as diseases. Labeling individuals as "schizophrenics" or "phobics" is dehumanizing (and is discouraged by the editorial style of this textbook), and critics like Thomas Szasz have argued

that mental disorders are social and ethical judgments, not matters of medical fact. There is abundant evidence that some mental disorders have a biological basis, but the criticisms of humanistic psychologists make the point that the disorder occurs in a human being who in many respects may be like any other person. Behaviors, experiences, or relationships may be normal or abnormal, but people are not.

TRAIT AND FACTOR MODELS

Individual differences are peripheral concerns in many social learning and humanistic theories of personality; they are the central focus of trait theories. The study of variations in human character and temperament goes back at least to Theophrastus, a Greek whose *Characters* depicted thirty different types. The *Morose type*, for example, he described as follows:

> A malignant temper sometimes vents itself chiefly in ferocity of language. The man whose tongue is thus at war with all the world, cannot reply to the simplest inquiry except by some such rejoinder as—'Trouble not me with your questions:‘ nor will he return a civil salutation.... He has no pardon for those who may unwittingly shove or jostle him, or tread upon his toe.... He will neither wait for, nor stay with anyone long: nor will he sing, or recite versus, or dance in company. It is a man of this spirit who dares to live without offering supplications to heaven.

Theories of Personality The scientific study of individual differences in personality can be traced to Sir Francis Galton in England, who laid the foundations of psychometrics, and to G. Heymans in the Netherlands, who undertook the first large-scale study of rated personality traits. The first major trait theorist in the United States was Allport, whose 1937 volume *Personality: A Psychological Interpretation* spelled out the basic issues in trait psychology. He defined a *trait* as “a neuropsychic structure having the capacity to render many stimuli functionally equivalent, and to initiate and guide equivalent (meaningfully consistent) forms of adaptive and expressive behavior.” In this view something in the brain of the morose man makes him see even simple questions or greetings as a personal affront, and his sullen attitude is expressed in a variety of social situations.

Allport believed that traits were concrete features of individuals that uniquely described them and that might be understood by a case study of a single individual. A contrasting view is that traits are dimensions of individual difference that can only be discovered by comparing and contrasting different individuals; individuals are then described in terms of their standing on a set of common traits. The two definitions are closely related; people who are more anxious than 99 percent of the population presumably have a neuropsychic structure that makes them so anxious.

Characteristics of Traits Although there are many different trait theories, there is general agreement on several key features of traits: (1) Traits are tendencies to show consistent patterns of thoughts, feelings, and actions. Behaviors that are specific to a single setting or situation may better be considered habits rather than traits; some evidence of cross-situational consistency is necessary to infer a trait. However, concrete instances of behavior have many determinants, including learned habits, aroused needs, social contexts, role requirements, and the influence of many different and potentially conflicting traits, so the influence of a specific trait on any particular behavior may be quite small. It is usually only by viewing behavior across many different situations that a consistent pattern can be detected. (2) Traits are relatively enduring features that characterize the individual. In this respect they are to be distinguished from transient moods or episodes of mental disorder that affect the individual. The fact that traits are relatively enduring does not mean that they cannot change; traits are not immutable even if they are durable. (3) Traits are continuously distributed, usually approximating a normal or bell curve. Although it is convenient to speak about “introverts” and “extraverts,” most individuals are “ambiverts,” showing some of the characteristics of introverts and some of the characteristics of extroverts. With the possible exception of masculinity and femininity, there is no consistent evidence of discrete personality types.

From time to time there has been controversy over the reality of traits, fueled by the fact that human beings easily and readily ascribe traits to others on the basis of little or no information, with correspondingly limited accuracy. These personality ascriptions may be triggered by stereotypes of age or physical appearance or may be quite idiosyncratic. Demonstrations of this fact in laboratory experiments by social psychologists, together with the relatively loose cross-situational consistency of most traits, led a generation of psychologists in the 1970s to conclude that traits were cognitive fictions. Subsequent work—particularly demonstrations that judges who knew the individual well agreed with each other and with the self-reports of individuals about their standing on a variety of traits—restored faith in the consensual validity of traits. However, the controversy does make the crucial point that some trait ascriptions are more accurate than others and that first impressions may be quite misleading. Psychiatrists ought not to assume that their clinical judgments of a patient's personality are correct; validated personality questionnaires and rating forms completed by knowledgeable others may be needed to portray and understand personality accurately.

Personality Structure and Factor Analysis The most important differences among trait theorists are in the specific traits they have conceptualized and measured. Jung identified introversion and extraversion as basic personality variables, Bandura emphasized self-efficacy, Rogers was concerned with openness to experience. Over the years, literally thousands of scales have been developed to measure traits that psychologists considered important in understanding personality. As early as 1936 Allport pointed to another source for identifying personality traits: the natural language. A monograph he published with Henry Odbert listed some 18,000 terms extracted from an unabridged dictionary that could be used to describe people; some of them were mere evaluations (e.g., *swell, awful*), but he regarded about 4000 as legitimate trait terms.

The problem for trait psychologists was how to choose a manageable set of traits from among the many possible constructs. It was obvious that trait terms were highly redundant—for example, *anxious, worrying, nervous, apprehensive*, and *fearful* reflect very similar, almost identical characteristics; what was needed was a procedure for identifying major groups of traits that covaried. Factor analysis, a statistical technique that reduces the complexity of a set of correlations among variables, was first used in personality research by J.P. Guilford, and has remained one of its basic tools. The factors, or dimensions, identified in this process correspond to groups of closely related traits; the set of basic dimensions identified by the factor analysis constitutes a model of the structure of personality traits.

Raymond Cattell developed one of the first and most influential factor models. He reasoned that in the course of cultural evolution any personality trait important in human social interaction would have been noticed and named; the 4000 trait terms identified by Allport and Odbert could thus be assumed to represent an exhaustive listing of personality characteristics—this has become known as the *lexical hypothesis*. Cattell grouped synonyms and near-synonyms together to obtain a set of 35 personality variables, and asked respondents to rate acquaintances on each of these sets of terms. He intercorrelated the ratings and factored the correlations, identifying 12 factors. Together with four more factors found in research using self-report questionnaires, these became the basis for the 16 Personality Factor Questionnaire (16PF), a self-report instrument that has been widely used in personality research and clinical psychology for 40 years.

It was originally hoped that factor analysis would provide an objective solution to the question of personality structure, but for many years there was little agreement among factor analysts. Eysenck believed that Cattell's model was unreplicable and needlessly complex. He proposed a simple and powerful two-dimensional model that identified extroversion–introversion *(E)* and neuroticism–emotional stability *(N)* as superfactors, and showed that if the scales of the 16PF were themselves factored, the two largest factors resembled his *E* and *N*. He and his wife, Sybil Eysenck, developed a series of instruments to measure these factors (and later a third superfactor called *psychoticism*) that have also been widely used, particularly in the United Kingdom. Eysenck's stature as a learning theorist and a critic of psychoanalysis contributed to the importance of these dimensions in psychiatric contexts.

Five-Factor Model Eysenck's two factors were widely replicated, but they seemed to omit many important characteristics, such as curiosity, aggression, and achievement striving. An alternative solution was offered in 1961 by two U.S. Air Force psychologists, Ernest Tupes and Raymond Christal. They began with the 35 clusters of traits identified by Cattell and obtained ratings on these clusters in eight different samples. They found that a five-factor solution fit the data in all eight samples. Two of the factors resembled Eysenck's *E* and *N*, but three other factors were new.

A small group of lexical researchers, including Warren Norman and Lewis R. Goldberg, continued to study personality structure as represented by natural language trait adjectives, and after 20 years came to the conclusion that the five-factor structure proposed by Tupes and Christal was essentially correct. Renewed interest in this model showed that the five factors could be recovered in analyses of self-reports as well as observer ratings, in ratings of children, college students, and older adults, and in several different languages, including non–Indo-European languages like Chinese, Hebrew, and Filipino. The factors appeared in analyses of trait adjectives, descriptive phrases, and questionnaire scales. Contemporary five-factor theorists differ somewhat on their conceptualizations of the factors and consequently give them somewhat different labels. The terms *neuroticism (N), extraversion (E), openness to experience (O), agreeableness (A)*, and *conscientiousness (C)* are used here. The five factors and some of the traits that define them are presented in Table 6.4-1.

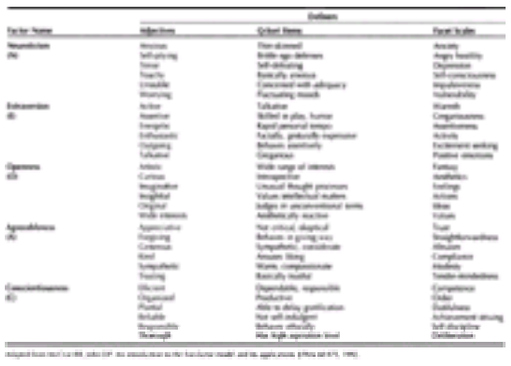

Table 6.4-1 Examples of Adjectives, California Q-Sort Items, and NEO-PI-R Facet Scales Defining the Five Factors

Many psychologists were skeptical of the lexical hypothesis that had led to the five-factor model. These critics believed that personality theory and clinical experience would lead to the identification of important traits for which no lay terms existed, and they continued to offer alternative models. Katharine C. Briggs and Isabel Briggs Myers operationalized Jung's psychological functions in the Myers-Briggs Type Indicator, which classifies individuals in terms of the dichotomies introversion versus extroversion, intuition versus sensing, thinking versus feeling, and judging versus perceiving. Timothy Leary argued that the traits that influence social interactions were better represented in a circular order than as a set of factors, and many instruments have been developed to measure this model.

A particularly important system was suggested by Theodore Millon, who was interested in personality traits associated with psychiatric disorders. His reviews of clinical literature led to a theory of personality and psychopathology that specified 11 personality disorders as extreme variants of normal traits. For example, the histrionic personality disorder is supposed to be related to the trait of gregariousness, the schizoid personality disorder to the trait of detachment. Millon's theory had a profound impact on the formulation of Axis II in the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) and in subsequent editions. His instrument, the Millon Clinical Multiaxial Inventory, has been widely used by psychiatrists and clinical psychologists.

The fact that trait theories of personality are usually tied to assessment inventories makes it relatively easy to make empirical comparisons, and since the late 1980s researchers in several countries have undertaken the task of relating different trait models. There is a growing consensus among these researchers that virtually all the traits measured by theory-based personality questionnaires—including those derived from psychodynamic, behavioral, and humanistic theories—are related to one or more of the five factors of Tupes and Christal. However, instruments vary in comprehensiveness. For example, the four scales of the Myers-Briggs Type Indicator correspond to four of the five factors, whereas measures of the interpersonal circumplex represent only two factors (extroversion and agreeableness). Table 6.4-2 lists some scales that have been shown empirically to be linked to each of the five factors. Thus, at the broadest level the problem of personality structure appears to have been resolved: personality is described by five basic factors.

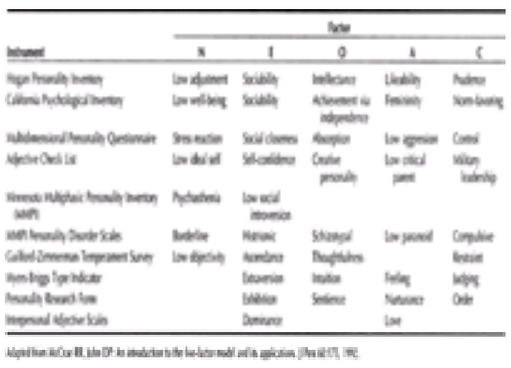

Table 6.4-2 Some Scales Empirically Related to Each of the Five Factors

However, personality cannot be exhaustively described in this way. Most trait psychologists adopt hierarchical models of trait structure and assume that the broadest factors are composed of more specific traits, which in turn are defined by discrete behaviors. In the Revised NEO Personality Inventory (NEO-PI-R), for example, six specific traits or facets are measured for each of the five factors (or domains) or personality. The facet scales are listed in Table 6.4-1; the hierarchical organization is illustrated in Figure 6.4-1. Assessment on the level of specific facets provides a more detailed and personalized portrait of the individual.

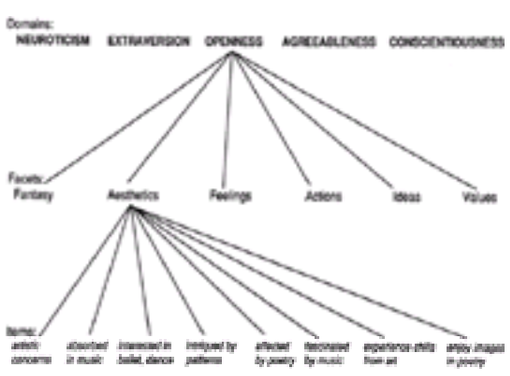

FIGURE 6.4-1 An example of hierarchical organization in the Revised NEO Personality Inventory: Domains, facets of openness, and items measuring openness to aesthetics.

Lifespan Development of Personality Traits Psychoanalytic, learning, and humanistic theories have usually offered causal explanations for individual differences. Thus, differences in self-efficacy are supposed to be caused by different histories of success in pursuing goals; variations in openness to experience might be the result of differences in the conditions of worth imposed by parents. The factor analysts who scoured the dictionary for trait terms usually bypassed this issue, being content to describe the personality differences found in adults. In principle, some traits might be inherited, some instilled by parents, some learned from experience; whatever their origin, they can be measured and used to predict important life criteria.

Until very recently it was generally assumed that personality was shaped primarily by a variety of environmental influences, including parental love and discipline, social and economic opportunities, and life experiences through childhood and adolescence. Surprisingly, this assumption has rarely been tested: there has been very little prospective longitudinal research documenting links between early childhood experiences and subsequent adult personality. A different research design using the techniques of behavior genetics can answer these questions by comparing personality measures in adults with different degrees of genetic and environmental similarity. For example, similarity between identical twins reared apart can be attributed to genetic influences, whereas similarity between adopted siblings reared together must result from environmental influences.

Since the 1970s behavior genetics studies using many different samples, personality measures, and methods of data analysis have concluded that personality traits are to a considerable extent heritable and to a considerable extent the result of unknown and idiosyncratic causes, but that they are hardly attributible to shared

environmental causes at all. Socioeconomic status, family diet, religious training, parental modeling, and all the other influences that children growing up in the same household would normally share seem to have little or no influence on adult personality. This conclusion applies as much to character traits such as achievement striving and modesty as to temperament traits such as anxiety and energy level. This dramatic and counterintuitive finding will doubtless reshape theories of personality. As Sandra Scarr commented, “Psychology has no adequate theories to account for individual variation in behavior because our theories address the wrong sources of variation.” Future theories will ascribe much more importance to genetic influences, and developmental psychology may become more concerned with explaining how heritable traits come to be expressed in different family and social settings.

For many years developmental psychologists assumed that personality development ended with adolescence. A 21-year-old is legally an adult and is unlikely to grow much in either physical height or intellectual capacity. However, recent research has shown consistent changes in personality between college age and middle adulthood. There is a dramatic decline in excitement seeking over that interval and cross-sectional and longitudinal studies of American college students have shown that *N, E*, and *O* decline during the decade of the 20s, whereas *A* and *C* increase. As a result, 30-year-olds are less emotional and better socialized than 20-year-olds.

There is reason to believe that these changes are not the product of the relatively indulgent American experience of adolescence. The same pattern of age differences is seen in less affluent countries like Croatia and in non-Western countries like Korea. Such cross-cultural studies suggest that there may be intrinsic maturational processes in personality development.

There have also been important developments in understanding personality change after age 30. Traits are defined as relatively enduring patterns of behavior, but most psychologists assumed that traits would be modified by life experiences. Jung postulated that the process of individuation required each individual to express all his or her potentials, and thus the young introvert would normally become an extravert in old age, and vice versa. Lay stereotypes of aging held that as they age, people become cranky, conservative, and depressed. Gerontologists rebutted these myths of aging, arguing that old age was more likely to bring maturity, wisdom, or detachment. Theories of adult development, popularized in Gail Sheehy's best-selling *Passages*, suggest that personality changed in stages, and in particular that men (and perhaps women) went through a midlife crisis in their 30s or 40s.

In sharp contrast to these theories are the findings from a number of independent longitudinal studies of personality in adulthood. These studies present a clear picture of predominant stability of the full range of personality traits. That is, the average levels of most traits neither increase nor decline much with age, and individuals tend to maintain the same rank order. The 30-year-old who is outgoing, curious, and hardworking is likely to become an outgoing, curious, and hardworking 80-year-old. This conclusion has been supported by studies using self-reports as well as observer ratings of all five factors of personality and appears to apply to both men and women. There are often dramatic changes in personality as a result of dementing disorders in old age, but normal life experience seems to have little impact on personality after age 30.

There is distressingly little data on the long-term effects of psychopathology on personality. Individuals in recovery from an episode of major depressive disorder generally score high on measures of *N*, and it is sometimes argued that this is a result of the experience of depression. However, the few prospective studies of the first onset of major depressive disorder typically show that these individuals scored high on *N* prior to the first episode, suggesting that high *N* may be an enduring feature of people who are prone to clinical depression.

Theories of Psychopathology The links between psychopathology and trait psychology are at once intimate and complex. For decades psychiatrists and clinical psychologists have administered psychological tests such as the Minnesota Multiphasic Personality Inventory (MMPI) and the Cattell's measure of personality, the 16PF, to inform the diagnosis of mental disorders; these same tests have been used routinely by trait psychologists to examine relations between personality and such criteria as vocational preference, creative potential, and coping with life stress. The dividing line between normal variations in personality dispositions and psychopathology is frequently unclear.

This poses more of a problem to psychiatric nosology than it does to trait theories of personality. Psychiatric diagnoses are supposed to represent the presence of a discrete disorder, and the fourth edition of DSM (DSM-IV) specifies the criteria that must be met to confer each diagnosis. This categorical model is appropriate for some disorders, but not others. For example, it may be very difficult to separate social phobia from extreme shyness and self-consciousness, or a schizoid personality disorder from marked introversion. This is entirely consistent with trait models of personality, which regard individual differences as continuously distributed variables.

Neuroticism and Psychopathology One theory of psychopathology states that some psychiatric disorders reflect extreme standing on personality traits, particularly those related to *N*. Among the traits that covary in normal populations to define this factor are predispositions to experience chronic levels of negative affects such as fear, anger, shame, and sadness. Individuals with very high standing on these traits may qualify for a diagnosis of generalized anxiety disorder, borderline personality disorder, social phobia, or dysthymic disorder.

Neuroticism may also be considered a risk factor for the development of psychiatric disorders that are not themselves trait-like. Several recent studies have demonstrated that individuals who score high on measures of *N* are at increased risk of subsequently receiving a diagnosis of major depressive disorder. Poor control of urges and impulses and excessive concern with physical functioning are also characteristics associated with *N*, and it might be hypothesized that individuals high in *N* are predisposed to develop eating disorders and conversion disorder (hypochondriasis). Neuroticism is a generalized disposition to experience psychological distress, and individuals seeking psychiatric treatment are almost always distressed. It is therefore not surprising that virtually all clinical populations, from drug abusers to schizophrenia patients, score high on measures of *N*.

Historically, the term *neurosis* or *psychoneurosis* was coined to identify psychiatric disorders of functional origin that were closely related to anxiety and its control. It survived in the revised third edition of DSM (DSM-III-R) in many secondary labels (*dysthymia*, for example, was also called *depressive neurosis*), but is not used in DSM-IV. Many personality psychologists object to the use of the term *neuroticism* as a label for a dimension of normal personality because of its suggestion of psychopathology. Many psychiatrists object to the term because it is tied to an outdated psychiatric nosology. However, the term serves a useful purpose: it is a reminder to clinicians that patients with a wide variety of diagnoses share many features related to chronic psychological distress, and a reminder to personality psychologists that the difference between normal and abnormal functioning is often only one of degree. The cliché that people are all more or less neurotic has some scientific basis.

Personality Traits and Personality Disorders Axis II of the DSM-IV is used for the diagnosis of personality disorders, which are defined as inflexible and maladaptive personality traits. It is reasonable to ask whether these traits are the same as or different from those encountered in nonpsychiatric populations. Several recent studies on this question have concurred in finding strong and replicable links between scales measuring personality disorders and the five factors in both normal and clinical populations.

Only high scores of *N* are associated with psychiatric impairment, but both poles of the other factors appear to be associated with specific forms of psychopathology. Individuals high in *E* tend to have histrionic and narcissistic personality disorders; those who are low in *E* have avoidant and schizoid personality disorders. High *C* is associated with obsessive-compulsive personality disorder; low *C* with antisocial personality disorder. Low *A*, or antagonism, is characteristic of individuals with paranoid, antisocial, and narcissistic personality disorders, as well as with the proposed sadistic personality disorder. High *A* is associated with dependent personality disorder. The hypothesized relations between personality traits and DSM-IV personality disorders are presented in Table 6.4-3.

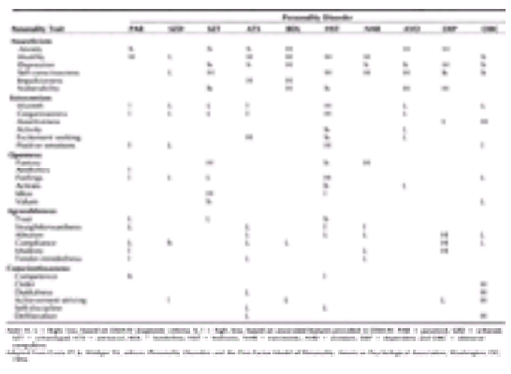

Table 6.4-3 Hypothesized Relations Between DSM-IV Personality Disorders and Five-Factor Model Personality Traits

It is a matter of current controversy just how these personality traits are related to the disorders: are normal personality traits carried to an extreme inherently maladaptive, or do these traits merely predispose individuals to develop disorders under certain circumstances? Some research has also called into question the meaningfulness of the syndromes recognized by DSM-IV, by showing that the symptoms used to define the disorders, when separately assessed, do not covary in ways that match the DSM-IV syndromes. Instead, the symptom clusters that do emerge are interpretable in terms of the five-factor model. As a result of such evidence, proposals have been made to replace the current categorical model by dimensional models that relate problems in adjustment to standing on basic dimensions of personality. This seems to be a logical extension of trait theories of psychopathology.

Application of Theory to Therapy Psychodynamic, behavioral, and humanistic theories all specify the causal mechanisms by which psychopathology is created and maintained and thus imply points of intervention. If maladjustment is caused by rigidly internalized conditions of worth, then unconditional positive regard in the therapeutic setting may provide a cure; if the problem is a learned behavior, then altering reinforcements may extinguish it. Trait models do not emphasize causal or developmental explanations and thus may seem to have no implications for psychotherapy; however, they have many.

Recent evidence on the substantial heritability of most personality traits clearly indicates that Allport was right: traits do have some underlying neuropsychic structure. Research on the psychophysiology of traits is a topic of growing interest and parallels the extensive work done on the neurophysiological basis of many forms of psychopathology. In this broad sense psychopharmacological approaches to psychotherapy are in principle consistent with trait theories of personality: if personality traits and disorders reflect brain processes, drugs that affect the brain may offer useful instruments for psychotherapy. However, there is still much to learn; for example, individuals with dysthymic disorder who score high on measures of trait depression often do not respond to antidepressant medication.

Personality Assessment Historically the chief role of trait psychology in psychotherapy has been in diagnosis and assessment. A number of self-report measures, such as the MMPI and the Millon Clinical Multiaxial Inventory, were designed specifically to measure psychopathology and include primarily items that tap psychiatric symptoms. They can be regarded as measuring psychopathological traits and states although they have often been used in college and volunteer samples as measures of personality per se. These instruments are chiefly of value as aids to psychodiagnosis. General personality questionnaires, including the 16PF, the Guilford-Zimmerman Temperament Survey, and the Edwards Personal Preference Schedule, have also been used for decades in clinical psychology and psychiatry as part of a complete psychological assessment. Several measures of the five-factor model have recently appeared, including the Hogan Personality Inventory and the NEO Personality Inventory (NEO-PI), and there has been considerable interest in the clinical application of the five-factor model. The primary advantage of this model is its comprehensiveness; by assessing traits from all five dimensions, the clinician can efficiently obtain a full portrait of the individual.

Personality psychologists and psychometricians have devoted years to the development of self-report inventories, and the utility of this approach to assessment is beyond doubt. Self-reports, however, are by no means infallible. Patients may not understand their own personalities or may deliberately misrepresent themselves. Concerns about defensiveness and socially desirable responding have led to the use of projective tests, the development of special validity scales to detect and correct for distorted responses, and reliance on the clinical judgment of the psychiatrist. Each of these possible solutions introduces problems of its own, however, and most clinicians rely on multiple sources of information.

One source of information that has been underutilized in clinical settings is informant ratings. Research since the 1980s has confirmed that ratings on standardized instruments by significant others—usually spouses or parents—can provide reliable and valid assessments of personality. These findings appear to hold for clinical as well as volunteer samples. Personality ratings may be particularly valuable when patients are incapacitated or are strongly motivated to present an overly favorable or unfavorable picture of themselves.

Uses of Trait Profiles Because traits are enduring and stable features of the patient's behavior and experience assessing a broad range of traits gives the clinician a sense of what the person is like, which can be useful for many purposes beyond the formulation of a diagnosis. A complete personality profile can point to the patient's strengths as well as weaknesses, can help predict the course of therapy, and can aid in the selection of an optimal mode of treatment.

Humanistic theories of personality stress human potentials for altruism, creativity, and commitment and argue that psychotherapy must use these assets. Trait theorists believe that some people are altruistic, creative, or committed but others are not. Assessing traits allows the clinician to identify and capitalize on the particular strengths that characterize each individual patient.

Standing on trait dimensions can also give clues to the probable course of therapy. Patients who are low on agreeableness are distrustful and uncooperative, and it may prove very difficult to form a therapeutic alliance with them; by contrast, patients who are extremely high on *A* may be excessively compliant and become dependent on the therapist. Conscientiousness involves commitment and self-discipline. Patients high in *C* will probably adhere to treatment recommendations and work hard to solve their problems; those low in *C* are less persistent and dedicated, and the therapist may have to work to motivate them.

Finally, a few controlled studies and a good deal of clinical experience suggests that personality traits influence the effectiveness of various kinds of treatment interventions. Interpersonal therapies, in which patients are required to speak a great deal about themselves, appear to be most effective for extraverts; pharmacological management may be superior for introverts. Similarly, individuals who are high in openness to experience benefit from such techniques as guided imagery, whereas those who are low in openness prefer biofeedback. Ideally, the choice of therapies should be guided not only by the nature of the disorder, but also by the enduring characteristics of the patient.

As an illustration of profile interpretation, Figure 6.4-2 provides data on a well-known public figure, Richard M. Nixon. As part of a project on personality traits of U.S. Presidents, two experts independently described Nixon using the observer rating form of the NEO-PI-R. Agreement between the two experts was very high, and their ratings were averaged.

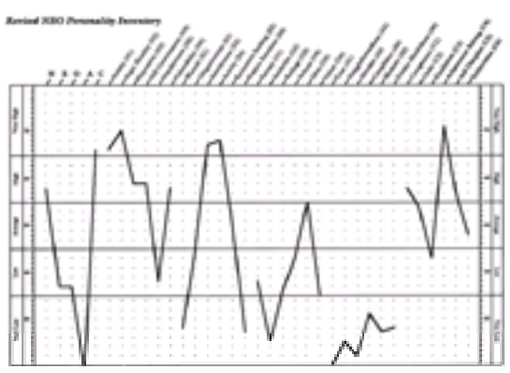

FIGURE 6.4-2 NEO-PI-R profile for Richard M. Nixon, based on combined ratings from two experts. (Data provided courtesy of Rubenzer S, Faschingbauer T, Ones D: In *Personality and the Presidency: A Scientific Inquiry*. Symposium presented at the Annual Convention of the American Psychological Association, August, 1996, Toronto. Profile form reproduced by special permission of the publisher, Psychological Assessment Resources, Inc, Lutz, FL, from the Revised NEO Personality Inventory by Paul T. Costa, Jr, and Robert R. McCrae © 1978, 1985, 1989, 1992 by PAR, Inc. Further reproduction is prohibited without permission of PAR, Inc.)

The left side of the profile sheet shows Nixon's standing on the five factors: high on *N*, average on *E*, low on *O*, very low on *A*, and very high on *C*. Specific traits, grouped by domain, are given toward the right of the profile sheet. Among the most notable features are Nixon's very high *N1:* Anxiety and *N2:* Angry Hostility and his very low scores on all six facets of agreeableness, reflecting both his personal distress and his antagonism toward others. However, the profile also shows some clear strengths, such as very high levels of *E3:* Assertiveness, *E4:* Activity, and *C4:* Achievement striving, that help explain his political successes.

Table 6.4-3 suggests traits that are likely to be associated with each of the DSM-IV personality disorders, and computer interpretations can compare observed profiles with these patterns. For example, Nixon's high scores on *N2:* Angry Hostility and *N4:* Self-Consciousness, and his low scores on *A2:* Straightforwardness, *A4:*

Compliance, *A5:* Modesty, and *A6:* Tender-mindedness are consistent with the diagnosis of narcissistic personality disorder. The profile in Figure 6.4-2 also suggests the possibility of paranoid, schizotypal, antisocial, and obsessive-compulsive personality disorders. Whether Nixon in fact would have met formal criteria for the diagnosis of any of these disorders is questionable, but he clearly shared some features of the disorders.

In addition to suggesting possible diagnoses, personality profiles can be used to anticipate the course of psychotherapy. For example, Nixon's generally low *O* scores mean that he would probably have been uncomfortable in therapy, and, among therapies, probably would have preferred directive techniques and behavior modification over free association and guided imagery. His low *A* scores suggest the likelihood of problems in forming a therapeutic alliance, but his high *C* scores mean that he would have worked hard at assigned tasks.

Psychotherapy and Personality Change If psychopathology is an expression or an outcome of personality traits, and if, as longitudinal studies demonstrate, personality traits change little over time, how can psychotherapy be effective? The pessimistic answer is that it cannot. Many psychiatric disorders are lifelong or recurrent, and treatment consists of management rather than cure. It is well known that those who have the best prognosis for recovery are those who are initially least impaired. In these cases the disorder may represent a transient adjustment reaction among individuals who have relatively healthy personality traits. Individuals very high in *N* and low in *A* and *C* may be poor candidates for psychotherapy.

However, so pessimistic a conclusion is unwarranted. Longitudinal studies show that people change little in the course of normal experience, but they do not rule out the possibility that direct interventions can make changes. It is unlikely that psychotherapy will make dramatic and lasting changes in basic personality traits, but more modest improvements may be enough to allow the patient to function adequately in daily life. Interventions may be particularly effective in early adulthood, when traits are not yet fully developed. Even without changing personality, therapy may help individuals to adapt to their own nature. The chronically anxious person may learn techniques of relaxation; the disagreeable individual may learn social skills that improve interpersonal relationships.

In some sense, most forms of psychotherapy can be seen as learning experiences. Psychoanalysts promote insight into unconscious conflicts; behaviorists help their clients understand the contingencies that reinforce troubling behavior; humanistic psychologists encourage patients to discover their true potential. Trait psychology can also be a source of insight. All human beings are in some respects alike, and it is comforting to learn that one is not alone in one's suffering. However, in other respects people are different from one another, and it can also be therapeutic to learn this fact. Helping patients to understand their own enduring dispositions can prepare them for some of the problems they face in life.

SUGGESTED CROSS-REFERENCES

Psychodynamic perspectives on personality and psychopathology are treated extensively in Section 6.1 on psychoanalysis and Section 6.3 on other psychodynamic schools. Chapter 24 discusses personality disorders. Chapter 7 on diagnosis and psychiatry deals with issues of assessment; Section 7.4 on personality assessment is particularly relevant. Section 3.3 on learning theory provides technical background for the discussion of behavioral approaches to personality, and Chapter 30 on psychotherapies—particularly Section 30.2 on behavior therapy, Section 30.6 on cognitive therapy, and Section 30.8 on brief psychotherapy—gives details about the application of theories of personality to therapeutic processes. A different view of adult development is explained in Chapter 50 on adulthood.

CHAPTER 7. DIAGNOSIS AND PSYCHIATRY: EXAMINATION OF THE PSYCHIATRIC PATIENT

7.1 PSYCHIATRIC INTERVIEW, HISTORY, AND MENTAL STATUS EXAMINATION

MYRL R. S. MANLEY, M.D.

The purpose of a psychiatric diagnostic interview is to gather information that will enable the examiner to make a diagnosis. Having established a diagnosis, the clinician can then make predictions about the future course of a disorder and the likely response to treatment. As with all areas of medicine, treatment decisions are guided by diagnosis. Unlike most disciplines of physical medicine, however, psychiatry has no external validating criteria, no laboratory tests to confirm or refute diagnostic impressions. Consequently the diagnosis is wholly a product of the skills and knowledge of the individual psychiatrist and can never be better than the judgment made by individual clinicians.

Because of the absence of external validating criteria or biologic markers, diagnostic reliability is an intrinsic problem in clinical psychiatry. Before 1980 the problem was compounded by official diagnostic descriptions that were narrative and impressionistic. Schizophrenia was overdiagnosed in the United States because the description failed to distinguish it sufficiently from mood disorders with psychotic symptoms. Starting with the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) of the American Psychiatric Association (APA) in 1980 and through subsequent editions and revisions, diagnostic criteria have been based on descriptive phenomenology of clinical symptoms and clinical course. The move away from interpretive, intuitive, and impressionistic diagnoses has succeeded in improving diagnostic reliability. It has also strengthened the medical model of psychiatry.

Medical Model and Psychodynamic Formulation The medical model has become the dominant mode of psychiatry in the United States and much of the rest of the world. In this model psychiatrists are seen as physicians who specialize in the treatment of psychiatric disorders. The function of the diagnostic interview is to gather sufficient information to establish a categorical diagnosis or diagnoses. The diagnosis is used to predict the future course of a disorder and its likely response to treatment, and it is the foundation for all subsequent therapeutic decisions.

In contrast, the adaptational model sees psychiatrists as specialists in behavior and adaptation whose expertise can benefit people whether or not they have a diagnosable psychiatric disorder. Psychoanalytic psychiatry is an example of this model. A psychoanalytic interview is less concerned with establishing a diagnosis than with surveying psychological functions as they have evolved over an individual's lifetime.

A psychodynamic formulation draws from the principles of psychoanalytic theory. It describes personality structure in terms of ego strengths (including principal defense mechanisms, regulation of drives, relationships with other people, and reality testing), principal psychological conflicts, and developmental history, with particular emphasis on early childhood. The psychodynamic formulation is not intended to produce a diagnosis but rather to describe an array of psychological and adaptive capacities. These descriptions allow the analytic psychiatrist to formulate a theoretical model that explains current symptomatic behavior and interpersonal or functional limitations. It serves as the template for the conduct of a psychoanalytic therapy by anticipating unconscious intrapsychic conflicts and unacknowledged developmental arrests or delays.

The psychodynamic formulation differs from a diagnostic interview using the medical model in several significant aspects. It is more concerned with the unique characteristics of the particular individual than with commonalties of a diagnostic class. The data of a psychodynamic formulation are overwhelmingly interpretive and inferential. Defense mechanisms cannot be seen; their existence can only be inferred from observed (or described) behavior. Moreover, the psychodynamic formulation is inextricably tied to a single theoretical school. Prior understanding of psychoanalytic theory is prerequisite to making the formulation, and experienced analysts may offer different formulations from the same data.

In clinical practice psychiatric assessments are likely to draw from both analytic and medical models and are shaped by the unique circumstances of individual patients. There are patients for whom a psychodynamic formulation is relatively more important and will thus take up a greater portion of the interview. Among these are persons being considered for a psychodynamic therapy or those with a constellation of complaints not subsumed in a conventional categorical diagnosis. There are also persons for whom a psychodynamic formulation may be of negligible importance, for example, an individual with a diagnosis of obsessive-compulsive disorder or simple phobia in which the planned therapies are pharmacological and behavioral rather than psychodynamic. However, even in these circumstances many psychiatrists prefer to have some sense of a person's psychological makeup and developmental history to avoid focusing on symptom relief to the exclusion of other areas of potential concern and to deal with resistances to therapy as they arise. The principles of psychoanalytic theory may offer a workable model for organizing and using these concepts.

PSYCHIATRIC EVALUATION

The psychiatric evaluation comprises two sections. The first, a section of histories (e.g., psychiatric, medical, family) includes the patient's description of how symptoms of the current episode have evolved, a review of past episodes and treatments, a description of current and past medical conditions, a summary of family members' psychiatric problems and treatments, and the patient's personal history, which reveals interpersonal and adaptive functioning over time. Information for the history will come from the patient but may be supplemented by collateral information from family members, social referral agencies, previous treating physicians, and old hospital records. The second section of the psychiatric evaluation, the mental status examination, systematically reviews emotional and cognitive functioning of the patient at the time the interview is conducted. Diagnostic criteria in DSM-IV draw from both the history and the mental status examination. An outline of the psychiatric assessment is presented in Table 7.1-1.

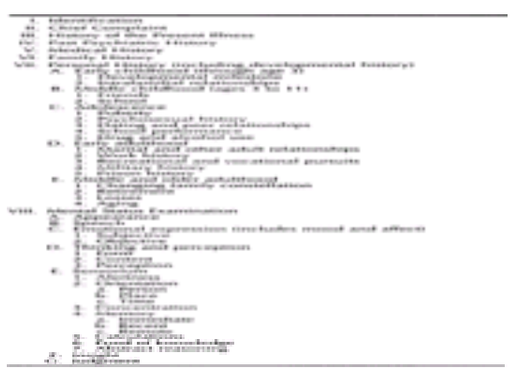

Table 7.1-1 Psychiatric History and Mental Status Examination

PSYCHIATRIC HISTORY

Identification The identification establishes the basic demographics of the patient. It includes age and sex, frequently includes racial or ethnic information, and occasionally includes religious affiliation. It is not necessary to list family, social, occupational, and educational information covered more fully in the personal history unless such information has direct diagnostic relevance. For example, although military service would not routinely be mentioned, it would be helpful to mention that a

patient is an excombatant when posttraumatic stress disorder is being considered. (The case from which the following examples are taken was provided by Richard Nathanson.)

> This is the first psychiatric hospital admission for Mr. A., a 21-year-old bisexual male employed part-time as a veterinarian's assistant. He currently lives with his boyfriend and has never been married.

Chief Complaint The chief complaint is a verbatim recording of the patient's reason for seeking treatment or evaluation. Putting the chief complaint in the patient's own words, even if implausible or nonsensical, conveys valuable information about the person's capacity for insight and self-observation.

> “I took an overdose of some pills but I'm fine now.”

History of the Present Illness This section is a chronological description of how symptoms in the current episode have unfolded over time. The psychiatrist needs to determine not only the nature of symptoms, but also when they emerged and how they have progressed. The characteristics of symptoms should be described in detail; small distinctions may be diagnostically useful. Stating that a patient suffers from insomnia is less useful than describing the insomnia. Difficulty in falling asleep, difficulty in maintaining sleep, and a decreased need for sleep are each associated with different disorders. Attention should be paid to pertinent negatives as well as pertinent positives. In a patient complaining of depression, for example, the absence of vegetative symptoms is significant and should be mentioned. Whether the patient has been in treatment, has been taking any psychotropic medication, and has (or has not) been compliant are essential elements of the history of the present illness. If a patient has stopped taking a prescribed medication the reasons should be determined. Noncompliance is a symptom that needs to be investigated and not simply dismissed as poor judgment or character weakness. Noncompliance has many possible causes: unpleasant adverse effects, failure to understand the necessity for chronic medication despite symptomatic improvement, insufficiently treated symptoms such as the fear of being poisoned by medication, a reluctance to see oneself as psychiatrically impaired, or simply lacking the transportation and money to get a prescription refilled. Any current alcohol or other substance use should be described, including amounts, frequency, and last use. It is also useful to ask why the person came for treatment at this time, and what the patient believes to be causing the present symptoms.

> The patient is a 21-year-old male with a history of one prior suicide attempt who was brought to the hospital emergency room by ambulance, accompanied by his boyfriend and roommate, after having taken an overdose of atenolol (Tenormin) (twenty-five 25-mg tablets), zolpidem (Ambien) (twenty 10-mg tablets), and possibly fluoxetine (Prozac) pills (number unknown) in a suicide attempt. All of these medications had been prescribed for the patient's boyfriend.
>
> The evening before, the patient had had a fight with his boyfriend. He believed that his boyfriend wasn't giving him enough time and was not committed to the relationship. They slapped and punched each other. The patient went to a bar with another friend where he consumed four beers and a shot of vodka. When he arrived back at home, his boyfriend told him to go to sleep, which he interpreted as a continued lack of interest on the boyfriend's part. He locked himself in the bathroom and took many of his boyfriend's pills. The patient filled the empty pill bottles with water and left them in plain view on the sink.
>
> The patient then unlocked the door and went to bed, telling his boyfriend where to find syrup of ipecac. (Mr. A. carries the ipecac in his knapsack to induce vomiting when he drinks too much alcohol.) His boyfriend saw the pill bottles, realized the patient had overdosed, and tried to induce vomiting by administering syrup of ipecac. Unable to get the patient to vomit, he called an ambulance.
>
> Mr. A currently drinks alcohol once or twice each week, usually on the weekends. A usual amount of alcohol for him consists of two vodka tonics and eight or nine beers. Often, he drinks until he blacks out. He used cocaine this past New Year's Eve (“a few lines”) and occasionally uses heroin intransally (unknown amounts). He denies any history of intravenous drug use.
>
> He remembers always speaking and thinking very quickly, because he was always “so bright and talented and good looking and smart.” In addition, he has needed little sleep since age 15. The racing thoughts, pressured speech, and decreased need for sleep have become more pronounced since September, when he started feeling “very up.” Since then he has been getting at most 5 hours of sleep each night without feeling tired. He says he can be very influential, but that he has no special powers. He reports that he gets angry quickly and that his mood can change very easily. Since September he's also felt more depressed and physically restless. He considers suicide frequently, “just to escape the boredom of life.” He has lost 6 pounds in the last 2 months. There is no history of hallucinations or of delusional thought.

Past Psychiatric History The past psychiatric history describes all previous episodes and symptoms whether treated or not. The history should begin with the first onset of symptoms and progress chronologically to the current episode. It describes symptoms in detail and clearly delineates their longitudinal progress. Disorders that are chronic and relapsing are distinguished from isolated episodes of disturbance. It is particularly important to obtain the fullest possible information on prior treatments. The best predictor of treatment response is past experience. If a person has taken psychiatric medication before, it is essential to determine not only which drug, but the dosage and length of treatment, to distinguish nonresponse from a subtherapeutic drug trial. Therapeutic benefits and adverse effects should be noted. Similarly, if a patient has received psychotherapy it is important to establish which modality of therapy, at what frequency, for what length of time, and with what benefit.

> The patient has a history of violent outbursts. His mother reports that as an infant, he would bang his head against the floor. Throughout his childhood, he got into fights with other children and would even attack family members and teachers. In seventh grade, he threw a chair at a teacher. Once he attacked his older brother and kicked him in the head repeatedly until he lost consciousness and required medical attention. During his senior year in high school, the patient was forced to see the school therapist because of a heated argument with a teacher. The teacher claimed that the patient tried to hit him, and though the patient denied this, he was expelled. He met with the psychologist five or six times and stopped treatment when he graduated. There is a history of one previous suicide attempt 2 years ago, precipitated by the infidelity of his first boyfriend. The patient fashioned a noose and began to hang himself. When he began to feel pain, he stopped. He never told anyone about this attempt and never sought or received treatment. Psychotropic medication has never been prescribed.

Medical History The importance of a thorough, accurate medical history is difficult to overstate. The occurrence of major illness or surgery is likely to be of considerable significance in a person's life and may be the precipitant of psychiatric disturbance. For example, in response to having a heart attack, a middle-aged man might develop anxiety, depression, and a fear of sex. In addition, many medical conditions and their treatments cause psychiatric symptoms that are clinically indistinguishable from primary psychiatric disorders. Hypoglycemia can cause panic and anxiety; hypercalcemia, depression and lethargy; and acute porphyria, psychotic symptoms. Moreover, the presence of underlying medical conditions will inform treatment decisions: tricyclic antidepressants will be avoided in patients with cardiac conduction abnormalities, and bipolar I disorder patients with a history of renal disease are more likely to be treated with an anticonvulsant than with lithium. The names and dosing schedules for all currently prescribed nonpsychiatric drugs should be obtained to avoid possible adverse interactions with any new prescription.

In many instances the findings from a current physical examination and laboratory studies will be important in the diagnostic assessment. This is always true of hospitalized psychiatric patients, and may be necessary for selected outpatients. Few primary psychiatric disorders include physical signs. (One exception is panic disorder, which may include tachypnea, tachycardia, hypertension, and dilated pupils.) Their presence always warrants medical evaluation. Aspects of the clinical history may also suggest the need for medical investigation: abrupt onset of symptoms in an older adult with no prior psychiatric history, symptoms atypical for purely psychiatric disorders (e.g., vomiting and diarrhea or shaking chills), or a history of recent illness or treatment. In addition, abnormalities of the sensorium section of the mental status examination are most typical of delirium and dementia and indicate the need to look for underlying medical conditions.

> The patient has had streptococcal pharyngitis five times in the past 4 years. At age 15, he fractured his right wrist in a fight. He denies any other medical conditions. He takes no medications and has no known drug allergies. He has never been hospitalized or undergone any surgical procedures.

Family History Many psychiatric disorders are familial, and many of those appear to have a genetic component to the cause. Knowing who is in the patient's family and which, if any, psychiatric disorders have been diagnosed may help in diagnosis and treatment planning. Caution is urged however against overinterpretation of such data. Experienced clinicians are good at establishing the presence of a family psychiatric history but are less able to identify specific disorders in family members not personally interviewed. Even when specific disorders can be clearly identified, the information is of limited use because our knowledge of spectrum

disorders—that is, which disorders occur together in families and the relative risk of their occuring together—is still embryonic. On the other hand, the family history can clearly show who is in the family, who is available for support, who may be exacerbating symptoms, whether a general vulnerability to psychiatric disorders exists, and what stresses have been caused by a family member's illness. It is also useful to establish which treatments have been attempted and which have been successful; treatment response is often familial.

> The patient's immediate family consists of his father (age 51), his mother (age 49), one older brother (age 26), and one younger sister (age 19). His father suffers from alcohol dependence. Family history is otherwise negative for psychiatric disorders, medical disease, dementia, addiction, suicide attempts, and violence.

Personal History The personal history is intended to describe events of major significance throughout a person's life, to highlight those that may be etiologically significant, and to describe functioning over time. Which elements of the personal history are important will vary from patient to patient and cannot easily be prescribed. The information presented in the personal history will be shaped by other information from the interview. The psychiatrist will make ongoing clinical judgments about what is important and what is not. Major items commonly include early childhood friendships, education and any changes in school performance, romantic involvements, work history, military or jail experiences, and leisure activities.

The personal history may or may not include a detailed developmental history. A full development history begins with significant events and complications during pregnancy and delivery. Was the pregnancy full term? Did the patient's mother use drugs or alcohol during the pregnancy? Were there prenatal complications? Milestones of development in infancy and childhood (walking, talking, bowel and bladder control) can be described, although the information may be lacking or unreliable if the adult patient is the only source of information. Social development in childhood is revealed through information about friendships, schooling, and extracurricular activities. Often of considerable use is the patient's recollections of intrafamilial relationships including their relationships with each other and each separately with the patient.

A landmark of adolescence is the onset of puberty. The age of menarche, the circumstance of its onset, and preparations are likely to be significant emotional events in the lives of women. The growth of pubic and axillary hair signals the onset of puberty for boys. Late-onset puberty often has significant emotional and social consequences for boys: they are often less confident, more self-conscious, and less likely to be widely popular or leaders in school. Early experiences in dating, first sexual experiences, and any confusion or discomfort about sexual orientation are all important aspects of adolescent development.

Adolescence is also often a time of first drug experimentation. Information about which drugs, how much, how often, and under what circumstances should be obtained as well as changing patterns of drug or alcohol use. The development of career goals, undertaking advanced education, starting a first job, entering the military, and establishing a partnership (including marriage) all signify the transition from adolescence to adulthood.

Development continues through an individual's lifetime. The changes in adulthood are less likely to be as clearly demarcated or as universal as the developmental milestones of childhood or adolescence, but for many people the achievement of career and family goals will predominate. The examiner should inquire about current relationships, whether the patient is currently married and has ever been married before. Qualitative descriptions of interpersonal relations are important in diagnosing personality disorders and assessing suitability for some kinds of psychotherapy. In addition, recent research has drawn attention to the importance of strong, emotional, personal bonds in maintaining both physical and mental health.

The review of a patient's work history includes a summary of the jobs held, the length of time in each, and the reasons for leaving. Of considerable importance is the possible discrepancy between aspiration and achievement. The examiner should determine the extent to which psychopathology has interfered with the capacity for sustained productive work.

It is useful to ask patients what they do with their free time. Avocational, recreational, and humanitarian pursuits are important in the lives of many adults, and their absence may be diagnostically significant. For some people, military or prison history is important. As adults grow older, new issues such as children leaving home, the death of one's parents, retirement, and the loss of friends will emerge.

Some writers have advocated obtaining a detailed developmental history for all patients (at least one writer argues for inclusion of a detailed prenatal history), but such information is rarely of use in formulating a diagnosis or planning treatment for adult patients. Unlike a psychoanalytic assessment, which may be stretched over several sessions and which attempts to be comprehensive in its survey of developing character traits and ego strengths, a clinical diagnostic interview is more focused. A solid knowledge of psychopathology shapes the interview as it progresses. It is difficult to justify the time and expense of obtaining a detailed developmental history for a person with, for example, a simple phobia, obsessive-compulsive disorder, or panic disorder. Such information is necessary neither for establishing the diagnosis, nor for prescribing and implementing effective treatment.

On the other hand, describing functional capacity over time is necessary and useful. Deteriorating school performance, an irregular work history with failure to progress to higher levels of responsibility, premature discharge from the military, an inability to sustain friendships or romantic involvements for any period of time, may all have diagnostic and prognostic significance. The distinction between schizophrenia and bipolar disorder, both chronic, relapsing conditions with the possibility of psychotic symptoms, was first made on the basis of deterioration in the former and stability of function in the latter. Personality disorders that by definition attempt to identify core *trait* features will present with characteristic difficulties in interpersonal relationships or work capacity relatively unchanged over the course of a lifetime. The personal history may contain information helpful in making a prognosis as well as diagnosis. For example, a good premorbid adjustment reflected in school and work history indicates a good prognosis in patients diagnosed with schizoaffective disorder.

The personal history also helps identify key events that may have helped precipitate current symptoms: divorce, loss of work, death of a family member, serious financial setbacks. However, with the exception of posttraumatic stress disorder, identification of a precipitating event is not required to make a diagnosis. It may be useful although not necessary. Sexual functioning should be reviewed in the personal history. Basic screening questions include whether the patient is currently sexually active, who are preferred partners, whether there has been a change in sexual functioning, and the extent to which sex is pleasurable. If sexual difficulties emerge, more detailed questions can follow. When complaints of sexual disturbances do occur, the information is likely to be more appropriate for the history of the present illness than for the personal history.

The patient grew up in a medium-size city. His relationships with family members have always been difficult. While he often got into physical fights with his brother and his father, there is no history of physical, verbal, or sexual abuse.

In school, he had difficulty controlling his behavior, getting into fights and cursing a great deal. He was a good student when he worked, receiving As and Bs and honors in middle school and in the ninth grade. He failed all of his classes in the sophomore year and needed to repeat the year. He attributed this to ignoring school and partying too much. During his last year of high school, he attended a special arts school, studying drama and jazz. He graduated from high school after 5 years.

He had trouble making friends. He had a girlfriend for 2½ years in high school, but they broke up because they argued too much. He met his first boyfriend at age 17, but this boy cheated on him, precipitating the previous suicide attempt. In the past 2 or 3 years, the patient has found himself primarily attracted to men but still considers himself bisexual.

After high school, he lived with his parents for almost 2 years. During that time, he played drums in a band and held part-time jobs as a sales clerk. These jobs never lasted more than a few months, usually ending in verbal fights with his employer. He applied to music school but was not accepted because of his poor high school performance. Six months before admission, he moved to a large city to live with his uncle, hoping to take classes without credit. Lack of financial resources required him to work instead. He worked for 24 hours each week, off the books, as a veterinarian's assistant. He felt that his uncle was too controlling and domineering and moved in with another friend in October. In November, he met his current boyfriend, Mr. B., at a bar. A week and a half later, he moved into the boyfriend's house in the suburbs. Mr. B. reports that his relationship with the patient has been characterized by extreme suspiciousness and neediness. The patient has recurrent thoughts that his boyfriend doesn't care about him and is cheating on him, even though there is no evidence.

The patient has no savings and is supported by his boyfriend. His parents have severe financial difficulties and are unable to help him. Contact with family members is presently limited to his mother and his aunt because he doesn't get along with any other family members.

The patient has had about 25 different sexual partners, about half male and half female. He does not always practice safe sex and has engaged in high-risk behaviors such as receptive anal sex without using a condom. Because of this, he has been tested for human immunodeficiency virus (HIV) infection four times. The result was negative each time, most recently 2 months before admission.

There is a significant history of substance abuse. During his second and third years in high school, he smoked marijuana two to three times each week. He stopped after graduation and has since smoked marijuana only two or three times. He used cocaine once in high school and only occasionally in the past 2 years, snorting a few lines each time. He has used lysergic acid diethylamide (LSD) and phencyclidine (PCP) but never regularly. He has smoked cigarettes since age 13, ranging from half a pack to 2½ packs a day. He stopped smoking for 9 months 3 years ago but resumed and currently smokes half a pack a day.

MENTAL STATUS EXAMINATION

The mental status examination of psychiatric patients is analogous to the physical examination in physical medicine. It provides a format for the systematic observation and recording of information about a person's thinking, emotions, and behavior. These data combined with information from the history are the basis for formulating a differential diagnosis. As is true for the physical examination, a physician conducting a mental status examination notes only those findings present at the time of interview. Historical information is excluded. A patient may report having had auditory hallucinations the day before, but unless they are present when the examination is conducted, hallucinations are not recorded in the mental status examination.

The physician must also be as objective as possible in making mental status observations. Since 1980 the various editions of DSM have emphasized descriptive phenomenology in making psychiatric diagnoses to the exclusion of inferred, intrapsychological processes, in an explicit attempt to enhance diagnostic reliability. Observed data are always more reliable than inferred data. Correspondingly, the mental status examiner should strive to record findings that are as free of interpretation or inference as possible.

The formal organization of the mental status examination ensures completeness. In the actual interview of a psychiatric patient it is seldom necessary to proceed with an inflexible, prescribed series of questions. Much of the mental status examination is observational and can be made in the course taking the history. There are several specific tests of cognitive function, but much of this information can be obtained simply by talking with a patient. The experienced clinician does several things simultaneously in conducting a psychiatric interview: establishing rapport, eliciting important historical information, recognizing areas of greater or lesser emotional intensity, and making ongoing mental status observations.

ORGANIZATION OF THE MENTAL STATUS EXAMINATION

Numerous variations on the mental status examination have been described. The specific format matters less than ensuring that the observations are complete and logically organized to facilitate diagnosis. The outline presented here and summarized in Table 7.1-1 is widely used.

Appearance A brief description is given of the patient's appearance, behavior, and manner of relating to the examiner, with particular attention paid to abnormalities. Is the patient overdressed or underdressed? Is the patient wearing excessive, garish make-up? Is the patient disheveled, unkempt, or ungroomed? Is the patient cooperative, oppositional, hostile, seductive, or impassive? Are there unusual movements? Is the patient making smacking or chewing motions? Is there a tremor? Is the patient pacing? Although a comprehensive psychiatric assessment always includes a physical examination, obvious signs of physical illness (e.g., pallor, jaundice, labored breathing, or dilated pupils) are also mentioned under “appearance.”

The patient is a muscular young man appearing his stated age, wearing jeans, a white t-shirt, and sneakers. He wears several rings on his fingers and bracelets on both wrists. There is an obvious healing cut on his upper lip, which is slightly swollen. He is unshaven, but has an overall neat appearance and adequate hygiene. He sits with his arms crossed in a chair that swivels and uses his feet to swivel through roughly 90 degrees back and forth throughout the interview. He maintains good eye contact.

Speech The speech section of the mental status examination describes the physical production of speech, not the ideas being conveyed. Observations may be made about volume, rate, spontaneity, syntax, and vocabulary. Any speech abnormality such as dysarthria or aphasia is described. The speech of a manic patient may be loud and pressured. Conversely, the speech of a depressed patient may be soft and hesitant.

He speaks spontaneously and very rapidly, becoming pressured at times, but he is interruptible. Volume is occasionally loud. Rhythm and expressive intonation are normal. Speech is understandable, but some words are poorly articulated because of the high rate of speech production.

Emotional Expression It has been a convention for many years to describe emotional expression in terms of mood and affect, and those terms are still used extensively. Mood has commonly been described as the prevailing emotional state, and affect as the expression and expressivity of a patient's emotions. The term *affect* derives from the psychoanalytical literature and was originally intended to describe the feeling tone accompanying ideas or mental representations of external objects. *Mood* in turn was believed to derive from the summation of affects. By definition, affect would fluctuate with an individual's changing thoughts. Mood was more constant over time.

In this author's opinion, there are compelling reasons to abandon the distinction between mood and affect and no longer include a description of affect in the mental status examination. In its original psychoanalytic meaning, affect could be inferred but not directly observed because it was an intrapsychological phenomenon.

Moreover, the neurobiology of mood disorders, as now understood, is far more complex than the product of feeling tones accompanying ideas. This was implicitly acknowledged in 1987 when the revised third edition DSM (DSM-III-R) replaced the category of affective disorders with mood disorders. In a diagnostic scheme that is phenomenologic-descriptive and atheoretical with regard to etiology, this author believes the concept of affect is an anomaly.

Equally important is the fact that *affect* has acquired multiple and sometimes contradictory meanings. The distinction between mood and affect tends to focus on two parameters: constancy versus change and internal versus external. There has been a tendency to link the two, so that what is constant and internal (mood) is distinguished from what is transitory and external (affect). This coupling does not conform to clinical reality. It is quite possible for an individual's subjective experience of emotion to shift rapidly (e.g., in some manic states or frontal lobe syndromes). It is also quite possible for the external expression of emotion to be unvarying despite changes in subjective experience, as for example is sometimes seen in the residual phase of schizophrenia. In addition to its different definitions, no research has shown that affect can be reliably rated even by experienced clinicians.

Rather than attempting to distinguish mood and affect, the author's position is that in the mental status examination it is preferable to describe subjective and objective components of emotional expression separately. The subjective component is how individuals describe their inner emotional state: I feel happy; I feel sad, anxious, hopeless, exhilarated, etc. The objective component describes the way in which emotion is communicated through facial expression, vocal tone, and body posture. The two may be discordant. A patient whose eyes are filling up with tears may describe himself as feeling “fine.” Both objective and subjective components of emotion may fluctuate rapidly or remain unvarying. Both may be intense or blunted, and both may be appropriate or inappropriate to the topic being discussed. The long-term predisposition to jollity, melancholy, exuberance, or restraint is *temperament* rather than *mood*. Because the mental status examination describes only what is observed at the time of interview, an evaluation of temperament is not possible. As mentioned above however, the terms *mood* and *affect* are in common use and are to be found in most outlines of the psychiatric report and mental status.

Subjectively he reports feeling angry and depressed because he is being kept on a locked ward. Objectively he appears tense, angry, and sad at different times. His emotional expression is labile, of full range, and appropriate to content. His eyes fill with tears at times.

Thinking and Perception If psychotic symptoms exist, they are most likely to be described in this section. *Thinking* is subdivided into two subcategories: form and content.

Thought Form *Thought form* refers to the way in which ideas are linked, not the ideas themselves. Thoughts may be logically associated and goal directed. If they are not, a disorder of thought form (also formal thought disorder or sometimes, thought disorder) may exist. A number of different formal thought disorders have been described and are listed in Table 7.1-2. No thought disorder is pathognomonic for a particular disorder. However, a specific disorder of thought form is sometimes more characteristic of one diagnosis than another and may thereby convey diagnostic significance. For example, clang associations and flight of ideas are most closely associated with manic states, derailment and thought blocking with schizophrenia.

Table 7.1-2 Formal Thought Disorders

His thoughts are generally logical and goal directed, although he is quite circumstantial, launching into emotional accounts of relevant ideas but including many irrelevant details. There is no evidence of flight of ideas, loosening of associations, perseveration, tangentiality, or thought blocking.

Thought Content *Thought content* describes a patient's ideas. Abnormalities of content include delusions, ideas of reference, and obsessions. *Delusions* are fixed, false beliefs that are not shared by others as part of a religious or subcultural group. They are rigidly held regardless of evidence to the contrary. Except for delusional disorders, the type of delusion is not pathognomonic but may be associated closely enough with a particular disorder to have diagnostic implications. For example, delusions of guilt and somatic delusions are characteristic of (but not unique to) major depression with psychotic features. Delusions of persecution may be seen in schizophrenia and mania.

The patient who believes that everyday neutral occurrences carry specific, unique, and personal significance is said to have *ideas of reference*. A person may believe, for example, that a television announcer is attempting to convey a hidden message or that a stranger passing by on the street is signaling something of significance by brushing his hair or blowing his nose. Depending on the fixity and details of the belief, some ideas of reference may also be delusional.

Obsessions are unwanted, intrusive thoughts experienced by patients as symptomatic and beyond their control. The content of an obsession may be virtually anything but is often a disturbing thought of doing something embarrassing, hurtful, or dangerous. For example a young father may have thoughts of his daughter being sexually molested, a middle-aged woman of shouting obscenities during a church service. Because of the effort to control their thinking and because patients with obsessions are often deeply chagrined by their content, it is necessary to inquire specifically about their presence and not rely on voluntary reporting. *Preoccupations* are thoughts that predominate a person's thinking but are usually not experienced as unwanted or symptomatic. Examples include preoccupations with health, with money or social status, or with injustices.

A careful psychiatric examination always includes an assessment of suicide potential—even if there is no evidence of suicidality in the history—and of the potential for violence toward others. It is best to ask simple and direct questions; for example, Do you think about hurting yourself or about taking your life? The evaluation of suicidality and violence are discussed more fully below.

Mistrustful, suspicious thought is evident: He is preoccupied with thoughts that his boyfriend may have cheated on him. He also expresses extreme mistrust of the staff's motives, believing that the staff overanalyzes and carelessly misinterprets his statements and actions. He threatens to elope from the unit, claiming to know several ways to escape. He has inflated self-esteem, claiming to be extremely talented in a lot of areas, conceding that there are people who are better than he is, but that with a little practice, for example, he can be the best musician ever. He denies current suicidal or homicidal thoughts, intent, or plan.

Perception Perceptual abnormalities include hallucinations and illusions. Hallucinations are sensory perceptions generated wholly within the central nervous system (CNS) in the absence of any external stimulus. They can occur in any sensory modality: auditory, visual, tactile, olfactory, or gustatory. Auditory and visual hallucination are the most common. The modality of hallucination has no diagnostic significance, with the exception of *formication*, a tactile hallucination of insects crawling over or under the skin, which is strongly associated with withdrawal from alcohol and other central nervous system (CNS) sedatives. Illusions originate with true sensory stimuli, which are then misprocessed or misinterpreted. A patient looking at the shadows created on a wall by a rustling curtain may actually see threatening monsters. Illusions are widely believed to be more common in delirium than in other psychiatric disorders, despite the absence of empirical confirmation. Depersonalization and derealization (the sense that oneself or the world are not real) may also be recorded as perceptual abnormalities in the mental status examination.

He described hearing a man's voice, muffled, but at times intelligible, saying his name or short phrases such as “they're wrong.” There was no evidence of hallucinations in any other modality.

Sensorium This section includes assessment of several cognitive functions that collectively describe the overall intactness of the CNS. Cognitive disorders such as the syndromes of delirium and dementia and psychiatric disorders caused by drugs or general medical conditions are particularly likely to result in abnormalities in the

sensorium. The set of cognitive functions described in this section are subserved by different brain regions and, taken as a whole, provide a survey of whole brain functioning.

Alertness Alertness describes the degree of wakefulness and may range from fully awake and alert to comatose and nonresponsive. The degree of alertness may be stable or fluctuating.

Orientation Orientation is conventionally described in three spheres: person, place, and time. Orientation to person reflects an understanding of who one is and one's relationship to others. Orientation to time and place exists in multiple dimensions. If a patient is disoriented it is important to establish the degree. Is a patient aware of being in a hospital but not know which hospital? Does the patient believe it is a hotel instead of a hospital? Does the patient know the city in which the interview is being conducted? The date, day of the week, and time of day? The calendar year? If not, can the patient describe the season or distinguish morning from afternoon? It is common for hospitalized patients who are removed from normal environmental cues to be mildly disoriented to time.

Concentration Concentration describes the ability to sustain attention over time. Concentration is one of the cognitive functions most easily assessed simply by talking with a patient. Patients who forget the examiner's question, are distracted by extraneous stimuli, or lose track of what they are saying have impaired concentration. Concentration may be more formally tested in several ways. One of the most commonly taught and frequently misused tests is “serial sevens” in which a patient is asked to count backward from 100 by 7s. This is a valid test of concentration only if the person can comfortably perform the mental subtractions and if it is carried out for a substantial period of time. It is not intended to test the ability to perform calculations; the ability to concentrate and the ability to perform calculations should be evaluated separately. Alternative tests of concentration include counting backward by 3s, reciting the alphabet backward, spelling *world* backward, and naming the months of the year backward.

Memory Memory must be evaluated across the spectrum of immediate to remote. The brain substrates for long-term memory are different from those for immediate recall and short-term memory. This is illustrated clinically by patients with an anterograde amnesia such as Korsakoff's syndrome, in which long-term and immediate recall may be intact but recent memory is grossly impaired. As with concentration, much information about memory will be revealed in the course of the general interview. One test of immediate recall is to say (without inflection or verbal spacing) a series of numbers and have the patient repeat the series. A progressively longer sequence of numbers is presented, and both forward and backward recall are tested. Most adults can easily recall five r six numbers forward and three or four in reverse. Recent memory is for events several minutes to hours old and may be evaluated by giving patients the names of three or four unrelated objects and asking them to repeat them after 5 to 10 minutes. Remote memory describes events 2 or more years old. It is usually revealed in the course of obtaining patients' histories, although it may be necessary to confirm facts through collateral sources.

Calculations Calculations describes the ability to manipulate numbers mentally. Simple addition, subtraction, or multiplication questions may be used. Problems of money and change are often helpful with patients with limited educational background. For example, if a magazine costs $3.50 and you pay with a ten dollar bill, how much change should you be given? As noted above, the person should not be asked to perform serial subtractions to test calculating ability since it also requires concentration.

Fund Of Knowledge Fund of knowledge must be tailored to the unique circumstances and educational level of the individual. Patients are often asked to name presidents of the United States, starting with the incumbent and proceeding backward as far as can be remembered. This is not appropriate for everyone; recent immigrants to the United States may have difficulty with this even though they could give a detailed political history of their home country. Questions about current events, key geographical facts (what ocean lies between South America and Africa?), and sports may further help in the assessment.

Abstract Reasoning Abstract reasoning describes the ability to mentally shift back and forth between general concepts and specific examples. The capacity for abstract reasoning is usually not achieved before ages 12 to 13, and for some people is never achieved. The patient's use of jokes, metaphors, or aphorisms during the interview often reveals this ability. Of all the frequently used ways to test abstract reasoning, asking proverb interpretation is probably the least useful. For example, a clinician might ask the patient, “What does it mean, when someone says, “People who live in glass houses shouldn't throw stones'?” A conventional response, one that is able to generalize from the specifics of the proverb to the generalization might be “Don't criticize others of what you are guilty yourself.” A nonabstract response would address the concrete particulars without grasping the larger meaning, for example, “You would break the glass.” (Some answers will be idiosyncratic and difficult to classify as either abstract or concrete: “The police would see you and would come to arrest you.”)

One difficulty in using proverbs to assess abstract reasoning is that people tend to recite meanings learned over the years rather than reasoning through the proverb when it is given in the mental status examination. Indeed, interpreting an unfamiliar proverb can be difficult even for well-educated people whose abstract reasoning is unimpaired. In addition, proverbs tend to be culture bound, and their interpretation may be better evidence of cultural literacy than of the capacity to reason abstractly. (Consider, for example, the East African proverb, “You can't cover a horned animal with a canvas cloth.” This means that “truth will eventually be revealed despite efforts to suppress it.”) One alternative to proverb interpretation in assessing abstract reasoning is to ask for the similarity between two or more items, which really means asking to what conceptual abstraction do both belong. (A dog and a spider are both living things.) Asking for differences seldom gives useful information about abstract reasoning because the only plausible answers tend to describe concrete physical properties (e.g., “One has four legs, the other eight”). In another test the patient is given three objects, two of which are conceptually related, and asked which object does not belong (e.g., shirt, sock and hammer).

Insight This portion of the mental status examination describes patients' capacity to recognize and understand their own symptoms and illness. It does not measure the severity of illness. Patients with mild somatoform disorders may fail to recognize the emotional origins of their physical symptoms. On the other hand, some psychotic patients understand that their hallucinations are a symptom of a psychiatric disturbance that needs better control.

Judgment Observations about judgment in the mental status examination address two issues: can the person recognize prevailing social norms of behavior and comply, and will this person be able to cooperate with medical evaluation and treatment. Of all areas in the mental status examination, this is the least descriptive and most inferential. The psychiatrist must often draw from information in the history to supplement mental status findings. Some writers have advocated posing hypothetical situations to patients, asking, for example, “What would you do if you found a sealed, stamped, addressed envelope lying on the sidewalk?” Problems arise in using these kinds of data, particularly to the exclusion of other information. The presumed correct response to such scenarios is often obvious, and the answer may be very different from the patient's actual behavior. Moreover such questions often miss the complexity of variables shaping behavior and are simplistic in assuming a single correct response. An indigent homeless person who would open the envelope to see if there was money inside may be demonstrating good judgment in the context of his or her circumstances. Judgment may be more usefully assessed by observing the patient's behavior during the interview and by asking for elaboration on true incidents in the recent history—for example, “Why did you stop taking the medication?” or “Tell me what you were thinking when you gave away your car keys and registration to a stranger. Does it seem like a good idea now? Would you do it again?” Some psychiatrists advocate describing intelligence in the mental status examination. This cannot be done with any validity or reliability without the use of standardized instruments, and even then it may be difficult to distinguish between intelligence and education. Rather than record an impressionistic hunch, the examiner will do better to present the data of the evaluation without interpretation. Areas that loosely correlate with intelligence are vocabulary (under *speech*) and fund of knowledge and abstract reasoning in the *sensorium*.

Alertness: Alert and awake throughout the interview

Orientation: Intact to person, place, and time

Concentration: Spelled *word* backward correctly; serial 7s performed correctly and without hesitation

Memory: Registration and recent memory (5 minutes) intact for 3/3 phrases (blue rose, 37, happiness); long-term memory appears intact as evidenced by his detailed recall of past events in the history.

Calculations: 6 × 12 = 72; $2.00 – 65 cents = $1.35

Fund of knowledge: Good. He knew presidents back to Carter. He said WWII started around 1940 and then spontaneously added, “Hitler and Normandy.” He knew that Einstein was responsible for the theory of relativity.

Abstract thinking: Somewhat concrete; similarities: apple/orange—“both fruits”; poem/statue—“both have form”; fly/tree—“both are nature, both are iridescent green, flies fly around crap, which is brown, the same color as tree bark”

Insight: Poor. The patient does not recognize the presence of any illness or that his behavior is dangerous, stating, “Maybe I have a very mild case of mania, but if I need to be here, then 90 percent of everyone in the world needs to be locked up.” He initially refused to take medication and repeatedly says he doesn't need to be “locked up,” that he can take care of his minor relationship problems as an outpatient. He calls his drinking “minimal” and doesn't realize that it precipitates dangerous, self-destructive behavior.

Judgment: Fair. He cooperates with staff even though he doesn't think he needs hospitalization because he fears that a history of involuntary commitment would make it difficult for him to realize his goal of becoming a teacher. He says that the next time he is angry with his boyfriend, he will “work it out,” and not try to kill himself.

TECHNIQUES FOR THE PSYCHIATRIC ASSESSMENT

The psychiatrist wants not only to ask the questions necessary for formulating a differential diagnosis, but also to establish rapport and create an atmosphere of confidence and trust. Relaxed and trustful patients are more likely to provide useful information than those who are nervous or on guard.

Time and Setting The initial psychiatric assessment usually lasts between 45 and 90 minutes, with the length of time agreed upon in advance. Sometimes additional time is necessary to complete the evaluation, in which case it is better to schedule an additional session. Extending the length of the first session unilaterally is a discourtesy to the patient whose time may be scheduled with other demands, and it risks fatigue for both parties. In addition seeing the patient at different times helps to determine more accurately which presenting features are purely situational and how they have changed with time.

The evaluation should be conducted in a comfortable room with pleasant lighting. While there is no reason to make the room impersonal, dramatic paintings, panoramic views, or expensive antiques may be distracting to a patient during a first visit. The psychiatrist should budget the full amount of time allotted for the interview and attempt to ensure that there are no interruptions during the session. Routine phone calls and messages should be intercepted by an answering machine or secretary. A comfortable waiting area should be provided for patients who arrive early. Many psychiatrists prefer to have the patient's and examiner's chairs of relatively equal size and height to minimize any sense of intimidation.

Interview The psychiatrist should have in mind the categories of information needed and their structural organization in the summary evaluation. However, it is seldom useful to proceed with a prescribed check-list of questions. Rather, the interview should be shaped as it progresses, with the psychiatrist's knowledge of psychopathology used to ask detailed or probing questions about significant issues as they emerge. It is often best to begin with a general, open-ended question (e.g., “How can I help you?” or “What brings you here today?”) and to allow the patient to talk freely for several minutes before interposing further questions. However, the psychiatrist must keep in mind the information needed to formulate a diagnosis and treatment plan and be prepared to structure the interview more tightly if the patient appears to be vague and rambling. If a patient talks on with no pauses or natural endings, it may be necessary to interrupt and redirect. This can be done with courtesy and minimal disruption. For example, the psychiatrist might say, “Excuse me for interrupting, but I'd like to come back for a moment to the trouble you mentioned having had with sleep. How many hours of sleep did you get last night?”

Open-Ended and Closed-Ended Questions Open-ended questions ask the patient to speak spontaneously with relatively little structure or organization imposed by the examiner (e.g., “Tell me about your growing up”). Closed-ended questions on the other hand ask for factual answers to specific questions. (e.g., “How far did you go in school?”) Open-ended questions are commonly associated with psychodynamic interviewing and closed-ended questions with phenomenologic-descriptive diagnostic interviewing; this is an unhelpful oversimplification. A skillful diagnostic interview uses both types of questions. It is often useful to begin the interview with broad open-ended questions and to become more closed-ended and directive as the interview progresses.

There are a number of advantages in starting with open-ended questions: the content is less limited by the examiner's preconceptions, disorders of thought form are more likely to be revealed in spontaneous speech than in two- or three-word answers, and emotional responses may be more obvious. In addition, many patients prefer to tell their stories with their own words and emphases without interruption. Other patients, such as those who are psychotic, depressed, or paranoid, may need more structured questions. Closed-ended questions are particularly useful in clarifying information, in gathering factual data efficiently, and in describing the absence of key symptoms. Patients are unlikely to spontaneously describe what does not exist.

Supportive and Obstructive Interventions Psychiatrists do much more during an interview than ask questions. They provide feedback and information, offer reassurances, and respond emotionally to what the patient is saying. The psychiatrist's facial expression and body posture (correctly or erroneously) conveys information to the patient. Interventions may be classified as supportive or obstructive depending on the extent to which they increase the flow of information and enhance or diminish rapport. Interventions classified as supportive include

Encouragement. Patient: I am not very good at putting things into words.

Doctor: I think you have described the situation very well.

Reassurance. Doctor: I can understand how those experiences must have frightened you, but I think it is very likely they'll respond to treatment.

Acknowledging emotion. Doctor: Even now it brings tears to your eyes when you talk about your mother.

Nonverbal communication. Body posture and facial expression that convey interest, concern, and attentiveness.

Interventions classified as obstructive include

Compound questions. Doctor: Have you experienced any change in your appetite and sleeping?

Judgmental questions. Doctor: How do you think your wife felt when she found out about your affair?

Why questions. Doctor: Why do you feel anxious when you go outside?

Not following the patient's lead. Patient: I have trouble sleeping through the night.

Doctor: Any change in appetite?

Patient: I keep waking up out of nightmares about my daughter.

Doctor: Do you have less energy than usual?

Minimization or dismissal. Patient: I'm not able to keep my checkbook balanced the way I need to.

Doctor: Oh, I wouldn't worry about it. Lots of people don't even try.

Premature advice. Patient: Work is almost unbearable. My supervisor watches me like a hawk and criticizes the tiniest little mistake I make.

Doctor: Why not write her a memo and outline your grievances?”

Nonverbal communication. Yawning, checking one's watch. Patients can often detect an interviewer's inattention by the *absence* of facial expression or body movement.

Psychiatric interviewing is a complex, multifaceted task that is shaped by the personalities and circumstances of the interview. The concept of supportive and obstructive interventions has broad, general use but cannot be applied rigidly. There are circumstances in which an intervention that would be obstructive with other patients may be helpful or even necessary. For example, although it is usually most helpful to follow the patient's lead, the psychiatrist interviewing a hypochondriasis patient or a depressed patient with somatic concerns may need to ignore or interrupt perseveration about physical symptoms and redirect the interview to other topics. In addition, at times the psychiatrist may appropriately ask patients how their misdeeds are perceived by others (a judgmental question) to test empathy.

Interpreting Behavior During an Initial Diagnostic Interview The psychoanalytic techniques of interpretation and clarification should be used minimally if at all during an initial diagnostic assessment. The psychiatrist is unlikely to have enough information to make accurate interpretations. Moreover, the context of a trusting long-term relationship that facilitates acceptance of interpretations will be lacking. Patients who arrive late for the session may well be manifesting anxiety or ambivalence or may equally well have been delayed by circumstances beyond their control. Rather than interpreting the lateness, the psychiatrist would do better to express regret at the late start and offer sympathetic understanding to the patient for the problems causing the lateness. Separately, the psychiatrist can ask whether the patient was nervous or had mixed feelings about coming for the evaluation.

An exception to the rule against interpretations in the first session is the patient for whom a psychodynamic psychotherapy may be recommended. The psychiatrist may then want to evaluate the patient's response to a gentle test probe to assess suitability for psychodynamic work.

A 28-year-old woman who asked to start therapy with a psychoanalytic psychiatrist missed her first session. At the second session she reported that she simply forgot the appointment. The psychiatrist asks, “Is it possible that you let yourself forget on purpose?”

The woman laughs and says, “Well to tell you the truth, it's really my boyfriend whose been pushing me to start therapy; I'm not so sure. Do you think it's a good idea?”

Recording and Note Taking Electronic recording of sessions is seldom necessary and is often detrimental. Patients become self-conscious and guarded when their every word is being recorded. Many patients are concerned about the uses to which the recordings will be put and are rightfully concerned about potential abuses. Few patients are likely to feel comfortable knowing that their sometimes critical comments about another person or intimate discussion of private issues might be heard by anyone other than the evaluating psychiatrist. Recordings must never be made without the patient's knowledge and consent.

Psychiatrists vary in the extent to which handwritten notes are taken during a session. Some examiners take no notes at all during the evaluation and then write a summary after the patient has gone. They argue that note taking is a distraction to both psychiatrist and patient, that it becomes a barrier to subtle emotional observation and understanding, and that some patients become preoccupied by what is being written down, thus contaminating what they say. By not taking notes during the interview they train themselves to remember better the details of the session. They point out that when they do rely on notes they are unlikely to remember anything that was not written down.

Other psychiatrists take almost continuous notes. They believe it is possible to do so unobtrusively and that it provides subtle reassurance to patients about the seriousness with which the examiner is taking their statements. The result, they believe, is a more accurate record, not vulnerable to the distortions of memory.

Still other psychiatrists take notes selectively, when they believe that accurate and detailed documentation is necessary (e.g., a complicated history of previous medication treatments and variable responses). Individual psychiatrists develop techniques that work well for them, but they must remain mindful of the impact their individual decisions have on the ability to get useable information. Flexibility and common sense must not be lost. It would be destructively unfeeling for a psychiatrist to continue note taking in the middle of an intense emotional moment with the patient sobbing. Requests by the patient that notes not be taken may be explored but should always be respected.

Whether or not notes are taken during the session, psychiatrists have a medical and legal obligation to maintain a written record of every patient encounter. Such records document that the encounter occurred and that the assessment was complete. The record contains the historical and mental status data on which a diagnosis and treatment recommendations are based. The physician describes in detail all treatment recommendations and other advice given. (Psychiatrists should also routinely compile written descriptions of all telephone exchanges with patients. This is particularly important if the telephone exchange includes a change in treatment.) It is helpful to keep in mind the legal rule of thumb: “If it isn't written down, it didn't happen.”

Special Problems in Interviewing

PSYCHOTIC PATIENTS Patients with psychotic symptoms have difficulty thinking clearly and reasoning logically. Their ability to concentrate may be impaired, and

they may be distracted by hallucinations and delusional beliefs. Psychotic patients are often frightened and may be quite guarded. Quite often, the evaluation of a patient with psychotic symptoms needs to be more focused and structured than that of other patients. Open-ended questions and long periods of silence are apt to be disorganizing. Short questions are easier to follow than long ones. Questions calling for abstract responses or hypothetical conjectures may be unanswerable.

For patients with hallucinations, the full phenomenology of the hallucination should be explored. The patient is asked to describe the sensory misperception as fully as possible. For auditory hallucinations this includes content, volume, clarity, and circumstances; for visual hallucinations, this includes content, intensity, the situations in which they occur, and the patient's response. The evaluator should distinguish between true hallucinations on the one hand and illusions, hypnagogic and hypnopompic hallucinations, and vivid imaginings on the other. Hallucinations are perceived as real sensory stimuli and should not be dismissed as fanciful; however the psychiatrist should ask questions about their fixity and the patient's level of insight. “Does it ever seem that the voices are coming from your own thoughts?” or “What do you think is causing the voices?”

Delusions by definition are fixed, false beliefs. Delusional patients often come to psychiatric evaluation having had their beliefs dismissed or belittled by friends and family. They will be on guard for similar reactions from the examiner. It is possible to ask questions about delusions without revealing belief or disbelief (e.g., “Does it seem that people are intent on hurting you?” rather than, “Is there a plot to hurt you?”). Careless use of psychiatric jargon should be avoided, particularly in evaluating delusions. Words such as *grandiose, paranoid*, and indeed the word *delusion* itself will seem harsh and judgmental and are unlikely to be helpful in eliciting information. Many psychiatrists have found that patients can speak more freely when asked to talk about the accompanying emotions rather than the belief itself (“It must be frightening to think there are people you don't know who are plotting against you.”) Although the psychiatrist does not attempt to reason them away, a gentle probe may determine how tenaciously the beliefs are held (“Do you ever wonder whether those things might not be true?”).

Patients with paranoid delusions (and patients with high levels of nondelusional suspiciousness) are best evaluated with a respectful, but somewhat distant, formality and with scrupulous honesty. Efforts to reassure or ingratiate often increase suspicion. The psychiatrist must keep in mind the possibility of being incorporated into a delusional belief and should ask about it directly (“Are you concerned that I might try to hurt you?”).

Disorders of thought form can seriously impair effective communications. The evaluating psychiatrist should note formal thought disorders while minimizing their adverse impact on the interview. When derailment is evident, the psychiatrist typically proceeds with questions calling for short responses. For a patient experiencing thought-blocking, the psychiatrist needs to repeat questions, remind the patient of what was already said, and in general provide an organization for thinking that the patient is unable to provide.

DEPRESSED AND POTENTIALLY SUICIDAL PATIENTS Severely depressed patients may also have difficulty concentrating, thinking clearly, and speaking spontaneously. The intensity of mood disturbance can seem all consuming and may well lead to distortions in thinking and perception. Some depressed patients will have psychotic symptoms in addition to cognitive difficulties. The psychiatrist evaluating a depressed patient may need to be more forceful and directive than usual. It will sometimes seem that the examiner must provide all the emotional and intellectual energy for both participants. Although depressed patients should not be badgered, long silences are seldom useful, and the examiner may need to repeat questions more than once. Ruminative patients—for example, those who continually repeat how worthless or guilty they are—will need to be interrupted and redirected.

All patients must be asked about suicidal thoughts. Depressed patients may need to be questioned more fully. A thorough assessment of suicide potential addresses intent, plans, means, and perceived consequences as well as history of attempts and family history of suicide. Many patients will mention their thoughts of suicide spontaneously. If not, the examiner can begin with a somewhat general question such as, “Do you ever have thoughts of hurting yourself?” or “Does it ever seem that life isn't worth living?” These can then be followed up with more specific questions. The examiner must feel comfortable enough to ask simple, straightforward, noneuphemistic questions. Asking about suicide does not increase the risk. The psychiatrist is not suggesting a course of action the patient has not already contemplated. Specific, detailed questions are essential for prevention.

Intent The examiner must determine the seriousness of the wish to die. Some patients report that they wish they were dead but would never intentionally do anything to take their own lives. This level of intent is often referred to as *passive suicidal ideation*. Other patients express greater degrees of determination. Near the other end of the spectrum of intent is the patient who says, “I've decided I have to kill myself and nothing you can say or do will change that.” At the most extreme level of determination are the patients most difficult to help, those who tell no one about their suicidal plans and proceed in a deliberate, systematic manner. It is also useful to ask about restraining influences, both internal and external (e.g., “Do you worry that you might not be able to resist those impulses?” or “How have you been able to keep from hurting yourself so far?”). Patients with auditory hallucinations commanding then to kill themselves often describe the hallucinations as irresistible despite any real desire to die.

Plans Patients with well-formulated plans are generally at greater risk than patients who don't know what they would do, but the method of suicide is not always a reliable indication of the risk. Even though some actions such as jumping or shooting are much more likely to be fatal than others, patients make mistakes. A pill overdose taken at the time a spouse is expected to arrive home may become deadly if the spouse is delayed in traffic. The psychiatrist should also ask about preparatory actions such as giving away goods or putting one's estate in order.

Means Asking patients about the intended means of suicide is helpful in two ways. First it clarifies the urgency of the situation; persons wanting to shoot themselves who have a loaded gun at home are more dangerous than those who have no idea where to find a gun. Second, the understanding of intent is sharpened by knowing whether a patient has thought through the steps necessary to carry out the action.

Perceived Consequences Patients who see something desirable resulting from their deaths are at increased risk for suicide. A reunion fantasy, the belief that a person will be reunited with a deceased loved one, may be a powerful motivating force toward suicide. On the other hand, some potentially suicidal patients are restrained by what they see as negative consequences (e.g., “My children need me too much; they'd never be able to get along without me,” or “I couldn't hurt myself. My parents would never get over their grief.”). The psychiatric history and the family history for all patients, even those not currently suicidal, should mention any previous suicide attempt or suicides by family members. Both circumstances are recognized to increase the current risk, even if previous attempts were thought to be superficial.

At times treatment must take precedence over evaluation. In rare circumstances the threat of suicide is so imminent that immediate action must be taken to hospitalize the patient. Even during a first evaluation session, the psychiatrist must be prepared to make whatever professional response is necessary to safeguard the well-being of the patient.

AGITATED AND POTENTIALLY VIOLENT PATIENTS Whether in a private office or a psychiatric emergency room, psychiatrists sometimes find themselves interviewing potentially violent patients. In these circumstances, the task is twofold: to conduct an assessment but also to contain behavior and limit the potential for harm.

Most unpremeditated violence is preceded by a prodrome of accelerating psychomotor agitation. The patient may begin pacing and pounding the fist in a hand. Speech may become loud, abusive, obscene, and threatening. The temporal arteries may begin to throb. Researchers and clinicians in emergency psychiatry suggest that the prodrome may last from 30 to 60 minutes before erupting into physical violence. Thus the psychiatric evaluator has both early signals of impending violence and a period of time in which the agitation may be quieted.

Several steps can be taken to minimize the agitation and potential risk. The interview should be conducted in a quiet, nonstimulating environment. There should be enough space for the comfort of both patient and psychiatrist, with no physical barrier to leaving the examination room for either of them. During the interview, the psychiatrist should avoid any behavior that could be misconstrued as menacing: standing over the patient, staring, or touching.

The psychiatrist must ask the questions necessary to complete an adequate evaluation but must attempt not to be provocative. It is certainly appropriate to allow the patient to drink water, use a bathroom, and, for extended evaluations in an emergency room, eat food. However, these should never be offered as bargaining chips (“I'll let you get a drink of water if you'll tell me what happened just before the police brought you here.”) The examiner must also avoid promising outcome in exchange for cooperation (“If you'll just talk with me for another half hour, I'll make sure you don't have to go into the hospital.”)

The psychiatrist should ask whether the patient is carrying weapons and may ask the patient to leave the weapon with a guard or in a holding area. The psychiatrist should not request that patient hand over any weapons. Dangerous mishaps can occur during the transfer; moreover, the sudden shift in power created by an armed psychiatrist may feel extremely threatening to paranoid patients. If the patient's agitation continues to increase, the psychiatrist may need to terminate the interview.

Depending on the setting, assistance from security personnel, physical, or chemical restraints may be appropriate. The physician's own subjective sense of comfort or fear should be heeded. A frightened, intimidated examiner may be incapable of an accurate professional evaluation.

PATIENTS FROM DIFFERENT CULTURES AND BACKGROUNDS Differences in race, nationality, and religion and other significant cultural differences between patient and interviewer can impair communication and lead to misunderstandings. Despite its widespread use throughout the world, the possible cultural biases of DSM-IV are still being debated; for example, the distinctions between mood disorders and somatoform disorders appear less valid in some countries than in the United States.

In addition, it may be difficult for a culturally naive psychiatrist to evaluate symptoms that are relative rather than absolute. There is usually no difficulty in documenting the presence of auditory hallucinations regardless of cultural differences. However, assessing whether or not a delusion is “bizarre” (as required by DSM-IV for delusional disorder) is more difficult because “bizarre” has meaning only in reference to cultural norms. The belief by East Africans in the direct intervention of ancestral spirits in the day-to-day life of individuals is commonplace. The chief executive officer of an American corporation who announces that he will divest the company of two subsidiaries because of signals he received that morning from ancestral spirits will be thought exceedingly bizarre by colleagues and shareholders. Personality disorders, whose criteria are preponderantly relative rather than absolute (e.g., “shows arrogant, haughty behaviors or attitudes”), are notoriously difficult to diagnose cross-culturally.

Apart from diagnostic categories, the vocabulary used to describe emotional distress varies from culture to culture. European-Americans commonly describe symptoms in terms of named emotions (“I've been feeling anxious and depressed all week”). Hispanic-Americans are more likely to describe physical symptoms (“I've had a headache all week, and I'm so tired I can hardly move”). Sometimes symptoms that are commonplace within a culture are unheard of to outsiders. Residents of Anglophonic countries in East and West Africa often describe the sensation of a snake crawling under their skin, moving from one part of the body to another. This appears to be a symptom of general emotional distress without particular diagnostic significance. Heard by a Western physician, the symptom may be misinterpreted as a somatic delusion or ignored altogether, because it does not register in the examiner's conceptual understanding of disorders.

Additional problems are encountered when doctor and patient speak different languages. When an interpreter is needed, the person should be a disinterested third party, unknown to the patient. Using family or friends to translate inevitably invites distortions in what the patient is said to report. Translators must be instructed to translate verbatim what the patient says—a difficult task for even the most experienced professional translators. Some words and expressions are simply untranslatable. It may be impossible to convey a formal thought disorder through translation.

An additional difficulty may arise in establishing rapport between doctor and patient of different ethnic or cultural groups. The use of honorifics, the extent of direct eye contact considered appropriate, or whether it is acceptable for men and women to shake hands, all vary considerably among different groups. Patients from minority groups may be quite guarded in speaking with a doctor from the majority group. Some groups such as traditional Chinese-Americans strongly believe that family problems should not be discussed outside the family, including with physicians. The evaluating psychiatrist must proceed with humility and respect. Rather than offer reassurances of understanding and acceptance, it is usually better to ask, “Have I understood this in the way you meant it?”

SEDUCTIVE PATIENTS The warmth, openness, acceptance, and understanding that are helpful to most psychiatric interviews may engender feelings of romantic longing in some patients, especially (but not exclusively) those who are lonely and socially isolated. Other patients may have flirtatious and seductive ways as their habitual style of relating with other people. Seductiveness may be manifested in a patient's dress, behavior, and in what is said. It runs the gamut from gentle suggestion to explicit proposition. A young man may sit with his legs spread wide apart, a young woman may wear a low-cut revealing dress, or a middle-aged woman, when shaking hands, may hold the psychiatrist's hand a few seconds longer than appropriate for the situation.

Of course sex is not the only enticement with which psychiatrists can be seduced. Patients may offer insider information for profitable trading in the stock market, promise an introduction to a movie star friend, or suggest that they will dedicate their next novel to the psychiatrist. While it is easy to understand that some offers by patients such as the possibility of a sexual involvement cannot be acted on without considerable harm to the patient, others may seem more innocuous. However, because they nearly always introduce a different agenda into the therapy than that originally contracted for and because they create additional, more ambiguous levels of obligation between therapist and patient, any psychiatric work is inevitably contaminated, and the ability to help the patient is compromised. Consequently, gaining material or social benefit from the patient other than the agreed upon fee is unethical.

Whether to offers of sex, money, or celebrity, the psychiatrist's response is the same. In the course of ongoing psychotherapy and in the context of an established relationship, seductive behavior is discussed and examined in an effort to understand its meaning. Is it for example, a way of distancing, of gaining control, or of compensating for feelings of vulnerability and inferiority? To what extent are the feelings being expressed by the patient part of the transference? The psychiatrist should make it clear that what is being offered will not be accepted, in a way that preserves good rapport and does not unnecessarily assault the patient's self-esteem.

Seductive behavior during an initial psychiatric assessment must be handled somewhat differently. When the behavior is mild and indirect, it may be best to ignore it; commenting on a woman's exposed cleavage only makes it clear that the psychiatrist is picking up sexual cues and is most unlikely to facilitate the interview. More-explicit propositions call for more-direct responses and may afford the psychiatrist the chance to explain the nature of the therapeutic relationship and the need to establish boundaries. The psychiatrist should also make clear that it is the violation of those boundaries that is being rejected and not the patient. For example, to the patient who offers a celebrity introduction, the interviewer might reply, “That's very nice of you to propose, but I think I will best be able to help you if we pretty much stick to the issues that brought you in to see me.”

PATIENTS WHO LIE A fundamental stance in psychiatric interviewing is recognizing that what is being heard may not be literal truth. The unreliability of memory and the vagaries of psychopathology through which a patient's narrative is processed will distort and falsify. The interviewer understands that what is historically untrue may nevertheless be emotionally true and is therefore a meaningful part of the diagnostic assessment or psychotherapy.

At times patients lie consciously with the explicit intent of deceiving the therapist. The purpose may be secondary gain (e.g., exemption from jury duty, a supply of psychoactive drugs, a leave of absence from graduate school), in which case the person is malingering. Malingering is not a mental disorder in DSM-IV. More rarely a patient will explicitly lie not for any obvious external advantage but simply for whatever psychological benefit is conferred by assuming the sick role, in which case the person may have a factitious disorder, which is a DSM-IV mental disorder.

Because psychiatrists do not have recourse to biologic markers or other external validating criteria, the patient's report must be accepted as an honest statement of experience. There is no way to establish whether a person is experiencing auditory hallucinations other than through self-report. Nevertheless, an experienced clinician may detect subtle discrepancies, internal inconsistencies, or suspiciously atypical symptoms; these can certainly be queried without necessarily assuming that the patient is lying.

> A 29-year-old woman describes almost unremitting migraine headaches and is asking for narcotic pain medication.
>
> Patient: I really need your help. The pain is unbearable. I can't do anything anymore. I just want to lie in bed in a dark room with the cover pulled over my head.
>
> Doctor: That does sound miserable. But I'm struck by the fact that you obviously care about your appearance and have given some time and attention to your hair, makeup, and the way you are dressed. Was that despite the pain you have been describing?

Of course the examiner is more likely to be deceived during the initial diagnostic assessment than in an ongoing psychotherapy in which the therapist has much more knowledge of a patient's background, thinking, and functioning over time. It may be difficult to catch a practiced liar in an initial session. Arguably the interviewer should not try. Being lied to angers most people, certainly no less psychiatrists who must depend on trust to perform their work. However, believing a patient's lies is not a professional failure. Psychiatrists are trained to detect, understand, and treat psychopathology, not to function as lie detectors. While a certain level of suspicion is essential in the practice of psychiatry, the clinician determined never to be taken in by deceitful patients will approach patients with such exaggerated suspiciousness that therapeutic work is not possible.

Finally, not all patients' untruths are conscious lies. Patients with somotoform disorders such as conversion disorder or pain disorder are presumably unaware of the

emotional bases of their physical complaints. In describing their somatic symptoms they are stating a psychological reality, not attempting to deceive the interviewer.

Empathy A diagnostic interview often provides considerable relief to patients. Puzzling and sometimes frightening symptoms are framed in the context of medical understanding. Bizarre experiences can be rationally understood and intelligently organized in meaningful ways that allow us to make informed predictions about treatment response and recovery. Of equal importance to an intellectual understanding is our capacity to understand emotionally the experiences of our patients.

Empathy is an essential characteristic of psychiatrists, but it is not a universal human capacity. An incapacity for normal understanding of what other people are feeling appears to be central to the disturbance of certain personality disorders such as antisocial and narcissistic personality disorders. While empathy can probably not be created, it can be focused and deepened through training, observation, and self-reflection. It manifests in clinical work in a variety of ways. An empathic psychiatrist may anticipate what is felt before it is spoken and can often help patients articulate what they are feeling. Nonverbal cues such as body posture and facial expression are noted. Patients' reactions to the psychiatrist can be understood and clarified.

Patients sometimes say, “How can you understand me if you haven't gone through what I'm going through?,” but clinical psychiatry is predicated on the belief that it is not necessary to have other people's literal experiences to understand them. The shared experience of being human is often enough. Whether in an initial diagnostic setting or in an ongoing therapy, patients draw comfort from knowing that we are not mystified by their suffering.

SUGGESTED CROSS-REFERENCES

Section 9.3 deals with the typical signs and symptoms of psychiatric illness, Section 9.5 deals with neuropsychological and intellectual assessment of adults, and Section 9.8 deals with psychiatric rating scales. Similarly, Chapter 10, on the clinical manifestations of psychiatric disorders, is an essential correlate to interviewing and examining the patient. More-specialized focus is provided in Section 2.1, which deals with the clinical assessment and approach to diagnosis in neuropsychiatry. Section 3.1 on perception and cognition and Section 3.4 on the biology of memory amplify points made in this section. Section 29.1 includes more-detailed information on suicide, and Section 29.2 includes information on other psychiatric emergencies. Additional relevant information is found in Chapter 45, which deals with mood disorders and suicide in children and adolescents. Taking a developmental history implies familiarity with the aspects of normal and abnormal development; readers may find the following sections of special interest: Section 6.2 deals with Erik H. Erikson and his ideas about child and adult development; Chapter 32 deals extensively with normal development in children and adolescents; adult development is covered at great length in Chapter 50; and normal aging is the focus of Section 51.2c.

7.2 PSYCHIATRIC REPORT AND MEDICAL RECORD

BENJAMIN J. SADOCK, M.D.

PSYCHIATRIC REPORT

The psychiatric report is a written document that details the findings obtained from the psychiatric history and mental status examination. For those who prefer to use it, the report may follow the outline described in the previous section; however, it may also be formatted in other ways, providing all the pertinent data are recorded.

The psychiatric report includes a final summary of both positive and negative findings and an interpretation of the data. It has more than descriptive value; it has meaning that helps provide an understanding of the case. The examiner addresses critical questions in the report: Are future diagnostic studies needed and if so which ones? Is a consultant needed? Is a comprehensive neurological workup needed including an electroencephalogram or computerized tomography scan? Are psychological tests indicated? Are psychodynamic factors relevant? The report includes a diagnosis made according to the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), which uses a multiaxial classification scheme consisting of five axes, each of which should be covered (see Figure 9.1-1). A prognosis is also discussed in the report, with both good and bad prognostic factors listed. Finally, a treatment plan discusses and makes firm recommendations about management issues.

A detailed outline of the psychiatric report follows. It is one of the most comprehensive available, developed jointly by the author and Harold I. Kaplan.

I. **Psychiatric history**
   A. *Identification:* name, age, marital status, sex, occupation, language if other than English, race, nationality, and religion if pertinent; previous admissions to a hospital for the same or a different condition; with whom the patient lives
   B. *Chief complaint:* exactly why the patient came to the psychiatrist, preferably in the patient's own words; if that information does not come from the patient, note who supplied it
   C. *History of present illness:* chronological background and development of the symptoms or behavioral changes that culminated in the patient's seeking assistance; patient's life circumstances at the time of onset; personality when well; how illness has affected life activities and personal relations—changes in personality, interests, mood, attitudes toward others, dress, habits, level of tenseness, irritability, activity, attention, concentration, memory, speech; psychophysiological symptoms—nature and details of dysfunction; pain—location, intensity, fluctuation; level of anxiety—generalized and nonspecific (free floating) or specifically related to particular situations, activities, or objects; how anxieties are handled—avoidance, repetition of feared situation, use of drugs or other activities for alleviation
   D. *Past psychiatric and medical history:* (1) emotional or mental disturbances—extent of incapacity, type of treatment, names of hospitals, length of illness, effect of treatment; (2) psychosomatic disorders: hay fever, arthritis, colitis, rheumatoid arthritis, recurrent colds, skin conditions; (3) medical conditions: follow customary review of systems; sexually transmitted diseases; alcohol or other substance abuse; at risk for acquired immune deficiency syndrome (AIDS); (4) neurological disorders: headache, craniocerebral trauma, loss of consciousness, seizures or tumors
   E. *Family history:* Elicited from patient and from someone else, since quite different descriptions may be given of the same people and events; ethnic, national, and religious traditions; other people in the home, descriptions of them—personality and intelligence—and what has become of them since patient's childhood; descriptions of different households lived in; present relationships between patient and those who were in family; role of illness in the family; family history of mental illness; where does patient live—neighborhood and particular residence of the patient; is home crowded; privacy of family members from each other and from other families; sources of family income and difficulties in obtaining it; public assistance (if any) and attitude about it; will patient lose job or apartment by remaining in the hospital; who is caring for children
   F. *Personal history (anamnesis):* history of the patient's life from infancy to the present to the extent it can be recalled; gaps in history as spontaneously related by the patient; emotions associated with different life periods (painful, stressful, conflictual) or with phases of life cycle
      1. Early childhood (through age 3)
         a. Prenatal history and mother's pregnancy and delivery: Length of pregnancy, spontaneity and normality of delivery, birth trauma, whether patient was planned and wanted, birth defects
         b. Feeding habits: breast-fed or bottle-fed, eating problems
         c. Early development: maternal deprivation, language development, motor development, signs of unmet needs, sleep pattern, object constancy, stranger anxiety, separation anxiety
         d. Toilet training: age, attitude of parents, feelings about it
         e. Symptoms of behavior problems: thumb sucking, temper tantrums, tics, head bumping, rocking, night terrors, fears, bed wetting or bed soiling, nail biting, masturbation
         f. Personality and temperament as a child: shy, restless, overactive, withdrawn, studious, outgoing, timid, athletic, friendly patterns of play, reactions to siblings
         g. Early or recurrent dreams or fantasies
      2. Middle childhood (ages 3 to 11); early school history—feelings about going to school, early adjustment, gender identification, conscience development, punishment; social relationships, attitudes toward siblings and playmates
      3. Later childhood (prepuberty through adolescence)
         a. Peer relationships: number and closeness of friends, leader or follower, social popularity, participation in group or gang activities, idealized figures; patterns of aggression, passivity, anxiety, antisocial behavior
         b. School history: how far the patient went, adjustment to school, relationships with teachers—teacher's pet or rebellious—favorite studies or interests, particular abilities or assets, extracurricular activities, sports, hobbies, relationships of problems or symptoms to any school period
         c. Cognitive and motor development: learning to read and other intellectual and motor skills, minimal cerebral dysfunction, learning disabilities—their management and effects on the child
         d. Particular adolescent emotional or physical problems: nightmares, phobias, masturbation, bed wetting, running away, delinquency, smoking, drug or alcohol use, weight problems, feeling of inferiority
         e. Psychosexual history
            i. Early curiosity, infantile masturbation, sex play
            ii. Acquiring of sexual knowledge, attitude of parents toward sex, sexual abuse
            iii. Onset of puberty, feelings about it, kind of preparation, feelings about menstruation, development of secondary sexual characteristics
            iv. Adolescent sexual activity: crushes, parties, dating, petting, masturbation, wet dreams and attitudes toward them
            v. Attitudes toward same and opposite sex: timid, shy, aggressive, need to impress, seductive, sexual conquests, anxiety
            vi. Sexual practices: sexual problems, homosexual and heterosexual experiences, paraphilias, promiscuity
         f. Religious background: strict, liberal, mixed (possible conflicts), relationship of background to current religious practices
      4. **Adulthood**
         a. Occupational history: choice of occupation, training, ambitions, conflicts; relations with authority, peers, and subordinates; number of jobs and duration; changes in job status; current job and feelings about it
         b. Social activity: whether patient has friends or not; is he or she withdrawn or socializing well; social, intellectual, and physical interests; relationships with same sex and opposite sex; depth, duration, and quality of human relations
         c. Adult sexuality
            i. Premarital sexual relationships, age of first coitus, sexual orientation

ii. Marital history: common-law marriages, legal marriages, description of courtship and role played by each partner, age at marriage, family planning and contraception, names and ages of children, attitudes toward raising children, problems of any family members, housing difficulties if important to the marriage, sexual adjustment, extramarital affairs, areas of agreement and disagreement, management of money, role of in-laws
iii. Sexual symptoms: anorgasmia, impotence, premature ejaculation, lack of desire
iv. Attitudes toward pregnancy and having children; contraceptive practices and feelings about them
v. Sexual practices: paraphilias such as sadism, fetishes, voyeurism, attitude toward fellatio, cunnilingus; coital techniques, frequency

d. Military history: general adjustment, combat, injuries, referral to psychiatrists, type of discharge, veteran status
e. Value systems: whether children are seen as a burden or a joy; whether work is seen as a necessary evil, an avoidable chore, or an opportunity; current attitude about religion; belief in heaven and hell

II. **Mental status**

Sum total of the examiner's observations and impressions derived from the initial interview

A. *Appearance*
1. Personal identification: May include a brief nontechnical description of the patient's appearance and behavior as a novelist might write it. Attitude toward examiner can be described here: cooperative, attentive, interested, frank, seductive, defensive, hostile, playful, ingratiating, evasive, guarded
2. Behavior and psychomotor activity: gait, mannerisms, tics, gestures, twitches, stereotypes, picking, touching examiner, echopraxia, clumsy, agile, limp, rigid, retarded, hyperactive, agitated, combative, waxy
3. General description: posture, bearing, clothes, grooming, hair, nails; healthy, sickly, angry, frightened, apathetic, perplexed, contemptuous, ill at ease, poised, old looking, young looking, effeminate, masculine; signs of anxiety—moist hands, perspiring forehead, restlessness, tense posture, strained voice, wide eyes; shifts in level of anxiety during interview or with particular topic

B. *Speech:* rapid, slow, pressured, hesitant, emotional, monotonous, loud, whispered, slurred, mumbled, stuttering, echolalia, intensity, pitch, ease, spontaneity, productivity, manner, reaction time, vocabulary, prosody

C. *Mood and affect*
1. Mood (a pervasive and sustained emotion that colors the person's perception of the world): how does patient say he or she feels; depth, intensity, duration, and fluctuations of mood—depressed, despairing, irritable, anxious, terrified, angry, expansive, euphoric, empty, guilty, awed, futile, self-contemptuous, anhedonic, alexithymic
2. Affect (the outward expression of the patients inner experiences): how examiner evaluates patient's affects—broad, restricted, blunted or flat, shallow, amount and range of expression; difficulty in initiating, sustaining, or terminating an emotional response; is the emotional expression appropriate to the thought content, culture, and setting of the examination; give examples if emotional expression is not appropriate

D. *Thinking and perception*
1. Form of thinking
   a. Productivity: overabundance of ideas, paucity of ideas, flight of ideas, rapid thinking, slow thinking, hesitant thinking; does patient speak spontaneously or only when questions are asked, stream of thought, quotations from patient
   b. Continuity of thought: whether patient's replies really answer questions and are goal directed, relevant, or irrelevant; loose associations; lack of cause-and-effect relationships in patient's explanations; illogical, tangential, circumstantial, rambling, evasive, perseverative statements, blocking or distractibility
   c. Language impairments: impairments that reflect disordered mentation, such as incoherent or incomprehensible speech (word salad), clang associations, neologisms
2. Content of thinking
   a. Preoccupations: about the illness, environmental problems; obsessions, compulsions, phobias; obsessions or plans about suicide, homicide; hypochondriacal symptoms, specific antisocial urges or impulses
3. Thought disturbances
   a. Delusions: content of any delusional system, its organization, the patient's convictions as to its validity, how it affects his or her life; persecutory delusions—isolated or associated with pervasive suspiciousness; mood-congruent or mood-incongruent
   b. Ideas of reference and ideas of influence: how ideas began, their content, and the meaning the patient attributes to them
4. Perceptual disturbances
   a. Hallucinations and illusions: whether patient hears voices or sees visions; content, sensory system involvement, circumstances of the occurrence; hypnagogic or hypnopompic hallucinations; thought broadcasting
   b. Depersonalization and derealization: extreme feelings of detachment from self or from the environment
5. Dreams and fantasies
   a. Dreams: prominent ones, if patient will tell them; nightmares
   b. Fantasies: recurrent, favorite, or unshakable daydreams

E. *Sensorium*
1. Alertness: awareness of environment, attention span, clouding of consciousness, fluctuations in levels of awareness, somnolesence, stupor, lethargy, fugue state, coma
2. Orientation
   a. Time: whether patient identifies the day correctly; or approximate date, time of day; if in a hospital, knows how long he or she has been there; behaves as though oriented to the present
   b. Place: whether patient knows where he or she is
   c. Person: whether patient knows who the examiner is and the roles or names of the persons with whom in contact
3. Concentration and calculation: subtracting 7 from 100 and keep subtracting 7s; if patient cannot subtract 7s, can easier tasks be accomplished—4 × 9; 5 × 4; how many nickels are in $1.35; whether anxiety or some disturbance of mood or concentration seems to be responsible for difficulty
4. Memory: impairment, efforts made to cope with impairment—denial, confabulation, catastrophic reaction, circumstantiality used to conceal deficit; whether the process of registration, retention, or recollection of material is involved
   a. Remote memory: childhood data, important events known to have occurred when the patient was younger or free of illness, personal matters, neutral material
   b. Recent past memory: past few months
   c. Recent memory: past few days, what did patient do yesterday, the day before, have for breakfast, lunch, dinner
   d. Immediate retention and recall: ability to repeat six figures after examiner dictates them—first forward, then backward, then after a few minutes' interruption; other test questions; did same questions, if repeated, call forth different answers at different times
   e. Effect of defect on patient: mechanisms patient has developed to cope with defect
5. Fund of knowledge: level of formal education and self-education; estimate of the patient's intellectual capability and whether capable of functioning at the level of his or her basic endowment; counting, calculation, general knowledge; questions should have relevance to the patient's educational and cultural background
6. Abstract thinking: disturbances in concept formation; manner in which the patient conceptualizes or handles his or her ideas; similarities (e.g., between apples and pears), differences, absurdities; meanings of simple proverbs, such as, “A rolling stone gathers no moss,”; answers may be concrete (giving specific examples to illustrate the meaning) or overly abstract (giving generalized explanation); appropriateness of answers
7. Insight: degree of personal awareness and understanding of illness
   a. Complete denial of illness
   b. Slight awareness of being sick and needing help but denying it at the same time
   c. Awareness of being sick but blaming it on others, on external factors, on medical or unknown organic factors
   d. Intellectual insight: admission of illness and recognition that symptoms or failures in social adjustment are due to irrational feelings or disturbances, without applying that knowledge to future experiences
   e. True emotional insight: emotional awareness of the motives and feelings within, of the underlying meaning of symptoms; does the awareness lead to changes in personality and future behavior; openness to new ideas and concepts about self and the important people in his or her life
8. Judgment
   a. Social judgment: subtle manifestations of behavior that are harmful to the patient and contrary to acceptable behavior in the culture; does the patient understand the likely outcome of personal behavior and is patient influenced by that understanding; examples of impairment
   b. Test judgment: patient's prediction of what he or she would do in imaginary situations; for instance, what patient would do with a stamped, addressed letter found in the street

III. **Further diagnostic studies**

A. Physical examination

B. Neurological examination
C. Additional psychiatric diagnostic interviews
D. Interviews with family members, friends, or neighbors by a social worker
E. Psychological, neurological, or laboratory tests as indicated: electroencephalogram, computed tomography scan, magnetic resonance imaging, tests of other medical conditions, reading comprehension and writing tests, test for aphasia, projective or objective psychological tests, dexamethasone-suppression test, 24-hour urine test for heavy metal intoxication, urine screen for drugs of abuse

IV. **Summary of findings**

Mental symptoms, medical and laboratory findings, and psychological and neurological test results, if available, are summarized. Include medications patient has been taking, dosage, duration.

Clarity of thinking is reflected in clarity of writing. When summarizing the mental status, for example, the phrase “Patient denies hallucinations and delusions” is not as precise as “Patient denies hearing voices or thinking that he is being followed.” The latter indicates the specific question asked and the specific response given. Similarly in the conclusion of the report one would write “Hallucinations and delusions were not elicited.”

V. **Diagnosis**

Diagnostic classification is made according to DSM-IV, which uses a multiaxial classification scheme consisting of five axes, each of which should be covered in the diagnosis

Axis I: clinical syndromes (e.g., mood disorders, schizophrenia, generalized anxiety disorder) and other conditions that may be a focus of clinical attention

Axis II: personality disorders, mental retardation, and defense mechanisms

Axis III: any general medical conditions (e.g., epilepsy, cardiovascular disease, endocrine disorders)

Axis IV: psychosocial and environmental problems (e.g., divorce, injury, death of a loved one) relevant to the illness

Axis V: global assessment of functioning exhibited by the patient during the interview (e.g., social, occupational, and psychological functioning); a rating scale with a continuum from 100 (superior functioning) to 1 (grossly impaired functioning) is used

VI. **Prognosis**

Opinion about the probable future course, extent, and outcome of the disorder; good and bad prognostic factors; specific goals of therapy

VII. **Psychodynamic formulation**

Causes of the patient's psychodynamic breakdown—influences in the patient's life that contributed to present disorder, environmental, genetic, and personality factors relevant to determining patient's symptoms; primary and secondary gains; outline of the major defense mechanism used by the patient

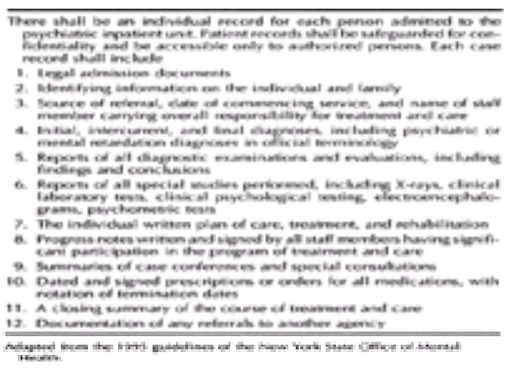
VIII. **Comprehensive treatment plan**

Modalities of treatment recommended, role of medication, inpatient or outpatient treatment, frequency of sessions, probable duration of therapy; type of psychotherapy; individual, group, or family therapy; symptoms or problems to be treated. Initially, treatment must be directed toward any life-threatening situations such as suicidal risk or risk of danger to others, which require psychiatric hospitalization. Danger to self or others is an acceptable reason (both legally and medically) for involuntary hospitalization. In the absence of the need for confinement, a variety of outpatient treatment alternatives are available: day hospitals, supervised residences, outpatient psychotherapy or pharmacotherapy among others. In some cases, treatment planning must attend to vocational and psychosocial skills training and even legal or forensic issues. Comprehensive treatment planning requires a therapeutic team approach using the skills of psychologists, social workers, nurses, activity and occupational therapists, and a variety of other mental health professionals, with referral to self-help groups (e.g., Alcoholics Anonymous [AA]) if needed. If either the patient or family members are unwilling to accept the recommendations of treatment and the clinician thinks that the refusal of the recommendations may have serious consequences, the patient, parent, or guardian should sign a statement to the effect that the recommended treatment was refused.

MEDICAL RECORD

The psychiatric report is a part of the medical record; however, the medical record is more than the psychiatric report. It is a narrative that documents all events that occur during the course of treatment, most often referring to the patient's stay in the hospital. Progress notes record every interaction between doctor and patient, reports of all special studies including laboratory tests, and prescriptions and orders for all medications. Nurses' notes help describe the patient's course: Is the patient beginning to respond to treatment? Are there times during the day or night when symptoms get worse or remit? Are there adverse effects or complaints by the patient about prescribed medication? Are there signs of agitation, violence, or mention of suicide? If the patient requires restraints or seclusion are the proper supervisory procedures being followed? Taken as a whole, the medical record tells what happened to the patient since first making contact with the health care system. It concludes with a discharge summary that provides a concise overview of the patient's course with recommendations for future treatment, if necessary. Evidence of contact with a referral agency should be documented in the medical record to establish continuity of care if further intervention is necessary.

Use of the Record The medical record is not only used by physicians but is also used by regulatory agencies and managed care companies to determine length of stay, quality of care, and reimbursement to doctors and hospitals. In theory, the inpatient medical record is accessible to authorized persons only and is safeguarded for confidentiality. In practice however, absolute confidentiality cannot be guaranteed. Guidelines for what material needs to be incorporated into the medical record are given in Table 7.2-1.



There shall be an individual record for each person admitted to the psychiatric inpatient unit. Patient records shall be safeguarded for confidentiality and be accessible only to authorized persons. Each case record shall include

1. Legal admission documents
2. Identifying information on the individual and family
3. Source of referral, date of commencing service, and name of staff member carrying overall responsibility for treatment and care
4. Initial, intercurrent, and final diagnoses, including psychiatric or mental retardation diagnoses in official terminology
5. Reports of all diagnostic examinations and evaluations, including findings and conclusions
6. Reports of all special studies performed, including X-rays, clinical laboratory tests, clinical psychological testing, electroencephalograms, psychometric tests
7. The individual written plan of care, treatment, and rehabilitation
8. Progress notes written and signed by all staff members having significant participation in the program of treatment and care
9. Summaries of case conferences and special consultations
10. Dated and signed prescriptions or orders for all medications, with notation of termination dates
11. A closing summary of the course of treatment and care
12. Documentation of any referrals to another agency

Adapted from the 1981 guidelines of the New York State Office of Mental Health.

Table 7.2-1 Medical Record

The medical record is also crucial in malpractice litigation. Robert I. Simon summarized the liability issues as follows:

> Properly kept medical records can be the psychiatrist's best ally in malpractice litigation. If no record is kept, numerous questions will be raised regarding the psychiatrist's competence and credibility. This failure to keep medical records may also violate state statutes or licensing provisions. Failure to keep medical records may arise out of the psychiatrist's concern that patient treatment information be totally protected. Although this is an admirable ideal, in real life the psychiatrist may be legally compelled under certain circumstances to testify directly about confidential treatment matters.

Outpatient records are also subject to scrutiny by third parties under certain circumstances, and psychiatrists in private practice are under the same obligation to

maintain a record of the patient in treatment as the hospital psychiatrist. Table 7.2-2 lists documentation issues of concern to third-party payers.

Table 7.2-2 Documentation Issues*

Personal Notes and Observations According to laws relating to access to medical records, some jurisdictions (such as in the Public Health Law of New York State) have a provision that applies to a physician's personal notes and observations. Personal notes are defined as “a practitioner's speculations, impressions (other than tentative or actual diagnosis) and reminders.” The data are maintained only by the clinician and cannot be disclosed to any other person. Psychiatrists concerned about material that may prove damaging or otherwise hurtful to the patient if released to a third party may consider using this provision to maintain doctor-patient confidentiality.

Patient Access to Records Patients have a legal right to access their medical records. This right represents society's belief that the responsibility for medical care has become a collaborative process between doctor and patient. Patients see many different physicians, and they can be more effective historians and coordinators of their own care with such information.

Psychiatrists must be careful in releasing their records to the patient if, in their judgment, the patient can be harmed emotionally as a result. Under these circumstances, the psychiatrist may choose to prepare a summary of the patient's course of treatment, holding back material that might be hurtful—especially if it were to get into the hands of third parties. In malpractice cases, however, it may not be possible to do so.

> An 18-year-old man claimed that he was refused admission to college because he indicated on his application that he had once seen a psychiatrist. In fact, that was not the reason admission was denied; nevertheless, he sued the school on those grounds. At trial it was revealed that he had been hospitalized on several occasions for severe psychotic episodes, some of which were associated with suicide attempts. The defendant school psychiatrist suggested to the judge that it might be harmful to the patient if he were present when excerpts of his psychiatric record were read aloud in the courtroom. The judge agreed, but the man's attorneys objected, and he was permitted to remain. Extensive narratives of his life and complex diagnostic evaluations of psychosis by various psychiatrists from different institutions were read. He became visibly upset during this process and began to attack his attorneys verbally. The court proceeding had to be interrupted.

Problem-Oriented Medical Record In 1969 Lawrence L. Weed published *Medical Records, Medical Education and Patient Care* in which he described the problem-oriented medical record. The problem-oriented medical record lists all health problems discovered in the initial workup. Problem areas are added to and corrected over time. Active problems are listed in one column, and as they are resolved, they are transferred to an inactive column. Progress notes are dated, titled, and numbered according to the problem list. As a final check, the record is audited for thoroughness, reliability, efficiency, and standards of treatment and outcome.

Problem-Oriented Record in Medical Education Many medical schools are using educational techniques based upon the problem-oriented medical record. Teaching and testing organizations such as the United States Medical Licensing Examination (USMLE) are relying on the ability of a student to deal with a problem-oriented medical record as an evaluation tool. In such exercises, students are provided with general patient information, which may include a summary of the physical examination and positive elements in the psychiatric report. Students must delineate the problem areas that need attention, determine preventive or treatment options for each problem, and understand the patient from biological, social, and psychological points of view.

Although the problem-oriented medical record is not the standard format used by psychiatrists, it has influenced how patients are viewed. For example, in DSM-IV, specific psychosocial and environmental problems that may affect diagnosis of mental disorders are recorded on Axis IV. The problems are divided into nine categories that can each affect the person adversely: (1) problems with primary support group (e.g., death of family member), (2) problems related to the social environment (e.g., absence of friends), (3) educational problems (e.g., discord with teachers or classmates), (4) occupational problems (e.g., stress at work), (5) housing problems (e.g., unsafe neighborhood), (6) economic problems (e.g., excess debt), (7) problems with access to health care services (e.g. no health insurance), (8) problems with the legal system (e.g., litigation), and (9) other problems (e.g., floods, earthquakes).

> A 55-year-old married man complains of being fearful that he will be forced to resign from an administrative job because his company is being downsized. He complains of anxiety, insomnia, and irritability and gives no history of previous dysphoric states. After a thorough evaluation it becomes apparent that the proximate cause of his symptoms is the probability of losing his job. Symptom removal is relatively simple with the aid of anxiolytic or hypnotic drugs; however, a more comprehensive approach is required. The therapist has to attend to the occupational problem that might include having the patient confront his superiors, applying for reassignment to another area within the company, seeking other employment, evaluating his assets for early retirement, job retraining, or other approaches directed toward the vocational crisis.

EVALUATION AND MANAGEMENT (E/M) SERVICE GUIDELINES

In addition to the classical psychiatric report described above, physicians (including psychiatrists) are being asked to follow documentation guidelines for evaluation and management services (E/M) developed jointly by the American Medical Association (AMA) and the Health Care Financing Administration (HCFA). The E/M guidelines were developed to help doctors record and document one of the more than 2000 diagnostic codes listed in International Classification of Diseases, 9th Revision, Clinical Modifications (ICD-9-CM) and DSM-IV. In 1989 physicians and other health care professionals were required to report ICD codes when billing Medicare, Medicaid, and private insurance carriers for reimbursement to doctors, hospitals, and patients.

Reason for E/M Guidelines Guidelines were developed to correct purported deficiencies in the reporting of health care services by hospitals and physicians. Audits in 1995 and 1996 by the Health Care Financing Administration (HCFA) alleged that over 23 billion dollars was overpaid to teaching hospitals and related facilities, which amounted to 14 percent of Medicare Part B fee-for-service payments.

Levels of Service There are four levels of E/M service depending on the types of history and type of examination. The types of history and examination that relate to each level are (1) *problem focused*—brief history of present illness, limited examination of the affected body area or organ systems; (2) *expanded problem focused*—brief history of present illness, review of systems pertinent to problem, limited examination of the affected body area or organ system and related organ system; (3) *detailed*—extended history of present illness, extended review of systems, pertinent past family and social history, extended examination of the affected body area and related organ systems; (4) *comprehensive*—extended history of present illness, extended review of systems, complete past family and social history, and a general multisystem examination or complete examination of a single organ system. Table 7.2-3 summarizes the four levels of service and their requirements.

Level of E/M Service	Chief Complaint	History of Present Illness	Review of Systems	Past/Family/Social History	Physical Examination*
1. Problem focused	Yes	Brief	N/A†	N/A	Limited
2. Expanded problem focused	Yes	Brief	Pertinent problem	N/A	Limited
3. Detailed	Yes	Extended	Extended	Pertinent	Extended
4. Comprehensive	Yes	Extended	Complete	Complete	Extended

*For psychiatrists, the mental status examination is equivalent to the physical examination; however, vital signs should be taken, if indicated.
†N/A, not applicable.

Table 7.2-3 Level of Evaluation and Management (E/M) Services

E/M and Psychiatry Psychiatrists are expected to use the E/M guidelines with some modifications. The guidelines assume appropriately that psychiatrists are expert in, and will spend most of their time performing, a psychiatric history and mental status examination. The E/M requirements for psychiatry are listed in Table 7.2-4. Psychiatrists are not expected to perform an extensive physical examination. The physical examination is relevant only as it pertains to the psychiatric problem and may include measurement of blood pressure and pulse, especially if the patient is taking medication. It also includes an assessment of the patient's general appearance including nutritional status, body habitus, presence of gross physical deformities, and attention to grooming. Demented patients, for example, often are unkempt. Depressed patients may exhibit stooped posture and a furrowed brow. Abnormal movements such as tics may reflect dystonic reactions to dopaminergic receptor antagonists such as chlorpromazine (Thorazine). Psychiatrists are not expected to examine organ systems, nor are they expected to perform a neurological examination. The patient should be referred to an internist or specialist (e.g., gynecologist) if special physical examinations are indicated on the basis of the history or review of systems.

- Description of speech including rate, volume, articulation, coherence, and spontaneity with notation of abnormalities (e.g., perseveration, paucity of language)
- Description of thought processes including rate of thoughts, content of thoughts (e.g., logical vs. illogical, tangential), abstract reasoning, and computation
- Description of associations (e.g., loose, tangential, circumstantial, intact)
- Description of abnormal or psychotic thoughts including hallucinations, delusions, preoccupation with violence, homicidal or suicidal ideation, and obsessions
- Description of the patient's judgment (e.g., concerning everyday activities and social situations) and insight (e.g., concerning psychiatric condition)

Complete mental status examination including

- Orientation to time, place, and person
- Recent and remote memory
- Attention span and concentration
- Language (e.g., naming objects, repeating phrases)
- Fund of knowledge (e.g., awareness of current events, past history, vocabulary)
- Mood and affect (e.g., depression, anxiety, agitation, euphoria, lability)

Content and documentation requirements

Level of examination	Perform and document
Problem focused	One to five elements identified by a bullet†
Expanded problem focused	At least six elements identified by a bullet†
Detailed	At least nine elements identified by a bullet†
Comprehensive	Perform all elements identified by a bullet†

† The areas covered in this examination have been established by many practitioners as being the most frequently used and most valuable for beginning medical students that for experienced clinicians who can rule in positive and negative findings without rigidly following a formal outline.
From American Medical Association and Health Care Financing Administration (1995).

Table 7.2-4 Elements of Examination in Psychiatry*

Psychiatrists may be expected to conduct a review of systems that seeks to identify signs or symptoms that the patient may be experiencing. In a brief problem-focused examination this is not required; however, in a comprehensive examination all bodily systems are reviewed. Table 7.2-5 lists a symptom review with examples about which the psychiatrist may inquire.

- Constitutional symptoms: Fever, weight loss, nutritional status
- Eyes: Visual acuity, diplopia
- Ears, nose, mouth, throat: Hearing, tinnitus, tonsillitis, twitching, mouth movements
- Cardiovascular: Dyspnea, palpitations, edema, leg or chest pain
- Respiratory: Hemoptysis, wheezing
- Gastrointestinal: Nausea, vomiting, melena, constipation, diarrhea, use of laxatives
- Genitourinary: Frequency, pain on urination, hematuria, difficulty starting stream, sexual problems
- Musculoskeletal: joint pain, limitation in range of motion, balance
- Integumentary (skin and/or breast): Moles, lumps, rashes
- Neurological: Vertigo, paralysis, paresthesia, syncope
- Endocrine: Changes in weight, nervousness, fatigue, menstrual history
- Hematologic and lymphatic: Bleeding, bruising, nosebleeds
- Allergic and immunological: Asthma, drug reactions, frequency of colds or infections

Table 7.2-5 Review of Systems

Critique of E/M Guidelines Many physicians complain that the E/M guidelines are extremely complex and that proper compliance with documentation takes time away from patient care. One 50-page HCFA publication explaining how to use the guidelines has been criticized as being useful for medical students just learning how to interview patients but unnecessary for experienced physicians who can document positive and negative findings accurately and succinctly. A work group of the American College of Physicians working with the HCFA and the AMA concluded in 1998:

> All of us recognize the need for Medicare carriers to....examine what we do. There has got to be a way to realistically record what you do in the office—but not to do it in the bureaucratic monstrosity whose only aim is documentation.

As a result of such criticism, the HCFA has placed the guidelines on hold; however, some private insurers are currently using them. With some modifications they will be mandated for use eventually in all specialties, including psychiatry.

CASE REPORT

The case report (also known as the case study) has an honored place in the history of psychiatry and in the advancement of medical knowledge. Single case studies are included in most medical and psychiatric journals, and they continue to provide a wealth of data about both common and uncommon conditions. Critics believe that case studies suffer from methodological flaws, since one cannot generalize from a single case study to a population at large, but authors of case reports rarely, if ever, make that claim. Rather, they limit themselves to objective, reliable reporting and the presentation of facts. Any hypothesis offered is usually tentative and conditional upon further testing.

With the rise of pharmacotherapy, case studies have assumed growing importance. The single case is of little value in the development of drugs; large samples studied over long periods of time are necessary to determine the efficacy and safety of a drug; however, the literature is replete with single case studies that signaled adverse drug reactions or new uses for an established drug.

The literature is also replete with reports by physicians and other researchers who used themselves as subjects of experiments. The many reports by doctors of their personal experience with illness are sobering reminders to the rest of the profession of what it means to be a patient. Sigmund Freud developed his theory of dream interpretation on the basis of his own dreams, and Jean Piaget derived the theories of cognition in children from observing his own children. William Beaumont demonstrated the relationship between human gastric functions and various emotional states in his patient Alexis St. Martin who had a gastric fistula that resulted

from a gunshot wound.

Below is a chronology of 86 famous “named” cases in psychiatry that date from 1577 to 1980. These single cases were culled from the literature by David Davis, Professor Emeritus in Psychiatry at the University of Missouri–Columbia School of Medicine. Some cases are of greater interest or importance than others, but all contributed to the slow, steady advance of psychiatric knowledge over the centuries.

1577 *Barbara Kremers*—10-year-old girl alleged to have fasted for 6 months; a possible instance of malingering. She was treated by Johann Weyer and reported in detail.

1622 *William Perry, the Boy of Bilson*—A 13-year-old boy who produced black urine. He eventually admitted to mixing his urine with ink, which illustrates how the concept of simulated disease was confused with witchcraft. Described by Richard Baddeley.

1774 *Fraulein Oesterlin*—Anton Mesmer treated her with magnets and developed the notion that the magnetic effect came from magnetic fluid emanating from his own person, an effect he called animal magnetism.

1775 *Maria-Theresa Paradis*—A blind musician treated by Mesmer whose sight was restored only in his presence then was lost again, presumably related to the effects of secondary gain.

1774–1824 *Katherina Emmerich*—A woman who had visions and displayed the stigmata of Christ's Passion. Described in detail by Clemens Brentano.

1785 *Victor Race*—Treated by Armand-Marie-Jacques de Chastenet, Marquis de Puységur, who magnetized him into an artificial somnambulism in which the patient could diagnose his own disease and describe its course. Puységur believed that cure resulted from the effect of the magnetizer's will rather than from magnetic fluid.

1788 *King George III*—A detailed review of his five episodes of illness documented over 58 years tends to substantiate the view that he suffered from a classic case of porphyria.

1799 *Victor, the Wild Boy of Aveyron*—A feral child discovered in a tree when he was 12 years old. Considered by Pinel to be incurably retarded but treated by Jean Marc Gaspard Itard.

1811 *Wild Peter of Hanover*—Was found wandering alone at age 12. Considered to be a specimen of true “natural man.” Reported by Blumenbach.

1815 *Mary Reynolds*—A person with dual personality known as “La dame de MacNish” said to have been described by John Kearsley Mitchell, the father of Weir Mitchell.

1826 *Friederiche Hauffe*—Also known as “The Seeress of Prevorst,” she was treated by Justinus Kerner with magnetic trances. During one trance she devised a “nerve-tuner” that Kerner then built and used in his treatment.

1832 *Kaspar Hauser*—A “feral” boy who appeared at the gates of Nuremberg in 1828. Described by Anselm Ritter von Feuerbach.

1836–1837 *Estelle L'Hardy*—Known as “La petite ressuscitée,” she was treated by Antoine Despine, Sr. During magnetic treatment, another personality emerged that apparently was the healthy one, which eventually became the dominant personality.

1842–1843 *Gottliebin Dittus*—A woman treated with exorcism by Johann Christoph Blumhardt. Comparisons have been drawn between his method and that used in the psychotherapy of patients with severe schizophrenia.

1843 *Daniel M'Naghten*—Glasgow paranoia patient who was tried for the willful murder of Edward Drummond, the private secretary to Sir Robert Peel. The questions put to the judges by the House of Lords were the basis for the M'Naghten Rules.

1858–1893 *Félida X*.—A patient with dual personality studied by Eugéne Azam and described as “dedoublement de la personnalité” in whom the first personality was not aware of the second personality while the second personality was aware of both.

1868 *Phineas Gage*—The first description of “frontal lobe syndrome,” presented by J. M. Harlow to the Massachusetts Medical Society. During a blasting operation in 1848 a long iron rod was driven through Gage's skull pushing out a cylindrical mass of gray matter from the left hemisphere. He survived for 20 years after the original accident.

1885 *Leonie*—A patient with multiple personality studied by Pierre Janet who found that she could be hypnotized from a distance and that the personality that emerged under hypnosis was a reenactment of previous hypnotic experiments.

1886 *Lucie*—Patient in the first case of cathartic cure that Pierre Janet published. He used hypnosis and automatic writing and described the nature of the rapport.

1888 *Blanche Wittman*—One of Charcot's most renowned subjects, known as “la reine des hysteriques.” She demonstrated Charcot's three stages of hypnosis and was later treated by Jules Janet (the brother of Pierre), at which time another personality emerged under hypnosis.

1889 *Marie*—Patient in Pierre Janet's second case of cathartic cure in which he demonstrated the importance of fixed subconscious ideas and the role they played in illness.

1889 *Emmy Von N*.—Sigmund Freud's first use of cathartic treatment. It was his first attempt to work with Breuer's method, differing only in having the patient recall the initial traumatic event under hypnosis, after which the patient had to suggest that the symptom disappear.

1890 *Achilles*—A patient with demoniacal possession cured by Pierre Janet by unraveling the fixed subconscious ideas.

1891–1893 *Madame D*.—The patient around whom Charcot developed his concept of dynamic amnesia as distinct from organic amnesia. She was also treated by Pierre Janet who encouraged her to talk freely under hypnosis to dissolve her fixed ideas.

1891 *Marcelle*—A patient illustrating psychological analysis and synthesis using hypnosis and automatic writing, described by Pierre Janet.

1891 *Ansel Bourne*—An early multiple personality patient with mutual amnesia for each personality. Bourne was examined by William James and described by Richard Hodgson.

1892 *Lucie R*.—A girl with an olfactory hallucination treated by *Sigmund Freud* by means of catharsis.

1892 *Katherina*—A girl with difficulty breathing, headache, and anxiety attacks related to early sexual trauma, described by Freud.

1892 *Elizabeth Von R*.—The patient who suggested Freud's technique of “free association,” which is described in the report.

1894 *Hélene Smith*—A medium whose real name was Catherine-Elise Muller. She was described by Theodore Flournoy, who used her to demonstrate the importance of forgotten childhood memories and the reversion to various stages of childhood in the patient's fantasies and suggested that these expressed secret wishes.

1894 *Justine*—A celebrated patient with a morbid fear of cholera cured by Janet with his method of analysis of fixed ideas.

1895 *Mr. N*.—A patient with hysterical amnesia treated under hypnosis by Auguste Forel.

1895 *Anna O*.—The patient, whose real name was Bertha Pappenheim, treated by Josef Breuer for a variety of hysterical symptoms including dual personality in 1881. This case convinced Freud of the power of unconscious memories and suppressed affects in hysteria. Reputedly her production of pseudocyesis was responsible for Breuer's lack of further exploration of the unconscious with Freud.

1895 *Irma*—The patient about whom Freud had his “dream of Irma's injection.” This is the first dream that he analyzed fully with his new technique of associations and recognized as a wish fulfillment.

1896–1904 *Madeleine*—A patient followed by Janet for 25 years. She walked on tiptoe, was subject to hysterical delusions, and showed the stigmata of the Passion. Based on her material Janet developed his theory of emotions and concepts of religious psychology.

1898 *Miss Beauchamp*—A patient whose eventual emergence of four personalities may have been unconsciously suggested by the investigator, Morton Prince. During treatment he succeeded in synthesizing one personality from them.

1899 *Hélène Preiswerk*—Carl Gustav Jung's cousin, a medium on whom he made observations that became the subject of his dissertation in 1902. During semisomnambulistic states a personality named Ivenes emerged, which Jung considered to be the adult personality of the medium.

1900 *Meb*—A patient with hysterical hallucinations with mystical and erotic themes treated by Janet with hypnosis, somewhat similar to the case of Achilles.

1902 *Irène*—Another patient with hysterical disturbance, somnambulistic crisis, hallucinations, and amnesia. During her treatment Janet found that hypnotic treatment had to be supplemented with mental stimulation and reeducation.

1903 *Nadia*—A girl obsessed by the fear of becoming fat (related to fear of rejection) treated by Janet and showing some resemblance to Binswanger's Ellen West.

1905 *Dora*—Patient with a complex hysterical cough treated by Sigmund Freud in 1900 using dream interpretation. The intricacies of the interpersonal relationships are described as well as mental mechanisms, including the therapeutic importance of transference.

1906 *Miss Frank Miller*—A patient prone to hypnagogic experiences who was reported by Flournoy. Jung later based his interpretations of mythology and history of religion on this account. By applying these ideas to his own fantasies he developed his notions of anima and self.

1908 *Little Hans*—A 4-year-old boy with horse phobia who was treated by Freud through the boy's father. This is the first case of child analysis and the first control analysis. It elucidated the mechanism of displacement and contributed to libido theory. Hans was later reputed to have become the famous opera impresario Rudolph Bing.

1909 *The Rat Man*—A patient with obsessional neurosis described by Freud. The patient was preoccupied with the idea of rats in the East that bored into his anus as punishment.

1909 *Hersilie Rouy*—The subject of two autobiographies depicting delusional claims of royal birth. Described by Paul Serieux and Joseph Capgras.

1911 *Daniel Paul Schreber*—Freud attempted a pathography based on Schreber's description of his delusion and on legal reports about him, and developed a theory of repressed homosexuality to account for Schreber's paranoid illness.

1916 *Doris Fisher*—A patient with five personalities described by Walter Franklin Prince.

1918 *The Wolf-Man*—A patient who suffered from lack of will-power treated by Freud and later by Ruth Mack Brunswick. He had a terrifying dream of wolves at age 3½. This case helped Freud understand countertransference.

1920 *Albert B*.—A 9-month-old child who was conditioned by J. B. Watson and R. Raynor to fear a rat.

1924 *Erna*—A 6-year-old child analyzed by use of play therapy. Reported by Melanie Klein.

1925 *Gregor Adamsberger*—A patient used by Theodore Reik to elucidate the unconscious facts traceable in the psychopathology of judicial error.

1925 *Elena F*.—A patient with dual personalities, one French, one Italian, which G. E. Morselli attempted to fuse. As a result of treatment, her psychotic symptoms disappeared. Described by Henri F. Ellenberger as perhaps the most remarkable case of multiple personality ever published.

1925 *Peter*—A boy with fear of a playroom rabbit who J. B. Watson treated by reconditioning.

1927 *Amala and Kamala*—Two feral children raised together in a den of wolves. First described by P. C. Squires.

1933 *Ikara*—A patient who reputedly described memories from a previous life; reported by Max Bircher-Benner.

1933 *Charles Poultney*—A patient with mutually amnestic multiple personality described by S. I. Franz.

1935 *Bill W*.—An autobiography of the founder of AA.

1941 *Isabelle*—A child who learned to speak after 6½ years of silence. Reported by Marie Mason.

1942 *Herbert Bryan*—Subject of a complete transcript of a phonographically recorded counseling process with additional therapist's comments, as described by Carl R. Rogers.

1942 *Clare*—A patient with compulsive modesty, dependence, and the compulsive need to force others to recognize her superiority. The analysis by Karen Horney illustrates her formulation of the social and cultural etiology of neurosis.

1943 *Tom*—A patient with gastric fistula on whom observations were made concerning the effect of normal situational stresses and various emotional states on his gastric function by Steward Wolf and Harold Wolff.

1944 *Ellen West*—A girl with a fear of becoming fat, treated by Ludwig Binswanger who applied the principles of existential analysis to clinical psychiatry and psychopathology.

1944 *Harold*—A criminal psychopath hypnoanalyzed by Robert M. Lindner.

1951 *Renée*—Patient is perhaps the best documented study of a single patient. The therapist, M. A. Sechahaye, entered the psychotic world of the patient, accepted

the symbolism involved, and attempted to materialize the patient's fundamental needs at a symbolic level, the so-called symbolic realization.

1953 *Marisa*—A patient with dual personality, reported by G. E. Morselli, in which electroencephalograms were found to differ in the two personalities.

1954 *Monte Durham*—Defendant in case in which Judge D. L. Bazelon in the Federal Appellate Court in Washington, D.C., ruled that a man should not be held responsible for an otherwise criminal act when his behavior was the "product of mental disease or deficiency."

1956 *Monica*—An infant girl with congenital atresia of the esophagus in whom a gastric fistula was established in the fourth day of life. George L. Engel and his colleagues made detailed observations of behavior and gastric secretion were made until she reached age 22 months, when the fistula was closed. She has been followed into adult life, and observations of her interaction with her own daughter have been described.

1957 *Eve*—A patient with multiple personality whose real name was Chris Sizemore, reported by Corbett Thigpen and Hervey Cleckley.

1960 *S. V. Shereshevski*—A man with hypermnesia studied by A. R. Luria for over 30 years. He could effortlessly memorize sequences or tables containing 50, 100, and more figures presented to him aurally or visually, some after an interval of 20 years.

1964 *Catherine Lake*—A patient was committed to St. Elizabeth's Hospital in 1962 with chronic brain syndrome due to arteriosclerosis with a psychotic reaction. She appealed on the grounds that a suitable alternative to "total confinement" in a mental hospital was warranted. This was the first major judicial concern over the treatment and rights of hospitalized patients.

1966 *Charles Rouse*—Patient who was committed to St. Elizabeth's involuntarily as criminally insane after being acquitted of an offense by reason of insanity but was not receiving treatment. This is a case of treatment and rights of hospitalized patients. The decision stated that "the purpose of involuntary hospitalization is treatment not punishment."

1969 *Rose R*.—A 63-year-old woman (whose real name was Sylvia) in whom forced reminiscence was induced by levodopa (Larodopa). She was the earliest patient described in a series treated by Oliver Sachs and originally published as "Incontinent Nostalgia induced by L-Dopa in 1970." (This case and others were depicted in a book *Awakenings* in 1973; a documentary TV film in 1973; three plays including A *Kind of Alaska* by Harold Pinter in 1982, with the character Deborah based on Rose R; a radio drama on CBC 1987; and a movie in 1987.)

1971 *Mary Barnes*—A patient treated by R. D. Laing who illustrates his acceptance of regression and rebirth in psychosis and his view of psychosis as a necessary stage in the achievement of health.

1971 *Sandra*—A 6-month-old infant whose behavior modification used lemon juice to control a life-threatening rumination.

1971 *Ricky Wyatt*—A mentally retarded patient at Alabama's Bryce Hospital whose guardian challenged the adequacy of his treatment, raising the issue of whether civilly or criminally committed mentally ill and mentally retarded patients have the right to adequate individual treatment. The class action was brought by patients and staff.

1972 *Archie W. Brawner*—Defendant who drank wine and went to a party. When several fights broke out, he left, returned with a gun, and shot and killed Billy Ford. He was diagnosed variously as having epileptic personality disorder or explosive personality. In his appeal against a conviction of second-degree murder the court decided to discard the Durham Rule and adopt instead the test recommended in 1962 by the American Law Institute in its model penal code.

1973 *Sybil*—Patient with dissociative identity disorder (multiple personality disorder) treated by Cornelia Wilbur. She exhibited 16 "personalities" and alleged that she had suffered sexual child abuse by her mother. Later researchers have questioned whether the therapist interpreted the patient's state correctly. Book of the same name was written by Flora Rheta Shreiber, and the story was also made into a movie.

1973 *Mercedes*—A black woman whose treatment deals with themes of social injustice, racism, and the ability to bear children. Example of Rollo May's existential therapy.

1974 *Martha*—An illustration of rational emotive therapy by Albert Ellis.

1975 *Kenneth Donaldson*—Man who had been civilly committed because of schizophrenia and confined at the Florida State Hospital for 14 years. He sued state hospital psychiatrists for money damages pursuant to the Civil Rights Act (i.e., deprivation of liberty), and appealed to the Supreme Court—right to liberty had been violated.

1975 *Rubie Rogers*—A chronic schizophrenic 39-year-old woman treated with haloperidol (Haldol) and one of seven patients at Boston State Hospital who filed a civil rights action against the superintendent and psychiatrists. After 74 days of trial and argument, an 8000-page transcript covering testimony of 50 witnesses, and a further 2000 pages of posttrial briefs, this case established the absolute right of patients to refuse treatment, although after a judicial finding of incompetence a guardian may authorize treatment.

1976 *Prosenjit Poddar*—Originally an untouchable from India, a student, and a voluntary outpatient at the Mental Health Clinic at the University of California who told his therapist he intended to kill a student, Tatiana Tarasoff. The therapist notified campus police that he was dangerous and should be committed under a 72-hour emergency observation law. However, the therapist's supervisor vetoed the recommendation. Two months later, he killed Tarasoff. Her parents sued the University of California for negligence. California Supreme Court ruled that a physician or psychotherapist who believes a patient may injure or kill someone must warn the potential victim, victim's relatives or friends, or authorities (known as the Tarasoff I decision—named for the victim). In 1982 the California Supreme Court issued a second ruling in the case of *Tarasoff v Regents of University of California* and broadened the duty to warn to include the duty to protect—known as Tarasoff II.

1977 *Nadia*—An autistic child, born in 1967 to a family of Ukraine emigres, who exhibited extraordinary drawing ability from age 3½ to 10.

1979 *John Rennie*—An involuntary patient with a bipolar illness at a New Jersey state hospital who objected to the forced administration of medications. This case concerning the right to refuse treatment established the use of an appeal process to determine a patient's dangerousness and competency and whether less restrictive treatment existed.

1980 *John W. Hinckley, Jr*.—A person with paranoid schizophrenia who shot President Ronald Reagan and Press Secretary James Brady. Hinckley was found not guilty by reason of insanity in 1982. The court testimony spawned an outcry about the unreliability of psychiatric diagnoses, which contributed to the refining of DSM criteria. This case also led to the Brady Bill, gun-control legislation (requiring a 5-day waiting period to cut down on the sale of handguns to felons and fugitives) that became law in 1993.

1980 *Michelle*—A Canadian housewife, Michelle Smith, treated by Lawrence Pazder, a psychiatrist who helped her "recover" memories of torture by a satanic cult at age 5. Their book *Michelle Remembers* set off the satanic-ritual-abuse craze of the ensuing decade.

See reference for D.A. Davis for citations for the cases above.

ETHICAL ISSUES

Psychiatrists continually make judgments about what is or is not appropriate material to include in the psychiatric report, the medical record, the case report, and other written communications about the patient. Such judgments often involve ethical issues. In a case report, for example, the patient should not be identifiable, a position made clear in the American Psychiatric Association's *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry*, which states that published case reports must be suitably disguised to safeguard patient confidentiality without altering material to provide a less-than-complete portrayal of the patient's actual condition. In some instances obtaining a written release from the patient that allows the psychiatrist to publish the case may also be advisable, even if the patient is

appropriately disguised.

Psychiatrists sometimes include material in the medical record that is specifically directed toward warding off future culpability if liability issues are ever raised. The following vignette illustrates one such instance.

> A psychiatrist noted in the chart that he discussed with the patient the important side effects of a particular medication he was about to prescribe. In fact, he only discussed the two adverse effects most commonly observed. He chose not to discuss others because he was concerned that the patient would develop them via suggestion and wrote that in the chart. When the patient developed an adverse effect (even though minor and not life threatening), he sued the psychiatrist for not advising him of that possibility. The case was settled in the psychiatrist's favor on the basis of the note in the medical record.

Psychiatrists in the military face unique ethical problems because confidentiality does not exist under the military code of conduct.

> A 19-year-old white single male, new to military service, presented with a history of periodic episodes of anxiety when taking showers in groups with other men. He identified himself as gay and recognized that his anxiety was related to his fear of acting out his sexual impulses, thus risking court-martial and dishonorable discharge should he ever be discovered. The psychiatrist was on the horns of a dilemma: whether to report the soldier to his commanding officer (as he was obliged to do under the military code) or to protect the soldier from acting on his impulses that would place him in danger (in keeping with the medical ethic to do no harm). After discussing various options, he and the patient agreed on the latter option. A diagnosis of anxiety disorder was made, which allowed the patient to receive an honorable discharge on medical grounds, based on a recognized psychiatric disorder. No record of his homosexual orientation was made.

With the advent of managed care and the need to send periodic progress reports and documentation of signs and symptoms to third-party reviewers to pay for treatment, some psychiatrists may diminish or exaggerate symptomatology. The following case report and discussion illustrates the ethical difficulties psychiatrists face in dealing with managed care.

> Mrs. P. admitted herself to the hospital because she was afraid she might kill herself. She was suffering from a major depressive episode, but she improved markedly during the first weeks on Dr. A.'s ward. Although Dr. A. believed that Mrs. P. was no longer suicidal, he thought she would benefit greatly from continued hospitalization. Because he knew that Mrs. P. could not afford to pay for hospitalization and that the insurance company would pay only if the patient was suicidally depressed, he decided not to document Mrs. P.'s improvement. He noted in the chart that "the patient continues to have a risk of suicide."
>
> This case illustrates one of the difficulties posed by cost constraints and managed care. Dr. A. responds to this difficulty by tailoring the chart. Does he engage in a form of deception? Yes, he intentionally misleads by what he writes and what he omits writing in the chart. Although what he writes is true in some literal sense, his statement is misleading in the context of treatment. Mrs. P. is not suicidally depressed in the way she was.
>
> What Dr. A. omits from the chart is also deceptive. Whether a particular omission is deceptive depends, in part, on the roles and expectations of the people involved. Not telling your colleague that you dislike his tie is not a deception. It is simply tact, unless your role or relationship involves the expectation that you offer your candid opinion. Dr. A.'s case is different. His professional role is to document the patient's course, and the expectation is that he will note any significant improvement. Thus his failure to document Mrs. P.'s progress accurately is a kind of deception.
>
> The second and more difficult question is whether deception is justified in this instance. The answer to that question depends on the reasons for the deception, the reasons against it, and the alternatives available.
>
> The reasons for this deception are obvious. Dr. A.'s aim and primary obligation is to help the patient. He believes that Mrs. P. would benefit greatly from continued hospitalization that she cannot afford. He may also believe that it is unfair for the insurance company to refuse to pay for inpatient treatment of nonsuicidal depression and that his deception rectifies that unfair practice.
>
> There are also important reasons against this deception. The first reason concerns honesty and social trust. It is a good thing if people can rely on what others say and write. Without some honesty and trust, many social exchanges and practices would be impossible. Deception, even for beneficent purposes, has real potential to damage social trust. A risk exists that deception may damage people's trust in the profession of psychiatry and even patients' trust in their psychiatrists. Damage to trust may, in turn, compromise treatment.
>
> The second reason concerns future medical treatment. If Mrs. P. seeks medical treatment in the future, the physicians who attend her will read the misleading notes. If they believe that the notes are an accurate account of the previous treatment, they may suggest an inappropriate treatment for the present problem. Even if they have doubts about the accuracy of the notes in her chart, they are deprived of an accurate history and report. In either case, the prior deception can hinder treatment.
>
> The third reason concerns obligations and coverage policies. Dr. A. seems to ignore the obligation he has to the population that is covered by the insurance policy. He shifts a burden onto this population by forcing the insurance company to pay for treatment it did not agree to cover. Perhaps the insurance company should pay for inpatient treatment in cases like Mrs. P.'s; perhaps its policies are unreasonable and unfair. But Dr. A.'s deception does not challenge the insurance company and pressure it to change its policy; nor does his deception encourage patients and their families to contest the company's policies. The use of deception simply circumvents, in an ad hoc way, a policy that should be challenged and discussed.
>
> Dr. A. also seems to ignore his obligation to future patients. By introducing an inaccuracy into the chart, he compromises the value of medical records research. His deception works, in a small way, to deprive future patients of the benefit of research that relies on medical records.
>
> Whether the deception is justified depends not only on the weight of the reasons for and against the deception but also on the available alternatives. One alternative is to tailor the chart. Another alternative is to describe Mrs. P.'s response accurately and discharge her to outpatient care. But a third alternative exists. Dr. A. can accurately document the patient's course and recommend continued hospitalization. He can petition the insurance company for coverage. If the insurance company decides not to approve further inpatient care for the patient, Dr. A. can appeal that decision. This alternative is more time consuming, and there is no guarantee it will succeed, but it avoids all the problems associated with the use of deception. (Reprinted with permission from Dwyer J, Shih A: The ethics of tailoring the patient's chart. Psychiatr Serv *49:*1309, 1998.)

FUTURE DIRECTIONS

The psychiatric report, which includes the psychiatric history and mental status examination, has remained fairly stable over the years, but diagnostic terms have undergone change and will continue to do so. In part, this represents true advances in our understanding of psychiatric illness, but as Karl Menninger stated: "Defining new syndromes and reordering them is always an avocation—a veritable addiction—of psychiatrists."

For example, in 1952 the American Psychiatric Association's Committee on Nomenclature and Statistics published the first edition of DSM (DSM-I). Four editions have been published since then, the last being DSM-IV in 1994. Many psychiatrists have been critical of the many versions of DSM that have appeared, and some such as Mark Zimmerman believe that any new revisions to DSM should follow a "restrained, sober and deliberate pace." In their book *The Selling of DSM*, Stuart Kirk and Herb Kutchins supported that position. They stated:

First, none of the revisions are stimulated by clinical practitioners demanding a new classification system. Second, the writing of each revision has become more time consuming, elaborate, and politically complex. Third, the numerous changes made with each revision are justified explicity or implicity as improving the scientific credibility of the classification system, although the scientific basis for them is often questionable. Finally, the process of revision inevitably begins by attacking the current system, even when it has only recently been adopted, and ends by claiming the superiority of the new one.

With others, the author believes that the publication of the various editions of DSM has been one of the most important developments in psychiatry in the past 50

years. The *Comprehensive Textbook of Psychiatry* has always relied on DSM as the template for deriving the table of contents and the organizing psychopathology. At the same time, contributors to this textbook are encouraged to critique DSM and to suggest changes as they see fit. The reader will find many such critiques throughout this book.

The issues of documentation and access to medical records will receive much more study in future years. Legislative patient privacy bills are before Congress as of this writing to protect and limit third-party access to medical records. In spite of this, however, the trend toward less patient privacy continues. Proposed legislation would give each person in America a unique medical identifier that could encode on microchip one's medical record from the cradle to the grave. Should this or similar legislation be enacted into law, medical privacy will continue to erode.

Finally, critics of current documentation processes claim that filling out forms developed by governmental agencies—more necessary for fiscal than for medical needs—takes time away from direct patient care. In the future, society will have to determine how far the process of documentation must proceed before the need to archive material unrelated to direct patient care interferes with the care of the patient.

SUGGESTED CROSS-REFERENCES

Psychiatric rating scales appear in Section 7.8 on psychiatric rating scales and Section 9.1 on classification of mental disorders. A detailed discussion of DSM-IV's multiaxial system appears in Section 9.1 on the classification of mental disorders. The psychiatric interview, history, and mental status examination are discussed in Section 7.2. Medical assessment and laboratory testing are discussed in Section 7.7. Computer-based testing of the psychiatric patient is covered in Section 7.9.

7.3 SIGNS AND SYMPTOMS IN PSYCHIATRY

BENJAMIN J. SADOCK, M.D.

William Osler (1898–1919) said of medicine in general: “It is learned only by experience; it is not an inheritance; it cannot be revealed. Learn to see, learn to hear, learn to feel, learn to smell, and know that by practice alone can you become expert.” And so it is with psychiatry. One sees the posture of depression, hears the neologisms in schizophrenia; smells the odor of alcoholism, and feels the violent patient's anger. Eventually, with practice, the psychiatrist learns the full range of signs and symptoms. It is the rare psychiatrist, however, who encounters them all.

Signs are objective; symptoms are subjective. Signs are the clinician's observations, such as noting a patient's agitation; symptoms are subjective experiences, such as a person's complaint of feeling depressed. In psychiatry signs and symptoms are not so clearly demarcated as in other fields of medicine; they often overlap. Because of this, disorders in psychiatry are often described as syndromes—a constellation of signs and symptoms that together make up a recognizable condition. Schizophrenia, for example, is more often viewed as a syndrome than as a specific disorder. This concept is expressed in the terms “schizophrenic spectrum” or “the group of schizophrenias.”

NORMALITY

The concept of normality is ambiguous, has multiple meanings, and is influenced by diverse and complex value systems. Normality is sometimes equated broadly with health. The World Health Organization (WHO) defines normality as a state of complete physical, mental, and social well-being. Most psychiatrists consider normality to be the absence of psychopathology; but that concept is limited by defining mental health as simply the absence of mental disease.

Psychiatry has been criticized over the years by certain groups for its portrayal of normality. The psychology of women, for example, has been criticized as sexist because it was formulated initially by men; similar criticism comes from other groups who believe the portrayal of their psychological issues is biased by placing undue emphasis on psychopathology rather than healthy attributes. A much discussed issue is the change in psychiatry's view of homosexuality from abnormal to normal that took place 25 years ago, an evolution shaped by cultural norms, society's expectations and values, professional biases, individual differences, and the political climate of the time. Many attempts have been made to define normality in psychiatry; however, none has been entirely satisfactory. Table 7.3-1 outlines the divergent views of several psychoanalytic thinkers and clinicians.

Theorist	Concept
Sigmund Freud	Normality is an ideal fiction.
Karl Menninger	Normality is the ability to adjust to the external world with contentment and to master the task of existence.
Alfred Adler	The person's capacity to develop social feeling and to be productive is related to mental health; the ability to work heightens self-esteem and makes one capable of adaptation.
Clara Kirk	Normality is the capacity to live without fear, guilt, or anxiety and to take responsibility for one's own actions.

Table 7.3-1 Concepts of Normality

MENTAL HEALTH

The concept of mental health is continually evolving out of new experience and new research. Major theoreticians include, among others, Daniel Offer and Melvin Sabshin, who formulated four perspectives of normality.

Normality as Health The first perspective is basically the traditional medical psychiatric approach to health and illness. Normality is equated with health, and health is an almost universal phenomenon. Behavior is assumed to be within normal limits when no manifest psychopathology is present. If all behavior were to be put on a scale, normality would encompass the major portion of the continuum, and abnormality would be the small remainder.

Normality as Utopia The second perspective conceives of normality as a blend of the diverse elements of the mental apparatus that culminates in optimal functioning. This approach seeks perfection. When discussing normality however, Sigmund Freud stated, “A normal ego is like normality in general, an ideal fiction.”

Normality as Average The third perspective is based on a mathematical principle of the bell-shaped curve. This approach considers the middle range to be normal and both extremes, deviant. Variability is described only within the context of total groups, not of one individual.

Normality as Process The fourth perspective stresses that normal behavior is the result of interacting systems. The normality-as-process perspective stresses changes over time rather than a cross-sectional definition of normality.

Investigators who subscribe to this approach are found in the behavioral and social sciences. Most typical are Erik Erikson's conceptualization of epigenesis of personality development and the seven developmental stages he described as essential to the attainment of mature adult functioning.

Karl Jaspers Karl Jaspers (1883–1969), the German psychiatrist and philosopher, described a “personal world”—the way the person thinks or feels—that could be either normal or abnormal. According to Jaspers, the personal world is abnormal when it (1) springs from a condition that is recognized universally as abnormal such as schizophrenia, (2) when it separates the person from others emotionally, and (3) when it does not provide the person with a sense of “spiritual and material” security.

Jaspers was a proponent of phenomenology, in which the clinician studies psychological signs and symptoms with the goal of understanding the internal experience of the patient. By carefully listening to the patient, the psychiatrist temporarily enters the mental life of the patient. Jaspers believed that to fully understand the signs and symptoms observed in the patient, the clinician must have no prior assumptions. A person who reports a hallucinatory experience, for example, must not be judged thereby as being abnormal or psychotic. To be used diagnostically, the phenomenon must occur repeatedly and be characteristic of a known disorder.

Some investigators are developing a research strategy that measures a person's mental state at various times during the day in different life settings to validate diagnosis. Thus a sign or symptom is examined within the context of its appearance. What is abnormal in one setting or at one time of day may be normal in another.

Finally, there is the commonly accepted and widely used definition by Robert Campbell, adapted from his Psychiatric Dictionary: Psychically normal persons are those

who are in harmony with themselves and with their environment. They conform with the cultural requirements or injunctions of their community. They may possess medical deviation or disease, but as long as this does not impair their reasoning, judgment, intellectual capacity, and ability to make harmonious personal and social adaptation, they may be regarded as psychically sound or normal.

Many psychiatric signs and symptoms can be understood as various points on a spectrum of behavior ranging from normal to pathological. It is extremely rare to have a pathognomonic sign or symptom in psychiatry, although in some cases he disturbance is specific to a neurological deficit. As John Nemiah wrote: “Psychiatry is a science of inexhaustible complexity. It is as infinite as the range of human emotions and behavior. One cannot possibly learn it all.” Because of that, psychiatry still remains as much art as science.

GLOSSARY OF SIGNS AND SYMPTOMS

abreaction A process by which repressed material, particularly a painful experience or a conflict, is brought back to consciousness; in this process, the person not only recalls but relives the repressed material, which is accompanied by the appropriate affective response.

abstract thinking Thinking characterized by the ability to grasp the essentials of a whole, to break a whole into its parts and to discern common properties. To think symbolically.

abulia Reduced impulse to act and think, associated with indifference about consequences of action. Occurs as a result of neurological deficit, depression, schizophrenia.

acalculia Loss of ability to do calculations; not caused by anxiety or impairment in concentration. Occurs with neurological deficit, learning disorder.

acataphasia Disordered speech in which statements are incorrectly formulated. Patients may express themselves with words that sound like the ones intended but are not appropriate to the thoughts, or they may use totally inappropriate expressions.

acathexis Lack of feeling associated with an ordinarily emotion-charged subject; in psychoanalysis, it denotes the patient's detaching or transferring of emotion from thoughts and ideas. Also called *decathexis*. Occurs in anxiety, dissociative, schizophrenic, and bipolar disorders.

acenesthesia Loss of sensation of physical existence.

acrophobia Dread of high places.

acting out Behavioral response to an unconscious drive or impulse that brings about temporary partial relief of inner tension; relief is attained by reacting to a present situation as if it were the situation that originally gave rise to the drive or impulse. Common in borderline states.

aculalia Nonsense speech associated with marked impairment of comprehension. Occurs in mania, schizophrenia, neurological deficit.

adiadochokinesia Inability to perform rapid alternating movements. Occurs with neurological deficit, cerebellar lesions.

adynamia Weakness and fatigability, characteristic of neurasthenia and depression.

aerophagia Excessive swallowing of air. Seen in anxiety disorder.

affect The subjective and immediate experience of emotion attached to ideas or mental representations of objects. Affect has outward manifestations that may be classified as restricted, blunted, flattened, broad, labile, appropriate, or inappropriate. *See also* **mood**.

ageusia Lack or impairment of the sense of taste. Seen in depression, neurological deficit.

aggression Forceful, goal-directed action that may be verbal or physical; the motor counterpart of the affect of rage, anger, or hostility. Seen in neurological deficit, temporal lobe disorder, impulse-control disorders, mania, schizophrenia.

agitation Severe anxiety associated with motor restlessness.

agnosia Inability to understand the import or significance of sensory stimuli; cannot be explained by a defect in sensory pathways or cerebral lesion; the term has also been used to refer to the selective loss or disuse of knowledge of specific objects because of emotional circumstances, as seen in certain schizophrenic, anxious, and depressed patients. Occurs with neurological deficit. For types of agnosia, see the specific term.

agoraphobia Morbid fear of open places or leaving the familiar setting of the home. May be present with or without panic attacks.

agraphia Loss or impairment of a previously possessed ability to write.

ailurophobia Dread of cats.

akathisia Subjective feeling of motor restlessness manifested by a compelling need to be in constant movement; may be seen as an extrapyramidal adverse effect of antipsychotic medication. May be mistaken for psychotic agitation.

akinesia Lack of physical movement, as in the extreme immobility of catatonic schizophrenia; may also occur as an extrapyramidal effect of antipsychotic medication.

akinetic mutism Absence of voluntary motor movement or speech in a patient who is apparently alert (as evidenced by eye movements). Seen in psychotic depression, catatonic states.

alexia Loss of a previously possessed reading facility; not explained by defective visual acuity. *Compare* **dyslexia**.

alexithymia Inability or difficulty in describing or being aware of one's emotions or moods; or elaboration of fantasies associated with depression, substance abuse, and posttraumatic stress disorder.

algophobia Dread of pain.

alogia Inability to speak because of a mental deficiency or an episode of dementia.

ambivalence Coexistence of two opposing impulses toward the same thing in the same person at the same time. Seen in schizophrenia, borderline states, obsessive-compulsive disorders.

amimia Lack of ability to make gestures or to comprehend those made by others.

amnesia Partial or total inability to recall past experiences; may be organic (*amnestic disorder*) or emotional (*dissociative amnesia*) in origin.

amnestic aphasia Disturbed capacity to name objects, even though they are known to the patient. Also called *anomic aphasia*.

anaclitic Depending on others, especially as the infant on the mother; anaclitic depression in children results from an absence of mothering.

analgesia State in which one feels little or no pain. Can occur under hypnosis and in dissociative disorder.

anankasm Repetitious or stereotyped behavior or thought usually used as a tension-relieving device; used as a synonym for obsession and seen in obsessive-compulsive (anakastic) personality.

androgyny Combination of culturally determined female and male characteristics in one person.

anergia Lack of energy.

anhedonia Loss of interest in and withdrawal from all regular and pleasurable activities. Often associated with depression.

anomia Inability to recall the names of objects.

anorexia Loss or decrease in appetite. In *anorexia nervosa* appetite may be preserved but patient refuses to eat.

anosognosia Inability to recognize a physical deficit in oneself (e.g., patient denies paralyzed limb).

anterograde amnesia Loss of memory for events subsequent to the onset of the amnesia common after trauma. *Compare* **retrograde amnesia**.

anxiety Feeling of apprehension caused by anticipation of danger, which may be internal or external.

apathy Dulled emotional tone associated with detachment or indifference; observed in certain types of schizophrenia and depression.

aphasia Any disturbance in the comprehension or expression of language caused by a brain lesion. For types of aphasia, see the specific term.

aphonia Loss of voice. Seen in conversion disorder.

apperception Awareness of the meaning and significance of a particular sensory stimulus as modified by one's own experiences, knowledge, thoughts, and emotions. *See also* **perception**.

appropriate affect Emotional tone in harmony with the accompanying idea, thought, or speech.

apraxia Inability to perform a voluntary purposeful motor activity; cannot be explained by paralysis or other motor or sensory impairment. In *constructional apraxia*, a patient cannot draw two- or three-dimensional forms.

astasia abasia Inability to stand or walk in a normal manner, even though normal leg movements can be performed in a sitting or lying down position. Seen in conversion disorder.

astereognosis Inability to identify familiar objects by touch. Seen with neurological deficit. *See also* **neurological amnesia**.

asyndesis Disorder of language in which the patient combines unconnected ideas and images. Commonly seen in schizophrenia.

ataxia Lack of coordination, either physical or mental. 1. In neurology, refers to loss of muscular coordination. 2. In psychiatry, the term *intrapsychic ataxia* refers to lack of coordination between feelings and thoughts; seen in schizophrenia and in severe obsessive-compulsive disorder.

atonia Lack of muscle tone. *See* **waxy flexibility**.

attention Concentration; the aspect of consciousness that relates to the amount of effort exerted in focusing on certain aspects of an experience, activity, or task. Usually impaired in anxiety and depressive disorders.

auditory hallucination False perception of sound, usually voices but also other noises such as music. Most common hallucination in psychiatric disorders.

aura 1. Warning sensations such as automatisms, fullness in the stomach, blushing, and changes in respiration, cognitive sensations, and mood states usually experienced before a seizure. 2. A sensory prodrome that precedes a classic migraine headache.

autistic thinking Thinking in which the thoughts are largely narcissistic and egocentric, with emphasis on subjectivity rather than objectivity, and without regard for reality; used interchangeably with autism and dereism. Seen in schizophrenia, autistic disorder.

behavior Sum total of the psyche that includes impulses, motivations, wishes, drives, instincts, and cravings, as expressed by a person's behavior or motor activity. Also called *conation*.

bereavement Feeling of grief or desolation, especially at the death or loss of a loved one.

bizarre delusion False belief that is patently absurd or fantastic (e.g., invaders from space have implanted electrodes in a person's brain). Common in schizophrenia. In nonbizarre delusion content is usually within range of possibility.

blackout Amnesia experienced by alcoholics about behavior during drinking bouts; usually indicates reversible brain damage.

blocking Abrupt interruption in train of thinking before a thought or idea is finished; after a brief pause, person indicates no recall of what was being said or was going to be said (also known as *thought deprivation*). Common in schizophrenia and severe anxiety.

blunted affect Disturbance of affect manifested by a severe reduction in the intensity of externalized feeling tone; one of the fundamental symptoms of schizophrenia, as outlined by Eugen Bleuler.

bradykinesia Slowness of motor activity, with a decrease in normal spontaneous movement.

bradylalia Abnormally slow speech. Common in depression.

bradylexia Inability to read at normal speed.

bruxism Grinding or gnashing of the teeth, typically occurring during sleep. Seen in anxiety disorder.

carebaria Sensation of discomfort or pressure in the head.

catalepsy Condition in which persons maintain the body position into which they are placed; observed in severe cases of catatonic schizophrenia. Also called *waxy flexibility; cerea flexibilitas. See alsc* **command automatism**.

cataplexy Temporary sudden loss of muscle tone, causing weakness and immobilization; can be precipitated by a variety of emotional states and is often followed by sleep. Commonly seen in narcolepsy.

catatonic excitement Excited, uncontrolled motor activity seen in catatonic schizophrenia. Patients in catatonic state may suddenly erupt into excited state and be violent.

catatonic posturing Voluntary assumption of an inappropriate or bizarre posture, generally maintained for long periods of time. May switch unexpectedly with catatonic excitement.

catatonic rigidity Fixed and sustained motoric position that is resistant to change.

catatonic stupor Stupor in which patients ordinarily are well aware of their surroundings.

cathexis In psychoanalysis, a conscious or unconscious investment of psychic energy in an idea, concept, object or person. *Compare* **acathexis**.

causalgia Burning pain that may be either organic or psychic in origin.

cephalagia Headache.

cenesthetia Change in the normal quality of feeling tone in a part of the body.

cerea flexibilitas Condition of a person who can be molded into a position that is then maintained; when an examiner moves the person's limb, the limb feels as if it were made of wax. Also called *catalepsy* or *waxy flexibility*. Seen in schizophrenia.

chorea Movement disorder characterized by random and involuntary quick, jerky, purposeless movements. Seen in Huntington's disease.

circumstantiality Disturbance in the associative thought and speech processes in which a patient digresses into unnecessary details and inappropriate thoughts before communicating the central idea. Observed in schizophrenia, obsessional disturbances, and certain cases of dementia. *See also* **tangentiality**.

clang association Association or speech directed by the sound of a word rather than by its meaning; words have no logical connection; punning and rhyming may dominate the verbal behavior. Seen most frequently in schizophrenia or mania.

claustrophobia Abnormal fear of closed or confining spaces.

clonic convulsion An involuntary, violent muscular contraction or spasm in which the muscles alternately contract and relax. Characteristic phase in grand mal epileptic seizure.

clouding of consciousness Any disturbance of consciousness in which the person is not fully awake, alert, and oriented. Occurs in delirium, dementia, and cognitive disorder.

cluttering Disturbance of fluency involving an abnormally rapid rate and erratic rhythm of speech that impedes intelligibility; the affected individual is usually unaware of communicative impairment.

cognition Mental process of knowing and becoming aware; function closely associated with judgment.

coma State of profound unconsciousness from which a person cannot be roused, with minimal or no detectable responsiveness to stimuli; seen in injury or disease of the brain, in such systemic conditions as diabetic ketoacidosis and uremia, and in intoxications with alcohol and other drugs. Coma may also occur in severe catatonic states and in conversion disorder.

coma vigil Coma in which a patient appears to be asleep but can be aroused (also known as *akinetic mutism*).

command automatism Condition associated with catalepsy in which suggestions are followed automatically.

command hallucination False perception of orders that a person may feel obliged to obey or unable to resist.

complex A feeling-toned idea.

complex partial seizure A seizure characterized by alterations in consciousness that may be accompanied by complex hallucinations (sometimes olfactory) or illusions. During the seizure, a state of impaired consciousness resembling a dreamlike state may occur, and the patient may exhibit repetitive, automatic, or semipurposeful behavior.

compulsion Pathological need to act on an impulse that, if resisted, produces anxiety; repetitive behavior in response to an obsession or performed according to certain rules, with no true end in itself other than to prevent something from occurring in the future.

conation That part of a person's mental life concerned with cravings, strivings, motivations, drives, and wishes as expressed through behavior or motor activity.

concrete thinking Thinking characterized by actual things, events, and immediate experience, rather than by abstractions; seen in young children, in those who have lost or never developed the ability to generalize (as in certain cognitive mental disorders), and in schizophrenic persons. *Compare* **abstract thinking**.

condensation Mental process in which one symbol stands for a number of components.

confabulation Unconscious filling of gaps in memory by imagining experiences or events that have no basis in fact, commonly seen in amnestic syndromes; should be differentiated from lying. *See also* **paramnesia**.

confusion Disturbances of consciousness manifested by a disordered orientation in relation to time, place, or person.

consciousness State of awareness, with response to external stimuli.

constipation Inability to defecate or difficulty in defecating.

constricted affect Reduction in intensity of feeling tone less severe than that of blunted affect.

constructional apraxia Inability to copy a drawing, such as a cube, clock, or pentagon, as a result of a brain lesion.

conversion phenomena The development of symbolic physical symptoms and distortions involving the voluntary muscles or special sense organs; not under voluntary control and not explained by any physical disorder. Most common in conversion disorder, but also seen in a variety of mental disorders.

convulsion An involuntary, violent muscular contraction or spasm. *See also* **clonic convulsion** *and* **tonic convulsion**.

coprolalia Involuntary use of vulgar or obscene language. Observed in some cases of schizophrenia and in Tourette's disorder.

coprophagia Eating of filth or feces.

cryptolalia A private spoken language.

cryptographia A private written language.

cycloplegia Paralysis of the muscles of accommodation in the eye; observed at times as an autonomic adverse effect (anticholinergic effect) of antipsychotic or antidepressant medication.

decompensation Deterioration of psychic functioning caused by a breakdown of defense mechanisms. Seen in psychotic states.

déjà entendu Illusion that what one is hearing one has heard previously. *See also* **paramnesia**.

déjà pensé Condition in which a thought never entertained before is incorrectly regarded as a repetition of a previous thought. *See also* **paramnesia**.

déjà vu Illusion of visual recognition in which a new situation is incorrectly regarded as a repetition of a previous experience. *See also* **paramnesia**.

delirium Acute reversible mental disorder characterized by confusion and some impairment of consciousness; generally associated with emotional lability, hallucinations or illusions, and inappropriate, impulsive, irrational, or violent behavior.

delirium tremens Acute and sometimes fatal reaction to withdrawal from alcohol, usually occurring 72 to 96 hours after the cessation of heavy drinking; distinctive characteristics are marked autonomic hyperactivity (tachycardia, fever, hyperhidrosis, dilated pupils), usually accompanied by tremulousness, hallucinations, illusions, and delusions. Called *alcohol withdrawal delirium* in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). *See also* **formication**.

delusion False belief, based on incorrect inference about external reality, that is firmly held despite objective and obvious contradictory proof or evidence and despite the fact that other members of the culture do not share the belief.

delusion of control False belief that a person's will, thoughts, or feelings are being controlled by external forces.

delusion of grandeur Exaggerated conception of one's importance, power, or identity.

delusion of infidelity False belief that one's lover is unfaithful. Sometimes called *pathological jealousy*.

delusion of persecution False belief of being harassed or persecuted; often found in litigious patients who have a pathological tendency to take legal action because of imagined mistreatment. Most common delusion.

delusion of poverty False belief that one is bereft or will be deprived of all material possessions.

delusion of reference False belief that the behavior of others refers to oneself; that events, objects, or other people have a particular and unusual significance, usually of a negative nature; derived from idea of reference, in which persons falsely feel that others are talking about them (e.g., belief that people on television or radio are talking to or about the person). *See also* **thought broadcasting**.

delusion of self-accusation False feeling of remorse and guilt. Seen in depression with psychotic features.

dementia Mental disorder characterized by general impairment in intellectual functioning without clouding of consciousness; characterized by failing memory, difficulty with calculations, distractibility, alterations in mood and affect, impaired judgment and abstraction, reduced facility with language, and disturbance of orientation. Although irreversible because of underlying progressive degenerative brain disease, dementia may be reversible if the cause can be treated.

denial Defense mechanism in which the existence of unpleasant realities is disavowed; refers to keeping out of conscious awareness any aspects of external reality that, if acknowledged, would produce anxiety.

depersonalization Sensation of unreality concerning oneself, parts of oneself, or one's environment that occurs under extreme stress or fatigue. Seen in schizophrenia, depersonalization disorder, and schizotypal personality disorder.

depression Mental state characterized by feelings of sadness, loneliness, despair, low self-esteem, and self-reproach; accompanying signs include psychomotor retardation or at times agitation, withdrawal from interpersonal contact, and vegetative symptoms such as insomnia and anorexia. The term refers to either a mood that is so characterized or a mood disorder.

derailment Gradual or sudden deviation in train of thought without blocking; sometimes used synonymously with *loosening of association*.

derealization Sensation of changed reality or that one's surroundings have altered. Usually seen in schizophrenia, panic attacks, dissociative disorders.

dereism Mental activity that follows a totally subjective and idiosyncratic system of logic and fails to take the facts of reality or experience into consideration. Characteristic of schizophrenia. *See also* **autistic thinking**.

detachment Characterized by distant interpersonal relationships and lack of emotional involvement.

devaluation Defense mechanism in which a person attributes excessively negative qualities to self or others. Seen in depression, paranoid personality disorder.

diminished libido Decreased sexual interest and drive. (Increased libido is often associated with mania.)

dipsomania Compulsion to drink alcoholic beverages.

disinhibition 1. Removal of an inhibitory effect, as in the reduction of the inhibitory function of the cerebral cortex by alcohol. 2. In psychiatry, a greater freedom to act in accordance with inner drives or feelings and with less regard for restraints dictated by cultural norms or one's superego.

disorientation Confusion; impairment of awareness of time, place, and person (the position of the self in relation to other persons). Characteristic of cognitive

disorders.

displacement Unconscious defense mechanism by which the emotional component of an unacceptable idea or object is transferred to a more acceptable one. Seen in phobias.

dissociation Unconscious defense mechanism involving the segregation of any group of mental or behavioral processes from the rest of the person's psychic activity; may entail the separation of an idea from its accompanying emotional tone, as seen in dissociative and conversion disorders. Seen in dissociative disorders.

distractibility Inability to focus one's attention; the patient does not respond to the task at hand but attends to irrelevant phenomena in the environment.

dread Massive or pervasive anxiety, usually related to a specific danger.

dreamy state Altered state of consciousness, likened to a dream situation, that develops suddenly and usually lasts a few minutes; accompanied by visual, auditory, and olfactory hallucinations. Commonly associated with temporal lobe lesions.

drowsiness State of impaired awareness associated with a desire or inclination to sleep.

dysarthria Difficulty in articulation, the motor activity of shaping phonated sounds into speech, not in word finding or in grammar.

dyscalculia Difficulty in performing calculations.

dysgeusia Impaired sense of taste.

dysgraphia Difficulty in writing.

dyskinesia Difficulty in performing movements. Seen in extrapyramidal disorders.

dyslalia Faulty articulation caused by structural abnormalities of the articulatory organs or impaired hearing.

dyslexia Specific learning disability syndrome involving an impairment of the previously acquired ability to read; unrelated to the person's intelligence. *Compare* **alexia**.

dysmetria Impaired ability to gauge distance relative to movements. Seen in neurological deficit.

dysmnesia Impaired memory.

dyspareunia Physical pain in sexual intercourse, usually emotionally caused and more commonly experienced by women; may also result from cystitis, urethritis, or other medical conditions.

dysphagia Difficulty in swallowing.

dysphasia Difficulty in comprehending oral language (*reception dysphasia*) or in trying to express verbal language (*expressive dysphasia*).

dysphonia Difficulty or pain in speaking.

dysphoria Feeling of unpleasantness or discomfort; a mood of general dissatisfaction and restlessness. Occurs in depression and anxiety.

dysprosody Loss of normal speech melody (*prosody*). Common in depression.

dystonia Extrapyramidal motor disturbance consisting of slow, sustained contractions of the axial or appendicular musculature; one movement often predominates, leading to relatively sustained postural deviations; acute dystonic reactions (facial grimacing, torticollis) are occasionally seen with the initiation of antipsychotic drug therapy.

echolalia Psychopathological repeating of words or phrases of one person by another; tends to be repetitive and persistent. Seen in certain kinds of schizophrenia, particularly the catatonic types.

ego-alien Denoting aspects of a person's personality that are viewed as repugnant, unacceptable, or inconsistent with the rest of the personality. Also called *ego-dystonia. Compare* **ego-syntonic**.

egocentric Self-centered; selfishly preoccupied with one's own needs; lacking interest in others.

ego-dystonic *See* **ego-alien**.

egomania Morbid self-preoccupation or self-centeredness. *See also* **narcissism**.

ego-syntonic Denoting aspects of a personality that are viewed as acceptable and consistent with that person's total personality. Personality traits are usually ego-syntonic. *Compare* **ego-alien**.

eidetic image Unusually vivid or exact mental image of objects previously seen or imagined.

elation Mood consisting of feelings of joy, euphoria, triumph, and intense self-satisfaction, or optimism. Occurs in mania when not grounded in reality.

elevated mood Air of confidence and enjoyment; a mood more cheerful than normal but not necessarily pathological.

emotion Complex feeling state with psychic, somatic, and behavioral components; external manifestation of emotion is *affect*.

emotional insight A level of understanding or awareness that one has emotional problems. It facilitates positive changes in personality and behavior when present.

emotional lability Excessive emotional responsiveness characterized by unstable and rapidly changing emotions.

encopresis Involuntary passage of feces, usually occurring at night or during sleep.

enuresis Incontinence of urine during sleep.

erotomania Delusional belief, more common in women than in men, that someone is deeply in love with them (also known as *De Clérembault's syndrome*).

erythrophobia Abnormal fear of blushing.

euphoria Exaggerated feeling of well-being that is inappropriate to real events. Can occur with drugs such as opiates, amphetamines, and alcohol.

euthymia Normal range of mood, implying absence of depressed or elevated mood.

evasion Act of not facing up to, or strategically eluding, something; consists of suppressing an idea that is next in a thought series and replacing it with another idea closely related to it. Also called *paralogia; perverted logic*.

exaltation Feeling of intense elation and grandeur.

excited Agitated, purposeless motor activity uninfluenced by external stimuli.

expansive mood Expression of feelings without restraint, frequently with an overestimation of their significance or importance. Seen in mania, grandiose delusional disorder.

expressive aphasia Disturbance of speech in which understanding remains but ability to speak is grossly impaired; halting, laborious, and inaccurate speech (also known as *Broca's, nonfluent*, and *motor aphasia*).

expressive dysphasia Difficulty in expressing verbal language; the ability to understand language is intact.

externalization More general term than *projection* that refers to the tendency to perceive in the external world and in external objects elements of one's own personality, including instinctual impulses, conflicts, moods, attitudes, and styles of thinking.

extroversion State of one's energies being directed outside oneself. *Compare* **introversion**.

fantasy Daydream; fabricated mental picture of a situation or chain of events. A normal form of thinking dominated by unconsciousness material that seeks wish fulfillment and solutions to conflicts; may serve as the matrix for creativity. The content of the fantasy may indicate mental illness.

false memory A person's recollection and belief by the patient of an event that did not actually occur. In *false memory syndrome* persons erroneously believe that they sustained an emotional or physical (e.g., sexual) trauma in early life.

fatigue A feeling of weariness, sleepiness, or irritability following a period of mental or bodily activity. Seen in depression, anxiety, neurasthenia, and somatoform disorders.

fausse reconnaissance False recognition, a feature of paramnesia. Can occur in delusional disorders.

fear Unpleasurable emotional state consisting of psychophysiological changes in response to a realistic threat or danger. *Compare* **anxiety**.

flat affect Absence or near absence of any signs of affective expression.

flight of ideas Rapid succession of fragmentary thoughts or speech in which content changes abruptly and speech may be incoherent. Seen in mania.

floccillation Aimless plucking or picking, usually at bedclothes or clothing, commonly seen in dementia and delirium.

fluent aphasia Aphasia characterized by inability to understand the spoken word; fluent but incoherent speech is present. Also called *Wernicke's, sensory*, and *receptive aphasia*.

folie à deux Mental illness shared by two persons, usually involving a common delusional system; if it involves three persons, it is referred to as *folie à trois,* etc. Also called *shared psychotic disorder*.

formal thought disorder Disturbance in the form of thought rather than the content of thought; thinking characterized by loosened associations, neologisms, and illogical constructs; thought process is disordered, and the person is defined as psychotic. Characteristic of schizophrenia.

formication Tactile hallucination involving the sensation that tiny insects are crawling over the skin. Seen in cocaine addiction and delirium tremens.

free-floating anxiety Severe, pervasive, generalized anxiety that is not attached to any particular idea, object, or event. Observed particularly in anxiety disorders, although it may be seen in some cases of schizophrenia.

fugue Dissociative disorder characterized by a period of almost complete amnesia, during which a person actually flees from an immediate life situation and begins a different life pattern; apart from the amnesia, mental faculties and skills are usually unimpaired.

galactorrhea Abnormal discharge of milk from the breast; may result from the endocrine influence (e.g., prolactin) of dopamine receptor antagonists, such as phenothiazines.

generalized tonic-clonic seizure Generalized onset of tonic-clonic movements of the limbs, tongue biting, and incontinence followed by slow, gradual recovery of consciousness and cognition; also called *grand mal seizure*.

global aphasia Combination of grossly nonfluent aphasia and severe fluent aphasia.

glossolalia Unintelligible jargon that has meaning to the speaker but not to the listener. Occurs in schizophrenia.

grandiosity Exaggerated feelings of one's importance, power, knowledge, or identity. Occurs in delusional disorder, manic states.

grief Alteration in mood and affect consisting of sadness appropriate to a real loss; normally, it is self limited. *See also* **depression; mourning**.

guilt Emotional state associated with self-reproach and the need for punishment. In psychoanalysis, refers to a feeling of culpability that stems from a conflict between the ego and the superego (conscience). Guilt has normal psychological and social functions, but special intensity or absence of guilt characterizes many mental disorders, such as depression and antisocial personality disorder, respectively. Psychiatrists distinguish shame as a less internalized form of guilt that relates more to others than to the self. *See also* **shame**.

gustatory hallucination Hallucination primarily involving taste.

gynecomastia Femalelike development of the male breasts; may occur as an adverse effect of antipsychotic and antidepressant drugs because of increased prolactin levels or anabolic-androgenic steroid abuse.

hallucination False sensory perception occurring in the absence of any relevant external stimulation of the sensory modality involved. For types of hallucinations, see the specific term.

hallucinosis State in which a person experiences hallucinations without any impairment of consciousness.

haptic hallucination Hallucination of touch.

hebephrenia Complex of symptoms, considered a form of schizophrenia, characterized by wild or silly behavior or mannerisms, inappropriate affect, and delusions and hallucinations that are transient and unsystematized. Hebephrenic schizophrenia is now called *disorganized schizophrenia*.

holophrastic Using a single word to express a combination of ideas. Seen in schizophrenia.

hyperactivity Increased muscular activity. The term is commonly used to describe a disturbance found in children that is manifested by constant restlessness, overactivity, distractibility, and difficulties in learning. Seen in *attention-deficit/hyperactivity disorder*.

hyperalgesia Excessive sensitivity to pain. Seen in somatoform disorder.

hyperesthesia Increased sensitivity to tactile stimulation.

hypermnesia Exaggerated degree of retention and recall. It can be elicited by hypnosis and may be seen in certain prodigies; also may be a feature of obsessive-compulsive disorder, some cases of schizophrenia, and manic episodes of bipolar I disorder.

hyperphagia Increase in appetite and intake of food.

hyperpragia Excessive thinking and mental activity. Generally associated with manic episodes of bipolar I disorder.

hypersomnia Excessive time spent asleep. May be associated with underlying medical or psychiatric disorder, narcolepsy, be part of the Klein-Levin syndrome, or be primary.

hyperventilation Excessive breathing, generally associated with anxiety, which can reduce blood carbon dioxide concentration and produce lightheadedness, palpitations, numbness, and tingling periorally and in the extremities, and occasionally syncope.

hypervigilance Excessive attention to, and focus on, all internal and external stimuli; usually seen in delusional or paranoid states.

hypesthesia Diminished sensitivity to tactile stimulation.

hypnagogic hallucination Hallucination occurring while falling asleep, not ordinarily considered pathological.

hypnopompic hallucination Hallucination occurring while awakening from sleep, ordinarily not considered pathological.

hypnosis Artificially induced alteration of consciousness characterized by increased suggestibility and receptivity to direction.

hypoactivity Decreased motor and cognitive activity, as in psychomotor retardation; visible slowing of thought, speech, and movements. Also called *hypokinesis*.

hypochondria Exaggerated concern about health that is based not on real medical pathology but on unrealistic interpretations of physical signs or sensations as abnormal.

hypomania Mood abnormality with the qualitative characteristics of mania but somewhat less intense. Seen in cyclothymic disorder.

idea of reference Misinterpretation of incidents and events in the outside world as having direct personal reference to oneself; occasionally observed in normal persons, but frequently seen in paranoid patients. If present with sufficient frequency or intensity or if organized and systematized, they constitute delusions of reference.

illogical thinking Thinking containing erroneous conclusions or internal contradictions; psychopathological only when it is marked and not caused by cultural values or intellectual deficit.

illusion Perceptual misinterpretation of a real external stimulus. *Compare* **hallucination**.

immediate memory Reproduction, recognition, or recall of perceived material within seconds after presentation. *Compare* **long-term memory; short-term memory**.

impaired insight Diminished ability to understand the objective reality of a situation.

impaired judgment Diminished ability to understand a situation correctly and to act appropriately.

impulse control Ability to resist an impulse, drive, or temptation to perform some action.

inappropriate affect Emotional tone out of harmony with the idea, thought, or speech accompanying it. Seen in schizophrenia.

incoherence Communication that is disconnected, disorganized, or incomprehensible. *See also* **word salad**.

incorporation Primitive unconscious defense mechanism in which the psychic representation of another person or aspects of another person are assimilated into oneself through a figurative process of symbolic oral ingestion; represents a special form of introjection and is the earliest mechanism of identification.

increased libido Increase in sexual interest and drive.

ineffability Ecstatic state in which persons insist that their experience is inexpressible and indescribable, that it is impossible to convey what it is like to one who never experienced it.

initial insomnia Falling asleep with difficulty; usually seen in anxiety disorder. *Compare* **middle insomnia; terminal insomnia**.

insight Conscious recognition of one's own condition. In psychiatry, it refers to the conscious awareness and understanding of one's own psychodynamics and symptoms of maladaptive behavior; highly important in effecting changes in the personality and behavior of a person.

insomnia Difficulty in falling asleep or difficulty in staying asleep. It can be related to a mental disorder, can be related to a physical disorder or an adverse effect of medication, or can be primary (not related to a known medical factor or another mental disorder). *See also* **initial insomnia; middle insomnia; terminal insomnia**.

intellectual insight Knowledge of the reality of a situation without the ability to use that knowledge successfully to effect an adaptive change in behavior or master the situation. *Compare* **true insight**.

intelligence Capacity for learning and ability to recall, integrate constructively, and apply what one has learned; the capacity to understand and think rationally.

intoxication Mental disorder caused by recent ingestion or presence in the body of an exogenous substance producing maladaptive behavior by virtue of its effects on the central nervous system. The most common psychiatric changes involve disturbances of perception, wakefulness, attention, thinking, judgment, emotional control, and psychomotor behavior; the specific clinical picture depends on the substance ingested.

intropunitive Turning anger inward toward oneself. Commonly observed in depressed patients.

introspection Contemplating one's own mental processes to achieve insight.

introversion State in which a person's energies are directed inward toward the self, with little or no interest in the external world.

irrelevant answer Answer that is not responsive to the question.

irritability Abnormal or excessive excitability, with easily triggered anger, annoyance, or impatience.

irritable mood State in which one is easily annoyed and provoked to anger. *See also* **irritability**.

jamais vu Paramnestic phenomenon characterized by a false feeling of unfamiliarity with a real situation that one has previously experienced.

jargon aphasia Aphasia in which the words produced are neologistic; that is, nonsense words created by the patient.

judgment Mental act of comparing or evaluating choices within the framework of a given set of values for the purpose of electing a course of action. If the course of action chosen is consonant with reality or with mature adult standards of behavior, judgment is said to be *intact* or *normal*; judgement is said to be *impaired* if the chosen course of action is frankly maladaptive, results from impulsive decisions based on the need for immediate gratification, or is otherwise not consistent with reality as measured by mature adult standards.

kleptomania Pathological compulsion to steal.

la belle indifférence Inappropriate attitude of calm or lack of concern about one's disability. May be seen in patients with conversion disorder.

labile affect Affective expression characterized by rapid and abrupt changes, unrelated to external stimuli.

labile mood Oscillations in mood between euphoria and depression or anxiety.

laconic speech Condition characterized by a reduction in the quantity of spontaneous speech; replies to questions are brief and unelaborated, and little or no unprompted additional information is provided. Occurs in major depression, schizophrenia, and organic mental disorders. Also called *poverty of speech*.

lethologica Momentary forgetting of a name or proper noun. *See* **blocking**.

Lilliputian hallucination Visual sensation that persons or objects are reduced in size, more properly regarded as an illusion. *See also* **micropsia**.

localized amnesia Partial loss of memory; amnesia restricted to specific or isolated experiences. Also called *lacunar amnesia; patch amnesia*.

logorrhea Copious, pressured, coherent speech; uncontrollable, excessive talking; observed in manic episodes of bipolar disorder. Also called *tachylogia; verbomania; volubility*.

loosening of associations Characteristic schizophrenic thinking or speech disturbance involving a disorder in the logical progression of thoughts, manifested as a failure to communicate verbally adequately; unrelated and unconnected ideas shift from one subject to another. *See also* **tangentiality**.

macropsia False perception that objects are larger than they really are. *Compare* **micropsia**.

magical thinking A form of dereistic thought; thinking similar to that of the preoperational phase in children (Jean Piaget), in which thoughts, words, or actions assume power (e.g., to cause or prevent events).

malingering Feigning disease to achieve a specific goal, for example, to avoid an unpleasant responsibility. *Compare* **factitious disorder**.

mania Mood state characterized by elation, agitation, hyperactivity, hypersexuality, and accelerated thinking and speaking (flight of ideas). Seen in bipolar I disorder. *See also* **hypomania**.

manipulation Maneuvering by patients to get their own way, characteristic of antisocial personalities.

mannerism Ingrained, habitual involuntary movement.

melancholia Severe depressive state. Used in the term *involutional melancholia* as a descriptive term and also in reference to a distinct diagnostic entity.

memory Process whereby what is experienced or learned is established as a record in the central nervous system (registration), where it persists with a variable degree of permanence (retention) and can be recollected or retrieved from storage at will (recall). For types of memory, see the specific term.

mental disorder Psychiatric illness or disease whose manifestations are primarily characterized by behavioral or psychological impairment of function, measured in terms of deviation from some normative concept; associated with distress or disease, not just an expected response to a particular event or limited to relations between a person and society.

mental retardation Subaverage general intellectual functioning that originates in the developmental period and is associated with impaired maturation and learning, and social maladjustment. Retardation is commonly defined in terms of intelligence quotient (I.Q.): mild (50–55 to 70), moderate (35–40 to 50–55), severe (20–25 to 35–40) and profound (below 20–25).

metonymy Speech disturbance common in schizophrenia in which the affected person uses a word or phrase that is related to the proper one but is not the one ordinarily used; for example, the patient speaks of consuming a “menu” rather than a “meal,” or refers to losing the “piece of string” of the conversation, rather than the “thread” of the conversation. *See also* **paraphasia; word approximation**.

microcephaly Condition in which the head is unusually small as a result of defective brain development and premature ossification of the skull.

micropsia False perception that objects are smaller than they really are. Sometimes called *Lilliputian hallucination. Compare* **macropsia**.

middle insomnia Waking up after falling asleep without difficulty and then having difficulty in falling asleep again. *Compare* **initial insomnia; terminal insomnia**.

mimicry Simple, imitative motion activity of childhood.

monomania Mental state characterized by preoccupation with one subject.

mood Pervasive and sustained feeling tone that is experienced internally and that, in the extreme, can markedly influence virtually all aspects of a person's behavior and perception of the world. Distinguished from affect, the external expression of the internal feeling tone. For types of mood, see the specific term.

mood-congruent delusion Delusion with content that is mood appropriate (e.g., depressed patients who believe they are responsible for the destruction of the world).

mood-congruent hallucination Hallucination with content that is consistent with either a depressed or manic mood (e.g., depressed patients hearing voices telling them that they are bad persons; manic patients hearing voices telling them that they have inflated worth, power, or knowledge).

mood-incongruent delusion Delusion based on incorrect reference about external reality, with content that has no association to mood or is mood inappropriate (e.g., depressed patients who believe that they are the new Messiah).

mood-incongruent hallucination Hallucination not associated with real external stimuli, with content that is not consistent with either depressed or manic mood (e.g., in depression, hallucinations not involving such themes as guilt, deserved punishment, or inadequacy; in mania, not involving such themes as inflated worth or power).

mood swings Oscillation of a person's emotional feeling tone between periods of elation and periods of depression.

motor aphasia Aphasia in which understanding is intact but the ability to speak is lost. Also called *Broca's expressive* or *nonfluent aphasia*.

mourning Syndrome following loss of a loved one, consisting of preoccupation with the lost individual, weeping, sadness, and repeated reliving of memories. *See also* **bereavement; grief**.

muscle rigidity State in which the muscles remain immovable; seen in schizophrenia.

mutism Organic or functional absence of the faculty of speech. *See also* **stupor**.

mydriasis Dilation of the pupil; sometimes occurs as an autonomic (anticholinergic) or atropine-like adverse effect of some antipsychotic and antidepressant drugs.

needle phobia The persistent, intense, pathological fear of receiving an injection.

negativism Verbal or nonverbal opposition or resistance to outside suggestions and advice; commonly seen in catatonic schizophrenia in which the patient resists any effort to be moved or does the opposite of what is asked.

negative signs In schizophrenia: flat affect, alogia, abulia, apathy.

neologism New word or phrase whose derivation cannot be understood; often seen in schizophrenia. It has also been used to mean a word that has been incorrectly constructed but whose origins are nonetheless understandable (e.g., “headshoe” to mean “hat”), but such constructions are more properly referred to as *word approximations*.

neurological amnesia 1. Auditory amnesia: loss of ability to comprehend sounds or speech. 2. Tactile amnesia: loss of ability to judge the shape of objects by touch. *See also* **astereognosis**. 3. Verbal amnesia: loss of ability to remember words. 4. Visual amnesia: loss of ability to recall or recognize familiar objects or printed words.

nihilism Delusion of the nonexistence of the self or part of the self; also refers to an attitude of total rejection of established values or extreme skepticism regarding moral and value judments.

nihilistic delusion Depressive delusion that the world and everything related to it have ceased to exist.

noeisis Revelation in which immense illumination occurs in association with a sense that one has been chosen to lead and command. Can occur in manic or dissociative states.

nominal aphasia Aphasia characterized by difficulty in giving the correct name of an object. *See also* **anomia; amnestic aphasia**.

nymphomania Abnormal, excessive, insatiable desire in a female for sexual intercourse. *Compare* **satyriasis**.

obsession Persistent and recurrent idea, thought, or impulse that cannot be eliminated from consciousness by logic or reasoning; obsessions are involuntary and ego-dystonic. *See also* **compulsion**.

olfactory hallucination Hallucination primarily involving smell or odors; most common in medical disorders, especially in the temporal lobe.

orientation State of awareness of oneself and one's surroundings in terms of time, place, and person.

overactivity Abnormality in motor behavior that can manifest itself as psychomotor agitation, hyperactivity (hyperkinesis), tics, sleepwalking, or compulsions.

overvalued idea False or unreasonable belief or idea that is sustained beyond the bounds of reason. It is held with less intensity or duration than a delusion, but is usually associated with mental illness.

panic Acute, intense attack of anxiety associated with personality disorganization; the anxiety is overwhelming and accompanied by feelings of impending doom.

panphobia Overwhelming fear of everything.

pantomime Gesticulation; psychodrama without the use of words.

paramnesia Disturbance of memory in which reality and fantasy are confused. It is observed in dreams and in certain types of schizophrenia and organic mental disorders; includes phenomena such as déjà vu and *déjà entendu*, which may occur occasionally in normal persons.

paranoia Rare psychiatric syndrome marked by the gradual development of a highly elaborate and complex delusional system, generally involving persecutory or grandiose delusions, with few other signs of personality disorganization or thought disorder.

paranoid delusions Includes persecutory delusions and delusions of reference, control, and grandeur.

paranoid ideation Thinking dominated by suspicious, persecutory, or grandiose content of less than delusional proportions.

paraphasia Abnormal speech in which one word is substituted for another, the irrelevant word generally resembling the required one in morphology, meaning, or phonetic composition; the inappropriate word may be either a legitimate one used incorrectly, such as “clover” instead of “hand,” or a bizarre nonsense expression, such as “treen” instead of “train.” Paraphasic speech may be seen in organic aphasias and in mental disorders such as schizophrenia. *See also* **metonymy; word approximation**.

parapraxis Faulty act, such as a slip of the tongue or the misplacement of an article. Freud ascribed parapraxes to unconscious motives.

paresis Weakness or partial paralysis of organic origin.

paresthesia Abnormal spontaneous tactile sensation, such as a burning, tingling, or pins-and-needles sensation.

perception Conscious awareness of elements in the environment by the mental processing of sensory stimuli; sometimes used in a broader sense to refer to the mental process by which all kinds of data, intellectual, emotional, as well as sensory, are meaningfully organized. *See also* **apperception**.

perseveration 1. Pathological repetition of the same response to different stimuli, as in a repetition of the same verbal response to different questions. 2. Persistent repetition of specific words or concepts in the process of speaking. Seen in cognitive disorders, schizophrenia, and other mental illness. *See also* **verbigeration**.

phantom limb False sensation that an extremity that has been lost is in fact present.

phobia Persistent, pathological, unrealistic, intense fear of an object or situation; the phobic person may realize that the fear is irrational but, nonetheless, cannot dispel it. For types of phobias, see the specific term.

pica Craving and eating of nonfood substances, such as paint and clay.

polyphagia Pathological overeating.

positive signs In schizophrenia: hallucinations, delusions, thought disorder.

posturing Strange, fixed, and bizarre bodily positions held by a patient for an extended time. *See also* **catatonia**.

poverty of content of speech Speech that is adequate in amount but conveys little information because of vagueness, emptiness, or stereotyped phrases.

poverty of speech Restriction in the amount of speech used; replies may be monosyllabic. *See also* **laconic speech**.

preoccupation of thought Centering of thought content on a particular idea, associated with a strong affective tone, such as a paranoid trend or a suicidal or homicidal preoccupation.

pressured speech Increase in the amount of spontaneous speech; rapid, loud, accelerated speech, as occurs in mania, schizophrenia, and cognitive disorders.

primary process thinking In psychoanalysis, the mental activity directly related to the functions of the id and characteristic of unconscious mental processes; marked by primitive, prelogical thinking and by the tendency to seek immediate discharge and gratification of instinctual demands. Includes thinking that is dereistic, illogical, magical; normally found in dreams, abnormally in psychosis. *Compare* **secondary process thinking**.

projection Unconscious defense mechanism in which persons attribute to another those generally unconscious ideas, thoughts, feelings, and impulses that are in themselves undesirable or unacceptable as a form of protection from anxiety arising from an inner conflict; by externalizing whatever is unacceptable, they deal with it as a situation apart from themselves.

prosopagnosia Inability to recognize familiar faces that is not due to impaired visual acuity or level of consciousness.

pseudocyesis Rare condition in which a nonpregnant patient has the signs and symptoms of pregnancy, such as abdominal distention, breast enlargement, pigmentation, cessation of menses, and morning sickness.

pseudodementia 1. Dementia-like disorder that can be reversed by appropriate treatment and is not caused by organic brain disease. 2. Condition in which patients show exaggerated indifference to their surroundings in the absence of a mental disorder; also occurs in depression and factitious disorders.

pseudologia phantastica Disorder characterized by uncontrollable lying in which patients elaborate extensive fantasies that they freely communicate and act upon.

psychomotor agitation Physical and mental overactivity that is usually nonproductive and is associated with a feeling of inner turmoil, as seen in agitated depression.

psychosis Mental disorder in which the thoughts, affective response, ability to recognize reality, and ability to communicate and relate to others are sufficiently impaired to interfere grossly with the capacity to deal with reality; the classical characteristics of psychosis are impaired reality testing, hallucinations, delusions, and illusions.

psychotic 1. Person suffering from psychosis. 2. Denoting or characteristic of psychosis.

rationalization An unconscious defense mechanism in which irrational or unacceptable behavior, motives, or feelings are logically justified or made consciously tolerable by plausible means.

reaction formation Unconscious defense mechanism in which a person develops a socialized attitude or interest that is the direct antithesis of some infantile wish or impulse that is harbored either consciously or unconsciously. One of the earliest and most unstable defense mechanisms, closely related to repression; both are defenses against impulses or urges that are unacceptable to the ego.

reality testing Fundamental ego function that consists of tentative actions that test and objectively evaluate the nature and limits of the environment; includes the ability to differentiate between the external world and the internal world and to accurately judge the relation between the self and the environment.

recall Process of bringing stored memories into consciousness. *See also* **memory**.

recent memory Recall of events over the past few days.

recent past memory Recall of events over the past few months.

receptive aphasia Organic loss of ability to comprehend the meaning of words; fluid and spontaneous but incoherent and nonsensical speech. *See also* **fluent aphasia; sensory aphasia**.

receptive dysphasia Difficulty in comprehending oral language; the impairment involves both comprehension and production of language.

regression Unconscious defense mechanism in which a person undergoes a partial or total return to earlier patterns of adaptation; observed in many psychiatric conditions, particularly schizophrenia.

remote memory Recall of events in distant past.

repression Freud's term for an unconscious defense mechanism in which unacceptable mental contents are banished or kept out of consciousness; important in both normal psychological development and in neurotic and psychotic symptom formation. Freud recognized two kinds of repression: (1) repression proper, in which the repressed material was once in the conscious domain and (2) primal repression, in which the repressed material was never in the conscious realm. *Compare* **suppression**.

restricted affect Reduction in intensity of feeling tone less severe than in blunted affect but clearly reduced. *See also* **constricted affect**.

retrograde amnesia Loss of memory for events preceding the onset of the amnesia. *Compare* **anterograde amnesia**.

retrospective falsification Memory becomes unintentionally (unconsciously) distorted by being filtered through a person's present emotional, cognitive, and experiential state.

rigidity In psychiatry, a person's resistance to change, a personality trait.

ritual 1. Formalized activity practiced by a person to reduce anxiety, as in obsessive-compulsive disorder. 2. Ceremonial activity of cultural origin.

rumination Constant preoccupation with thinking about a single idea or theme, as in obsessive-compulsive disorder.

satyriasis Morbid, insatiable sexual need or desire in a male. *Compare* **nymphomania**.

scotoma 1. In psychiatry, a figurative blind spot in a person's psychological awareness. 2. In neurology, a localized visual field defect.

secondary process thinking In psychoanalysis, the form of thinking that is logical, organized, reality oriented, and influenced by the demands of the environment; characterizes the mental activity of the ego. *Compare* **primary process thinking**.

seizure An attack or sudden onset of certain symptoms, such as convulsions, loss of consciousness, and psychic or sensory disturbances; seen in epilepsy and can be substance induced. For types of seizures, see the specific term.

sensorium Hypothetical sensory center in the brain that is involved with clarity of awareness about oneself and one's surroundings, including the ability to perceive and process ongoing events in light of past experiences, future options, and current circumstances; sometimes used interchangeably with *consciousness*.

sensory aphasia Organic loss of ability to comprehend the meaning of words; fluid and spontaneous but incoherent and nonsensical speech. *See also* **fluent aphasia; receptive aphasia**.

sensory extinction Neurological sign operationally defined as failure to report one of two simultaneously presented sensory stimuli, despite the fact that either stimulus alone is correctly reported. Also called *sensory inattention*.

shame Failure to live up to self-expectations; often associated with fantasy of how person will be seen by others. *See also* **guilt**.

simultanagnosia Impairment in the perception or integration of visual stimuli appearing simultaneously.

somatic delusion Delusion pertaining to the functioning of one's body.

somatic hallucination Hallucination involving the perception of a physical experience localized within the body.

somatopagnosia Inability to recognize a part as one's own (also called *ignorance of the body* and *autotopagnosia*).

somnolence Pathological sleepiness or drowsiness from which one can be aroused to a normal state of consciousness.

spatial agnosia Inability to recognize spatial relations.

speaking in tongues Expression of a revelatory message through unintelligible words; not considered a disorder of thought if associated with practices of specific Pentecostal religions. *See also* **glossolalia**.

stereotypy Continuous mechanical repetition of speech or physical activities; observed in catatonic schizophrenia.

stupor 1. State of decreased reactivity to stimuli and less than full awareness of one's surroundings; as a disturbance of consciousness, it indicates a condition of partial coma or semicoma. 2. In psychiatry, used synonymously with *mutism* and does not necessarily imply a disturbance of consciousness; in *catatonic stupor*, patients are ordinarily aware of their surroundings.

stuttering Frequent repetition or prolongation of a sound or syllable, leading to markedly impaired speech fluency.

sublimation Unconscious defense mechanism in which the energy associated with unacceptable impulses or drives is diverted into personally and socially acceptable channels; unlike other defense mechanisms, it offers some minimal gratification of the instinctual drive or impulse.

substitution Unconscious defense mechanism in which a person replaces an unacceptable wish, drive, emotion, or goal with one that is more acceptable.

suggestibility State of uncritical compliance with influence or of uncritical acceptance of an idea, belief, or attitude; commonly observed among persons with hysterical traits.

suicidal ideation Thoughts or act of taking one's own life.

suppression Conscious act of controlling and inhibiting an unacceptable impulse, emotion, or idea; differentiated from repression in that repression is an unconscious process.

symbolization Unconscious defense mechanism in which one idea or object comes to stand for another because of some common aspect or quality in both; based on similarity and association; the symbols formed protect the person from the anxiety that may be attached to the original idea or object.

synesthesia Condition in which the stimulation of one sensory modality is perceived as sensation in a different modality, as when a sound produces a sensation of

color.

syntactical aphasia Aphasia characterized by difficulty in understanding spoken speech, associated with gross disorder of thought and expression.

systematized delusion Group of elaborate delusions related to a single event or theme.

tactile hallucination Hallucination primarily involving the sense of touch. Also called *haptic hallucination*.

tangentiality Oblique, degressive, or even irrelevant manner of speech in which the central idea is not communicated.

tension Physiological or psychic arousal, uneasiness, or pressure toward action; an unpleasurable alteration in mental or physical state that seeks relief through action.

terminal insomnia Early morning awakening or waking up at least 2 hours before planning to. *Compare* **initial insomnia; middle insomnia**.

thought broadcasting Feeling that one's thoughts are being broadcast or projected into the environment. *See also* **thought withdrawal**.

thought disorder Any disturbance of thinking that affects language, communication, or thought content; the hallmark feature of schizophrenia. Manifestations range from simple blocking and mild circumstantiality to profound loosening of associations, incoherence, and delusions; characterized by a failure to follow semantic and syntactic rules which is inconsistent with the person's education, intelligence, or cultural background.

thought insertion Delusion that thoughts are being implanted in one's mind by other people or forces.

thought withdrawal Delusion that one's thoughts are being removed from one's mind by other people or forces. *See also* **thought broadcasting**.

tic disorders Predominantly psychogenic disorders characterized by involuntary, spasmodic, stereotyped movement of small groups of muscles; seen most predominantly in moments of stress or anxiety, rarely as a result of organic disease.

tinnitus Noises in one or both ears, such as ringing, buzzing, or clicking; an adverse effect of some psychotropic drugs.

tonic convulsion Convulsion in which the muscle contraction is sustained.

trailing phenomenon Perceptual abnormality associated with hallucinogenic drugs in which moving objects are seen as a series of discrete and discontinuous images.

trance Sleeplike state of reduced consciousness and activity.

tremor Rhythmical alteration in movement, which is usually faster than one beat a second; typically, tremors decrease during periods of relaxation and sleep and increase during periods of anger and increased tension.

true insight Understanding of the objective reality of a situation coupled with the motivational and emotional impetus to master the situation or change behavior.

twilight state Disturbed consciousness with hallucinations.

twirling Sign present in autistic children who continually rotate in the direction in which their head is turned.

unconscious 1. One of three divisions of Freud's topographic theory of the mind (the others being the conscious and the preconscious) in which the psychic material is not readily accessible to conscious awareness by ordinary means; its existence may be manifest in symptom formation, in dreams, or under the influence of drugs. 2. In popular (but more ambiguous) usage, any mental material not in the immediate field of awareness. 3. Denoting a state of unawareness, with lack of response to external stimuli, as in a coma.

undoing Unconscious primitive defense mechanism, repetitive in nature, by which a person symbolically acts out in reverse something unacceptable that has already been done or against which the ego must defend itself; a form of magical expiatory action, commonly observed in obsessive-compulsive disorder.

unio mystica Feeling of mystic unity with an infinite power.

vegetative signs In depression, denoting characteristic symptoms such as sleep disturbance (especially early morning awakening), decreased appetite, constipation, weight loss, and loss of sexual response.

verbigeration Meaningless and stereotyped repetition of words or phrases as seen in schizophrenia. Also called *cataphasia. See also* **perseveration**.

vertigo Sensation that one or the world around one is spinning or revolving; a hallmark of vestibular dysfunction, not to be confused with dizziness.

visual agnosia Inability to recognize objects or persons.

visual amnesia *See* **neurological amnesia**.

visual hallucination Hallucination primarily involving the sense of sight.

waxy flexibility Condition in which person maintains the body position into which they are placed. Also called catalepsy.

word approximation Use of conventional words in an unconventional or inappropriate way (metonymy or of new words that are developed by conventional rules of word formation) (e.g., “handshoes” for gloves and “time measure” for clock); distinguished from a *neologism*, which is a new word whose derivation cannot be understood. *See also* **paraphasia**.

word salad Incoherent, essentially incomprehensible mixture of words and phrases commonly seen in far-advanced cases of schizophrenia. *See also* **incoherence**.

xenophobia Abnormal fear of strangers.

zoophobia Abnormal fear of animals.

SIGNS AND SYMPTOMS REVISITED

Descriptions of signs and symptoms in psychiatry have remained fairly constant over the years; however some terms fall in and out of favor. In the various editions of *Diagnostic and Statistical Manual of Mental Disorders* (DSM), for example, some terms have been retained and others omitted, and some terms are not common to DSM and the *International Classification of Diseases* (ICD)

The fourth edition of DSM (DSM-IV) eliminated the diagnosis of organic mental disorder in an attempt to indicate that all mental disorders may have a biological basis,

or medical cause. The diagnosis of organic mental disorder is called “delirium, dementia, and amnestic and other cognitive disorders” in DSM-IV. The 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), however, retains the diagnostic category of organic mental disorders.

Neurasthenia is omitted from DSM-IV but is retained in ICD-10. Although a significant number of patients diagnosed with neurasthenia can also be classified as having a depressive or anxiety disorder, many patients cannot, and ICD-10 reflects that fact.

DSM-IV eschews the term “psychogenic.” Nevertheless, it appears in ICD-10 to refer to the fact that life events or difficulties play an important role in the genesis of many psychiatric disorders. Similarly, DSM-IV has eliminated the term “neurosis,” which is used in ICD-10. The author regards both as useful terms that should be retained.

The grouping of signs and symptoms with diseases, disorders, or syndromes may be influenced by social traditions, prevalent customs or philosophies, and even unconscious determinants such as the classifier's view of the world. Over 35 years ago, Karl Menninger anticipated the structure of the mathematical device currently in use in DSM-IV. He wrote: “If the patient has, let us say, five symptoms, one can look up each of these symptoms and find which disease is so characterized under all five headings. Then, *voila*! the diagnosis!” Menninger suggested that the trend toward tabulating disease states was antithetical to understanding the person experiencing the illness and deemphasized the compassionate approach toward the patient that is the hallmark of psychiatry. That mathematical approach is reflected in the algorithms and decision trees used in DSM-IV and in the various computer programs that record signs and symptoms to provide a diagnosis.

All those who work with the mentally ill must consider that a description of a sign and symptom is a fact that can be validated by a group of observers. It is not emotive. A description of signs and symptoms is the science of psychiatry; the skill of the observers and their creative imagination and ability to empathize is the art of psychiatry.

SUGGESTED CROSS-REFERENCES

Section 7.2 describes the psychiatric report and medical record. Chapter 8 on clinical manifestations of mental disorders, provides examples of signs and symptoms in psychiatric disorders. Section 9.1 describes the classification of mental disorders.

7.4 CLINICAL NEUROPSYCHOLOGY AND INTELLECTUAL ASSESSMENT OF ADULTS

REX M. SWANDA, PH.D., KATHLEEN Y. HAALAND, PH.D., AND ASENATH LARUE, PH.D.

Clinical neuropsychology is a specialty in psychology that examines the relationship between behavior and brain functioning in the realms of cognitive, motor, sensory, and emotional functioning. In general, the clinical neuropsychologist integrates the medical and psychosocial history with the reported complaints and the pattern of performance on neuropsychological procedures to determine whether results are consistent with a particular area of brain damage or a particular diagnosis. Although neurological syndromes are often the focus of referrals, the neuropsychological examination also has a valuable place in diagnosing and treating behavioral symptoms that are associated with other medical, psychological, and psychiatric conditions.

NEUROPSYCHOLOGY AND OTHER DISCIPLINES

The unique contributions of neuropsychology can be clarified by examining its relationship to the closely allied disciplines of clinical psychology, behavioral neurology, and neuropsychiatry.

Clinical Psychology Clinical neuropsychology is recognized by the American Psychological Association as a distinct specialty area, with board certification through the American Board of Clinical Neuropsychology under the auspices of the American Board of Professional Psychology. It is primarily differentiated from general clinical psychology by its focus on thorough and extensive evaluation of a broad range of cognitive and emotional factors and their potential relationship to brain damage. There is considerable overlap between the two areas in the approach to assessment, chiefly characterized by reliance on the psychometric foundations of reliability, validity, and normative standards to define behavioral symptoms and complaints objectively. Emotional factors are the province of both. Both evaluate cognition, although the clinical psychologist generally focuses on issues involving general intellectual, academic, and vocational skills rather than neurological factors. Both clinical psychologists and neuropsychologists are involved in treatment, which can include psychotherapy as well as cognitive retraining to remediate deficits. Psychoeducational functions are also served by both fields in discussing symptoms, assessment results, and their implications with patient, caregivers, and other health professionals.

Behavioral Neurology and Neuropsychiatry The medical specialties of behavioral neurology and neuropsychiatry overlap considerably with clinical neuropsychology. However, the neuropsychologist's unique contribution to the assessment of cognitive deficits lies in the theoretical background in cognitive psychology as well as psychometrically based methods, which use standardized instruments with age- and education-based normative data whenever possible. In contrast, the behavioral neurologist and neuropsychiatrist are more likely to use a mental status examination to identify cognitive deficits, relying on internal norms, which are based upon the individual clinician's extensive experience with the examination procedures or pathognomonic signs (e.g., dysfluent speech, visual neglect). The behavioral neurologist is trained to diagnose a broad spectrum of neurological disorders, the neuropsychiatrist's focus lies in diagnosing neurological features of psychiatric patients, and the neuropsychologist focuses on the cognitive and behavioral manifestations of a broad range of disorders that can produce cognitive impairment. Ideally, all three work together to provide complementary perspectives to a patient's workup.

HISTORY

Clinical neuropsychology has its roots in psychology, neurology, and psychiatry. The groundbreaking work of Pierre Broca and Carl Wernicke in the nineteenth century first suggested that complex functions such as speech and auditory comprehension could be localized to particular areas in the left hemisphere. In 1909, Karl Brodmann published a “cytoarchitectonic” map of the cerebral cortex (Fig. 7.4-1), based on different histological patterns of cells in various parts of the cortex. Over the years, this representational map has proved to have value in identifying functional differences across distinctive cortical regions and has become a standard reference for identifying cortical areas. Views of functional localization were repopularized in the 1960s by Norman Geschwind, who emphasized the importance of connections among different parts of the brain in producing complex behavior. Arthur Benton's Iowa school developed a series of carefully constructed psychometric tests, based on concepts that had originally been identified by behavioral neurology to assess specific deficits relative to the normal population. At about the same time, Hans-Lukas Teuber defined the concept of “double dissociation,” which is regarded as the strongest evidence for localization of a particular function. This notion is based on observations of mutually exclusive brain-behavior relationships, such that damage affecting region 1 produces performance deficits in test A but not in test B, while damage affecting region 2 produces performance deficits in test B but not in test A. Aleksandr Luria, the Russian neuropsychologist, also developed notions of functional localization but used a theoretical framework that associated component cognitive processes with complex skills and their neuroanatomical correlates. In the United States, Ralph Reitan applied the psychometric standards of North America to a number of instruments for the express purpose of assessing brain damage, resulting in the widely used Halstead-Reitan Neuropsychological Test Battery.

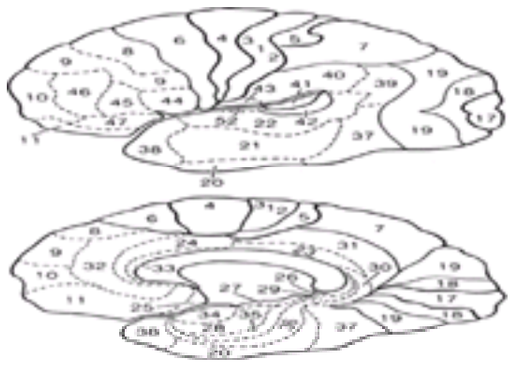

FIGURE 7.4-1 Brodmann areas of the human cortex, showing convex surface **(top)** and medial surface **(bottom)**. (Reproduced with permission from Elliott HC: *Textbook of Neuroanatomy*. Lippincott, Philadelphia, 1969.)

NEUROANATOMICAL CORRELATES

The early history of neuropsychology was driven in large part by the goal of linking behavioral deficits to specific neuroanatomical areas of dysfunction or damage. Although this emphasis served the important function of validating neuropsychological tests that are commonly used today, the localizing function of neuropsychological assessment is now less important in light of recent advances in neuroimaging techniques. Increasing knowledge in the neurosciences has also led to a more sophisticated view, in which complex cognitive, perceptual, and motor activities are controlled by neural systems rather than single structures within the brain. For instance, neuroanatomical studies have identified multiple parallel circuits that interconnect various cortical and subcortical sites, and each of these different circuits appears to subserve different behavioral functions. While the complexity of these relationships is important to appreciate, it is also necessary to understand that certain areas within both the cerebral cortex and subcortical areas, such as the basal ganglia, influence some behaviors more than others. An understanding of these brain-behavior relationships is particularly helpful when evaluating patients with focal damage, to ensure that the neuropsychological

evaluation adequately assesses relevant behavior that is likely to be associated with that area and its interconnecting pathways.

HEMISPHERIC DOMINANCE AND INTRAHEMISPHERIC LOCALIZATION

Many functions are mediated by both the right and left cerebral hemispheres. However, important qualitative differences between the two hemispheres can be demonstrated in the presence of lateralized brain injury. Various cognitive skills that have been linked to the left or right hemisphere in right-handed people are listed in Table 7.4-1. Although language is the most obvious area that is largely controlled by the left hemisphere, the left hemisphere is also generally considered to be dominant for limb praxis (i.e., performing complex movements, such as brushing teeth, to command or imitation) and has been associated with the cluster of deficits identified as Gerstmann syndrome (i.e., finger agnosia, dyscalculia, dysgraphia, and right-left disorientation). In contrast, the right hemisphere is thought to play a more important role in controlling visuospatial abilities and hemispatial attention, which are associated with the clinical presentations of constructional apraxia and neglect, respectively.

Left Hemisphere	Right Hemisphere
Aphasia	Visuospatial deficits
Right-left disorientation	Impaired visual perception
Finger agnosia	Neglect
Dysgraphia (aphasic)	Dysgraphia (spatial, neglect)
Dyscalculia (number alexia)	Dyscalculia (spatial)
Constructional apraxia (details)	Constructional apraxia (Gestalt)
Limb apraxia	Dressing apraxia
	Anosognosia

Table 7.4-1 Selected Neuropsychological Deficits Associated With Left or Right Hemisphere Damage

Although lateralized deficits such as these are typically characterized in terms of damage to the right or left hemisphere, it is important to keep in mind that the patient's performance can also be characterized in terms of preserved brain functions. In other words, it is the remaining intact brain tissue that drives many behavioral responses following injury to the brain—and not only the absence of critical brain tissue.

Language Disorders The special role of the left hemisphere in the control of language functions in most right-handed individuals has been validated in many studies. These include the results of sodium amytal testing in epilepsy surgery patients as well as the incidence of aphasia following unilateral stroke to the left versus right hemisphere. Although it is rare for right-handers to be right hemisphere dominant for language, it does occur in about 1 percent of the cases. Hemispheric dominance for language in left-handed people is less predictable. About two thirds of left-handers are actually left hemisphere dominant for language, while about 20 percent each are right hemisphere dominant or bilaterally dominant.

A number of classification systems have been developed over the years to describe various patterns of language breakdown. A common method takes into account the presence or absence of three key features: (1) fluency, (2) comprehension, and (3) repetition (i.e., intact ability to repeat verbally presented words or phrases).

Broca's Aphasia Broca's aphasia (also called nonfluent, or expressive aphasia) has traditionally been characterized by impaired verbal fluency, intact auditory comprehension, and somewhat impaired repetition. It has long been thought to be associated with damage to Broca's area (i.e., left inferior frontal convolution) or Brodmann area 44 (Fig. 7.4-1). However, more-recent neuroimaging data in stroke patients has shown that the full syndrome of Broca's aphasia, including agrammatism (telegraphic speech), is found only in the presence of more extensive damage that encompasses the suprasylvian area from Broca's area to the posterior extent of the sylvian fissure.

Wernicke's Aphasia Wernicke's aphasia (also called fluent or receptive aphasia) is characterized by intact verbal fluency, impaired comprehension, and somewhat impaired repetition. It has been associated with damage to Wernicke's area in the region of the superior temporal gyrus. The impaired ability to comprehend has a direct impact on the individual's ability to self-monitor language output and may be related to a breakdown of the syntactic structure of language. It would not be unusual for an affected patient to fluently produce unintelligible strings of utterances that might potentially be confused with the so-called jargon aphasia which is associated with schizophrenia.

Conduction Aphasia Patients with conduction aphasia demonstrate relatively intact auditory comprehension and spontaneous speech, because of the preservation of Wernicke's and Broca's areas. However, the ability to repeat words and phrases is specifically impaired, traditionally attributed to damage to the arcuate fasciculus, which interconnects Wernicke's and Broca's areas.

Global Aphasia Another common classification, global aphasia, is characterized by impairment in all three dimensions of fluency, comprehension, and repetition. In reality many patients with aphasia cannot be neatly classified within a specific system because the pattern of deficits does not exactly fit clear descriptive categories. In fact, detailed language assessment of most aphasic patients typically demonstrates deficits in all three areas, although the degree of deficit among the three areas varies.

Limb Apraxia Limb apraxia and other cognitive-motor skills deficits are more commonly seen with left than with right hemispheric damage. There are data that show that the difference in the incidence of limb apraxia after left or right hemispheric damage is not as great as with language. This suggests that left hemisphere dominance for disorders of complex movement is not as strong as for language. While limb apraxia has not traditionally been considered to be of substantial functional importance, recent data reviewed by Leslie Rothi and Kenneth Heilman also suggest that limb apraxia significantly affects rehabilitation outcome. For instance, ideomotor limb apraxia can be associated with impaired spatiotemporal execution of complex movements, which results in orientation errors, such as carving a turkey by moving the knife up and down rather than back and forth. Conceptual apraxia might result in using the wrong object to perform a movement, such as attempting to use a toothbrush to eat. Finally, sequencing errors and ideational errors can lead to disrupted activities, such as trying to light a candle before striking the match.

Arithmetic Arithmetic skills can be impaired after either left or right hemispheric damage. Left hemispheric damage, especially of the parietal lobe, produces difficulty in reading and appreciating the symbolic meaning of numbers (number dyslexia). Left hemispheric damage can also be associated with impaired conceptual understanding of the problem (anarithmetria). In contrast, the deficits in arithmetic computation that can accompany right hemispheric damage are more likely to be observed in written problems. These emerge as problems with the spatial aspects of arithmetic, such as errors resulting from hemispatial neglect, poor alignment of columns, or visual misperceptions and rotations that can result in confusion of signs for addition and multiplication.

Spatial Disorders Right hemispheric damage in right-handers is frequently associated with deficits in visuospatial skills. Common assessment techniques include drawings and constructional or spatial assembly tasks.

Visuospatial Distinctive qualitative errors in constructing block designs and in drawing a complex geometric configuration (e.g., Rey-Osterreith Complex Figure) can be seen with either right or left hemispheric damage. In the presence of lateralized damage to the right hemisphere, impaired performances often reflect the patient's inability to appreciate the gestalt or global features of a design. In the example shown in Figure 7.4-2, this is seen in the patient's failure to maintain the 2 × 2 matrix of blocks, which is instead converted into a column of four blocks. In contrast, damage to the left hemisphere commonly results in inaccurate reproduction of internal details of the design, including improper orientation of individual blocks, but the 2 × 2 matrix (i.e., the gestalt) is more likely to be preserved. Similar differences can be seen with drawings, as in the example of the Rey-Osterreith Complex Figure shown in Figure 7.4-3. The patient with right parietal damage draws isolated details of the design, while failing to convey the interrelationship of the details in the overall design configuration. In contrast, the patient with left hemisphere damage tends to maintain the global framework of the design but lose the details. Therefore, many neuropsychologists emphasize that a neuropsychological understanding of the impairment depends not just on a set of test scores, but also on a qualitative description of the type of error. This often allows the impairment to be linked to a specific

neuroanatomical region as well as enabling a better understanding of the mechanisms of the deficit for rehabilitation purposes.

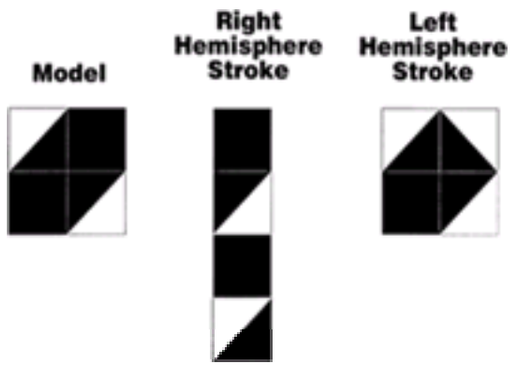

FIGURE 7.4-2 Examples of Block Design constructions seen in a right hemispheric stroke patient and a left hemispheric stroke patient.

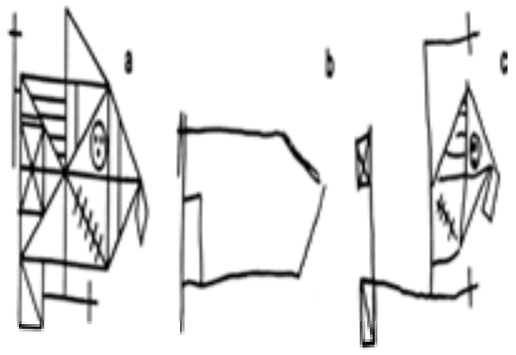

FIGURE 7.4-3 Rey-Osterreith Complex Figure **(a)** model, and drawings from memory by **(b)** a patient with left hemispheric injury and **(c)** a patient with right hemispheric injury. (Courtesy of Academic Press.)

In another example, damage to the right hemisphere tends to be associated with decreased appreciation of global features of visual stimuli, while left hemispheric damage tends to be associated with decreased analysis of local features and detail. This notion is illustrated in Figure 7.4-4, where a left hemisphere–damaged patient reproduces ambiguous figures as a simple triangle or letter “M” with no regard for the internal characters that actually make up the designs. In contrast, the local approach of a patient with right hemispheric damage emphasizes the internal details (small rectangles or letter “Z”) without appreciation for the gestalt that is formed by the internal details. This example also illustrates the important point that behavioral responses (including errors) are driven as much by preserved regions of intact brain functioning as by the loss of other regions of brain functioning.

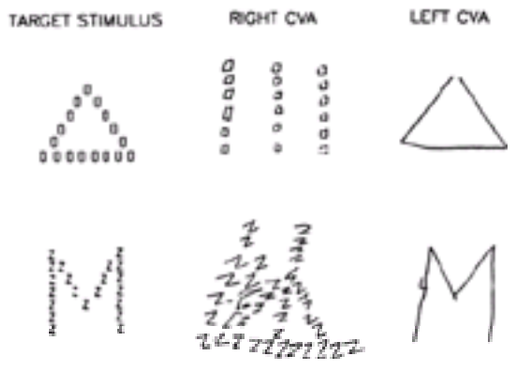

FIGURE 7.4-4 Global local target stimuli with drawings from memory by a patient with right hemispheric cerebrovascular accident (CVA) and by a patient with left hemispheric CVA. (Courtesy of Academic Press.)

Neglect Failure to detect visual or tactile stimuli or to move the limb in the contralateral hemispace is most commonly associated with right hemispheric damage. Visual neglect can be assessed at bedside with line cancellation and line bisection tasks, in which the paper is placed at the patient's midline, and the patient is asked to either cross out all the lines on the page or to bisect the single line presented. The method of double simultaneous stimulation is another standard procedure for demonstrating the deficit. Neglect has devastating functional effects and should be a standard consideration in the evaluation process. It is most frequently associated with right parietal damage, but damage to other areas within the cerebral cortex and subcortical areas can also produce this problem.

Dressing Apraxia This syndrome tends to arise in association with spatial deficits following right hemispheric damage. The resulting difficulty in coordinating the spatial and proprioceptive demands of dressing can be seen in the patient's difficulty in identifying the top or bottom of a garment, as well as right-left confusion in inserting the limbs into the garment. As a result, dressing time can be painfully protracted, and the patient may actually display more functional dependence than might otherwise be expected from assessment of simple motor or spatial skills alone.

Memory Disorders Memory complaints constitute the most common referral to neuropsychology. Thorough neuropsychological examination of memory considers the modality (e.g., verbal versus spatial) in which the material is presented and uses presentation formats that systematically assess different aspects of the information processing and storage system that forms the basis for memory. Accumulated research indicates that specialized processing of verbal and spatial memory material tends to be differentially mediated by the left and right hemispheres, respectively. In addition to interhemispheric differences in functional localization, specific memory problems can be associated with breakdown at any stage in the information processing model of memory. These stages include (1) registration of the material through *attention*, (2) initial processing of the material within *short-term memory*, (3) encoding and storage of material in *long-term memory*, and (4) *retrieval* processes, in which material moves from long-term memory storage back into consciousness. A great advantage of neuropsychological assessment is that these various types of memory problems can be readily isolated and described during the examination. Once identified, the specific nature of the deficit can then have important implications for diagnosis, treatment, and prognosis.

Encoding The initial encoding of material can be influenced by a variety of factors, including deficits in attention, language, and spatial processing abilities. Encoding is usually measured by immediate recall of information (e.g., narrative stories, designs) or by demonstrating learning of new material across multiple trials (e.g., word lists). Because attention itself can be affected by many factors, including neurologically based disorders (e.g., head injury, acute confusional state) and psychiatric disorders (e.g., depression, anxiety), this is a particularly important aspect of a proper assessment of memory.

Retrieval and Storage Deficits in recall can be associated with impaired retrieval, in which case the material is still present but not readily accessible, or it can be due to impaired storage of information. The best way to differentiate these problems is to assess recognition, typically by using test conditions that offer some version of a multiple-choice format. If the patient can demonstrate intact recognition, the problem lies in poor retrieval, but if recognition is impaired, the problem is better attributed to impaired storage of new information. This distinction is important because the functions of retrieval and storage are subserved by different neuroanatomical

structures. Impaired storage is associated with dysfunction of the medial temporal lobe–diencephalic systems, while impaired retrieval can be associated with a variety of structures, including the frontal lobes. Since it is always easier to recognize than to recall memory material, these techniques also offer a reasonable basis for assessing the possibility of malingering.

Executive Function The prefrontal lobes and their interconnections are thought to play an important role in controlling executive functions. As conceptualized by Muriel Lezak, these executive functions include volition (i.e., formulation of a goal, motivation to achieve the goal, and awareness of one's own ability to achieve the goal), planning, purposive action (response initiation, maintenance, switching, and stopping), and execution (which requires self-monitoring and self-correction as well as control of the spatiotemporal aspects of the response). Damage to the frontal lobes has also been associated with personality changes as was historically exemplified by the famous nineteenth century case of Phineas Gage, who became irresponsible, socially inappropriate, and unable to carry out plans after a tamping iron was blown through his frontal lobes. Although hemispheric differences in the control of executive functions by the frontal lobes have not been as well documented as in the parietal and temporal lobes, the Montreal Neuropsychology Group led by Brenda Milner has identified asymmetry in the control of verbal and design fluency.

The prefrontal lobes and their interconnections have been separated into the dorsolateral, orbitofrontal, and anterior cingulate divisions. Jeffrey Cummings has identified neurobehavioral roles for each of these divisions and linked them to differential neuroanatomical relationships between cortical and subcortical areas. Though this conceptual organization has not been examined in great detail, it provides a useful working model. All of these syndromes are associated with specific corticostriate circuits and are identified here by their cortical sites.

The dorsolateral prefrontal lobe circuit is associated with higher cognitive functions, such as working memory, hypothesis generation, retrieval and initation of unique words and designs, organization of information (e.g., clustering word lists on the basis of semantic category), and development of alternating and sequential motor programs. The orbitofrontal syndrome is characterized by marked personality changes, such as instability, lability, and impulsivity. The anterior cingulate circuit is associated with impaired response initiation (i.e., akinetic mutism in the most extreme case) and response inhibition. These patients have difficulty inhibiting prepotent responses on “go–no go” tests (e.g., “When I say red, squeeze my hand; when I say green, do nothing”).

PSYCHOMETRIC ISSUES

One of the strengths of neuropsychological assessment lies in the detailed quantitative record it provides for different areas of cognitive performance as well as the foundation of normative standards on which interpretations are based. Considering the normative database for any given test is particularly important to ensure that deficits seen on individual test performances cannot be explained by such demographic characteristics of the patient as age, education, or cultural considerations. Of course, this approach also depends on the care that has been expended in developing and validating specific testing techniques. Ethical guidelines for psychological assessment established by the American Psychological Association require that tests have demonstrated validity and reliability for the particular clinical application in which they are used. These guidelines serve as the basis for valid judgments to be made about change over time, based on a given individual's performance over successive examinations. This foundation also ensures that test scores can be regarded as comparable even when administered by different examiners and in different settings.

Validity Validity refers to a test's ability to measure what it purports to measure. Validity can be ascertained by (1) correlating scores from a particular test with other, well-established measures of the same skill, (2) relating test scores to diagnostic classifications or to measures of brain structure and function, or (3) relating test outcomes to aspects of everyday functions that are thought to depend on that skill (e.g., comparing pencil-and-paper tests of visuospatial skill with ability to find one's way around a shopping center). Historically, neuropsychological tests have been validated by examining their ability to differentiate brain-damaged patients from non–brain-damaged patients. More recently, they have been validated against neuroradiological or neurosurgical data and diagnostic categories (e.g., patients with multiple sclerosis vs. medical controls). Less attention has been paid to relation between neuropsychological test outcomes and everyday function, although modest correlations have been documented between test outcomes, self-care activities, and selected complex skills.

Reliability Reliability refers to the consistency of test scores. Tests are judged by their (1) internal consistency (i.e., the extent to which all items appear to be measuring the same thing), (2) by their ability to yield similar scores across multiple test occasions in normal individuals, and (3) by the consistency in scores obtained when different persons administer and score a test. Individual cognitive measures often have lower reliabilities than composite scores derived from several measures. Within a particular ability domain, some measures exhibit higher reliabilities than others. For example, within the Wechsler Memory Scale–Revised, some tests of Attention and Delayed Recall have fairly low test-retest reliabilities (e.g., r = .68 and .45, for Digits Backward and delayed recall of word pairs, respectively), but the composite index scores for Attention/Concentration and Delayed Recall have acceptably high test-retest stability (r = .93 and .84, respectively). This underscores the importance of using more than one test to measure each type of ability in a thorough neuropsychological evaluation.

Predictive Utility In selecting tests for diagnostic applications, it is important to estimate in advance the predictive utility of particular tests for particular diagnostic discriminations. An estimation of predictive utility considers the sensitivity, specificity, and positive and negative predictive values of a test. A test that yields positive findings for most persons with disease and negative outcomes for most persons without disease has both high sensitivity and specificity. Often, published values for sensitivity and specificity are based on ideal comparisons (e.g., clear cases of Alzheimer's disease versus carefully screened normal controls) and do not permit estimation of how useful a test will be in a general clinical population.

Base Rates Computation of positive and negative predictive values addresses different and potentially more practical questions: given a positive test outcome, what is the probability of having disease? And, given a negative test outcome, what is the probability of not having disease? Positive and negative predictive values are computed as the ratio of accurate positive findings to total positive outcomes and the ratio of accurate negative findings to total negative outcomes, respectively. Predictive values are judged relative to estimated base rates of illness within the referral setting. For example, if the base rate of dementia among older adults referred for psychiatric assessment is 50 percent, then any test that purports to ascertain dementia must have a predictive value above 50 percent to warrant its application.

Another aspect of base rate is related to the frequency with which abnormal neuropsychological findings are obtained in normal individuals. Figure 7.4-5 illustrates the importance of appreciating the fact that non–brain-damaged individuals without psychiatric problems may perform in the impaired range. In fact, important normative standards developed by Robert Heaton, Igor Grant, and Charles Matthews indicate that few healthy individuals complete a neuropsychological protocol without any impaired scores, while as many as 38 percent of “normals” perform in the impaired range on 6 or more discrete scores in a 40-score battery. Given these data, a naive approach to neuropsychology that considers an individual to be impaired by simply counting the number of test scores in the impaired range would be very misleading. This information is particularly important when assessing for subtle deficits in mild head injury. These data also underscore the importance of basing conclusions upon a pattern of deficits. In other words, the strongest evidence of brain injury would be a pattern of consistent impairment on several measures within the same cognitive domain, as opposed to impairment on isolated tasks that represent several different cognitive domains.

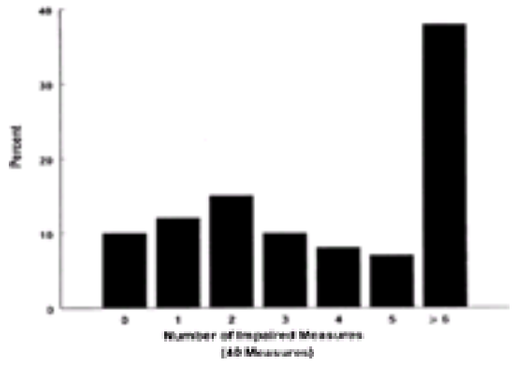

FIGURE 7.4-5 Graph showing percentages of normal individuals who score in the impaired range on 0 to 6 or more neuropsychological measures in a battery of 40 measures. The predictive value of neuropsychological tests varies considerably for different diagnostic questions. Certain performance impairments are highly specific to deficits

in specific brain regions. However, in many neurological diagnoses, multiple brain systems can be affected, and there is overlap in affected systems across disease entities. In testing for dementia, for example, neuropsychological outcomes are more sensitive than specific, and they must be used in combination with other medical and historical data to arrive at a more specific diagnosis. This underscores the importance of interpreting neuropsychological data in the context of the patient's history.

Normative Data Considerable research in recent years has been directed toward expanding the normative database for clinical neuropsychological tests with respect to important demographic factors. Normative data are now available for many cognitive measures across a broad age range. On average, persons in their early 70s score about a standard deviation unit lower than those in their 20s on tasks that combine cognitive processing demands with requirements for speed of performance, so it is important to compare a given individual's performance on these tasks with that of age peers. Education can have an even stronger effect on many aspects of cognitive performance. For subtests of the Wechsler Adult Intelligence Scale–Revised, for example, education accounts for an average of 26 percent of the variance in performance, compared with just under 9 percent of the variance that is attributable to age. Cultural factors and linguistic background can affect familiarity with particular stimuli, such as the use of clocks to tell time, or can influence the manner in which common tasks are routinely performed, such as remembering telephone numbers. Gender differences are relatively small on most clinical neuropsychological tests, but there are a few types of tasks, such as those measuring motor speed and strength, for which it is important to consider gender. Among healthy individuals, the combined effects of age, education, and gender account for about 45 percent of the variability in intelligence test performance and for about 64 percent of the variance in the average impairment rating from the Halstead-Reitan Neuropsychological Test Battery.

Estimates of Premorbid Functioning For the neuropsychologist to conclude that deficits are present, premorbid levels of functioning must be estimated, usually on the basis of educational and occupational history as well as performance on tests that are usually minimally affected by brain damage (e.g., fund of vocabulary and general information). Impairment is usually defined on the basis of any statistically significant deviation from that level of estimated premorbid ability. As illustrated in the normal bell curve shown in Figure 7.4-6, statistically significant findings on any given set of tests would be at least one standard deviation unit above or below the mean (or average) performance established for that individual, either in comparison to established normative standards or in relation to that individual's own performance across the other tests. For example, a 32-year-old Anglo patient from the Midwest who has only 4 years of education and has worked as a laborer, may have a premorbid level of functioning estimated to lie in the borderline to low-average range, which represents the population that performs at least one standard deviation unit below average. Therefore, most test scores would be expected to hover around that level. To demonstrate the likely presence of brain injury, such a patient would have to have test scores at least two standard deviation units below average or pathognomic signs of definite impairment consistent with the medical history, such as signs of lateralized neglect or aphasia. This is another example of the importance of considering the context of other demographic and cultural factors in the interpretation of neuropsychological evaluation. How would this same patient be considered at age 81 years instead of 32 or with an advanced academic degree? Would the considerations differ if a patient with that same age, education, and work experience had only recently emigrated to the United States from Haiti?

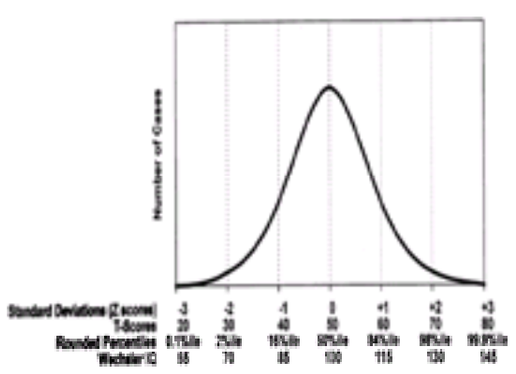

FIGURE 7.4-6 Normative (bell) curve comparing *Z*-scores, *T*-scores, percentiles, and Wechsler I.Q. scores.

Moderating Factors Performance on neuropsychological tests can be influenced by transient or situational factors. Alcohol and other substance use can impair attention, memory, and speed of cognitive processing, as can many prescription medications, especially in elderly and brain injured persons. Psychiatric disorders such as bipolar I disorder, major depressive disorder, or psychotic disorders can undermine cognitive performance, rendering formal testing invalid in severe conditions or reducing scores below expected levels in mild cases. For many clinical neuropsychological tests, the impact of drug use and psychiatric state on neuropsychological performance has been documented through research. However, the entire performance profile, combined with clinical observation and input from the patient and collaterals, must be considered in interpreting the impact of these moderating variables. An experienced neuropsychologist should be expected to specify relevant factors that could be expected to undermine or contribute to lower-than-expected performance, such as impaired vision or hearing loss, acute illness, or recent significant stressors.

GENERAL REFERRAL ISSUES

Most neuropsychological referrals are made for diagnostic purposes, to ascertain if brain impairment is present or to differentiate among different neurological or psychiatric disorders. Other important uses of testing include establishing a baseline of performance for assessing future change and planning for rehabilitation or management of behaviors affected by brain impairment. The specific methods of neuropsychological assessment reflect the individual's unique presentation of symptoms and complaints, history and development, the perspective of the neuropsychologist, and the referral question.

Level of Functioning A common referral issue involves documentation of level of functioning for a variety of purposes, including assessment of change or competence, especially in the presence of diagnoses such as dementia, stroke, and head injury.

Differential Diagnosis Like those of any other diagnostic procedure, the results of a neuropsychological examination must be interpreted in light of all available information, including the history and any associated medical factors that are documented or reported for the individual. Many neurological, psychiatric, and functional complaints have clusters of symptoms in common, with complaints of concentration or memory problems being among the most frequently reported problems. For example, impaired attention and concentration is commonly found among many groups of patients who have a history of mild closed-head injury, psychiatric issues (e.g., depression, posttraumatic stress disorder, anxiety), or any of several types of neurological disorders that are associated with subcortical involvement (e.g., Parkinson's disease, multiple sclerosis, human immunodeficiency virus [HIV]-related cognitive decline). Therefore, a pattern of cognitive impairment across several critical areas of functioning does not necessarily provide a sufficient basis for a specific diagnostic conclusion; it must be integrated with the medical and relevant psychosocial factors to arrive at a pecific differential diagnosis.

Age- or Stress-Related Cognitive Change Many middle-aged and older adults have concerns about everyday concentration and memory failures, and with heightened public awareness about conditions such as Alzheimer's disease, an increasing number of these individuals seek evaluations for these concerns. Neuropsychological testing provides a detailed, objective picture of different aspects of memory and attention, which can be helpful in reassuring healthy persons about their abilities. It also provides an opportunity for assessing undetected mood or anxiety disorders that may be reflected in cognitive concerns and for offering suggestions about mnemonic strategies that can sharpen everyday function.

Mild Traumatic Brain Injury A significant proportion of persons who have suffered a mild traumatic brain injury complain of problems with attention, memory, and mood in addition to headache or other forms of pain for many months after the injury. Many of these individuals show no clear evidence of brain injury on magnetic resonance imaging (MRI) or other neuroradiological tests. Neuropsychological testing can be a crucial method for determining the extent of objective cognitive deficit, examining the role of psychological factors in perpetuating cognitive problems, and assessing for possible residual brain impairment. Many such patients receive medications for mood or anxiety problems, possibly in combination with pain medications, and many could benefit from psychological help in managing chronic pain and psychological distress. In addition, many of these patients are in litigation, which can complicate the neuropsychologist's ability to identify the causes for impairment. Although outright malingering represents a relatively infrequent complication, more-subtle presentations of chronic illness behavior must be a prominent consideration when potential legal settlements or disability benefits are in question. This is particularly important in the case of mild head injury, when subjective complaints may be disproportionate to the objectively reported circumstances of the injury, especially since most follow-up studies of mild head injury indicate return to

neuropsychological baseline with no objective evidence of significant cognitive sequelae after 3 to 12 months following injury.

Poststroke Syndromes After the recovery from acute stroke, patients may be left with residual deficits, which can affect memory, language, spatial skills, reasoning, or mood. Neuropsychological testing can help identify areas of strength, which can be used in planning additional rehabilitation and can provide feedback on the functional implications (e.g., for work or complex activities of daily living) of residual deficits. Such assessment of functional skills can also be helpful to a psychiatrist who is managing mood and behavioral symptoms or dealing with family caregivers.

Detecting Early Dementia When concerns about a person's memory functioning are expressed by relatives instead of the patient, there is a higher probability of a neurological basis for the functional problems. Neuropsychological testing combined with a good clinical history and other medical screening tests is highly effective in distinguishing early dementia from the milder forms of declining memory and executive functioning that can be seen with normal aging. Neuropsychological evaluation is particularly helpful in documenting cognitive deterioration and differentiating among different forms of dementia, such as Alzheimer's disease and frontal lobe dementia. In addition, an incentive for early diagnosis of dementia now lies in the fact that a portion of patients with early dementia may be candidates for memory-enhancing therapies (e.g., tacrine [Cognex] or donepezil [Aricept]), and testing can provide an objective means for monitoring treatment efficacy. Other conditions that warrant neuropsychological assessment for early detection and potential treatment include HIV-related cognitive deficits and normal-pressure hydrocephalus.

Distinguishing Dementia and Depression A substantial minority of patients with severe depression exhibit serious generalized impairment of cognitive functioning. In addition to problems with attention and slowing of thought and action, there may be significant forgetfulness and problems with reasoning. By examining the pattern of cognitive impairments, neuropsychological testing can help to identify *pseudodementia*, a dementia-like condition seen in elderly patients with depressive disorders. Perhaps more common is a mixed presentation, in which depression coexists with various forms of cognitive decline, increasing the severity of cognitive dysfunction beyond what would be expected from the neurological impairment alone. Neuropsychological testing can provide a baseline for measuring the effectiveness of antidepressant therapy in alleviating cognitive and mood symptoms.

Change in Functioning Over Time In many cases, it may be most productive and clinically essential to reexamine a given patient with follow-up neuropsychological assessment after 6 months to a year, because many neurological diagnoses carry clear expectations regarding normal rates of recovery and decline over time. This is illustrated by the population of patients who complain of cognitive sequelae following mild head trauma, for whom the current literature indicates that the greatest proportion of recovery of function is likely to occur over the initial 6 months to a year postinjury. Although subtle signs of recovery can continue after that period, failure to improve following the injury—or worsening of complaints—would clearly indicate the probability of contributing psychological factors, the existence of a preexisting condition, such as dementia, or outright malingering.

Assessment of Competence Neuropsychologists are often asked to consult in determining individuals' competence to make decisions or to manage personal affairs. Neuropsychological testing can be useful in these cases by documenting areas of clear and significant impairment and identifying areas of strength and well-preserved skill. However, opinions about competence should not be based on test findings alone but must include other, more direct observations (e.g., in-home assessment, collateral interviews) of everyday function. Standards of competence vary from state to state but are generally defined by state statute. As a general rule of thumb, however, in the interests of protecting individual rights, consideration of competence is usually best approached in the narrowest possible sense, so as to infringe as little as possible on individuals' freedom to represent their own interests. Therefore, requests for neuropsychological assessment for purposes of competency should identify as specifically as possible those aspects of decision making and behavior that are of concern. Frequent concerns about competence arise with regard to the individual's ability to make (1) financial and legal decisions, (2) health care treatment decisions, and (3) decisions regarding living situations or placements, which often require institutional care arrangements. Other issues that involve higher standards of competence include ability to drive or ability to work or practice in a given profession (e.g., air traffic controller, surgeon, financial advisor). Although decisions regarding competence in any of the above areas must ultimately be made by judicial or legislatively empowered bodies (e.g., state licensing boards), the behaviorally based recommendations from a neuropsychological examination can provide crucial data on which decisions of competency are likely to be based.

Forensic Evaluation Neuropsychological evaluation of individuals in matters pertaining to criminal or civil law requires specialized knowledge beyond expertise in neuropsychology. Although neuropsychological evidence may be pertinent in criminal cases, the involvement of neuropsychologists is frequently elicited in matters involving head injury, especially in the case of mild head injury associated with motor vehicle accident. As a distinct subspecialty, this area of practice requires integration of knowledge of statutes, laws, precedents, and legal procedures as well as expertise in identifying and describing the impact of an injury or event on cognitive, emotional, and behavioral functioning.

COGNITIVE SCREENING BY OTHER HEALTH CARE PROFESSIONALS

A wide range of health care professionals are involved in assessment of cognitive and emotional status. Although many informally estimate a patient's cognitive state, research has shown that systematic use of a structured mental status examination greatly increases the accuracy of detecting cognitive impairment, much as depression rating scales increase the accurate identification of mood disorder. One of the most widely used screening instruments for documenting gross changes in mental status is the Mini-Mental State Examination (MMSE). It is widely used in general medical and geriatric settings as an initial assessment of mental status and can serve, along with a careful history, as an indicator for more precise neuropsychological evaluation. This is particularly true if performance on the MMSE deteriorates over time. While the MMSE is likely to underestimate the prevalence of cognitive deficits in well-educated older persons with early Alzheimer's disease or in younger adults with focal brain injury, it will probably overestimate the presence of cognitive deficits in persons with little education. Therefore, cutoff scores for concluding that impairment is present must be adjusted for age and education.

Although cognitive mental status examinations can be useful in screening for gross signs of cognitive impairment, they do not suffice for distinguishing specific causes of cognitive impairment and are not interchangeable with neuropsychological testing. The in-depth analysis and standardized testing approach offered by neuropsychological assessment is most useful in cases of questionable or mild impairment, when there is evidence or complaint of persistent focal impairments, or when psychiatric and neurological symptoms coexist.

DOMAINS OF FORMAL NEUROPSYCHOLOGICAL ASSESSMENT

Neuropsychological examination systematically assesses functioning in the realms of attention and concentration, memory, language, spatial skills and sensory and motor abilities, as well as executive functioning and emotional status. Overall intellectual abilities are not only described as a reflection of current abilities, but subtest variability can also be used to indicate any differences from documented or estimated levels of intellectual functioning at some earlier point in time. Psychological contributions to performance are also considered with regard to personality and coping style, emotional lability, presence of thought disorder, developmental history, and significant past or current stressors. The expertise of the neuropsychologist lies in integrating findings obtained from many diverse sources, including the history, clinical presentation, and several dozen discrete performance scores that make up the neuropsychological data. The overall summary of the examination can be expected to describe distinctive patterns in the individual's ability to process efficiently and integrate materials that differ in structure and complexity as well as modality of presentation and response.

The actual practice and procedures of clinical neuropsychology have developed in two general directions, which are effectively described in greater detail in texts by Lezak and by Grant and Kenneth Adams.

Battery Approach The battery approach, exemplified by the Halstead-Reitan Neuropsychological Test Battery, grew directly out of the psychometric tradition in psychology. This battery includes a large variety of tests that measure most cognitive domains as well as sensory and motor skills. Typically, all parts of the test battery are administered regardless of the patient's presenting problem. This approach has the advantage of identifying problems that the patient has not mentioned and that the medical history may not necessarily predict. It has the disadvantage of being time consuming (i.e., 6 to 8 hours) and originally did not include a very thorough assessment of memory or attention.

Hypothesis-Testing Approach The qualitative hypothesis-testing approach is historically best exemplified by the work of Luria and more recently developed as the Boston process approach by Edith Kaplan and her colleagues. It is characterized by detailed evaluation of areas of functioning that are related to the patient's complaints and predicted areas of impairment, with relatively less emphasis on aspects of functioning less likely to be impaired. The hypothesis-testing approach has been particularly helpful in illuminating the differential roles of the two hemispheres, as discussed above. This approach has the advantage of efficiently honing in on areas of impairment and producing a detailed description of the deficits from a cognitive processing standpoint, but it has the shortcoming of potentially overlooking

unexpected areas of deficits.

Integration of Quantitative and Qualitative Methods Historically, these two approaches were diametrically opposed, but the two approaches have converged increasingly in the 1990s so that the differences are not as apparent. These changes in clinical practice are particularly driven by the growing impact of economic factors that make it less practical to evaluate patients for long periods of time. Neuropsychologists who use either approach increasingly use screening evaluations as a first step in efficiently determining whether a diagnosis can be made with less information or whether additional testing is necessary to identify more-subtle problems. Therefore, even neuropsychologists who emphasize a hypothesis-testing approach are likely to begin with a screening protocol that efficiently assesses the major areas of neuropsychological functioning. This may or may not be followed by additional testing in selected areas that might clarify the reasons for the deficits demonstrated on the screening evaluation.

Neuropsychological Examination Techniques The past decade has seen a virtual explosion in the growth of more-sophisticated and better-standardized tests and procedures for neuropsychological evaluation. Although a comprehensive listing of tests and techniques is beyond the scope of this chapter, excellent reviews of current techniques are found in texts by Lezak as well as Otfried Spreen and Esther Strauss. Asenath LaRue also has published detailed observations about pertinent assessment issues in aging and neuropsychology. A list of examples of common neuropsychological tests and techniques is provided in Table 7.4-2.

Table 7.4-2 Selected Tests of Neuropsychological Functioning

Interview The clinical interview provides the single best opportunity for identifying the patient's concerns and questions, eliciting a direct description of current complaints from the patient, and understanding the context of the patient's history and current circumstances. Although the patient is typically the primary interview source, it is important to seek corroborating information from interviews with caregivers or family members and thorough review of relevant records, such as medical and mental health treatment and educational and employment experiences.

Intellectual Functioning Assessment of intellectual functioning serves as the cornerstone of the neuropsychological examination. The Wechsler intelligence scales have represented the traditional gold standard in intellectual assessment for many years, based on carefully developed normative standards. The scope and variety of subtests on which the summary intelligence quotient (I.Q.) values are based also provide useful benchmarks against which to compare performances on other tests of specific abilities. The latest revision of this instrument, the Wechsler Adult Intelligence Scale–III, offers the additional advantage of greatly extended age norms (ages 16 to 89) and direct normative comparisons to performances on the Wechsler Memory Scale–III. In general, the Wechsler intelligence scales use a broad set of complex verbal and visuospatial tasks that are normatively summarized as a Verbal I.Q., a Performance I.Q., and Full Scale I.Q. In the context of a neuropsychological examination, the patient's performance across the procedures provides useful information regarding longstanding abilities as well as current functioning. Most neuropsychologists recognize that the summary I.Q. values provide only a ball-park range for characterizing an individual's general level of functioning. Therefore, it is usually more appropriate and meaningful to characterize an individual's intellectual functioning in terms of the range of functioning (e.g., borderline, low average, average, high average, superior) represented by the I.Q. value rather than the specific value itself.

Careful examination of the individual's performance across the various verbal and performance subtests is crucial for observing the patient's pattern of strengths and weaknesses, as well as the degree to which these performance characteristics are consistent with the history and performance on other aspects of the neuropsychological examination. Estimation of longstanding (premorbid) intellectual abilities is as important as the measurement of current functioning, to gauge the degree to which an individual may have deteriorated. However, it may be difficult to demonstrate subtle cognitive decline in individuals who fall into either extreme of the intellectual spectrum, with premorbid abilities in the superior or borderline ranges of functioning.

With regard to the question of differential hemispheric representation, the Verbal I.Q. and Performance I.Q. have historically been reported to be associated with left and right hemispheric functioning, respectively, over the past few decades. However, more-recent views indicate that in addition to language and spatial skills, the subtests of the Wechsler intelligence scales reflect other contributions such as speed and sustained concentration. Therefore, well-trained neuropsychologists do not simply assume that a discrepancy between Verbal I.Q. and Performance I.Q. is due to unilateral hemispheric damage. Important clues to the nature of the contributing problem can often be gleaned by considering the pattern of performance across other aspects of the examination and by carefully analyzing the types of errors observed. For example, in addition to visual-spatial demands, the Performance I.Q. subsets (e.g., Block Design, Picture Arrangement) tend to be timed and depend more on novel problem-solving skills than the Verbal subtests. Clearly then, low Performance I.Q. relative to Verbal I.Q. might reflect more-general executive problem-solving deficits or generalized slowing, perhaps in association with depression or any of a number of neurological syndromes with motor symptoms (e.g., Parkinson's disease, multiple sclerosis).

Attention Attention underlies performance in virtually all other areas of functioning and should always be considered as a potential contributor to impaired performances on any tests that require vigilance or rapid integration of information. Measures of attention and concentration have traditionally been included in the Wechsler intelligence and memory scales to assess orientation and freedom from distractibility. These procedures also provide a useful basis for anticipating the individual's ability to comprehend, process information, and otherwise engage in the assessment process. Digit Span requires patients to repeat increasingly longer strings of digits as a way of assessing ability to process relatively simple information, while Digit Span Backward reflects more-complex simultaneous processing and cognitive manipulation demands. The Mental Control subtest includes measures that require serial addition and recitation of automatic (or overlearned) sequences of numbers or letters. More-demanding specialized techniques have been developed that are highly sensitive to subtle deficits in rapid simultaneous processing. For example, in Dorothy Gronwall's Paced Auditory Serial Addition Test patients successively sum pairs of numbers at increasingly faster rates of presentation, adding each new digit to the immediately preceding digit. Other procedures for assessing attention and sustained concentration can be found in the form of pencil-and-paper measures of digit, letter, or symbol cancellation, and various versions of computer-assisted measures of attention and vigilance.

Memory Complaints of memory problems constitute one of the most common reasons for referral to neuropsychology. As described above, the neuropsychologist uses an information-processing approach to assess memory problems that might involve difficulty with encoding, retrieval, or storage of new information. The Wechsler Memory Scale–III is the latest revision of a widely used battery of subtests with several measures of attention, memory, and new learning ability. The original version, developed by David Wechsler in 1945, was adapted in the 1970s by Elbert Russell to include immediate and delayed recall comparisons and was supplemented by the development of older-age norms from several laboratories. A revised version of the battery, published in 1987, formalized these modifications and added five summary indexes: Verbal and Visual Memory, General Memory, Attention/Concentration, and Delayed Memory. The current version, published in 1997, offers additional advantages by extending the normative comparisons to age 89, adding procedures for standardized assessment of recognition (to determine if impaired recall performance is due to impaired retrieval or storage), and linking normative comparisons to performances on the Wechsler Adult Intelligence Scale–III.

Many clinicians choose not to administer the entire Wechsler Memory Scale and instead use particular procedures for which standardized normative data are available. For basic assessment of memory encoding and recall, Logical Memory assesses the individual's ability to recall two different narrative stories immediately after presentation and again following a 30-minute delay. The difference between the amount of material recalled immediately and following the delay constitutes a sensitive measure of memory retention. Visual Reproduction requires immediate and delayed recall of increasingly complex geometric designs, each of which is presented for 10 seconds prior to being drawn by the patient. Retention of the material following a similar 30-minute delay interval can be measured against standardized normative data. The Wechsler Memory Scale–III also includes a working memory index, which may be useful for further differentiating memory impairment due to encoding problems from those due to retention problems.

A well-standardized example of a verbal list-learning technique is the California Verbal Learning Test. This procedure uses five learning trials of a 16-item shopping list that is made up of four exemplars from each of four semantic categories (fruits, tools, spices, and clothing). Aside from measuring several aspects of learning and memory, this test also yields rich qualitative data about the patient's use of higher-order conceptual strategies and the efficiency of verbal learning. Proactive interference is examined by a single free-recall trial of a second list of words. Free and cued recall of the original list after both short and long delays, as well as a recognition trial, further examine the memory processes of storage, retention, and retrieval. Published norms extend to age 80 for males and females. Administration in clinical practice typically requires 20 to 25 minutes, not counting a 20-minute delay interval, so this task may be too demanding for more-impaired individuals. However, recent findings suggest that it might serve as a sensitive early cognitive marker for dementia of the Alzheimer's type.

An alternative list learning procedure to consider for older patients is Paula Fuld's Object Memory Test, in which the patient must identify (tactually or visually) 10 common objects that are hidden in a bag, then attempt to learn the list over a series of five “selective reminding” trials. This is a specialized technique for measuring memory retention and storage, in which patients are asked to learn a list of items over five trials. At the end of each recall trial, subjects are selectively reminded of only those words that were omitted. This test is especially useful for patients with hearing impairment, and the normative standards afford limited comparisons with older individuals who are either community-residing or in assisted living arrangements. The Weschler Memory Scale–III also includes a list-learning task that may be useful for screening purposes, especially for elderly persons or patients whose premorbid functioning is estimated to be below average.

Language Assessment of language examines both expressive abilities and comprehension. However, most neuropsychologists screen for language impairment rather than administer an extensive formal language assessment battery, such as the Boston Diagnostic Aphasia Examination. Expressive language is commonly assessed by measures of verbal fluency that require rapid generation of words within semantic (e.g., names of animals) and phonetic categories (e.g., words beginning with specified letters of the alphabet). Another measure of expressive language, the Boston Naming Test–Revised, provides a standard 60-item measure of visual confrontation naming ability. Standardized evaluation of comprehension often uses procedures that systematically assess one-, two-, and three-step commands in a format such as the Token Test or by examining comprehension of more-complex narrative material, as in the Complex Ideational subtest of the Boston Diagnostic Aphasia Examination.

Visuospatial Functions Complex visuospatial abilities can be assessed through procedures that were developed in Benton's laboratory, such as Facial Recognition and Judgment of Line Orientation. Visual constructional ability, another important aspect of the examination, taps into the person's ability to draw spatial designs or assemble two- or three-dimensional figures (Fig. 7.4-2 and Fig. 7.4-3). In addition to the significant visuospatial component, these tasks reflect contributions of executive-planning and organizational abilities. More-impaired individuals can be asked to copy simple geometric forms, such as a Greek cross or intersecting pentagons.

The widely used technique of Clock Drawing provides a surprisingly sensitive measure of planning and organization, especially for older individuals suspected of dementia. While problems involving poor organization, perseveration, and possible neglect are obvious in the drawing that is illustrated in Figure 7.4-7, more-subtle difficulties can also be detected, especially when a patient's performance is evaluated in light of premorbid expectations. Like virtually all assessment techniques, even this relatively simple procedure must be used in a standard manner. Most neuropsychologists use the same set of instructions each time, offering the patient a single sheet of unlined paper and saying, “Now I would like you to draw a clock. Put all the numbers on the clock, and set the time to 10 after 11.” Encourage the patient to use the whole page and draw a relatively large clock, so that evidence of neglect or executive deficits in organization and planning can be easily seen. Although the rich qualitative information that can be gleaned from this task may not suffice alone for diagnostic purposes, this measure provides a useful screening technique—especially for older or more seriously impaired individuals—and can serve as a basis for deciding whether to refer the patient for more-detailed neuropsychological examination.

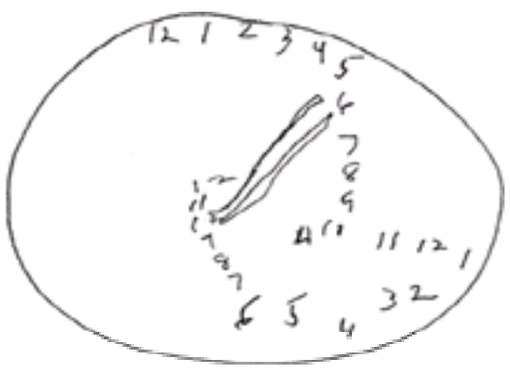

FIGURE 7.4-7 Clock drawing by a patient with vascular dementia, showing poor planning and organization, perseveration, and possible neglect.

The Rey-Osterreith Complex Figure Test is a more demanding constructional task that requires the individual to copy a highly complex geometric configuration and then draw the figure from memory. Important qualitative information having to do with problem-solving strategies can be extracted by carefully monitoring and documenting the strategy that is used in drawing the figure. Figure 7.4-2 and Figure 7.4-3 illustrate different spatial deficits seen on the Block Design and Complex Figure constructional tasks in the presence of lateralized brain damage in either the right or left hemispheres.

Sensory and Motor Functions Double simultaneous stimulation in the visual, tactile, and auditory modalities is a standard component of the Halstead-Reitan Neuropsychological Test Battery and can be useful for assessing the integrity of basic sensory functions. Grip Strength and rapid Finger Tapping are commonly used measures of motor strength and speed that are sensitive to lateralized brain dysfunction. A related measure, the Grooved Pegboard, assesses the individual's ability to efficiently integrate tactual motor dexterity, motor speed, and eye-hand coordination, but performance on this measure may be bilaterally impaired following unilateral brain injury because of its high demands for cognitive integration.

Executive Functions One of the most important aspects of the neuropsychological examination lies in the assessment of higher executive functions, which play an important role in the planning and initiation of independent activities, self-monitoring of performance, inhibition of inappropriate responses, switching between tasks, and planning and control of complex motor and problem-solving responses. Although the prefrontal lobes have long been considered important in mediating these functions, more-recent developments in the neurosciences have led to increased appreciation of the essential role played by extensive cerebral interconnections between subcortical and cortical regions of the brain.

An underlying executive component is implied to some degree in many of the techniques discussed above. For example, complex attention, as assessed on a serial addition task, depends on the ability to flexibly shift focus and sustain a cognitive set. Memory functions rely on the ability to process information efficiently, including the use of strategies to organize incoming information (e.g., clustering words in a memory list on the basis of semantic categories). In fact, memory deficits that can be attributed to retrieval failure in the information-processing model of memory are often associated with other executive deficits. However, some techniques are often used specifically as primary measures of executive functions. In the Wisconsin Card Sorting Test an individual sorts a long series of cards with designs according to various principles that can only be gleaned by incorporating feedback from the examiner. This measure, then, assesses the individual's ability to generate and test various solutions, to flexibly respond to changing circumstances, and to integrate new information with past experience to maximize the efficiency of the response. However, recent data show that deficits on this test do not depend solely on the frontal lobes. Other techniques based largely on the work of Luria are more qualitative and assess the individual's ability to inhibit inappropriate motor responses as well as the tendency to perseverate when asked to draw a series of repetitive graphomotor sequences. Figure 7.4-8 contains several examples of such sequences. In each case, the sample is presented with instructions for the patient to reproduce the sample and continuously repeat the segment across a page. Each prior sequence should be covered or removed from the patient's view before going on to the next, so that any tendency to reproduce elements from a prior sequence can properly be interpreted as evidence of perseveration.

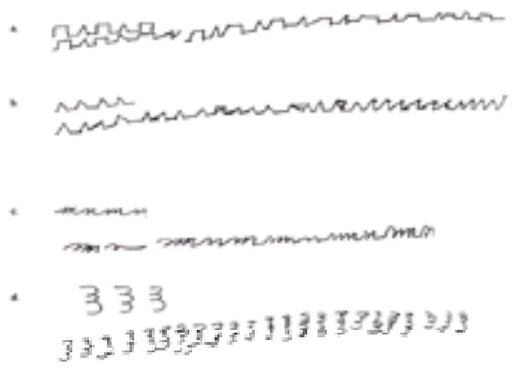

FIGURE 7.4-8 Patient reproductions of Repetitive Graphomotor Sequences, showing perseveration of elements across designs (from **a** to **b**) and within designs (**c** and **d**).

Therapeutic Discussion of Results A key component of the neuropsychological examination process is the opportunity to discuss results of the examination with the patient and family or other caregivers. This meeting can be a powerful therapeutic opportunity to educate and clarify individual and relationship issues that can affect the patient's functioning. If the patient's active cooperation in the initial examination was appropriately enlisted, the patient will be optimally prepared to invest value and confidence in the findings of the examination. At the time of the results discussion, it is useful to review the goals of the examination with the patient and supportive family or caregivers and to clarify the expectations of those who are present. Typically, these sessions include information about the patient's diagnosis, with emphasis upon the natural course and prognosis as well as compensation and coping strategies for the patient and family. Given the impact of chronic neurological disease upon the family system as well as the patient, explicit discussion of these issues is critical in maximizing adjustment to brain injury. It is equally important to relate the impact of the results to the patient's current living circumstances, future goals, and course of adjustment. It is not unusual for strong emotions and underlying tensions within family relationships to come to light in the context of honest discussion, and so the results discussion can be an important therapeutic opportunity to model effective communication and problem-solving techniques.

SUGGESTED CROSS-REFERENCES

The neuropsychological and intellectual assessment of children is discussed in Section 7.6. Section 7.5 addresses personality assessment. The biology of memory is discussed in Section 3.4. Attention-deficit disorders are discussed in Chapter 39. Communication disorders are the subject of Section 37.

7.5 PERSONALITY ASSESSMENT: ADULTS AND CHILDREN

RUSSELL L. ADAMS, FH.D., AND JAN L. CULBERTSON, FH.D.

Numerous books have been written about personality assessment and many focus solely on one particular approach to personality assessment. *Personality* refers to an individual's enduring and pervasive personal motivation, emotion, interpersonal style, attitudes, and traits. *Personality assessment* is the systematic measurement of an individual's personality.

REASONS FOR PSYCHOLOGICAL REFERRAL

Psychological tests can be expensive and require a considerable amount of time to administer, score, and interpret. Testing is not routinely done on all psychiatric patients, as the costs would be prohibitive. Even in today's cost-containment environment, psychological testing of selected patients can be helpful from both a clinical and a cost-benefit-analysis perspective.

Assisting in Differential Diagnosis Some patients present diagnostic dilemmas, yet a diagnosis can be essential for both treatment and understanding the cause and prognosis of the disorder.

> A previously high-functioning 35-year-old female with no psychiatric family history was driving in the country with her husband. All of a sudden, without provocation and with no known drug use, she asked her husband to stop the car. She got out of the car and told him that she had received a message that that particular spot was holy and had great significance. A voice told her to get out of the car and run around in a circle approximately 120 feet in diameter. Following this episode she did not sleep for 24 hours. She became hypomanic, talked loudly, neglected personal hygiene, and experienced grandiose delusions. She felt that she was a messenger from Andre, a person who lived on that land some 3000 years ago. Her grooming and personal hygiene deteriorated, and she got violent toward others who questioned her emotional stability. The differential diagnosis includes schizophrenia and bipolar disorder. Testing could help in determining the differential diagnosis and in formulating a treatment plan.

Aiding Psychotherapy Psychological tests can be useful in psychotherapy, especially short-term, problem-centered therapy in which understanding patients and their problems must be accomplished quickly. Psychological assessment can be used in pretreatment planning, assessing the progress of therapy, and evaluating its effectiveness. Patients need to have objective information about themselves at the time of therapy if they are to go about changing themselves productively. Personality tests, particularly objective tests, allow patients to compare themselves with objective norms and evaluate the extent and magnitude of their problem. Testing also can reveal areas of the patient's life that may be problematic, but for which the patient may not have a full appreciation. Information about the patients' ability to reveal information about themselves can also be helpful. Sometimes a test report can be the subject of an early treatment session. Psychological tests may reveal considerable information concerning the patient's inner life, feelings, and images that may facilitate therapy. Psychological testing can provide baseline information at the beginning of therapy, so that repeat testing can be used to assess change during the course of therapy.

Need for Specific Information Psychological tests can often assist in specific problem areas. For example, a young college student may be unsure what to major in (“I don't know what to do the rest of my life.”) Vocational interest inventories such as the Strong Vocational Interest Inventory or the Kuder Occupational Interest Survey may help to define the student's vocational interest. The Strong Vocational Interest Inventory compares a given individual's responses with those of a large group of successful individuals in a variety of occupations. Testing results can show that a student's interests are similar, for example, to those of persons successful in occupations such as social work or public administration and dissimilar to those of engineers or scientists.

EVALUATING THE USEFULNESS OF PERSONALITY ASSESSMENT INSTRUMENTS

The quality of personality tests varies widely, from well-constructed, empirically validated instruments to psychological tests in the Sunday supplement of the newspaper or on the Internet. Evaluating the usefulness of particular psychological instruments can challenge even the well informed.

Just as the *Physician's Desk Reference* helps the physician evaluate the usefulness of medications, the Buros *Mental Measurement Yearbook* helps the psychologist evaluate the usefulness of personality instruments and other psychological and achievement tests. The *Mental Measurement Yearbook* is a reference source of critical reviews of individual tests. In these reviews, the scientific underpinnings of each test are evaluated by an expert in the field. The reviews generally address such issues as the reliability and validity of the tests, the normative group used in construction, and various empirical studies used to check the reliability and validity of the instrument. The advantages and disadvantages of the test are described. The reviews generally describe situations in which use of the test is appropriate. Practical information concerning the test publisher, length of time of administration, and other considerations is also included. (The *Mental Measurement Yearbook* is available in most university libraries and can be ordered through the book's publisher.)

Normative Sample When one evaluates a personality assessment instrument, certain factors concerning the samples used to construct the test should be considered. Basic issues such as the size and representativeness of the sample used to construct the test must be evaluated. A sample of 30 persons with a given diagnosis in a single location is seldom appropriate, because so many moderating factors affect results, such as age, education, sex, and racial or ethnic grouping. These factors frequently affect the norms and appropriate controls must be included for these variables in many cases.

For example, the Minnesota Multiphase Personality Inventory–2 (MMPI-2), a well-constructed instrument, had approximately 2900 subjects tested initially. However, approximately 300 subjects were eliminated because of test invalidity or incompleteness of needed information. The final group comprised 2600 community volunteers, 1462 females and 1138 males. The MMPI-2 normative group was selected using census data as a guide and was broadly representative in terms of region of the country, racial composition, age, and formal education. Despite efforts to control for moderating variables, the sample was slightly overrepresentative in higher education levels. Obviously, the cost of obtaining a large census-based normative sample is enormous, and few tests can meet these challenging criteria. Nevertheless, many tests that fall short of the national sample (and most do) can be useful in the hands of an experienced clinician who is sensitive to the problem and makes appropriate clinical adjustments in interpreting the results.

Test Characteristics To be useful, any psychological test must be completed, in its entirety, by the intended test taker. If the questions are offensive or difficult to understand, the person taking the test may not complete all items. These omissions can create problems, especially when normative tables are used to interpret results. An instrument should be short enough to complete in a relatively short period of time. The Beck Depression Inventory or the Geriatric Depression Scale can easily be completed in 5 to 10 minutes. Because of its short length, the test can be given repeatedly to a depressed patient in treatment to monitor changes over time. The MMPI-2, on the other hand, takes approximately 1 to 1½ hours to complete. This test is not appropriate for repeat testing over a short period of time. Most tests are easily scored and compared with normative tables.

Test Validity Perhaps the most important characteristic in evaluating the scientific merit of a given personality test is the validity of the instrument. Does the test measure what it purports to measure? If a test is designed to measure depression, does it indeed measure depression? Although validity may seem to be a simple issue to address, it can become complex, especially when one is trying to measure such characteristics as self-esteem, assertiveness, hostility, or self-control. The test developer must first operationally define the personality characteristic in question. A number of different approaches have been used to measure validity,

including face validity, logical content validity, construct validity, criterion validity, factor validity, among others.

Face Validity Face validity refers to the content of the test items themselves. In other words, do the items appear to measure what they purport to measure? For example, does a depression scale ask questions concerning sadness, guilt, sleep disturbance, weight loss, helplessness, hopelessness, or suicidal thoughts? One problem with face validity is that professionals differ in their subjective appraisal of individual items. One psychologist may think a given item does indeed measure the concept under consideration, while other professionals may not. To address these differences in definition, the test developers may use an approach known as *logical content validity*. With this approach, in which the manual describes the procedure used to select items for the test, results will not depend significantly on the subjective judgment of any one professional. For example, in developing the Taylor Manifest Anxiety Scales, a number of different psychologists were asked to review items from the Minnesota Multiphasic Personality Inventory (MMPI) that seemed to measure a formal definition of manifest anxiety, and only those items agreed on by this group of psychologists were included. Many creative approaches have been used to demonstrate the logical content validity of various tests.

Criteria and Construct Validity While face validity refers to the degree that test items appear on the surface to measure what the instrument, as a whole, purports to measure, criterion validity uses data outside the test itself to measure validity. For example, if a test was designed to measure hypochondria, one would expect a patient with a high score to have more visits to the physician's office, complain of more physical symptoms, and use prescribed and over-the-counter medications more extensively. These criteria are objective, are external to the test itself, and can be independently measured. Scores on the hypochondria instrument can be statistically correlated with a number of separate objective criteria such as those mentioned above to determine whether the test measures the theoretical construct of concern (*construct validity*).

Concurrent and Predictive Validity To determine test *concurrent validity*, these external measures are obtained when the test is given to the sample of subjects. Thus, the concurrent validity of the test reveals that at a given time, those with high scores on the test were more likely to manifest the behavior than those with low scores. Occasionally, however, a test developer is interested in predicting future events. For example, a test designed to predict marital satisfaction among engaged couples may use as an external criterion the couples' future marital satisfaction and marital status. Thus the external criterion must be obtained a number of years later for the test to have predictive validity. Because of the difficulty in obtaining such information several years later, predictive validity is seldom available in most personality tests, although when such data are available they can be valuable.

The *discriminant validity* of a test tells whether or not the test can discriminate between known groups of patients at a given time. For example, can a test of depression statistically discriminate nondepressed subjects from subjects who suffer from independently diagnosed major depressive disorder, adjustment disorder with depressed mood, and dysthymic disorder? Can a measure of depression statistically discriminate mild, moderate, and severe major depressive disorder?

Factor Validity Factor validity uses a multivariate statistical technique known as factor analysis to determine whether certain major groups of items on a given test cluster together empirically. For example, on a personality test measuring depression, do items concerning vegetative symptoms tend to covary? Are there other clusters of items on the depression test measuring cognitive problems, mood disturbance, and social withdrawal?

Reliability To be useful, a test must not only be valid, but must also be reliable. *Reliability* refers to the degree to which a test consistently measures what it purports to measure. The key word here is *consistently*. For example, a patient with agoraphobia takes a new agoraphobia test today and takes the same test tomorrow. However, on second testing the scores change markedly, although the patient had not received any treatment or undergone any change in the underlying agoraphobia. This test is not useful because it does not measure the trait in question consistently. The test has poor reliability. Several means of checking reliability exist, including test-retest reliability, internal consistency reliability, and parallel form reliability.

Test-Retest Reliability Test-retest reliability is obtained by administering the same test to a group of subjects on two occasions and statistically correlating the results. For a test to be useful, the correlation coefficient should be at least .80 if the two tests were administered within 2 weeks of each other and if the trait in question is stable.

Internal Consistency Reliability Another way to determine internal consistency reliability is to divide a given test into two equal parts and correlate the two halves for the test with each other statistically. This technique determines the *split-half reliability* of a test. The first half of the test should be highly correlated with the second half of the test if the test is measuring what is purportedly being measured consistently. Alternatively, the odd-numbered items could be correlated with the even-numbered items (odd-even consistent reliability). When a test is split into two parts and the scores obtained correlate with each other, the resulting correlation coefficients statistically underestimate the true reliability of the test because the magnitude of the correlation is influenced by the number of items in the test. Hence, if there were half that number of items in the original test, the results would be underestimated. The Spearman-Brown formula is used to correct for this underestimation. Again, a reliability coefficient of .80 to .85 is needed to demonstrate usefulness in most circumstances. However, the higher the reliability as measured by the correlation coefficient, the better the test instrument. No test is perfectly reliable. The highest possible correlation coefficient is 1.0 and the lowest is 0, assuming no negative correlation.

To determine how internally consistent a given test is, a test developer also may use a statistical technique called Cronback's Coefficient Alpha. With this statistic, one can determine the average correlation among all the items on the test. The higher the average correlation, the better the reliability.

Parallel Form Reliability Sometimes two separate forms of the same test are needed. For example, if taking a test at one time by itself influences patients scores the second time they took the same test, then parallel forms of the tests are needed. *Parallel forms* of a test measure the same construct with different items. The correlation coefficient between the two parallel forms of the same test is computed to ensure that the test does in fact measure the same construct. Such parallel form reliability should be .90 or higher.

Use of Standard Error of Measurement to Assess Reliability The usefulness of a given test can be assessed by examining the test's standard error of measurement, which should be included in the test's manual. The *standard error of measurement* (SEM) is a single statistic used to estimate the score of a given patient if the patient took the same test again within a short period of time. For example, a patient takes a given test today and obtains a score of 90. The SEM on the test is 3. An SEM of 3 together with an individual's score of 90 on the test means that if that individual taking that same test again tomorrow would score within ± 1 SEM of the original test performance (e.g., + or – 3 points) 68 percent of the time. Thus, the patient in question should score between 87 (90 – 3) and 93 (90 + 3) on the test 68 percent of the time when taking the same test again. The same individual would score ± 2 SEM units (e.g., 2 × 3 = 6) 95 percent of the time on second testing.

In the above example, the patient with an original score of 90 on a given test would score between 84 (90 – 6) and 96 (90 + 6) on second testing 95 percent of the time. Other things being equal, the smaller the SEM relative to the standard deviation of the tests, the better. SEM is calculated by the test developer based on the tests' reliability.

ASSESSMENT OF PERSONALITY IN ADULTS

Objective Personality Tests Objective personality tests have a rather straightforward approach. Patients are usually asked specific standard questions in a structured written or oral format. All patients are typically asked the same questions. The data obtained from a given patient are compared with similar data obtained from the normative group. The degree to which the patient deviates from the norm is used in the interpretation. The patient's responses are scored according to agreed-upon criteria, and the scores are then compared with normative tables and often converted to standardized scores, percentiles, or both. The MMPI-2 is an example of an objective personality test.

Literally hundreds of different objective personality instruments exist. Table 7.5-1 contains a representative sample of objective personality tests, with a concise description of the test and its strengths and weaknesses. The MMPI-2 is the most frequently used objective personality test by far.

Table 7.5-1 Objective Measures of Personality in Adults

Focusing on the MMPI-2 should orient the reader to both objective personality assessment and objective personality development. This is not meant to imply that the MMPI-2 is the only valid and reliable objective personality instrument or that other objective personality tests are not as useful for a particular purpose. Many useful objective personality instruments exist.

MMPI-2 Two excellent books on the MMPI-2 are James N. Butcher's *The MMPI-2 in Psychological Treatment* and John R. Graham's *MMPI-2 Assessing Personality and Psychopathology*. The MMPI-2 consists of 568 true-or-false questions concerning a wide variety of issues. The patient completes the test with a pencil. The MMPI-2 is relatively easy to administer and score and takes approximately 1 to 1½ hours for most patients to complete. It requires only an eighth grade reading comprehension. The test provides a number of internal checks for measuring the patient's cooperation. The patient is simply asked to answer true and false to such questions as “I have a good appetite” or “No one seems to understand me.”

Scoring the MMPI-2 involves adding up the number of responses on numerous scales and comparing the results with certain normative information. Interpretation of the MMPI-2 is more straightforward than that of many other tests because of the vast amount of empirical information available concerning the MMPI-2. More than 12,000 articles and books have been published on this test to date.

There are over 115 translations of the MMPI-2. The test is also cost-effective because relatively little professional time is involved in the administration and scoring. The patient is simply given instructions and then completes the test independently in the professional's office. In certain situations, the MMPI-2 can be administered on the computer. A computer can also plot test profiles and compute various supplemental scales. The number of available specialized scales increases the usefulness of the MMPI-2 with various populations (e.g., patients with posttraumatic stress disorder, college students who are maladjusted, or prisoners with violent tendencies).

Questions cover a wide range of different areas. When a patient takes the MMPI-2, questions are not grouped in any particular order. Various items in the test can be selected, sorted, and analyzed according to various criteria as an aid in interpretation. The most common scales of the MMPI-2, including the validity scales, clinical scales, content scales, supplemental scales, and critical items are discussed below.

VALIDITY SCALES Patients can approach a mental status interview in a variety of ways. They can be painfully honest and straightforward with the interviewer, revealing their innermost aspirations and fears. They may be somewhat distrusting of the interviewer and may try to slant the content of the interview to obtain the outcome they want. They may be disingenuous or even attempt to be deceitful by malingering. Obviously, the information obtained by psychiatrists or other mental health professionals in an interview may well be colored by the patient's approach to the interview. Some patients by their very nature or reserve may use denial successfully or have little insight into their feelings and thoughts.

When patients are administered personality tests such as the MMPI-2, they approach the test as they approach an interview. One advantage of the MMPI-2 is that the test has been devised to assess different test-taking attitudes (e.g., fake bad, fake good, social desirability responding). Use of the validity scales yields information that helps the clinician interpret the remaining scales of the MMPI-2. Is the patient overly defensive? Is the patient attempting to fake good or fake bad? Does the patient maintain a reasonable balance between self-disclosure and excessive defensiveness?

Lie Scale The Lie Scale consists of 15 items designed to measure general frankness. The items include questions concerning personal characteristics that are highly desirable in our culture but infrequently practiced (e.g., “I have never failed to tell the truth,” “Once in a while I think of things too bad to talk about” or “I do not always tell the truth”). Patients who score high on the lie scale may be psychologically naive or defensive. They may want to be seen in a positive light or they may have difficulty admitting common human frailties.

F-Scale The F-Scale is one of the longest scales, consisting of 60 items that received positive responses from 10 percent or fewer of the normative samples. This scale includes such items as “Evil spirits possess me at times” and “Most any time I would rather sit and daydream than do anything else.”

Items on the F-Scale have quite diverse content and may indicate severe psychopathology such as hallucinations or delusions. Most people in the normal sample responded to fewer than five of these items. Individuals who obtain exceptionally high scores on this scale are often either extremely pathological or trying to claim mental illness falsely. As with all personality tests, interpretation depends greatly on the setting in which the test was given, as base rates for different settings and circumstances differ. For example, patients who have been seen for court sanity evaluations have a different base rate of symptom magnification than patients seen for adjustment problems in an outpatient clinic.

Backpage Infrequency (Fb) Scale A few patients, particularly those with passive aggressive tendencies, will start to complete the MMPI-2 and toward the end of the test may respond to the items in a random fashion. The patient may simply want to finish the test quickly and leave the testing situation. The Fb scale for the MMPI-2 is designed to pick up this tendency.

Variable Response Inconsistency (VRIN) Scale The VRIN Scale consists of 67 pairs of items. Each question of the pair probes for the same or similar information in a slightly different way. For example, the test questions asked are similar to the following: (1) I sleep very poorly at night and (2) I wake up fully refreshed each morning. A patient who responds “true” to question 1 would normally respond “false” to the question 2. Failure to do so reflects inconsistency.

CLINICAL SCALES The clinical scales are generally considered the substance of MMPI-2 interpretations. The original clinical scales have an empirical base in the sense that the items were selected because they differentiated between specific clinical groups and the normative control group. The control group for the original MMPI developed in the 1940s consisted of 1500 persons who were visitors to the University of Minnesota hospitals and other normal groups. Clinical groups varied in size, but for the most part contained at least 50 subjects. For example, the schizophrenic scale was developed with patients with different types of schizophrenia, and the depression scale was developed with a sample of psychiatric patients with depression, including some with manic-depressive illness (bipolar I disorder). Table 7.5-2 briefly describes the original sample groups. Although most clinical scales were developed by using a specific clinically defined group, researchers with the MMPI soon learned, for example, that a given patient with schizophrenia did not simply score high on the schizophrenia scale and low on all other scales. A schizophrenic patient might score high on many scales but the highest score might well be on the schizophrenic scale. If all patients who scored high on the schizophrenic scales were given diagnoses of schizophrenia, a large number of false positives would result. To address this confusion, clinicians began to refer to the clinical scales by a number (0 to 9) rather than by the diagnostic entity that underlies its development.

Table 7.5-2 MMPI Scale Development

COMBINING SCALE ELEVATIONS IN CODE TYPES As has been illustrated, interpreting single-scale evaluations on the MMPI-2 is problematic; therefore, most clinicians use a combination of scale elevations in interpretation. This procedure usually involves using the patient's highest two clinical scales that exceed a *t*-score of 65 to provide a configured interpretation that takes into account the relation between the scales. In this approach, for example, a 1-2 or 2-1 code type would be the same. In other words, a patient who scored highest on scale 1 (Hs) and second highest on scale 2 (D) would be considered to have the same basic profile as an individual who scored highest on scale 2 (D) and second highest on scale 1 (Hs).

A 3-point code, likewise, would list the three highest scales, all of which normally would be above a T-score of 65. These scales also would usually be significantly higher than all the other clinical scales.

On the MMPI-2, uniform *t*-scores are used on clinical scales except in scales 5 and 0. *Uniform* t-*scores* are standardized scores in which the percentile equivalent and distribution are matched among the various clinical scales in terms of skewness and kurtosis. Thus a uniform *t*-score of 65 on scale 7 is roughly equivalent to a uniform *t*-score of 65 on scale 9. The use of uniform *t*-score rather than linear *t*-scores was one of the improvements of the MMPI-2 over the original MMPI.

A review of the interpretation of common two- and three-code types can be found in most standard textbooks on the MMPI, some of which are included in the References. Certain MMPI authorities have used slightly more complex means of interpreting the MMPI-2. This approach emphasizes specific relationships about multiple scales. For example, Harold Gilderstadt and Jan Duker described criteria in their book *A Handbook for Clinical and Actuarial MMPI Interpretation* for what is referred to as a 1, 2, 3, 4-type scale as follows:

1. Hs, D, Hy, and Pd greater than *t*-score 70 and higher than all other scales.
2. Si less than *t*-score of 70.
3. L, F, and K less than *t*-score 70 unless two or more scales are greater than 100, in which case F, less than *t*-score 80.

The problem in using this complex method is that in many settings only a relatively small percentage of patients match these criteria. In other words, if one uses this method rigidly, a substantial number of patients seen in an inpatient unit would not precisely match one of these complex criteria.

CONTENT SCALES FOR MMPI-2 Several efforts have been made to group items according to certain specified dimensions. With respect to the MMPI-2, Butcher and colleagues developed the method used most frequently. These 15 narrow-band scales were developed by use of a combination of rational and statistical procedures. Development of the procedure resulted in internally consistent, relatively independent scales in which item overlap between scales is minimal. Scales include such content areas as anxiety, anger, cynicism, low self-esteem, fears, obsessiveness, and depression, among many others. Norms for both males and females were simply derived using the same uniform *t*-scores used in the MMPI-2 clinical-scale formation. Reliability data on the scales are acceptable, given the relatively few items in some of the content scales.

Scoring guidelines have been presented by Graham in *MMPI-2 Assessing Personality and Psychopathology*. Validity data for the new scales are limited at the current time; however, data accumulation is expected over the years. Since efforts were made to develop reasonably homogeneous items, interpretation of these scales consists of examining high scores and low scores. For example, patients with high scores on the low self-esteem scale tend to have poor self-concept, to anticipate failure, to be overly sensitive to criticism, and to have trouble making decisions. Low scorers, on the other hand, are self-confident and decisive. A given content scale such as the anger scale, considered alone, is similar to rapid assessment instruments.

HARRIS & LINGOES CONTENT SCALES Most of the MMPI clinical scales were developed using empirical key approaches. For example, an item was included in the depression scale because that item discriminated patients in the reference group from persons in the normal group. Although this method is scientifically sound, the approach results in the inclusion of subtle items that seemingly may have little to do with depression. For example, items such as “I sometimes tease animals” (false) and “It takes a lot of argument to convince most people of the truth” (false) are included in the depression scale (D) even though on the surface they have little to do with depression. Such items are called subtle items. Obvious items are those with strong face validity, such as “I wish I could be as happy as others” (true) and “I brood a great deal” (true). The depression subscale reflects a heterogeneous item group coming from a variety of aspects of depression such as subjective depression, psychomotor retardation, mental dullness, etc. The same total score might reflect a quite different combination of items. Knowing which items in combination actually contribute to the total score can be helpful in interpretation. The Harris & Lingoes subscale can help in that process.

The Harris & Lingoes scales were developed logically by grouping items in a given clinical scale into standard scales judged to reflect a more homogeneous trait. Thus, the Harris & Lingoes scales for depression reflect separate scales for subjective depression (D1), psychomotor retardation (D2), physical malfunction (D3), mental dullness (D4), and brooding (D5).

The Harris & Lingoes scales serve two major purposes: (1) to see which group of items were elevated for a patient scoring high on a given clinical scale and (2) to see why a marginally elevated scale was elevated. For example, one patient who scored marginally high on the depression scale may be evidencing psychomotor retardation and no subjective depression, while another may be just the opposite.

SUPPLEMENTAL SCALES The MMPI contained 566 items, and numerous investigators have used the items to develop special-purpose or supplemental scales. By 1972 over 450 supplemental scales were developed, and the number has kept growing. Scales have been developed to predict success in psychotherapy (Es) and to differentiate alcoholic patients from nonalcoholic patients (MACR) and assaultive prisoners from others not committing a crime (overcontrolled hostility, Oh). Many doctoral dissertations describe research conducted to uncover a new supplemental scale. The success of supplemental scales in accomplishing their stated purpose varies considerably. Many such scales were used for only one study; others such as the MacAndrew Alcoholism (MAC) Scale have been used in many studies over the years.

COMPUTER SCORING AND INTERPRETATION The MMPI-2 can be scored by a computer program. A typical computer scoring program not only scores individual items into validity, clinical, content, and supplemental scales, but also prints out certain positive critical items marked by the patient. These programs save considerable time because the program scores all the material, which may take hours to score by hand. Few clinicians have the time or patience to score routinely the vast number of scales found in the output of a typical computer program. The MMPI-2 computer programs can also be used to interpret the test clinically or at least give clinical hypotheses concerning the patient. These computer-generated reports are in narrative format. Since the report comes from a computer, one may get the impression that the information is more valid or accurate than a clinical interpretation. Although attempts have been made to validate narrative statements made by the computer, efforts have only begun in this regard. One problem with computer interpretation of narrative reports is that the algorithms underlying the narrative reports are proprietary information owned by the company producing the program and are not available to the general user.

Rapid Personality-Assessment Instruments Rapid assessment instruments are narrow-spectrum, self-report, objective instruments that measure some unidimensional aspect of personality. The instrument is written in clear, simple language and provides face validity. Typically, these short instruments can be completed in less than 15 minutes. The scoring is simple and straightforward, usually just adding up the number of positive responses. Many instruments have cutting

scores above which an individual is considered to have a clinically significant problem in that area.

Literally hundreds of such measures exist that can assess a wide variety of personality states and such traits as geriatric depression, obsessive-compulsiveness, impulsivity, and state-trait anger. Table 7.5-3 presents a list of such measures. The overall score typically provides an index of the magnitude of the patient's problems. Most of these tests can be used repeatedly to assess change over time. Most of the instruments were developed with relatively small samples and have just been reported in a few studies; however, a few instruments are widely used.

Table 7.5-3 Rapid Personality Instruments

Some rapid assessment instruments were developed out of the behavioral assessment tradition. One advantage of short personality-assessment procedures is high face validity for the domain of the behavior in question. Most instruments have standardized instructions and small normative groups. Performances of patients with the psychiatric problem in question (anger dyscontrol, or geriatric depression) are frequently reported in terms of mean performance and standard deviation. One can find a rapid assessment instrument to assess many of the common psychiatric problems seen today. Another advantage of these instruments is the ease of administration and scoring. The major disadvantage is that they differ greatly in their reliability and validity. Normative groups are frequently small and are obtained in one location. Most do not have national examples. Many of these short instruments have few if any studies of their construct validity. Most do not systematically assess response style such as faking bad, faking good, or social desirability responding. Examples of the hundreds of rapid assessments include measures of bulimia, obsessive-compulsive behavior, sexual functioning, fear and panic, and personal beliefs.

Projective Personality Test Projective personality tests, in contrast to objective personality instruments, are more indirect and unstructured. Unlike objective tests, in which the patient may simply mark “true” or “false” to given questions, the variety of responses to projective personality tests is almost unlimited. Instructions are usually general, allowing the patient's fantasies to be expressed. Patients generally do not know how their responses will be scored or analyzed, making it difficult to obtain a desired result. Projective tests typically do not measure one particular personality characteristic such as Type A personality (i.e., narrow band measurement) but instead are designed to assess a personality as a whole (i.e., broad-band measurement).

Projective tests often focus on latent or unconscious aspects of personality. Obviously, psychologists and others differ in the degree to which they rely on unconscious information. In many projective techniques the patient is simply shown a picture of something and asked to tell what the picture reminds them of. Projective techniques (objective hypothesis) assume that when presented with an ambiguous stimulus such as an inkblot, for which there are an almost unlimited number of responses, the patients' responses will reflect fundamental aspects of their personality. The ambiguous stimulus is a sort of screen on which individuals project their own needs, thoughts, or conflicts. Different persons have different thoughts, needs, and conflicts and hence widely different responses. A schizophrenic patient's responses often reflect a rather bizarre, idiosyncratic view of the world.

Hundreds of different projective techniques have been developed—most of which are not widely used today. Table 7.5-4 contains a list of commonly used projective tests with a brief description, and the strengths and weaknesses of each. This Chapter focuses on the more widely used projective instruments, including the Rorschach test, Thematic Apperception Test (TAT), and sentence completion test.

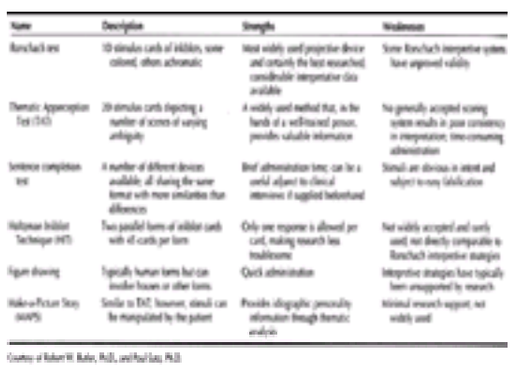

Table 7.5-4 Projective Measures of Personality

The literature on projective techniques is vast. The history of projective techniques goes back many years. Arthur Carr pointed out in the fourth edition of the *Comprehensive Textbook of Psychiatry* that Shakespeare appreciated the importance of one's association to ambiguous stimuli. In an effort to feign insanity, Hamlet associated to a cloud formation certain images that presumably reflected his personality.

Rorschach Herman Rorschach, a Swiss psychiatrist, developed the first major use of projective techniques around 1910. The Rorschach test is the most frequently used projective personality instrument. The test consists of 10 symmetrical, ambiguous inkblots. The inkblot card appears as if ink was poured onto a piece of paper and folded over—hence the symmetry. These 6½ by 9½ inch inkblot cards are the standard stimuli and by convention are referred to by Roman numerals I to X. The cards are presented on thick cardboard, often referred to as plates. Half of the inkblot cards (I, IV, V, VI, and VII) are achromatic (black and white and shades of gray), and the remaining are chromatic. An example of a Rorschach card (card I) can be seen in Figure 7.5-1.

FIGURE 7.5-1 Plate I of the Rorschach Test. (Reprinted with permission from Hermann Rorschach, Rorschach®-Test.© Verlag Hans Huber AG, Bern, Switzerland,

1921, 1948, 1994.)

Using Samuel Beck's approach, the patient is given in essence the following instructions: “You'll be given a series of cards one by one. The cards have on them designs made up of inkblots. Look at each inkblot and tell the examiner what you see on each card and anything that may be represented there. Look at each card as long as you like, only be sure to tell the examiner everything that you see on the card as long as you look at it. When you have finished with these cards give the examiner a sign that you are through with them.”

Minimal interaction between the examiner and the patient occurs while administering the Rorschach, which ensures that standardization procedures are upheld. The examiner writes down verbatim what the patient says during the free-association or response-proper phase. If the patient rotates the card during the response, appropriate notation is made on the test protocol. After the patient has responded to all 10 cards, an inquiry phase begins. During this phase, the patient is asked, “What about the card reminds you of the response you gave?” An almost unlimited range of responses is possible with the Rorschach test and most projective tests. Six different scoring and interpretation systems for the Rorschach tests are available for the clinician. A structural summary of the various measures derived from the patient's response is usually computed.

Scoring and interpretation of the Rorschach test can be time consuming. Administering and scoring the Rorschach test usually takes about 1½ to 2 hours. Typically, responses are scored according to the location on the blot where the response was seen. What about the blot caused the patient's response is referred to as the determinants. The actual content of the patients' response (e.g., animals, human anatomy) is also scored. The scoring system is elaborate and can result in dozens of different indexes being computed; however, the reliability of some of these measures has been questioned. Although the reliability and validity of the Rorschach test as a personality instrument are limited, many studies do support its usefulness as a personality assessment instrument in the hands of a qualified and experienced psychologist.

The limited scientific support of the Rorschach test, however, has resulted in critical reviews by some psychologists. A number of graduate schools of clinical psychology no longer offer formal coursework in the Rorschach test, although most still do.

Table 7.5-5 gives sample responses of four patients to Rorschach card I. Notice how different the responses are to this same card and how the responses reflect the patients' underlying personality.

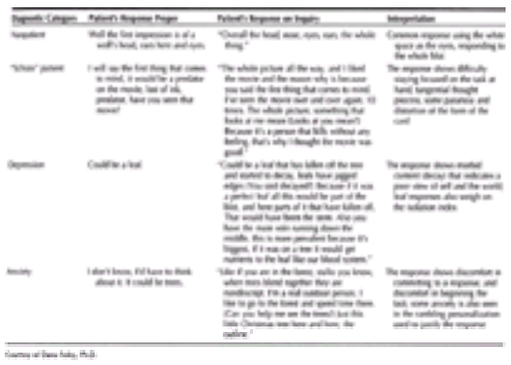

Table 7.5-5 Sample Rorsachach Responses and Interpretation to Card I by Diagnostic Category

Table 7.5-6 shows certain cluster variables that are derived from John Exner's scoring system. The interpretive utility of these cluster variables is also described in the Table.

Cluster Variable	Interpretive Value
Control stress tolerance	Can assess a person's stress tolerance, ability to control behavior, and responses in the environment; can assess a person's style of processing information
Situation-related stress	Can assess the amount of situational stress affecting a person's capacity for control
Affective features	Can assess how a person manages emotional stimuli, types of emotional features (e.g., depression and anger), and ability to modulate their affect
Self-perception	Can assess how persons view themselves and ability to look at themselves
Interpersonal perception	Can assess how a person views others, ways a person interacts with others, and how well a person identifies with others
Information processing	Can assess how persons organize information in their world and how they process it
Cognitive mediation	Can assess the conventionality of a person's perceptions and degree of reality distortions
Ideation	Can assess aspects of ideation such as processing style, use of defenses such as fantasy and intellectualization, and whether thoughts proceed in a logical, coherent fashion or have some thought slippage

Table 7.5-6 Cluster Variables (Exner System) and Basic Interpretive Utility

Thematic Apperception Test Although the Rorschach test is clearly the most frequently used projective personality test, the TAT is probably in second place. Many clinicians include both the TAT and the Rorschach test in a battery of tests for personality assessment. The TAT consists of a series of 10 black and white pictures that depict individuals of both sexes and of different age groups who are involved in a variety of different activities. For example, on card 1, a young boy is shown sitting at a table, looking at a violin. Card 2 depicts a farm scene in which a young woman in the foreground is carrying books in her hands; a man is working in the fields nearby, and an older woman is seen in the background. Typically, a patient is shown 10 TAT cards and asked to make up stories about them. The patient is asked to tell what is going on in the picture; what was going on before the picture was taken; what the individuals in the picture are thinking and feeling; and what is likely to happen in the future. An example of a TAT card is presented in Figure 7.5-2. Some examples of typical sample responses to the TAT appear in Table 7.5-7.

FIGURE 7.5-2 Card 12F of the Thematic Apperception Test. (Reprinted with permission from Henry A. Murray, Thematic Apperception Test, Harvard University Press, Cambridge, MA. Copyright © 1943 President and Fellows of Harvard College, © 1971 Henry A Murray.)

Diagnostic Category	Indicated Response
Nonpatient	This lady has a serious look on her face. She had been talking with the older woman in the background. The older woman had been trying to persuade her to do something that she did not feel was quite right. The younger lady is thinking "I can't do what she wants." She is feeling resentful put upon by this woman. The young lady is frustrated by the request. She is trying to think of a response to the request. What happens in the future is she ignores the old woman's request.
"Schizo" patient	This young lady is about to be killed by that witch in the background. The witch is getting ready to poison her. You have to be careful nowadays, the witch wants all of her money and her car. I know I have to watch out. Everybody will get you if they can. I don't trust anyone. Better safe than sorry. . . . I'm not sorry for what I've done, sorry is not something a person should be. Love means you don't have to say you are sorry.
Depression	I hate pictures like this, I am not really good at it anyway. The lady in front is thinking about her mother. Her mother was not an evil lady but the young lady feels like her mother didn't care about her, didn't love her and was very selfish. Her mother didn't provide support. The young woman is thinking that she has been deprived and emotionally abused. The young lady will think for a few minutes and will then go into the bedroom to be by herself.
Anxiety	The young lady is getting ready to go to work but she doesn't want to go. She rented a room from the old lady in the background. The young lady is about to get fired at work. She does not like her job but she needs the money. She doesn't know how she is going to support herself when she loses her job. She goes out to work but has a miserable day. She eventually loses her job and the old landlady kicks her out of her room.

Table 7.5-7 Sample Thematic Apperception Test Responses to TAT Card 12F

Henry Murray developed the TAT at the Harvard Psychological Clinic in 1943. The stories the patient make up concerning the pictures, according to the projective hypothesis, reflect the patient's own needs, thoughts, feelings, stresses, wishes, desires, and view of the future. According to the theory underlying the test, a patient identifies with a particular individual in each picture. This individual is called the hero. The hero is usually close to the patient in age and frequently of the same sex, although not necessarily. Theoretically, patients attribute their own needs, thoughts, and feelings to this hero. The forces present in the hero's environment represent the *press* of the story, and the *outcome* is the resolution of the interaction between the hero's needs and desires and the press of the environment. The TAT, in the hands of a skilled interpreter, can reveal considerable information about the patient's personality that can then be combined with information obtained from the interview and other testing.

The TAT by itself is not an effective diagnostic instrument, nor was it designed to be. Moreover, as measured by traditional methods of assessing reliability and validity, the TAT lacks the scientific merit of objective instruments. The fact that it remains reasonably popular today, however, speaks to its usefulness in clinical practice.

Sentence Completion Test Although a projective instrument, the sentence completion test is much more direct in soliciting responses from the patient. The patient is simply presented with a series of incomplete sentences and asked to complete the sentence with the first response that comes to mind. Examples of possible incomplete sentences are as follows:

> My father seldom....
>
> Most people don't know that I'm afraid of....
>
> When I was a child, I....
>
> When encountering frustration, I usually....

The purpose of the test is to elicit, somewhat indirectly, information about the patient that cannot be elicited from other measures. Since the patient responds in writing, the examiner's time is limited. The length of time it takes to complete this test varies greatly, depending on the number of incomplete sentences. Tests can range from fewer than 10 sentences to more than 75.

There are many variations of sentence completion tests. Some clinicians have developed their own. One form developed by Julian Rotter has some established validity and reliability, but most sentence completion tests do not. Special-purpose sentence completion tests have been developed to measure different problem areas. For example, one sentence completion test is used with patients who have chronic pain, and another to assess issues concerning transsexual patients. The sentence completion test is seldom if ever used alone but is combined with other appropriate instruments.

Advantages of the sentence completion are short administration time, ease of administration, variety of instruments, and ease of construction. Disadvantages are lack of reliability and validity studies and ease of fabrication and deception.

Behavioral Assessment Behavioral assessment involves direct measurement of a given behavior. Rather than focus primarily on human characteristics, such as repression, ego strength, or self esteem (vague terms to a behaviorist), strict behavioral measurement concentrates on the direct measurement that can be observed, such as the number of temper tantrums per unit time; duration, intensity, and number of hyperventilation episodes; or the number of cigarettes smoked per 24-hour period.

Although an early strict behaviorist would count only behaviors that were observable, a broader definition of behavior has emerged, under which just about anything people do, whether overt (e.g., crying, swearing, or handwashing) or covert (e.g., feeling and thinking), is considered behavior. To measure covert behavior, the patient is typically the informant. For example, to measure dysfunctional thinking, patients may simply carry a mechanical counter and press it every time they have a particular target self-disparaging thought during a given period of time.

Direct Counting of Behavior Measuring overt behavior is direct and can be done by the patient, a family member, or an impartial observer. Cognitive behavior therapists use these measurements to establish baselines for a given undesirable behavior (e.g., violent thoughts that the patient may wish to reduce). Similarly, behavior that the patient wants to increase can also be measured (time spent studying, time out of bed, distance walked on a treadmill). Follow-up measures of the behavior monitor progress and quantify improvement.

Different aspects of a target behavior can be counted or measured, such as frequency (e.g., number of behavioral occurrences), duration (length of time behavior occurred), and intensity. Occasionally a behavior occurs so frequently that counting each occurrence becomes problematic. In such instances, one can simply have the individual indicate whether or not the behavior occurred during a given period of time.

The advantage of counting specific behavior is that it is direct, is objective, is easily understood, and quantifies behavioral change. The problem with counting specific behavior is that many patients have so many different symptoms it would not be possible to quantify them all. Sometimes counting a target behavior itself alters the behavior. Covert behavior can be measured by use of a number of different approaches; for example, asking patients to keep a log of dysfunctional thoughts concerning their employer during a given 18-hour period.

Rating Scales Rating scales have been developed to detect various aspects of personality. On some of these scales, patients simply rate themselves on a given scale dimension such as sadness: 1 = I am not sad, 7 = I wish I were dead. On other scales a significant other person is asked to rate the patient: 1 = the patient seldom mentions being sad, 7 = the patient says he or she would be better off dead. Some of the more commonly used rating scales are designed to quantify information obtained by the mental health professional during a mental status interview.

Brief Psychiatric Rating Scale One of the more commonly used interview rating scales is the Brief Psychiatric Rating Scale (BPRS). To use the BPRS, the psychologist or psychiatrist completes a mental status interview with the patient and then rates that patient on a series of 18 psychiatric symptoms such as motor retardation, blunted affect, conceptual disorganization, anxiety, and guilt. Expanded definitions of each of these terms are provided to the examiner. The interviewer rates each domain on a seven-point Likert scale from “not present,” the lowest rating, to “extremely severe,” the highest rating. An experienced interviewer can complete the ratings in 2 or 3 minutes. The BPRS has been used extensively in drug-outcome and other studies. The advantage of the BPRS is that the interrater reliability is reasonably high for a rating scale of this nature. A summary of over 300 studies using the BPRS found an interrater reliability correlative of .80 or above on the total score in most studies. The first author has used this instrument to teach medical students to observe patient's behavior, and relatively inexperienced medical students can establish reasonably good reliability. Other advantages of the BPRS include the ease and speed of rating and the well-defined symptom

description.

One disadvantage of this scale is examiner subjectivity. Another disadvantage is that interviewers can only rate patients on what they personally observe during the interview. Examiners differ greatly in their style of conducting a mental status interview; thus an examiner may ask many questions in one given area, (e.g., somatic concern) while relatively overlooking another area (e.g., suspiciousness). Another examiner might do just the opposite.

Schedule for Affective Disorders and Schizophrenia (SADS) The BPRS ratings are made on the basis of a mental status interview and do not require that the examiner ask any specific questions of the patient. This approach allows flexibility but results in considerable variation interview style. A flexible interview results in different information being gathered by different interviewers. The SADS, on the other hand, is a highly structured interview instrument. The interviewer is required to ask each patient a series of prescribed questions to ensure that all relevant areas are addressed. However, the structured interview does vary somewhat from patient to patient because of the branching quality of the interview schedule. For example, a patient is asked a question similar to the following: “Have you ever heard voices or other things that weren't there or that other people couldn't hear or see?” Based on the patient's response, the examiner asks other detailed, prescribed follow-up questions concerning hallucination, or if the response was negative, the interviewer moves on the next question in a different area. This approach ensures that all areas are covered in a comprehensive fashion. The SADS is especially helpful for establishing a reliable diagnosis. The SADS can also be used as an index of behavioral severity. Behavioral changes can be determined by repeated administration.

The SADS is quite time consuming, mainly because it is comprehensive. After an initial evaluation using the complete SADS, a condensed SADS (SADS/C) can be used for follow-up.

The advantage of the test is that it is comprehensive and has reasonably good reliability. One disadvantage is its length; another is that in the structured interview the interviewer must read questions from a lengthy booklet, which makes it difficult to establish eye contact and rapport with the patient. The SADS has been used for both research and clinical purposes, probably more frequently for the former.

ASSESSMENT OF PERSONALITY IN CHILDREN AND ADOLESCENTS

Assessment of emotional and interpersonal characteristics in children presents many challenges to the clinicain because of the discontinuities in development that exist throughout childhood, adolescence, and adulthood. Many clinicians are reluctant to assign the diagnosis of a personality disorder before the ages of 16 to 18 years because of the rapid changes that occur during childhood. However, assessment of children and adolescents can often reveal antecedent symptoms, behaviors, or traits associated with emotional disorders at an age when these problems are quite amenable to intervention. For this reason, facility in assessment of emotional disorders in children and adolescents is important for mental health professionals.

Special Considerations in Assessment of Children Children with symptoms of emotional or behavioral disorders are best assessed within developmental and ecological contexts—both of which help one to interpret the child's symptoms from the perspective of developmental influences on behavior, with consideration of the risk and protective factors in the child's social environment. Indeed, the balance of risk and protective factors often provides important clues to the etiology of the child's current problems and the prognosis for effective intervention.

Developmental Context Knowledge about the normal sequence and transitions of development forms a fundamental backdrop from which to view children's suspected psychopathology. The major developmental transition of infancy related to formation of a secure attachment relationship with significant caregivers gives way to the movement from dependence to greater self-reliance in the toddler years. The developmental tasks most salient during the preschool years involve development of a growing capacity for empathy and self-control, while showing a desire to master developmental tasks. Within the early to middle elementary years, youngsters strive for greater mastery of knowledge and intellectual and academic skills, leading to feelings of productivity and competence. The developmental tasks of adolescence center around separation-individuation, resolving conflicts with authority figures, peer group identification, and realistic appraisal and evaluation of self-qualities. Although development is not in linear stages, familiarity with the primary developmental tasks and transitions of each age period provides an important context in which to view current symptoms.

Decisions about appropriate assessment methods are also based on developmental factors. Before children participate in projective testing procedures such as story-telling tasks, the clinician must have developmental information about their level of expressive language, receptive language, and conceptualization ability. Knowledge of children's reading proficiency is critical when presenting them with self-report measures. If children are asked to complete projective drawings, information about their level of visual-motor development is important for interpretation. Young children often do not have the motor or language abilities to provide meaningful responses to projective testing procedures, but they may reveal much about their socialization abilities, fears, anxieties, and significant relationships through play. Therefore, play observation techniques can be a useful alternative to more-formal projective measures. Likewise, some adolescents may resist providing responses on projective measures that require verbal disclosure to a clinician but willingly complete objective paper-and-pencil personality measures that require a less direct response. Choosing an approach to assessment with the developmental context in mind enhances the validity of the information obtained.

Ecological Context The broad social and ecological context of children's family, peer group, and social relationships and the culture in which they live can influence the interpretation of assessment information. From a developmental psychopathology perspective, most psychopathology is expressed as an interaction among various factors that are operating at the levels of the individual (including developmental and personality attributes), the family (e.g., parenting skill, the security of primary attachment relationships, marital stability, extended family support), the community (e.g., influences of work, school, informal social networks, socioeconomic factors, family social isolation), and the larger cultural context of society (e.g., cultural values and beliefs that govern behavior).

Two 4-year-old girls were referred by their Head Start teacher because of concerns about the recent onset of regressive behavior (e.g., enuresis during the school day, immature speech patterns). The girls were interviewed separately but were reluctant to talk with the clinician. A play interview was set up with each, using dolls and a dollhouse with a variety of furniture. The first girl assumed the role of “mother,” and played out the scenario of feeding and diapering the baby doll in a nurturing manner. The second girl was aggressive in her play, with enactment of the adult dolls hitting the child dolls and making them “die.” The child dolls were described as having blood on them. The family context for the first girl revealed that a new baby sibling had been born just prior to the onset of regressive symptoms; the infant was born prematurely, and the mother spent much time with the infant in the hospital. Both the arrival of the new sibling and the mother's separation from her 4-year-old daughter created the social context for the emergence of the child's regressive behavior. In the second case, the girl's mother was interviewed and initially denied any recent stresses in the family. After the clinician questioned her further and provided a description of her daughter's play, the mother revealed that she had a new boyfriend who had just moved into the house. She ultimately revealed that she had noted her daughter's fear of the boyfriend and her frequent tearfulness at home. She reported suspecting that her boyfriend might be sexually molesting her daughter and agreed to call Protective Services in the presence of the clinician to make a report.

As these cases illustrate, there can be vastly different explanations for similar presenting symptoms, and often the projective assessment procedures only suggest concerns, without providing enough specific information about the nature and etiology of the problems. The social context can reveal both risk and protective factors that are important in conceptualizing the child's problems. For instance, in the case of the 4-year-old girl who was sexually abused, the presence of the mother's boyfriend in the home was a risk factor, as were the mother's isolation from her extended family, poverty, and living in a dangerous, violent neighborhood. However, protective factors included the mother's strength in wanting to protect her daughter by admitting the problem, making a report to Protective Services, and forcing the boyfriend to leave the home. Another protective factor was a concerned and observant Head Start teacher who noted the girl's behavioral change and sought help immediately. The ecological approach allows one to examine the possible multiple determinants of emotional psychopathology in children and elucidates the interaction between the risk and protective factors in the child's life.

Use of Informant Information Children and adolescents are usually referred for assessment because of concerns of their parents or caregivers. Teachers may also be the source of specific concerns. For this reason, information relevant to the diagnosis is typically obtained from these significant adults who can provide important information regarding the child's behavior in various settings. Reliance on persons other than the client as reporters of the primary symptoms is a fundamental difference in the diagnostic process with adults and children.

The validity of the information presented about children's symptoms is often a concern to clinicians. During intake, parents often express feelings of anxiety, frustration, or both regarding their child's problems, and their descriptions of the child may be exaggerated or vague (e.g., “she never minds” or “he always acts like a monster”). It is not uncommon for depressed parents to report an increase in number and severity of symptoms in their children. When one suspects that the informant's perceptions may be distorted, collateral information must be obtained from teachers or others familiar with the child's current problems. A primary task is helping informants translate imprecise complaints to specific descriptions of behaviors of concern, using methods that help the clinician ascertain the nature,

frequency, and severity of symptoms. Several behavioral assessment procedures are useful in providing age- and sex-referenced ratings of symptom characteristics.

Specialized Training Clinicians who conduct personality assessment of children need training not only in clinical assessment methods, but also in developmental psychology and child psychopathology. Presentation of many emotional disorders in prelatency years differs from postlatency presentation. For instance, young children with depression may exhibit predominant symptoms of conduct problems, tantrums, oppositional behavior, and hyperirritability rather than the presentation most often associated with older children and adults (depressed mood, diminished interest in activities, vegetative symptoms, anhedonia, etc.). Training and experience in assisting the child to meet the demands of the testing situation are also critical. Children's ability to participate in testing depends on their attention and concentration ability, anxiety regarding separation from significant others during the testing, fatigue or hunger states, motivation and persistence ability, and the relatively greater influence of familial, cultural, and environmental variables. A clinician with specialized training in working with children will both understand these influences on child test-taking behavior and have the skills to work with the children to achieve more valid results.

ASSESSMENT OF CHILDREN AND ADOLESCENTS

Like assessment of adults, personality assessment of children can be accomplished via three primary methods: projective, objective, and behavioral tests and procedures. The projective methods involve direct interaction with the child and adolescent, whereas objective and behavioral methods often involve obtaining information from significant adults in the child's life as well as from direct interaction with the child. With the evolution of more sophisticated statistical methodology and psychometric science in recent years has come the development of new objective and behavioral measures of personality. Improved validity indexes and psychometric procedures that take into account informant reporting are now routinely included. Many of the projective procedures have changed less, though improvements in developmental norms for interpretation have increased the diagnostic validity of measures such as the Rorschach test.

Projective Assessment Procedures As stated in the adult section, objective tests of personality present the patient with a structured set of questions and a finite range of answers. Projective tests, on the other hand, present more ambiguous stimuli and ask the adult or child to make up something (i.e., story, percept, or drawing) from the stimulus. The most common projective assessment procedures for children and adolescents are the Rorschach test, various projective story-telling measures (e.g., Roberts Apperception Test, Children's Apperception Test [CAT]), projective drawings (e.g., human figure and Kinetic Family drawings), and incomplete sentence procedures (Table 7.5-8).

Name	Age Range	Description
Rorschach inkblot test	5 years–adulthood	Consists of 10 inkblots, some colored and others achromatic, used as basis for eliciting associations that reveal disrupted personality development.
Children's Apperception Test (CAT)	3–10 years	Two versions of the CAT—animal and human—depict characters in various social situations and are used to elicit stories from children. Younger children are felt to identify more readily with the animal figures, while older children are usually presented the human figures. Scoring and interpretation are based on psychodynamic theory.
Adolescent Apperception Cards	11–19 years	Eleven picture cards focus on parent–peer–and sibling–adolescent interaction, pulling for themes of physical and sexual abuse, neglect, peer acceptance, loneliness, depression, drug use, and domestic violence. Two versions are available: one depicting white teenagers and the other, black teenagers.
Roberts Apperception Test for Children (RATC)	6–15 years	Sixteen picture cards—with parallel male and female versions depicting white or black characters—are designed to elicit information about both adaptive and maladaptive functioning. The interpersonal futures links the adaptive and clinical scales in order to specific people in the child's life and facilitates a better understanding of the interaction with family members, peers, teachers, and others. Has standardized scoring system and normative data for cut interpretation.
Tell-Me-A-Story (TEMAS)	5–18 years	Multicultural apperception test with 23 color picture cards (15 of which are sex specific) depicting minority (Hispanic, black) or nonminority characters. Measures 10 personality functions (e.g., aggression, interpersonal relations, self-concept), 10 cognitive functions (e.g., time, theory), impulses, and 7 affective functions (e.g., happy, sad, angry, fearful). Has an objective scoring system and normative data based on a diverse cultural and ethnic sample.
Projective drawings	3 or 4 years through adolescence	Various versions exist, from individual drawings of human figures, a house, and tree to kinetic drawings of family. Simple, cost-effective measures that provide information on children's perception of self and relationships with others. Especially useful with children who have difficulty with verbal expression. Objective scoring available for some drawings (e.g., human figures), but interpretation of other types of projective drawings is often subjective.
Sentence- and story-completion tests	8 or 9 years through adolescence	A number of different formats available, each providing a sentence stem or initiating a story, after which the child is asked to complete the sentence or story. Provides information on such factors as interpersonal relationships and dynamics, self perception, wishes and worries.

Table 7.5-8 Projective Assessment Procedures for Children

Rorschach Inkblot Test Projective instruments such as the Rorschach test allow the clinician to explore dynamics of the child's personality by gathering information on both the child's perceptual-cognitive world and the inner fantasy world. The Rorschach test ideally is used as part of a more comprehensive battery that includes an interview with the child and significant adults, expressive (play) techniques, and perhaps story-telling techniques, to allow the child maximum freedom and spontaneity of expression.

The Rorschach test with children has a long research and clinical history of examining developmental norms and symbolic interpretations. Various normative studies have added to its interpretive validity, with the comprehensive studies of John E. Exner and Irving B. Weiner discussed in *Assessment of Children and Adolescents*, the third volume of their book *The Rorschach: A Comprehensive System*, providing the most recent and detailed normative data available for children ages 5 to 16 years. Exner's descriptive statistics for the normative data are provided in tables for each year of age; computerized programs for obtaining the structural summaries in the context of these developmental norms are also available. The clinician using the Rorschach test to evaluate children and adolescents must take care to analyze the structural summary within the context of appropriate age norms, as a given result interpreted as normal for a young child could be of concern in an adolescent. Children's Rorschach responses have been examined as a function of their cognitive functioning, academic performance, and behavioral problems within the school setting. The underlying conceptual framework for this work hypothesizes a direct relation between secondary process development and school achievement. A published review of projective tests suggests that the child who can deal successfully with drive-laden impulses through play and fantasy is seen as more capable, open, and flexible. According to Exner and Weiner, the Rorschach test is not particularly good at discriminating one specific personality disorder from another, as is, for instance, a structured clinical interview. However, the Rorschach test can provide useful information regarding the way children with personality disorder traits view the world and can shed light on manifestations of flawed or disrupted personality development.

As with adults, there are numerous systems for administering and scoring the Rorschach test with children, but all ask children to say what they see on the blot (i.e., the percept), followed by an inquiry referring back to each response. Whether the inquiry should be done following the child's free association responses to all 10 blots or whether the inquiry is best accomplished after each individual blot is controversial. Proponents of the latter approach suggest that young children may have difficulty remembering their reasoning behind the original free associations or may become fatigued by the end of the test, thus limiting their cooperation and responsiveness to the inquiry. Research by Exner and Weiner found the latter approach to inquiry to be unnecessary in their large child sample, except for a small percentage of children who were seriously disturbed. Of most concern is that inquiry immediately following each free association response may contaminate subsequent responses; thus reserving the inquiry until free association responses have been obtained for all 10 blots is preferred. Clinicians must also be aware of state anxiety as a potential confounding variable in children's responses to the Rorschach test. Care in building rapport and an explanation of the purpose and process of testing can ease the situational anxiety.

As with adults, scoring is done on the basis of response characteristics, or determinants, such as form, color, shading, texture, and dimensionality. The content and form quality of the child's responses is also used in scoring and interpretation.

Projective Story-Telling Procedures In projective story-telling approaches, the child is presented with a picture stimulus of human or animal figures in rather ambiguous situations. The child is asked to make up a story about the figures—a story that has a beginning and an end and includes the thinking and feeling of the persons represented in the pictures. A fantasy response is evoked, and the resulting projective information is a combination of the perceptual and the imaginative. Stories are typically analyzed for repetitive, unique, intense, or problematic themes, beliefs, or affects. This procedure closely resembles the TAT approach used in adults.

Children's Apperception Test The initial CAT, developed in 1949, used animal figures and was developed for children ages 3 to 10 years. Animal figures were thought to be more culture-free than human characters. In 1965, the human figures version (CAT-H) was produced, showing human figures in situations as analogous as possible to those pictured in the animal version. During administration, the cards are presented individually in the numbered order of the card (because certain cards were designed for sequential impact). The child is asked to tell a story about each picture (e.g., what is going on, what happened before, what will happen next). There is some debate about the use of prompts with young children, and whether such prompts (e.g., How did the story end?) may contaminate important projective information. Generally, prompts are often necessary to help the young child understand what is expected. Young children have a tendency to merely describe or label portions of the picture and may not understand the concept of telling a story with a beginning, middle, and conclusion. However, the clinician must always guard against overly intrusive or helpful prompts that guide the child's responses in a particular direction or suggest a specific format for the story. The various scoring protocols for CAT have focused on analysis of ego functions and evaluating the relative use of various defense mechanisms. However, qualitative interpretation is also made on the basis of recurrent or sequential themes and determination of identification figures, while taking into consideration the child's family and case history

information.

Comparisons have been made between CAT and the Rorschach test as to the types of information obtained and the overlap between them. These tests have been found to complement rather than duplicate each other, as they tap different aspects of personality functioning. The CAT generally can be expected to reflect interpersonal and familial relationships, ego functioning, sources of discomfort, and conflicts and past traumas. In contrast, the Rorschach test, according to M. R. Haworth, explores deeper levels of personality, emotional responsiveness, mechanisms for control, the extent of reality contact, and available defenses.

Although the CAT continues to be used, its picture stimuli are quite outdated in appearance and often do not appeal to children today. Further, clinicians are not as apt to be trained formally in the psychodynamic theories of interpretation that are used with the CAT. Newer apperception tests, such as the Roberts Apperception Test for Children (RATC), are being used with increasing frequency because of their modern appearance and because they use scoring procedures that are less reliant on psychodynamic theory.

Roberts Apperception Test for Children The manual for the RATC offered several criticisms of existing picture apperception tests as a rationale for the development of the RATC. It reported that most of the previously developed techniques either were not developed specifically for children or were appropriate for a limited age range. Second, the nature of the stimulus characteristics of the cards, rather than the child's unique personality, often was the primary determinant of the child's responses. Finally, the existing tests lacked a standardized system for scoring the thematic content and structural characteristics of the child's responses. Therefore, the interpretation of thematic apperception tests was subjective and often based on the clinician's own experiences, theoretical orientation, and personality style. The RATC was designed to overcome these limitations by using stimulus cards that (1) depict children and are designed for use with children ages 6 through 15 years, (2) emphasize everyday interpersonal events of contemporary life, (3) are consistent in their presentation, and (4) are easily scored, objective measures that yield high interrater agreement. In addition, the RATC provides normative data for 200 well-adjusted children ages 6 through 15 years to aid in clinical interpretation. Interpretation of the RATC, like that of other projective measures, is based on the assumption that children presented with ambiguous drawings of children and adults in everyday interaction will project their typical thoughts, concerns, conflicts, and coping styles into the stories they create.

The RATC uses 16 stimulus cards, with parallel male and female versions, that represent important interpersonal themes (e.g., parental disagreement and affection, peer conflicts, observation of nudity, and sibling rivalry). A supplemental version of the RAT has African-American figures. The responses are scored on a number of scales measuring both adaptive and maladaptive functioning. Table 7.5-9 illustrates the Profile Scales and Indicators.

Adaptive scales:	Reliance on Others
	Support-Other
	Support-Child
	Limit Setting
	Problem Identification
	Resolution 1
	Resolution 2
	Resolution 3
Clinical scales:	Anxiety
	Aggression
	Depression
	Rejection
	Unresolved
Indicators:	Atypical Response
	Maladaptive Response
	Refusal

Table 7.5-9 Profile Scales and Indicators for Roberts Apperception Test for Children

In addition, the child's responses may be scored on the Interpersonal Matrix, which summarizes the relations between the scales and indicators, and the figures identified in the child's stories. In general, the standardized scoring procedures aid interpretation and clinical utility of this scale.

Projective Drawing Techniques Projective drawing techniques are often helpful in establishing rapport and engaging shy or negative children who are reluctant to become involved in more-verbal interaction with the clinician. The nondirective nature of the technique allows the child time to adjust to the testing environment and to the clinician without being propositioned for a verbal response. The nonverbal nature of the task also makes it amenable to younger children and those who are cognitively impaired or non-English–speaking.

Two common approaches to projective drawings are the House-Tree-Person and Kinetic Family Drawing. In the former, the child is first asked to draw a person and, after completing that drawing, is asked to draw a person of the sex opposite to that of the person in the first drawing. When finished, the child is asked to draw a house and then a tree. Interview questions asking the child to identify the humans, tell what they are doing in the picture, or how they are feeling can shed light upon the child's thoughts about the drawings. With the house, the child may be asked who lives in the house, what they are doing, etc. Kinetic Family Drawing is accomplished by telling the child to “Draw a picture of your family doing something.” The drawing can elicit verbal comments that concern family cohesiveness or conflict, the perceived role of the child within the family system, relationships with significant others within the family and the degree of interaction versus isolation of various family members, and family structure and the hierarchy of power.

In addition to the verbal information elicited from the drawings, graphic analysis can include placement of the drawing on the page, overworking or sketchiness of the lines, size and relative placement of the drawings, pencil pressure used, amount of detailing, symmetry, indicators of dissociation (i.e., incongruities between the graphic drawing and the verbal description of it), and use of shading or color.

As with other projective techniques, projective drawings are not intended to be used alone to make interpretations of personality functioning. Corroborating information to support any interpretations of the drawings must be obtained through interview or other test procedures that could shed light on the meaning of the child's performance.

Story- and Sentence-Completion Techniques A story-completion technique often begins with a sentence (or a couple of sentences) that represents the beginning of a story plot to be completed by the child. An illustrative example from the Madeline Thomas Stories follows:

A boy goes to school. During recess he does not play with the other children. He stays by himself in a corner. Why?

Story-completion techniques are useful in adding clinical information about rather focal problems and possibly the child's problem-solving skills in addressing these problems. Although there is little research on diagnostic utility and standardized scoring and interpretation schemata, the qualitative information obtained is often worth the time expended in administering the technique.

Sentence-completion procedures can be administered in various formats. One approach is to read the sentence stems to the child rapidly while asking the child to respond with the first information that comes to mind. This approach may reduce response latencies and loosen the child's defenses to response, especially if the items are rather repetitive. Often, information about family dynamics and relationships, and the child's self-esteem, wishes, and worries are revealed more directly than with other projective techniques. Valuable clinical information can be obtained by noting the child's response latencies, the positive or negative tone of the responses, and the predominant mood endorsed in the responses. Another administration approach allows children to write the answers to the sentence stems on a paper, working at their own pace. This is often the best approach to use with adolescents, who value autonomy. Another advantage of sentence-completion techniques is their economy and flexibility of administration.

Objective Personality Measures Objective approaches to child personality assessment typically have straightforward test stimuli and clear instructions regarding completion of the tests, as opposed to projective approaches that typically use more-unstructured, ambiguous test stimuli. Objective tests typically have good standardization, reliability, and validity, and they often are norm-referenced to provide comparisons with a particular criterion group.

The advantages of using objective measures with children are similar to those used with adults. Disadvantages include the length of the measures (most have several hundred questions to which the informant must respond), the reading level required for completion (which could place children and adolescents at a disadvantage),

and the initial expense of purchasing either computer administration or computer scoring software. Despite the disadvantages, objective personality measures remain an important part of a comprehensive personality assessment by providing a broad survey of major areas of psychopathology at the initial stages of the evaluation. Descriptions of some of the major objective personality measures follow, and a more complete listing is provided in Table 7.5-10.

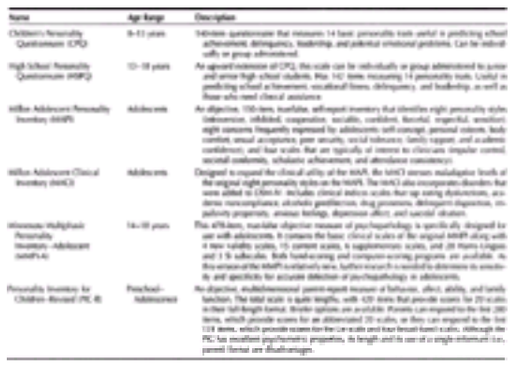

Table 7.5-10 Objective Personality Measures for Children

Robert P. Archer states in his book *MMPI-A: Assessing Adolescent Psychotherapy* that the Minnesotta Multiphasic Personality Inventory–Adolescent (MMPI-A) serves two important functions in assessment of adolescents: (1) it provides an objective evaluation and description of an adolescent's level of functioning related to selected standardized dimensions of psychopathology, and (2) repeated administration can provide a means of assessing ongoing changes in psychopathology, perhaps as a result of intervention. The MMPI-A should be administered in most cases only to adolescents from 14 to 18 years. On occasion, 12- and 13-year-old adolescents who meet the administration guidelines can be evaluated with the MMPI-A, but it should not be administered to anyone younger than 12 years of age. Above age 18, the MMPI-2 is the most appropriate version to administer. This lengthy measure demands that an adolescent of any age be able to read and understand the items (which are written at an average seventh-grade level) and tolerate the time and persistence required to complete the measure. Trained personnel must administer the test in a supervised environment. The MMPI-A is geared toward a population at risk for psychopathology and is not particularly useful for exploring personality styles of nonclinical adolescents.

One concern about the use of the MMPI-A and other objective personality measures during adolescence is the stability of the symptomatology. Most would agree that the MMPI-A is best used to obtain a description of current adolescent psychopathology rather than to make long-term predictions regarding future functioning. The ongoing maturational changes in adolescent personality development most likely account for the lack of stability in predictions of future psychopathology; this underscores the need for the clinician to be sensitive to the developmental issues in this population.

Millon Clinical Multiaxial Inventories Among the most widely used objective measures of child personality is the Millon series of assessment instruments. Two of the scales are specific to adolescents: the Millon Adolescent Personality Inventory (MAPI) and the Millon Adolescent Clinical Inventory (MACI). The original MAPI was designed to be used in both clinical and nonclinical (e.g., vocational, educational) settings to provide an appraisal of adolescent personality and concerns. The goal of Millon and his colleagues was to create a broad instrument that would be valid and reliable in assessing the inherent traits and current state of adolescents. The MAPI is written at a sixth-grade reading level and provides information on eight personality styles that mirror Millon's theory of personality (Table 7.5-10 provides a listing of the MAPI scales). At maladaptive levels, the personality styles correspond to Axis II disorders found in the revised third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R). In addition, the MAPI contains 12 additional scales: 8 that focus on worries that many teens experience, and 4 that address specific behaviors of concern. Because of its nonclinical nomenclature and design, the MAPI can be used successfully to identify personality styles and concerns in a population of normal adolescents. Prior to the development of the MACI, the MAPI was used with clinical populations as well. However, as Mark Marvish stated in *The Use of Psychological Testing for Treatment Planning and Outcome Assessment*, the MAPI shares the same disadvantage as the MMPI-A: the stability of prediction based on its scores varies.

The MACI was designed to assess maladaptive levels of the original eight MAPI personality styles. In addition, it added items to correspond to the three new personality disorders added to the fourth edition of DSM (DSM-IV), and it identifies adolescents who have marked tendencies toward borderline functioning. The 12 personality patterns assessed by the MACI are given descriptive rather than diagnostic labels, partly because of the problems of predictive stability within the adolescent population. The MACI also added several new clinically oriented scales to the original MAPI format; whereas the MAPI had 4 scales that address behavioral adjustment problems, the MACI expanded this section to include 11 scales that reflect more extremely maladjusted behaviors (see Table 7.4-9).

Given the recent development of the MACI, empirical support for its validity, reliability, and interpretation is needed. However, it is well grounded in theory, and it benefits from the empirical information gained with its predecessor, the MAPI.

Personality Measures for Specific Disorders in Children In contrast to the multidimensional personality measures discussed above, several measures address more-specific disorders in children, such as depressive and anxiety disorders. Several of these measures are described in Table 7.5-11.

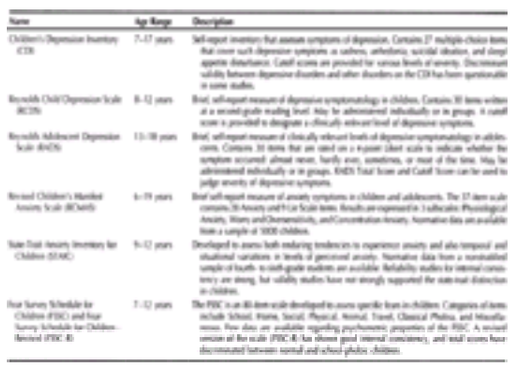

Table 7.5-11 Personality Measures for Specific Disorders in Children

Often clinicians use the multidimensional personality measures to obtain a broad overview of risk for psychopathology and then use the narrower-band, more specific measures to explore a particular set of symptoms in greater detail. Neither type of personality inventory is used to confirm a diagnosis, but both provide valuable information about the nature and severity of symptoms that can be combined with other approaches to arrive at a diagnosis.

Advantages of the specific personality inventories include their brevity, low cost in terms of time to administer, and ease in scoring and interpreting. However, as with similar adult measures, caution is needed in reviewing the psychometric qualities of these personality measures, particularly with regard to discriminant validity for the disorder under study versus other disorders versus results for children without disorders. Many of the scales were developed for children in a narrow age range, with a small normative sample that is not representative or stratified, and they have questionable discriminant validity. As long as the clinician uses these measures as part of a more comprehensive approach to diagnosing emotional problems and understands their strengths and weaknesses, the measures can be useful.

Behavioral Assessment Procedures Behavioral assessment procedures offer a highly structured method of obtaining information about behavioral and emotional functioning and social competencies of children and adolescents. These procedures include direct observations and informant ratings on age- and gender-normed scales. The popularity of these measures has grown in recent years, in part because of their improved psychometric properties, their cost-effectiveness, and their

utility in multitrait-multimethod diagnostic procedures (Table 7.5-12).

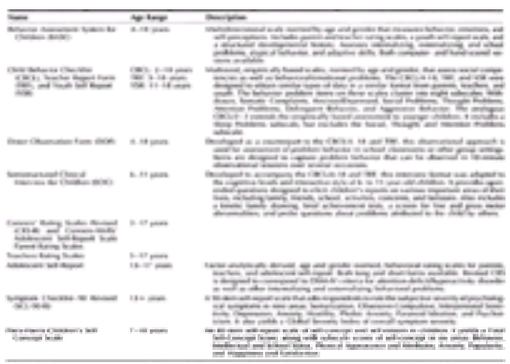

Table 7.5-12 Behavioral Assessment Procedures for Children

Validity of Informant Reports Use of behavioral rating scales raises questions about the validity of informant information. The research on agreement among various raters of child behaviors is consistent in showing greater agreement between raters who interact with a child in similar situations (e.g., between mothers and fathers) than between raters who interact with the child in different situations (e.g., between parents and teachers, or parents and children). Thomas Achenbach and colleagues found that agreement tends to vary across age and types of problems rated: agreement was greater for 6- to 11-year-olds than for adolescents, and for externalizing behavior problems than for internalizing them. Sex differences are also apparent when the number of reported behavioral problems is examined. Achenbach reports that both parents and teachers observe more behavioral and emotional problems for referred and nonreferred males than for females in childhood and adolescence. Achenbach says that studies of youth self-report of problems reveal that 11- to 18-year-old females report more problems than males of the same age. Differences in number of problems reported are also a function of the type of population (inpatient versus outpatient versus nonreferred). According to Achenbach for nonreferred males and females, children's self-ratings of total problems were higher than parent or teacher ratings. In an inpatient sample, Alan Kazdin and colleagues reported that children rated their own symptoms of depression and aggression lower than their mothers did but not lower than their fathers. Yet the magnitude of the children's self-ratings relative to those of other children accurately discriminated diagnostic groups. Catherine Stanger and Michael Lewis, in a study of interrater (i.e., parent, teacher, youth) agreement with 13-year-old youths, demonstrated that the youths rated themselves significantly higher than all other raters on all scales and that mothers and fathers rated more behavioral concerns than teachers, especially for internalizing problems. Stanger and Lewis say that the research to date suggests the importance of collecting information from multiple informants regarding child and adolescent behaviors and that ratings of no one informant can be substituted for those of another.

Advantages and Disadvantages of Behavioral Approaches There are several advantages of the behavioral approaches to assessment of behavior and emotional functioning in children and youths. These procedures are cost-effective in that they maximize the amount of information obtained with little clinician time. They often have convenient hand-score or computer-scoring methodology, another cost-effective aspect. Use of behavioral assessment increases the likelihood of obtaining information from multiple sources (e.g., teachers, parents) across multiple settings (e.g., school, home, day care). These sources of information are necessary for some diagnoses, such as attention deficit/hyperactivity disorder. Many of the scales are empirically derived, factor-analytical scales that are normed for age and sex and generally possess good psychometric properties.

Disadvantages of behavioral rating methods for children include questions about the validity of informants' reports and concerns about informant reading level. The behavioral ratings are filtered through the perceptions of the informant, and the degree of frustration, emotional pathology (e.g., depression) and intellectual and academic skills of the informant are critical to understanding the report. There is much debate about how to handle discrepant ratings across informants. Although perfect correlation is not expected, the issue of how to weigh one person's observations against those of another remains unresolved.

Behavioral Assessment System for Children (BASC) The BASC is a relatively new (1992) scale developed as a multimethod, multidimensional approach to evaluating the behavior and self-perceptions of children from 4 to 18 years of age. It is *multimethod* in that it has five components that can be used individually or in any combination: a self-report scale on which children or adolescents can describe their own emotions and self-perceptions, two rating scales (one for parents and one for teachers) that gather descriptions of the child's observable behavior, a structured developmental history, and a form for recording and classifying direct observations of the child's classroom behavior. It is *multidimensional* in that it measures many aspects of behavior and personality, including both positive and negative dimensions. The BASC allows comparison of information from multiple sources and offers various types of validity checks that allow the clinician to evaluate the consistency and veracity of the informants. Scales are consistent across age, gender, and forms (i.e., parent, teacher). For the Parent and Teacher Rating Scales, the Externalizing Problems Scale includes subscales of aggression, hyperactivity, and conduct problems; the Internalizing Problems Scale includes subscales of anxiety, depression, and somatization; and the School Problems Scale includes subscales of attention and learning problems. The Other Problems Scale includes two subscales: atypicality and withdrawal. Finally, the Adaptive Skills Scale includes adaptability, leadership, social skills, and study skills. The Self-Report of Personality (SRP) contains four primary scales that differ from the parent and teacher versions. The Clinical Maladjustment Scale includes subscales of anxiety, atypicality, locus of control, social stress, and somatization. The School Maladjustment Scale includes attitude toward school, attitude toward teachers, and sensation seeking. The Other Problems Scale includes depression and sense of inadequacy subscales; and the Personal Adjustment Scale includes subscales of relations with parents, interpersonal relations, self-esteem, and self-reliance. Information obtained on each of the scales can be referenced against national age norms (general, male, and female versions) or clinical norms. Special indexes are incorporated into the BASC to assess the validity of each respondent's responses (F index). Critical items may be interpreted individually on the Parent and Teacher Rating Scales. On the SRP, patient responses are also viewed on an L (“fake good”) index and the V index designed to detect invalid responses caused by poor reading comprehension, failure to follow directions, or poor contact with reality.

The BASC offers the clinician a psychometrically well-developed behavioral measure that takes only 10 to 20 minutes to complete. An advantage of the BASC, compared with many other rating scales, is the clear distinction between attention and hyperactivity symptoms for children suspected of having attention-deficit/hyperactivity disorder. The BASC thus provides information in a format to support clinical subtyping of attention-deficit/hyperactivity disorder. A disadvantage is the amount of time necessary to score and develop the profiles for each rating scale by hand. Computer scoring is likely the most cost-effective way to make use of this scale, to avoid spending undue time on tedious scoring procedures.

Achenbach Child Behavior Checklists The checklists developed by Achenbach have been perhaps the most widely used behavioral rating scales in child and adolescent clinics in recent years. Like the BASC, the Achenbach scales include a parent rating (the Child Behavior Checklist, [CBCL]), a teacher rating (Teacher Report Form, [TRF]), and a self-report (Youth Self-Report, [YSR]). The CBCL is appropriate for children 4 to 18 years of age; the TRF, for children 5 to 18 years old; and the YSR, for those 11 to 18 years old. Each scale is interpreted in comparison with a large normative sample stratified by age and sex. A cross-informant computerized scoring paradigm is provided to assist with comparisons of the CBCL, TRF, and YSR measures for a given subject.

A version of the CBCL for toddlers (CBCL/2–3) was developed in 1992 and has gained in popularity since that time. It includes five of the subscales from the CBCL and adds a subscale on Sleep Problems. A separate computerized scoring system is available for this version of the CBCL.

Other Behavioral Personality Approaches Many other behavioral approaches to assessment are available in addition to behavior rating scales, as discussed above. Direct observations of child and adolescent behavior can be a useful adjunct to other assessment procedures, whether the observation is unstructured or structured according to a specific format. For instance, Russell Barkley and colleagues developed a structured observational paradigm, the Restricted Academic Playroom Situation, designed to provide an analog situation for observing and recording symptoms of attention-deficit hyperactivity disorder during individual academic work. In this paradigm, the child or adolescent doing independent math problems is observed in a clinic playroom with toys or age-appropriate materials present. The child is told to complete as many math problems as possible, to remain on the chair at the table, and not to touch the toys or materials. Interval ratings are made in five behavioral categories: off task behavior, fidgeting, being out of seat, vocalizing, and playing with objects. Many structured observational paradigms offer normative data against which to compare the clinical behaviors of interest, thus helping the clinician to place the observational information within a broader context.

REFERRAL FOR PSYCHOLOGICAL ASSESSMENT

Interpretation of personality tests requires specialized training and experience in psychology. Although certain rapid and narrow band personality instruments (e.g., Beck Depression Inventory) can be administered and interpreted without extensive training, more wideband objective tests and most projective personality instruments require considerable training in psychology. For this reason, psychiatrists and other physicians should refer to psychologists for interpretation of personality tests. Referral is especially important in medicolegal situations.

7.6 NEUROPSYCHOLOGICAL AND INTELLECTUAL ASSESSMENT OF CHILDREN

IDA SUE BARON, PH.D. AND EILEEN B. FENNELL, FH.D.

Neuropsychological and intellectual assessment of children involves a systematic application of standardized procedures. The testing produces results that enable the neuropsychologist to make an informed opinion about brain-behavior relationships or about behavioral interrelationships when direct inference about the status of the central nervous system cannot be made. The testing is generally requested as part of a multidimensional evaluation that includes other medical, educational, and psychological data. The contribution of neuropsychological testing is that it offers unique data that sharpen appreciation of the bases for a variety of deficits or dysfunction. These may range widely (e.g., from mild developmental delay of uncertain etiology to pronounced cognitive dysfunction as a result of disease or trauma). Neuropsychological data also allow temporal judgments, because long-standing problems present with a different pattern or profile of functioning than those attributable to immediate or recent events. Additionally, obtaining comprehensive baseline data enables future documentation of interval change consequent to a specific treatment regimen, such as the late effects of systemic therapy for an oncology patient, the protracted recovery course following closed head injury, the prognosis for a child whose seizures are well controlled with antiepileptic drugs, the pattern of preserved and residual dysfunction following surgical intervention for a brain tumor.

It is useful to have a framework to understand the significant contribution of neuropsychological and intelligence assessment for children with various disorders and conditions. This increases the probability that appropriate referrals are made, that the nature of the evaluation is understood, that results are integrated appropriately, and (most importantly) that treatment recommendations are implemented in concert with other relevant data acquired about the child. The neuropsychological evaluation is likely one of several consultations or procedures requested. Its strength is in the meaningful recommendations that are individually based and considered with respect to the child's environment (e.g., school, hospital, rehabilitation center), the resources available, the child's chronological age and developmental level, and whether it serves clinical or research purposes.

Importantly, neuropsychological testing determines both strengths and weaknesses in cognitive and emotional functioning. Understanding both capabilities and deficits is necessary to delineate how neuropsychological data can contribute practically to treatment recommendations and cognitive rehabilitation (i.e., have ecological validity). The concluding interpretation of a neuropsychological assessment depends on the psychologist's ability to combine clinical observations with the results of a structured objective examination to make a clinical judgment about a child's distinctive cognitive, behavioral, and emotional functioning.

Testing also provides an opportunity to appraise intractable behavior that is not likely to be ameliorated despite intervention. For example, a teenager whose sloppy, dysgraphic handwriting continues to be a source of personal frustration and low grades is unlikely to make significant gains in a treatment program designed to improve fine motor control, as might be expected for a younger child. Teachers need to reduce their emphasis on the quality of written production and instead judge the teenager on the content of what has been learned. At this age, recommendations for improving keyboard skills and teacher acceptance of computer-assisted written output, for instance, may be more advantageous to a teenager's academic performance and self-image than continued insistence on a mode of production never mastered sufficiently compared with peers despite years of attempts.

FACTORS UNIQUE TO TESTING CHILDREN

Children bring a number of complicating factors to the evaluative process that makes their evaluation quite unlike an evaluation of an adult. Among these are the influences of maturational change, brain reorganization, behavioral variability, differing diagnostic considerations, different brain-behavior rules, and the highly relevant influence of environment, personality, and psychosocial factors.

Maturational Change For the adult, deficit is commonly expressed as a loss of function. Maturation is complete, and a neurological insult has the effect of making an aspect of the adult's behavioral repertoire dysfunctional. For example, an aphasia may follow a cerebral vascular accident in the cerebral hemisphere principally mediating language function. In contrast, a child with a vascular lesion in the left hemisphere who has not reached developmental maturity may show neurobehavioral effects that are far more variable.

If a child sustains a cerebral insult, a number of different outcomes may be observed. There may be no appreciable effects of the insult; that is, the effects of interference in normal development are not immediately discernible even with careful assessment. However, dysfunction may be detected when the child “grows into the deficit” at a later developmental stage. For example, poor academic achievement in a highly visual subject such as geometry may result from head trauma at a young age (impaired visuoperceptual function) or from an inherited learning disability that is only manifested when the academic task requirements are complex enough to make this disability evident. A second possible outcome is delayed development. For example, language acquisition may slow after a viral illness. A third possibility is that development is halted. No further progress occurs in a particular functional area. A fourth possibility is that behavior regresses. Loss of previously acquired skills because of a loss of functional ability is analogous to loss of function in the adult. For example, motor developmental milestones accomplished at age-appropriate times may be lost as intracranial pressure increases due to hydrocephalus, or language may regress or disappear in the presence of an acquired epileptiform aphasia.

Brain Reorganization The potential for brain organization (plasticity) is often dramatic in childhood, and a large literature attests to the potential for recovery of function after childhood disorder or dysfunction. However, cognitive recovery in childhood, while impressive, is not necessarily complete. The full implications of a neurological insult may not be apparent for years. Further, it is not unusual for a child's recovery to follow a different course than that of an adult. For example, a child's prognosis following severe head trauma and prolonged coma, hemispherectomy or lobectomy, or early lateralized deficit can differ predictably and dramatically from that for an adult.

Behavioral Variability Children express more behavioral variability during the test session than is typical for adults. The constraints, rules, and limit setting required during the child's test session far exceed that usually required when testing an adult. Determination of when a best performance is being obtained may be more difficult, and evaluating motivation and appropriate concern about performance is not easy. This becomes apparent, for example, when reevaluation of a child previously tested elsewhere reveals a deliberate withholding of information with the previous examiner because of personal dislike for the examiner or the testing situation or in defiance of parental pressure for testing.

Different Diagnostic Considerations Evaluation of a child requires diagnostic considerations different from those for an adult. Children present with a different set of symptoms from those typical of adults with the same condition. For example, brain tumor in a child more often presents acutely with headache, nausea, and vomiting rather than with gradual cognitive changes or psychiatric symptoms, or a child's seizure type may change with increasing chronological age, whereas seizure type in an adult is more stable. Expectations about cognitive functioning based on a typical adult presentation may not be accurate for a child.

Different Brain-Behavior Rules Established brain-behavior rules derived from empirical study of adults do not readily translate to children. The effects of interference in brain development may be appreciable but do not follow the rules associated with adult brain-behavior relations. For example, in some circumstances a small focal lesion may result in diffuse disorder rather than being limited to a discrete behavioral presentation. Unlike in adults, one cannot identify specific brain regions in children as dysfunctional. It is even difficult to make direct reference to lesions in the substrate of the brain. This has been the source of much misinformation and confusion in interpretation of test results. For example, the adult assessment literature often refers to tests of frontal lobe function; however, these same tests and other tests that superficially appear to be measuring the same behavioral indexes cannot reasonably ascribe frontal lobe dysfunction to a child. Specificity of a test to a brain region is more problematic for the very young child but in some instances may be considered if the child is over 11 years of age. Further, children have

different clinical manifestations of underlying neurological compromise from adults. Therefore, the same cause may not yield the same profile of functioning for the child and the adult.

Environmental, Personality, Psychosocial Factors Environmental, personality, and psychosocial factors strongly influence a child's behavior. These factors may affect the expression of a deficit, may confound the assessment of cognitive sequelae of brain impairment, and may influence the choice of treatment recommendations. A consideration of context and how it affects cognitive, behavioral, and emotional functioning is increasingly recognized to be extremely important.

Thus, the conclusions one can reach after a neuropsychological evaluation also differ for a child and an adult. Rather than identify neural system failure or focal abnormality or address the brain substrate specifically, the intent in a child evaluation is to describe the child's full range of capabilities so that needed intervention and remediation of targeted problems can be planned. These interventions must be appropriate for the child's specific developmental level, and neuropsychological data are useful in establishing where the child is on the developmental continuum.

H. Gerry Taylor and Jack Fletcher discuss four common fallacies that lead to misinterpretation of the capacity of neuropsychological procedures to evaluate cerebral status in children. These are related to the differences in assessing children and adults. The fallacies are that (1) procedures from adult neuropsychology are differentially sensitive to childhood brain disorders, (2) tests developed for adults measure similar abilities in children, (3) the nature or pattern of deficits associated with learning or behavioral problems can be assumed to signal abnormal brain status, and (4) dysfunction describes the brain rather than the behavior. Careful attention to these potential interpretive fallacies is critical when one requests or receives the results of a child's neuropsychological evaluation.

DEVELOPMENTAL MODELS

No life-span model of neuropsychological development exists. Such a model ideally would provide continuity in understanding developmental progression or plateau in neurological disorders affecting normal development, encourage a broader consideration of function and methodologies, and encourage definition and differentiation of functions during active stages of developmental gain or delay rather than relying on post hoc analyses. Such a model would also allow formulation of age-related specific recommendations that might positively influence developmental course and provide a basis for outcome measurement. Further, such a model would encourage expansion of knowledge about the natural history of normal and abnormal brain-behavior relationships in childhood and encourage innovations or new techniques that better science and practice.

A few developmental models have been tentatively proposed in the child neuropsychology literature despite the inherent obstacles to their development. These have generally been directed toward older children, adolescents and, more rarely, infants and young children. A functional organizational approach has been suggested to separate the different types of variables underlying a developmental neuropsychology focused on behavioral theory and research. An emphasis was rightly placed on the importance of development and the active processes of change. The neuropsychologist's role was conceptualized as extending beyond simplistic inferences about brain status based on behavioral test results or observations toward a focus on relations among the manifest disabilities and basic competencies, and on relations between behavioral variables and central nervous system factors. A later assessment model by Taylor and Fletcher provided an overview of the behavioral and biological levels of analysis common in the neuropsychological assessment of children. Four components of assessment were presented: (1) manifest disability, a description of the child's failure to master age-appropriate behavior; (2) assessment of the child's cognitive or psychosocial traits that affect the manifest disability; (3) evaluation of relevant environmental variables that relate directly to the psychosocial traits; and (4) evaluation of biological variables that relate to, and influence, the cognitive traits. As the field of child neuropsychology matures, the usefulness of a developmental model to guide assessment and intervention practices will likely be demonstrated.

REFERRALS

Referral questions are important because they determine the focus of the initial stages of a psychological assessment. The psychologist needs clarity and completeness in the referral question to understand the purpose of the neuropsychological consultation and for presumptive diagnostic considerations. Since questions raised by the referral source affect the early phases of the test session, they should be stated in some detail. For example, a referral that states “child with heart disease and probable attention-deficit/hyperactivity disorder, please evaluate” provides some direction. But it is clearly insufficient compared with a referral that is more complete—for example, “5-year-old white male with a history of coarctation of the aorta repair requiring neonatal resuscitation on several occasions. Currently he has school issues (e.g., spaciness) yet academically is doing well. He has difficulty remembering routine tasks. Please evaluate for possible neuropsychological deficit.” The difference between these two statements is obvious; the former provides minimal direction, while the second identifies a number of serious medical problems with potential clinical significance. The direction one should take with the patient based on the first referral is indeterminate. The second referral raises immediate concerns about late effects of serious cardiac abnormality and early oxygen deprivation, the possibility of epileptiform activity, executive function deficit associated with early brain insult, and involvement of subcortical structures important for learning and retrieval of information.

Referral Questions in Psychiatry Referral questions about psychiatry patients may originate for varying reasons. As pointed out by Rebecca Rieger and the first author of this section, four types of questions are typically asked. The first question is whether the observed behavior is primarily a consequence of cerebral-processing dysfunction (i.e., whether a contributing organic element confounds or contributes to the clinical presentation). This question asks whether the observed behavior has a basis in neuropsychological impairment that was not fully appreciated in other neurodiagnostic investigations. For example, impaired social interactions and inappropriate responses to social cues characterize some children's behavior, including that of the child with Asperger's disorder. Also, hallucinations may result from primary psychiatric cause or an undiagnosed complex partial epilepsy. Thus, the observed behavior may be illuminated by consideration of a strong neurological or neuropsychological basis.

A second question is whether the clinical picture involves comorbidity. One must understand the impact of one disorder on another—for example, how attention–deficit/hyperactivity disorder affects a child with a mood disorder or whether there is documentation of neuropsychological impairment related to chronic substance abuse in a teenager with a conduct disorder. Coexisting conditions have obvious differential treatment considerations, but understanding their interaction is essential.

The third question is whether data can confirm that development is normal or whether the data suggest that the child's development has been delayed or inhibited as a consequence of neurological impairment. The neuropsychologist must be familiar with the stages of normal child psychological and neuropsychological development and the dynamic transitions that characterize movement from one developmental level to the next. The neuropsychologist must also recognize truly abnormal development and not ascribe a deficit to behavior that is normal for the child at that developmental stage.

A fourth question is how the neuropsychological data influence treatment and rehabilitation planning. For example, does the child have sufficient expressive language, abstract reasoning, and judgment for highly verbal (e.g., psychoanalytic) therapy? Recommendations may suffice after one evaluation. However, neuropsychological data also allow fine-grained serial testing. This allows assessment of the effects of a specific treatment regimen or clinical population for research purposes or serial reevaluation of a single child for clinical purposes.

Review of the referral question is only a first step in the exploratory process associated with child testing. Adjustments are made as the testing session progresses. For example, if tests requiring speed and nonverbal perception are less well performed than verbal tests that have no time constraints, evidence of more-specific types of visuoperceptual or visuospatial deficit may be sought. Alternatively, one may ask whether the speeded psychomotor performance and organization of action required by these tasks determine the low scores, whether periods of inattention vary within a brief time interval and within a test independent of the sensory modality being assessed, or whether the acquisition of new information and its retrieval over acute and long-chronic conditions are impaired. Thus, a continuous testing of alternative hypotheses occurs in response to behaviors observed clinically as well as to those revealed by formal test instruments. The formal neuropsychological evaluation provides an opportunity to establish whether evidence of dysfunction exists that was not detected by other neurodiagnostic procedures or never elicited in clinical interviews or clarified by other data obtained in a careful history taking and record review. A neuropsychological examination attempts to learn how the brain functions by asking the child to demonstrate many different types of behavior. Doing so yields a dynamic picture of the brain as it works to accomplish these functions, and observing such dynamic behavior, one can identify problems the child is experiencing in accomplishing these tasks as well as determining how well the child can perform a wide variety of cognitive tasks.

Referral Populations Certain patient populations are appropriately referred for neuropsychological evaluation, while others benefit less from this consultation. A child with a history of developmental delay in language or visuomotor functioning should be assessed in the preschool years (ages 3 to 5 years) to determine the type and degree of delay, the specific recommendations needed (e.g., speech and language, occupational, or physical therapy) and the risk for problems with learning and achievement on school entry. A child with a significant delay in mental or cognitive development may need to be assessed for appropriate school placement according

to state guidelines. Children who have sustained direct insult to the central nervous system (e.g., brain tumor, vascular malformation, viral or bacterial infection, or cerebrovascular infarction) should be assessed to determine the effects of these cerebral insults on their intellectual and neuropsychological development. Children who are born with malformations of the brain or spinal cord or who have genetic or metabolic disorders that can affect normal development need to be assessed for the degree to which these developmental disorders have affected brain growth and functional maturation. Many types of seizure disorders of childhood and antiepileptic drugs can directly disrupt development. Children with medical disorders such as acute lymphocytic leukemia that require prophylactic chemotherapy or radiation are at risk for developing neuropsychological dysfunction secondary to the treatment regimen. Chronic medical conditions such as renal failure, diabetes, or chronic heart disease may affect a child's brain functions. In a number of developmental disorders (e.g., learning disabilities, attention-deficit/hyperactivity disorder, Tourette's disorder, childhood anxiety, and depression), the question of a comorbid disorder may arise. A variety of other instances may lead to a request for neuropsychological evaluation, such as the child with disruptive or aggressive behavior or conduct disorder, as well as those who manifest some features of a pervasive developmental disorder. A less common (and likely less helpful) referral is the moderately to severely retarded child. In the extreme low range of intellectual functioning, differential identification of strengths and weaknesses may be difficult because of the child's limited cognitive abilities. The usefulness of traditional child neuropsychological assessment in pervasive developmental disorders, childhood schizophrenia, or mood disorders awaits proved demonstration. Research has attempted to identify specific potential brain dysfunctions in these disorders with neuropsychological research methods. The usefulness of a typical neuropsychological examination for these clinical populations requires further investigation and clarification.

Once the child is evaluated, a written report summarizing the neuropsychological evaluation is prepared. This report addresses the concerns stated in the reason for referral and confirms or disconfirms the original considerations. The conclusions may suggest new possibilities or amend incomplete or erroneous preliminary assumptions. The conclusions should elaborate on the child's full range of abilities, providing detail about how the intact or impaired abilities affect diverse cognitive functions and extrapolating to predictions about the child's behavior in real-life situations.

TEST APPROACH

A variety of acceptable approaches to neuropsychological test selection exist. Most commonly encountered are those that involve (1) a fixed battery, (2) a battery and supplemental tests, (3) a process approach, and (4) an eclectic or flexible approach. Proponents of the fixed battery administer a specific, unchanging set of tests that generally have been normed on the same population. The range of tests within the battery is assumed to sample sufficient behavior for valid conclusions. The widely recognized Halstead-Reitan Neuropsychological Test Battery is one such battery. Scores obtained on a battery or within a test containing multiple subparts may be comparable (i.e., they are scaled similarly and standardized on the same population) or they may need to be converted for commonality of meaning. However, inflexible test batteries are not useful for the neuropsychologist who is concerned with individualizing an approach on the basis of specific referral questions. In general, most fixed batteries have been designed to answer a specific set of questions. For example, the Halstead-Reitan battery is designed to answer the following questions: Is there an organic brain lesion? Is it focal or diffuse? Is it chronic or acute? Is it lateralized? Is it localized?

Proponents of administering a test battery supplemented by additional tests choose complementary tests that cover weaknesses in the core battery. A core battery may be particularly insensitive to the condition being assessed, and the addition of other test measures successfully expands the database. For example, the Halstead-Reitan Neuropsychological Test Battery fails to sufficiently tap functions often compromised by closed head injury. The addition of tests of new learning and memory for different modalities (e.g., auditory and verbal and visual encoding, storage, and retrieval) and of attention and executive function reduces the likelihood that important cognitive sequelae of a head injury will be missed. Neuropsychologists who endorse a process approach emphasize the utility of considering qualitative aspects of a performance in addition to quantitative aspects. They also value testing-the-limits procedures to better understand how someone solves a problem or reacts to additional specific probes or information about the task. The usual quantitative data are then supplemented by alternative scoring and careful recording of the process that the child used to achieve the desired end point. Systematically highlighting qualitative behavioral features of the child's behavior may add valuable information that clarifies how a child integrates information and produces a specific behavioral response.

The eclectic, (or flexible), approach is perhaps the most increasingly common procedure endorsed by neuropsychologists. Tests are chosen on the basis of the specific functions they are likely to assess. Tests may be selected from established fixed batteries, but complete batteries are generally not used. Often the neuropsychologist uses a personalized selection of core tests as an efficient screening battery, which is then elaborated on during the test session, in response to the child's behavior during the session and the particular profile that emerges as the session progresses.

Both the process and the eclectic or flexible approaches have special utility in child assessment. Both approaches encourage the neuropsychologist to attempt to evaluate functional areas for which clinical instruments are not available or are not well standardized. Reliance is encouraged on a creative application of key developmental concepts through informed observation, directed interview with significant adults, and the use of more naturalistic activities.

No matter which approach is preferred, testing should allow the neuropsychologist to highlight specific indexes of impairment and ascribe a useful treatment plan to ameliorate the underlying problem that generated the referral. With data from multiple sources, including real world observations or reports, hypotheses about functional strengths and weaknesses are more easily translated into intervention recommendations.

TEST SELECTION

Neuropsychological testing involves administering instruments that range widely in the specificity or generality of what they purport to assess. The tests also range in their applicability to different clinical populations. Some tests that are sensitive to impairment resulting from one condition may be insensitive to the effects of another. For example, tests that may reveal a reading disorder may not prove as useful for the child who has had a traumatic brain injury. In the former case, extensive evaluation of aspects of receptive and expressive language take precedence over tests that target functions especially vulnerable to change. In the latter case, tests of functions that are most vulnerable to change as a consequence of an acquired insult are needed, such as those that evaluate mental control, attentional components, new learning, and flexible problem-solving behavior and information processing.

Because a single test result rarely confirms either normality or dysfunction, conclusions are reached only after consideration of all available data. Current test results are weighed in relation to historical information including prior testing, data from other allied health evaluations, and data from appropriate statistical sources that serve as a comparison group. Intact functioning may be suggested by normative sample comparisons, but impaired functioning may be documented when intraindividual comparisons are made. For example, a child may obtain an average verbal intelligence quotient (I.Q.) score and average scores on tests of receptive and expressive language. However, other test data may document above-average functioning on tests that do not have a strong language component, which suggests that comparison only with the normative group is insufficient and that average function for this child indicates relative weakness. Thus, average function is an insufficient basis for concluding there is no impairment. Tests of right and left upper extremity motor and sensory-perceptual function may find evidence of right-sided impairment, supporting a hypothesis of compromised left cerebral function. These data attest to differences in functioning between the child's right and left sides and are independent of conclusions reached by comparing the child with other children.

Further, tests have different applicability depending on whether their principal use is for clinical evaluation or research investigation. Research test batteries may include some commonly used intellectual and neuropsychological measures that may be modified, shortened, or adapted to answer a specific research question. For example, many research protocols do not use the complete Wechsler Intelligence Scale for Children (WISC) to assess intellectual functions but instead include two or three subtests that are highly correlated with Verbal, Performance, or Full Scale I.Q. Similarly, selected aspects of a particular function may be emphasized rather than the full range of measures (e.g., verbal list learning). A research protocol may include experimental tasks which are neuropsychological in nature but are designed to answer a limited or specific question, such as how much does verbal recitation of a word list disrupt speed of motor tapping. Finally, a research battery may be specifically designed to be administered serially and may, for example, only measure speed, tracking, or attention. As a result, a research battery may not cover the full range of assessment measures that may be covered in a typical clinical examination.

DOMAINS OF TESTING

The field of psychological assessment is expanding; more well-normed tests exist and more behaviors can be assessed. There is an increasing transition to looking at subdomains of some cognitive areas and their importance and relevance for different clinical populations. Cognitive domains are partitioned in an effort to understand preservation of function and identify functions that are vulnerable. As a result, it is no longer acceptable to obtain only general intelligence data (i.e., mental age compared with chronological age) or administer a few broad tests that have limited or no validity with respect to specific brain functions. Current procedure is to examine discrete functions not routinely examined in the recent past, such as attention and alertness, executive function, learning and retrieval, affective social interaction, and communication and language readiness. The neuropsychologist chooses to assess a number of cognitive domains of function with varying degrees of

completeness. Table 7.6-1 presents a list of the common domains or broad areas of function that are commonly assessed in a clinical neuropsychological evaluation.

General intelligence
Academic achievement
Executive functioning
Attention, concentration, orientation
Receptive and expressive language
Sensory-perceptual functioning
Motor functioning
Visuospatial analysis and constructional skills
Learning and retrieval
Personality and behavioral assessment
General development and adaptive behaviors

Table 7.6-1 Domains Assessed in a Neuropsychological Evaluation

Areas of function assessed in a neuropsychological evaluation are listed in Table 7.6-2 along with a sampling of tests appropriately considered within each broad neuropsychological domain and a summary description of what they measure. (The tests listed are intended only as examples of tests that measure an aspect of the specific domain within which it falls.)

Table 7.6-2 Selected Neuropsychological Tests and Function Assessed by Cognitive Domain

Tests of Intelligence and Achievement Generally, a comprehensive evaluation screens each relevant domain to establish integrity of function. The decision to administer more detailed testing within a domain is based on the referral question, the response to screening measures, and behaviors observed during the test session. A growing number of tests are available for inclusion in an individually designed test session. The choice depends on examiner experience and preference.

Table 7.6-3 lists commonly used intelligence and academic achievement tests. These tests vary, and the choice of instrument is based on age of the child, available standardization data, conceptual basis, and range of subtests available to address the referral question. For example, the Stanford-Binet Intelligence Scale is appropriate for children beginning at 2½ years of age. It yields a composite I.Q. score and scores for four scales: verbal reasoning, abstract visual reasoning, quantitative reasoning, and short-term memory. The Kaufman Assessment Battery for Children is applicable for children 2½ to 12½ years of age. It makes a conceptual distinction between simultaneous and sequential processing. A composite score and scores for each of these processing concepts are derived. The McCarthy Scales of Children's Abilities has normative data for children between 2½ and 8½ years of age. It allows for computation of a General Cognitive Index, based on results of three other indexes: verbal, perceptual-performance, and quantitative. It also yields a memory index and a motor index. The Test of Nonverbal Intelligence is a language-free measure of intelligence, aptitude, abstract reasoning, and problem solving, appropriate for children with communication problems or those who do not read or write well. It is similar to the Raven's Matrices Test but was normed in the United States. It is appropriate for children aged 6 years or older.

Intelligence tests
Bayley Infant Scale of Development–2nd edition (1–42 months)
McCarthy Scales of Children's Intelligence (2.5–8.5 years)
Kaufman Assessment Battery for Children (2.5–12.5 years)
Stanford-Binet Intelligence Test, 4th edition (2.5 years–adult)
Wechsler Preschool and Primary Scale of Intelligence–Revised (4–6.5 years)
Wechsler Intelligence Scale for Children–III (6–16 years)
Test of Nonverbal Intelligence–3 (6–89 years)
Raven's Progressive Matrices (Coloured or Standard) (5.5 years–adult)
Academic achievement tests
Wide Range Achievement Test–3rd edition
Woodcock Johnson Psycho-Educational Test Battery–Revised
Peabody Individual Achievement Test–Revised
Wechsler Individual Achievement Tests
Bracken Basic Concept Scales (school screener)

Table 7.6-3 Selected Intelligence and Academic Achievement Tests

Intelligence and achievement tests are not validated with respect to brain function, but they provide valuable data for a neuropsychological evaluation. The Wechsler Intelligence Scale for Children–III (WISC-III) is the most commonly administered general intelligence test for children at least 6 years of age. It is a battery comprising 13 subtests (10 core tests and 3 alternates). Three summary I.Q.s are obtained: (1) the Verbal I.Q., based on five verbal subtests; (2) the Performance I.Q., based on five performance subtests; and (3) the averaged index of general intellectual functioning, the Full Scale I.Q. Language expression, comprehension, and application of verbal skills in problem solving are assessed within the Verbal Scale. Nonverbal visuoperceptual analysis, synthesis, expression, psychomotor speed, and visuomotor efficiency are assessed within the Performance Scale. Neither scale assesses several important factors that influence successful performance, such as motivation, creativity, organizational skill, or study habits. Four additional index scores can be obtained. The Verbal Comprehension Index is based on performances on the information, similarities, vocabulary, and comprehension subtests. The Perceptual Organization Index is based on performances on the picture completion, picture arrangement, block design, and object assembly subtests. The Freedom from Distractibility Index is based on arithmetic and digit span performances. The Processing Speed Index is based on coding and symbol search performances.

The individual subtests may be particularly useful because each depends on a variety of capabilities, and dysfunction of any one could result in a low score. Possible deficit is then suggested that can be more directly assessed with specific neuropsychological test measures. For example, a low score on the picture arrangement subtest that requires sequencing nonverbal material may suggest visual organization problems. This could be explored further with tests of visuomotor organization such as copying complex designs, tests of the motor and sensory integrity of the right side of the brain, graphomotor sequencing and upper extremity motor sequencing, and other tests with a high sensitivity to visual planning, organization, and production deficits. Thus, the pattern, or profile, of the WISC-III subtest scatter may illuminate a neuropsychological problem, but it does not confirm the problem. It is not common for an individual subtest score to convincingly highlight neuropsychological dysfunction in the child, as it might in the adult. Additional confirmation that these data provide accurate evidence of a problem is necessary.

There are six subtests within the Verbal Scale:

Information requires that the child provide factual information learned over time, both at school and at home, about events, people, objects, and places.

Similarities requires abstract verbal reasoning and verbal expression of the underlying concept connecting word pairs.

Arithmetic requires mental manipulation of numbers (i.e., numerical reasoning) to respond orally and attention and concentration.

Vocabulary assesses word knowledge and verbal fluency.

Comprehension requires common sense and socially appropriate solutions for a variety of practical social situations.

Digit Span assesses immediate recall of number strings (forward and backward) and attention and concentration for auditorily presented stimuli.

There are seven subtests within the Performance scale:

Picture Completion requires attention to essential visual detail and visual discrimination.

Coding involves copying in response to a key set of number-symbol pairs, visuomotor coordination, speed, and attention and concentration.

Picture Arrangement requires appreciation of social nuance in a series of pictures and planning a logical sequence.

Block Design requires visuospatial analysis and synthesis and abstract visual problem solving.

Object Assembly requires visuoperceptual analysis and synthesis of pieces of recognizable objects into a meaningful whole.

Symbol Search requires visuomotor speed, visuoperception, attention and concentration, and vigilance.

Mazes requires visuomotor planning, attention and concentration, and vigilance.

Self-Report and Parent-Report Tests A large number of tests and procedures exist that the neuropsychologist may administer to the child or the parents to determine the type, frequency, and severity of behavioral problems or symptoms that the child may manifest. Table 7.6-4 provides a list of commonly used self-report and parent-report instruments and tests and procedures administered to parents to identify the child's specific developmental attainments and adaptive behaviors.

Personality, behavior, and symptom report
Child Behavior Checklist
Personality Inventory for Children–Revised
Reynolds Depression Scale (adolescents)
Children's Depression Inventory (6–13 years)
Children's State-Trait Anxiety Scale
Revised Children's Manifest Anxiety Scale
Harter Scales of Perceived Competence
Eyberg Child Behavior Inventory (oppositional-defiant/conduct disorder)
Conners Rating Scales (hyperactivity, inattention, conduct disorder)
General development and adaptive behaviors
Child Development Inventory
Vineland Adaptive Behavior Scales

Table 7.6-4 Personality, Behavior, and Symptom Report Measures and General Development and Adaptive Behaviors

Two commonly used parent measures include the Child Behavior Checklist and the Personality Inventory for Children–Revised. Both allow the parent to report a variety of social, academic, physical, intellectual, and psychiatric problem behaviors that their child may exhibit. Each measure contains a variety of subscales that assess the presence of specific problematic behaviors as endorsed by the parent. Scores are standardized on the basis of fairly large normative samples. The child's score is compared with scores of the age-appropriate normative group. While both scales were originally developed in a mental health setting, each instrument has been used in a variety of clinical settings among different pediatric diagnostic groups, and clinical sample norms are available.

Other self-report measures have been developed to assess specific childhood diagnoses or symptoms, such as depression or anxiety disorders. A similar parent-report format has also been developed for other childhood disorders such as oppositional defiant disorder, attention-deficit/hyperactivity disorder, and conduct disorder. As with many other child diagnostic instruments, it is helpful to refer to the normative sample data to determine the utility of the test in certain specific medical conditions or among particular ethnic or socioeconomic minority groups. The typical neuropsychological report includes the reference group used for specific test findings.

The effect of parent distress on parent-report measures must be considered. It is insufficient to have a parent complete these questionnaires without an adjunctive interview. The clinical interview permits the neuropsychologist to evaluate the degree to which parental distress about their child's behavior may have led them to overendorse problems. Alternatively, some parents consistently minimize or fail to report symptoms. They may be unaware of or in denial about their child's behavioral difficulties. This may have a negative impact on their willingness to institute treatments recommended from the neuropsychological evaluation.

Tests of General Development and Adaptive Functioning Tests of general development and adaptive functioning are also useful in a neuropsychological evaluation (see Table 7.6-4). These tests are designed to elicit specific information about behaviors that a parent or other caregiver has observed. These behaviors are grouped according to developmental progress, and the child's attainments are compared with those of a same-age, normative group. The Child Development Inventory, normed through age 6 years but applicable to the older, but delayed child, has subscales that assess social skills, gross and fine motor skills, language, self-help skills, and general development. The Vineland Adaptive Behavior Scales include four subdomains (communication, social skills, daily living, and motor skills) as well as a composite Adaptive Behavioral Score. The child's scores are converted into scores that identify variations from typical age-appropriate attainments, and the child's development across the subdomains can be compared with age norms. Unlike the Child Development Inventory, which has a yes-no format, the Vineland scales require extensive training in parent interviewing for accurate scoring.

Tests of Attention and Executive Functioning Sometimes tests assess aspects of functioning related to more than one domain. For example, the Trail Making Test requires the child to draw a line between numbers in sequence for Part A (i.e., 1-2-3-4-...) and to alternate between numbers and letters in sequence for Part B (i.e., 1-A-2-B-3-C-4-D...). This test has been considered both a test of attention, because it requires focus and sustained attention to complete the sequencing, and a test of executive function, because it requires simple mental shifting between the two automatic language sequences. Because it is timed, it is also used to index the speed with which these tasks are accomplished. It is in the final interpretation that the assignment of a test to a function is justified, based on the full range of behavior sampled during the assessment. As a result, a test-by-test interpretation of brain dysfunction is not acceptable clinical practice. Instead, the total performance across a variety of domains must be integrated in the summary interpretation of the examination.

Subdomains of function are receiving greater attention in the neuropsychology literature. Attention and executive functioning are two domains that have been discussed and empirically tested from the perspective of the child neuropsychologist.

The data sources for attention in infants and young children are largely the examiner's direct observations, the indirect observations reported by a reliable caretaker,

and rating of behaviors related to attention. For older children, specific components of attention have been hypothesized along with tests that most likely measure these components. Table 7.6-5 presents fractionated subcomponents of attention and of executive function that have been considered in the recent literature.

Attention	Executive function	
Focus/execute	Plan	Inhibit
Sustain	Organize	Shift flexibly
Encode	Initiate	Monitor
Shift	Sustain	Evaluate

Adapted from Mirsky AE, Anthony BJ, Duncan CC, Ahearn MB, Kellam SG: Analysis of the elements of attention: A neuropsychological approach. Neuropsychol Rev 2:109, 1991, and Denckla MB: Executive function, the overlap zone between attention-deficit/hyperactivity disorder and learning disabilities. Int Pediatr 4:155, 1989.

Table 7.6-5 Subdomains of Attention and Executive Function

Four factors were empirically identified by Allan Mirsky and colleagues. They proposed a four-factor model and associated neuroanatomical regions and tests for each factor. The first factor, *focus execute*, refers to the child's ability to scan the stimulus field and respond in a meaningful way. A deficit related to focus is suggested if the child gives the stimulus material cursory attention or cannot perform a task under distraction conditions. Tests sensitive to this perceptual motor speed factor are the Wechsler Digit Symbol and Coding subtests, the Stroop Test, the Trail Making Test, and letter and number cancellation tasks. Implicated brain regions are the inferior parietal lobe, superior temporal cortex, and corpus striatum. The second factor, *sustain*, refers to the child's ability to be vigilant and attend for a time interval. Observation of the child's ability to complete tasks on a consistent basis or noting the degree to which the child must be redirected back to a task after having been engaged by the task, provide clinical indexes of the sustain factor. The computerized Continuous Performance Test was cited for sustain. Critical brain regions include the tectum, mesopontine regions of the reticular formation, and midline reticular nucleus of the thalamus. The third factor, *encode*, refers to sequential registration, recall, and mental manipulation of information. Tests included the Wechsler Digit Span and Arithmetic subtests. Involvement of the amygdala, hippocampus, and superior temporal region was proposed. The fourth factor, *shift*, refers to the child's ability to be flexible and adaptive. The Wisconsin Card Sorting Test is sensitive to shifting capacity. Critical brain regions are the prefrontal cortex and anterior cingulate.

The literature on the development of regulatory functions across the age span and the importance of the domain of executive function have been growing. A variety of abilities are subsumed under the heading executive function. For example, the ability to initiate, sustain, inhibit, and shift was proposed by Martha Denckla. Initiate or drive refers to goal-setting and deciphering the means to an end. Sustain refers to how well one can fixate on a task and organize oneself. Inhibit is the capacity to monitor, evaluate, and adapt. Shift is the ability to change ideas in response to environmental factors.

Executive control functions are thus a collection of varying abilities that involve regulatory control over thought and behavior in the service of goal-oriented problem solving. Besides formal tests, clinical data about executive function can be obtained by observing the child's ability to problem solve in the natural environment and initiate play, by parental interview regarding the child's inhibitory abilities, by assessing how flexible a child is when faced with a changing routine, and on ratings on specific behavioral scales. Children have differential developmental trajectories for executive function subcomponents. The neuropsychologist must consider these when focusing an assessment toward those that are relevant for a particular developmental period. The problems of executive regulation of cognition and behavior are potentially relevant to children who have acquired brain injury, lead poisoning, or in utero toxic exposure and to many other diagnostic groups. Increasing attention is also being directed toward the interplay of executive functions and attention-deficit/hyperactivity disorder.

STATISTICAL CONCEPTS

A variety of statistical terms are commonly used by neuropsychologists in the test reports written after an examination. It is useful to have a familiarity with these terms and the statistical bases of test interpretation.

The expectation that a test has good reliability and good validity is not always satisfied in neuropsychology testing. *Reliability* refers to the likelihood that an individual will obtain a test score at one point in time that is similar to the score obtained if the test is readministered at another point in time. It is a reference to consistency. *Validity* refers to whether the test is measuring what it is intended to measure; for example, whether a test that seems to measure auditory attention is in fact a good test of auditory attention.

Published psychological tests are accompanied by test manuals that describes their statistical features. Included among these is the *standardization sample*, the population of subjects on whom the test was normed. The psychologist compares the examinee with the standardization sample to determine if the published normative data are a fair and representative sample for the examinee. For example, normative data may be provided for different levels of education, different cultural backgrounds, different sex, and different ages. There may also be tables that enable conversion of test scores to mental age equivalents, to relate the child's actual functioning to that of younger or older children. Not all tests have sufficient normative data to allow ideal comparisons. Therefore, psychologists also rely on a substantial research literature that addresses the usefulness of different tests with different clinical populations. Together, test manuals and empirical studies provide a more comprehensive basis, ensuring the most reliable and valid assessment of a child and appropriate analyses of the test results.

The actual score on a test is the *raw score*. The raw score conveys no comparative information and must be converted to a score that has meaning across individuals and across tests. Psychological test scores are commonly converted to standardized scores; then two or more scores can be compared on the basis of their standard deviation from a mean (i.e., average) score. The *standard deviation* (SD) is an index of the average amount of deviation of the scores from the mean. It is calculated by squaring and averaging individual deviations (the variance) and then extracting the square root of the variance. Test manuals provide the needed standard deviations, facilitating interpretation of specific scores. For example, the Wechsler series of intelligence tests are constructed so that subtest scores have a mean of 10 and a standard deviation of 3. A score deviation greater than 1 SD in either direction is significant. Allowance is made for the *standard error of measurement*, the range of how much a score can vary. This range is determined by the standard error of measurement (i.e., the actual error band around each obtained score or how a test score will vary if the test is readministered). These ranges are presented in tabular format for many standardized tests. By referring to the appropriate table within the test manual, the neuropsychologist can determine that an I.Q. of 100 falls between these two scores with either a 5 percent level of confidence (the probability that the score will normally fall outside this range is less than 5 percent) or a more restrictive 1 percent level of confidence.

For example, if a child's I.Q. is reported to be 100, the likelihood is that the child's true score falls somewhere between two scores. This range is determined on the basis of the standard error of measurement (i.e., the actual error band around each obtained score) or, practically, how a test score will vary if the test is readministered. These ranges are presented in tabular format for many standardized tests. Thus, standardized scores and the nonstandardized percentile score enable comparison of one person's results with the results of others and make intraindividual comparisons possible for performances on different tests if the standardization sample is similar. These conversions are essential for valid interpretation. Therefore, a score two points lower cannot be interpreted as indicating a poorer performance than the higher score if they are within the same acceptable range of variability.

For a difference between two subtest scores to be considered statistically significant, it must have a specific magnitude (e.g., more than 1 SD). However, because there is allowance for the standard error of measurement, a lower score cannot be interpreted as clearly indicating a poorer performance than the higher score. It is common for the lay reader of psychological reports to misinterpret a “lower” score as indicating poorer performance or impairment when both scores may fall within the same acceptable range of variability and thus be accurately interpreted by the neuropsychologist as equivalent.

Certain standard scores are more commonly referred to in psychological reports than others. One standard score that is frequently used is a deviation I.Q. The summary score obtained on the Wechsler intelligence tests is a deviation I.Q. These scores have a mean of 100 and a standard deviation of 15. Sometimes scores are reported as T-*scores*. A *T*-score has a mean of 50 and a standard deviation of 10. A conversion to a Z- *score* means that the mean is zero and the standard deviation is 1. Reporting standard scores allows the reader to consider the degree to which a child exceeds expected average performance or fails to reach the mean

level. Table 7.6-6 presents selected WISC-III I.Q. scores, their standard deviations from the mean, and their percentile rank equivalents.

I.Q. Score	Number of SDs from the Mean	Percentile Rank Equivalent
145	+ 3	99.9
130	+ 2	98
125	+ 1 2/3	95
120	+ 1 1/3	91
115	+ 1	84
110	+ 2/3	75
105	+ 1/3	63
100	0 (Mean)	50
95	− 1/3	37
90	− 2/3	25
85	− 1	16
80	− 1 1/3	9
75	− 1 2/3	5
70	− 2	2
55	− 3	0.1

Table 7.6-6 Relation of Selected WISC-III I.Q. Scores to Standard Deviations From the Mean and Percentile Rank Equivalents

A hypothetical normal distribution curve approximates score distributions. A range from –1 to +1 standard deviation (e.g., I.Q. score between 85 and 115, *T*-score between 40 and 60, *Z*-score between –1.0 and +1.0) is the range within which 68 percent of the population falls, with 34 percent falling on either side of the mean. Approximately 95 percent of the scores will fall within 2 standard deviations of the mean, and approximately 98 percent of the scores will fall within 3 standard deviations of the mean. Performance that falls 2 standard deviations below the mean or lower indicates significant negative deviation from average performance and is often assigned as a critical cutoff point. Extreme performance (either extremely low or extremely high on the normal distribution) is represented by a score that falls 3 standard deviations away from the mean in either a positive or negative direction.

Each standard score can be assigned to a nonstandard score, a percentile. For example, a score that falls at the 50th percentile is the score that can be expected to be obtained by 50 percent or fewer of the population; the person does as well or better than 50 percent of the normative population or, alternatively, 50 percent of the normative population do better.

Descriptive ability ranges are often referred to in psychological reports to summarize test performance for both the lay person and the statistically sophisticated reader. Over time, these terms have achieved a commonality among readers that makes it advantageous to report them. They are based on a statistical foundation as well, however, and should be interpreted accurately. For example, the Wechsler I.Q.s are assigned to descriptive ability ranges based on their standard deviation from the mean of 100. The ranges and comparable standard scores and percentiles for the Wechsler descriptive ability ranges are summarized in Table 7.6-7. For example, a score from 90 to 109 falls within the average range, and therefore between the 25th and 75th percentiles.

	Standard Score	Percentile Range	Population (%)
Very superior	>129	≥98	2.2
Superior	120–129	91–97	6.7
High average	110–119	75–90	16.1
Average	90–109	25–74	50
Low average	80–89	9–24	16.1
Borderline	70–79	2–8	6.7
Deficient	<70	≤2	2.2

Table 7.6-7 Descriptor Ranges, Intelligence Quotients and Theoretical Population Percentages

The reader of psychological reports may see reference to two additional terms, the sensitivity and specificity of a test. *Sensitivity* refers to how often a test correctly identifies as impaired an individual who is truly impaired. Sensitivity is given as a percentage (i.e., true positive for correct identification). *Specificity* refers to how often a test identifies a normal individual as normal. Specificity is given as the percentage of true negative, or percentage that correctly identifies normal controls.

A final type of score refers to the presence of a test behavior as a sign (pathognomonic sign) of impairment. This type of score is analogous to findings on physical examination for mental status examination that are evidence of pathology. For example, just as decreased limb tone suggests a long motor tract sign, mirror movements on a tapping test in an older child suggest the failure to develop normal suppression of motor movements across the corpus callosum. Similarly, the child whose spontaneous speech at age 8 years is notable for sound substitutions (e.g., /tw/ for /th/) is showing evidence of a developmental articulation disorder. Finally, the concept of delay versus hard signs is also useful. Typically, the *delay* implies that the behavior is normal for a younger child, whereas a hard sign implies a lateralized or focal finding that often points to pathology of a specific brain region. The concept of “delay” has sometimes been used to suggest that with time the behavior will develop to normal for age. In reality, many delayed behaviors become functional deficits as the child ages but the behavior is maintained.

SUGGESTED CROSS-REFERENCES

Supplemental approaches to testing are described in different chapters of this book. Section 7.4 describes the neuropsychological and intellectual assessment of adults. Chapter 33 details the psychiatric examination of children. Information relevant to the syndromes discussed in this section may be found in Section 2.5 on neuropsychiatric aspects of head trauma, Chapter 35 on learning disorders, Chapter 38 on pervasive developmental disorders, Chapter 39 on attention-deficit disorders, and Section 48.6 on pharmacotherapy.

7.7 MEDICAL ASSESSMENT AND LABORATORY TESTING IN PSYCHIATRY

RICHARD B. ROSSE, M.D., LYNN H. DEUTSCH, D.O. AND STEPHEN I. DEUTSCH, M.D., IH.D

Traditionally the medical assessment of psychiatric patients has been designed to detect underlying medical conditions thought to contribute to psychiatric symptomatology. In some studies the rates of physical illness in certain psychiatric populations (e.g., the chronic mentally ill) are reported to be quite high. Because of the high incidence of physical problems and morbidity in some psychiatric populations, it has even been argued that qualified psychiatrists should assume the role of primary care physicians for such patients. Regardless of whether the psychiatrist is functioning as a medical specialist or primary care provider, psychiatrists are now expected to be able to direct the medical evaluations of their patients.

Psychiatric manifestations of a medical illness (e.g., anxiety, depression, hallucinations, delusions, delirium) are not specific to any one medical condition. Hence, the clinician needs to be able to consider a list of different organic possibilities for the patient's psychiatric symptoms. Table 7.7-1 outlines a list of medical conditions that can present with psychiatric symptoms. Each of these possibilities can argue for a different set of laboratory or diagnostic tests. The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) requires as a criterion that the patient's condition not be attributable to a known medical condition or substance. This implies that possible organic causes for the patient's psychiatric complaints have been actively excluded. When an organic factor is identified as being contributory to a patient's psychiatric presentation, the patient's diagnosis indicates the presumed organic etiology. The discovery of an organic cause for a psychiatric presentation can have profound treatment implications for directing the therapy away from mere symptomatic treatment towards a therapeutic intervention appropriate to the underlying medical problem. The psychiatrist needs to remain current with the psychiatric literature that describes the medical mimics of psychiatric disease.

Table 7.7-1 Some Medical Conditions That May Present With Neuropsychiatric Symptoms

Laboratory and diagnostic testing has also become increasingly important for the safe and maximally effective use of certain psychotropic medications. Such testing may involve assessment of certain baseline (pretreatment) laboratory and other diagnostic tests (e.g., electrocardiogram [ECG]) to establish a patient's capacity to tolerate a particular medication. The laboratory is also used during medication use to monitor therapeutic concentrations in blood, to confirm compliance, and to detect unrecognized toxicity. The specific laboratory and diagnostic tests used during the baseline and follow-up evaluations depend on the medication being used and the patient's age and medical condition. Clinicians need to be knowledgeable about the potential toxicities of the medications they use. They need to understand which organ systems are affected adversely by the psychotropic agents they employ and to be knowledgeable about the tests that best probe for potential toxicity. Finally, the laboratory is also essential in the assessment and management of patients with substance use disorders.

MEDICAL HISTORY AND PHYSICAL EXAMINATION IN PSYCHIATRY

A medical history and review of systems are important in the evaluation of psychiatric patients. When it comes to arriving at an appropriate diagnosis for a patient, some studies suggest that the history is the most helpful, the laboratory testing is the least helpful, and the physical examination is of intermediate value. Unfortunately, it is often difficult to get a reliable medical history and review of systems from certain neuropsychiatric patients (e.g., those with dementia, delirium, psychosis, and depression or those who are agitated and uncommunicative). In such patients the clinician must rely on alternative sources of medical history (e.g., medical records, family members). Unfortunately, this is an era in which economic pressures limit the amount of time available or scheduled for examining patients and their charts, and often history taking suffers the most under such pressures.

The traditional parameters of the medical history start with the patient's current physical complaints, the history of their onset, and current medications (including over-the-counter medications, vitamins, and home remedies). The medical history should include an assessment of the patient's past overall health; investigation into past injuries (such as motor vehicle accidents, head trauma, periods of unconsciousness); surgeries; occupational and toxic exposures; illicit drug use; alcohol, tobacco and caffeine use; previous hospitalizations for medical reasons; and any allergies to medications. A traditional review of systems may elicit symptoms suggestive of underlying medical disease. Many psychiatrists think that the therapeutic alliance is strengthened by the process of being involved with the medical evaluation of patients, including performing a physical examination. However, the psychiatric practitioner must use judgment in determining who can best complete the medical evaluation of particular patients, especially those with paranoia and sexual concerns. When a physical examination is performed, a chaperone should be present when appropriate. If the psychiatrist defers performing a physical examination, it should be for as short a period of time as possible (and only after careful consideration of the risks and benefits of deferring such an examination). The reasons for deferring the examination should be carefully documented, and the time frame for completing the physical examination provided.

LABORATORY TESTING

Although some clinicians and researchers support a frugal and selective approach for ordering screening tests for psychiatric patients, others claim that important medical problems are missed by restrictive screening protocols. Consensus is lacking on which tests should be included in a screening battery for psychiatric patients. However, all agree that the relevance of any test that is ordered should be clear to the physician who orders it. Different patient populations may be best served by different screening test batteries (some less selective than others). For instance, broader laboratory screening evaluations are often justified in the following patient populations: (1) patients over the age of 65, (2) patients living in poverty, (3) patients with histories of drug or alcohol abuse, (4) institutionalized patients, and (5) patients with evidence of cognitive impairments or self-neglect. In the future improvements in the information available to the clinician at the clinician-computer interface at the time of order entry should help mental health clinicians make more appropriate decisions regarding which tests to order. Expert computer systems that allow for input of appropriate patient history and physical examination findings should be able to further cue the psychiatrists about which tests should be ordered.

Choosing the Tests The patient's history and physical examination typically dictate which tests are ordered. Laboratory abnormalities are typically useful when they optimize clinical outcomes; that is, if the test results will contribute to the detection of a previously unrecognized medical condition or otherwise influence treatment. Diagnostic testing can also serve a therapeutic function by reassuring the patient or family that other serious medical problems do not appear to be present. Table

7.7-2 lists some diagnostic tests used in the evaluation of a wide range of psychiatric patients; Table 7.7-3 lists numerous psychiatric indications for various tests.

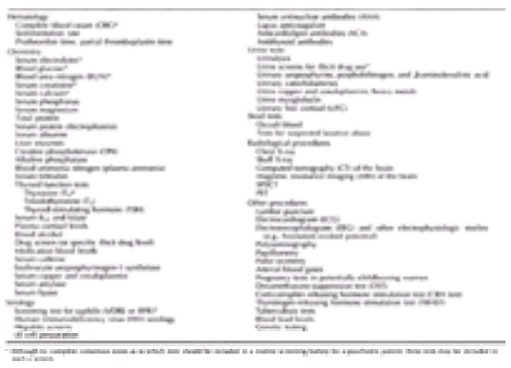

Table 7.7-2 Laboratory Diagnostic Tests of Potential Relevance to the Psychiatric Patient

Table 7.7-3 Psychiatric Indications for Diagnostic Tests

Follow-Up Tests Follow-up laboratory testing is important whenever a significant test abnormality has been found. Additional tests may help to determine the cause or seriousness of an abnormality, or simply represent a repeat of a previously ordered test to determine the reproducibility of the result. Certain experts in the field of diagnostic testing are concerned that extensive testing strategies increase the chances of irrelevant and clinically insignificant "abnormal" results and create a cascade of further unnecessary testing. In addition to some of this further testing being unnecessary and expensive, it has been argued that some follow-up testing can even be dangerous for the patient. Consultation with medical colleagues in the relevant subspecialty can help guide the psychiatrist in the most appropriate use of follow-up tests.

Sensitivity, Specificity, and Predictive Value Three terms that help the clinician to interpret the significance of test results are *sensitivity, specificity*, and *predictive* value. *Sensitivity* is the proportion of subjects with a positive test result who have the disease out of all the subjects affected with the disease. Hence, sensitivity reflects the ability of an abnormal test result to correctly identify persons who actually have the disease. The more false negatives a test has, the lower its sensitivity. *Specificity* refers to the proportion of negative test results among a population of persons who do not have the disease. The more false positives a test has, the lower the test's specificity. Tests with low sensitivity or specificity are inadequate as screening tests. *Predictive value* can be described as *positive or negative.* A positive predictive value is the probability of having the disease given a positive test whereas negative predictive value is the probability of not having the disease given a negative test result. Table 7.7-4 provides the formulas for sensitivity, specificity, and predictive value.

Sensitivity (probability of a positive test result in one who has the disorder)
Sensitivity = true positives/true positives + false negatives × 100%

Specificity (probability of a negative test result in one who does not have the disorder)
Specificity = true negatives/true negatives + false positives × 100%

Predictive value of a positive test result (percentage of all positive test results that are true positives)
Predictive value = true positives/true positives + false positives × 100%

Predictive value of a negative test result (percentage of all negative test results that are true negatives)
Predictive value = true negatives/true negatives + false negatives × 100%

Table by Darrell G. Kirch, M.D.

Table 7.7-4 Sensitivity, Specificity, and Predictive Value

Laboratory and diagnostic tests do not have absolute sensitivities, specificities, and predictive values. Also, different laboratories use different cut-off values to provide the critical values that determine whether a result is abnormal or normal (i.e., positive or negative). In general, "normal" laboratory values for healthy persons are often described as those that fall within two standard deviations of the mean of a normal population. However, few laboratory values have been demonstrated to fall within a true Gaussian distribution. Varying cut-off values will change the sensitivity and specificity of a test. Changes in cut-off values that increase the sensitivity of a test typically decrease its specificity and vice versa. Moreover, the predictive value of a test varies with the actual prevalence of the disorder in the population being studied. Hence, tests with high sensitivity could be of little value as screening tests if the prevalence of the disorder in the population being screened is very low. Patients with many signs, symptoms, and risk factors for a particular disease increase the predictive value of a positive test result suggestive of the disease. Patients with few signs, symptoms, or risk factors for a particular disease are less likely to belong to a population afflicted with the disease; thus, the predictive value of a negative test result is increased in such patients. Therefore, it is important to integrate all aspects of the patient's presentation (e.g., history, review of systems, physical examination, other test results) as well as an understanding of a particular test's sensitivity, specificity, and predictive value when interpreting the significance of a laboratory result.

SPECIAL POPULATIONS

Geriatric Patients Geriatric patients are more likely to have at least one chronic medical disease or disability, therefore the diagnostic assessment of the geriatric patient requires a rigorous search for organic factors that may be related to the presenting psychiatric symptoms. Screening laboratory tests are considered especially important in the psychiatric evaluation of a geriatric patient with a recent onset of psychiatric symptoms, change in behavior, or symptoms resistant to therapy. A more extensive laboratory screening battery is generally justified in older neuropsychiatric patients. The specific set of screening tests is typically determined by the history and clinical presentation, but often includes a complete blood count (CBC) with differential; a full chemistry panel (e.g., "chem 20"); thyroid function tests (e.g., at least a serum thyroid-stimulating hormone [TSH]), serological tests for syphilis, B_{12}, and folate; a midstream urine test; chest X-ray, and ECG.

Urinary Tract Infection Urinary tract infection is a common medical problem in older patients. In addition to symptoms of dysuria, increased frequency, abdominal pain, nausea, and vomiting, these infections can present with mental status changes. Geriatric patients may not become febrile in the presence of serious infections. Urinalysis usually demonstrates bacturia, enteric rods, and pyuria, but these may be absent in the geriatric patient. Urine culture and sensitivity should follow for a

definitive diagnosis. Males with urinary tract infections unrelated to catheterization and females with recurrent infections should have a urological referral.

Anemia Anemia is a laboratory abnormality found in more than 30 percent of geriatric outpatients. Whereas younger patients display the more classic signs of pallor, weakness, and fatigue, the older anemic patient may present with confusion, apathy, or behavioral change. In the elderly an anemia workup should be pursued because symptoms may improve with only a small change in the serum hemoglobin. Laboratory workup for anemia typically begins with a CBC with differential, platelet count, reticulocyte count, and peripheral smear. Based on these studies, the anemia can usually be classified as microcytic, macrocytic, or normocytic. In the elderly the anemia may present as a combination of several pathological processes. Additional laboratory tests in the workup of a microcytic anemia include a serum iron level, total iron-binding capacity (TIBC), serum ferritin, and stool exam for occult blood. The presence of chronic disease in the elderly may lead to a normal TIBC and mask the more typical laboratory findings of low iron and elevated TIBC. Therefore, in the presence of low serum ferritin and negative stool for occult blood, colonoscopy may be indicated to identify the source of blood loss. Macrocytic anemia may be secondary to vitamin B_{12} or folate deficiency. Red cell folate concentrations are a more accurate reflection of folate than serum folate concentrations but may not be available in all laboratories. Pernicious anemia is the most frequent cause of vitamin B_{12} deficiency in the elderly and may present with psychiatric symptoms such as delirium, hallucinations, personality changes, delusions, depression, anxiety, or mania. Neurological exam may reveal paresthesias and abnormal proprioception. The neuropsychiatric symptoms can occur prior to the hematological changes, making serum B_{12} and folate levels important laboratory tests to consider in any elderly patient with psychiatric symptoms. Certain clinical features are more common in patients with a history of heart failure or atherosclerotic heart disease: specifically, fatigue, shortness of breath, worsening angina pectoris, and peripheral edema. Mental status changes of confusion, depression, agitation, and apathy may occur in older anemic patients with no previous psychiatric history. Dizziness is a common complaint in these patients, and pallor may be detected in the mucosa of the oral cavity and conjunctiva.

Thyroid Disease Thyroid disease in the elderly is common and can present with an atypical picture. Nonspecific symptoms such as fatigue and constipation or a change in functional ability are associated with thyroid disease. Hypothyroidism in the elderly may present with symptoms of lassitude, constipation, cold intolerance, fatigue, and cognitive impairment. These symptoms may be attributed to depression or degenerative dementia. Myxedema coma is a medical emergency that occurs primarily in patients over age 50. Older patients with hyperthyroidism may present with typical symptoms (e.g., heat intolerance, weight loss, tremor, palpitations, and atrial fibrillation) or with apathetic hyperthyroidism (manifested by anorexia and fatigue).

Hearing and Visual Loss Over 25 percent of patients 65 years and older manifest hearing impairment, which can lead to social isolation, depression, and confusion. The hearing impairment, usually in the high-frequency range, may interfere with conversation and the psychiatrist needs to consider this in the diagnostic process. The workup for hearing impairment includes an otoscopic examination of the external ear for impaction of cerumen. If the ear is clear, patients can be screened with a handheld audioscope or referred to audiology.

Visual impairment is present in 15 percent of persons 65 and older and twice that in patients over age 85. Cataracts and macular degeneration account for the majority of these cases, but glaucoma and diabetic retinopathy are other important causes of visual deficits. Screening tests of visual acuity include a visual acuity chart. Patients with visual problems should be appropriately referred to rule out the presence of serious eye disease. Persons used to adequate visual functioning in their youth who have to adjust to failing vision in old age can be at risk of considerable depression.

Dementia The neuropsychiatric condition most closely associated with increasing age is dementia. All geriatric patients presenting to a psychiatrist should be screened with a brief cognitive screening examination such as the Mini-Mental State Examination (MMSE). If new cognitive deficits are present that are not accounted for by limited education, a laboratory workup for reversible causes of dementia is indicated. The National Institutes of Health Consensus Development Conference Statement on the Differential Diagnosis of Dementing Diseases recommends careful screening for a patient with new onset of dementia in an attempt to identify treatable causes of dementia. Regarding the choice of diagnostic tests, the conference recommendation is as follows—"the best diagnostic test is a careful history and physical and mental status examination by a physician with a knowledge of and an interest in dementia and dementing disease." The conference report goes on:

> the laboratory tests that are used should be individualized based on the history and physical and mental status examination. Overtesting may expose the patient to discomfort, inconvenience, excess cost, and the likelihood of false-positive tests that may lead to additional unnecessary testing. Undertesting also has hazard; for example, in elderly persons, medical diseases may have nonspecific presentations such as dementia.

Besides a thorough medical history and physical and neurological examinations, laboratory tests typically used in a dementia evaluation include a CBC with differential, sedimentation rate, blood chemistry panel (with liver and kidney function tests), serum electrolytes (some include magnesium and zinc blood levels), thyroid function tests, B_{12} and folate levels, and a serological test for syphilis. It has been argued that human immunodeficiency virus (HIV) testing should be considered in the laboratory evaluation of the patient with dementia because some patients may be reluctant to admit to a history that would have put them at risk of HIV infection, and neurological involvement is a common sequela of HIV infection. Chest X-ray and ECG are also usually included, and a brain imaging study such as computed tomography (CT) or magnetic resonance imaging (MRI) are now considered standard; electroencephalograms (EEG) are also frequently obtained. Some clinicians are even ordering single photon emission computed tomography (SPECT) scans to further their understanding of their patient's dementing condition. On SPECT and positron emission tomography (PET) scans, single focal perfusion defects, or multiple areas of patchy hypoperfusion are suggestive of ischemic brain changes (vascular dementia) whereas dementia of the Alzheimer's type typically shows decreased perfusion in temporoparietal areas bilaterally. Lumbar puncture is obtained only if meningitis is suspected.

Patients Taking Tacrine Tacrine (Cognex) is a reversible cholinesterase inhibitor used in the treatment of dementia of the Alzheimer's type. Because this medication is associated with liver toxicity, baseline (i.e., pretreatment) and follow-up serum transaminase levels (specifically serum glutamic pyruvic transaminase [SGPT], now known as alanine aminotransferase [ALT]), need to be obtained. SGPT levels are monitored every other week for at least the first 16 weeks of treatment. Treatment typically continues according to the recommended titration schedule as long as the SGPT concentration remains less than two times the upper limit of normal (ULN). During tacrine treatment, the drug manufacturer recommends that ALT monitoring be done weekly if blood levels of this serum transaminase rise to above two times ULN (but remain less than three times ULN). If ALT concentrations rise to between three and five times ULN, the medication is reduced by 40 mg a day. Blood level monitoring is relaxed to every other week only after the ALT levels return to normal limits. It is recommended that tacrine treatment be halted if ALT levels rise to greater than five times ULN. In patients whose serum liver enzymes return to normal levels and who can be rechallenged, weekly blood level monitoring is recommended for at least the first 16 weeks after the initiation of the rechallenge. If serum ALT levels remain in the normal range, monitoring can be reduced to monthly for 2 months and every 3 months thereafter. Patients who become jaundiced with total bilirubin levels greater than 3 mg/dL in association with ALT elevations are immediately and permanently discontinued from tacrine.

Self-Abusers Various diagnostic assessments can be useful in the evaluation of the patient who engages in deliberately self-injurious behavior. Clues to such behavior include wrist or arm lacerations or scars; the presence of open wounds, bruises, burns, or abrasions; or evidence of swelling or deformity secondary to injury. Self-damaging behavior might even cause skull deformities. Blood toxicology is important for the evaluation of the patient who has overdosed on prescribed or abused drugs. The degree of organ involvement in the overdose can be assessed by the appropriate diagnostic tests. For instance, in the case of an overdose of a tricyclic antidepressant an ECG is used to assess the degree of cardiac toxicity. In the context of acetaminophen (Tylenol) overdoses, liver function tests are important, and in the context of aspirin overdose, serum electrolyte determinations are needed to assess anion gap. Deformity in a region of the body would require an X-ray evaluation of the appropriate area. Usually, consultation with medical or surgical colleagues is necessary to resolve issues related to self-inflicted injury in the psychiatric patient.

Restrained Patients Certain patients are restrained to prevent them from inflicting further harm on themselves or others. Because such individuals cannot attend to their own needs, they must be carefully monitored. The assessment of these patients includes the frequent monitoring of vital signs and vigilance for signs of dehydration (e.g., dry mouth, loss of skin turgor) and improper restraint technique (e.g., edema, swelling, or abrasions). The extremities need to be checked regularly to ensure adequate circulation. Very agitated patients might need to have their urine checked for evidence of myoglobinuria secondary to muscle breakdown. For patients in whom the etiology of the agitated behavior is unclear, the laboratory is vital in assessing possible "organic" causes (e.g., serum and urine toxicology screens, serum blood screens for evidence of infection or electrolyte disturbance, CT scans if there is the suggestion of possible stroke). Lumbar puncture with analysis of cerebrospinal fluid (CSF) would be necessary in a patient with signs of meningeal irritation or other clinical findings suggestive of infection.

Psychiatric Patients With Weight Loss Certain psychiatric conditions are associated with patients experiencing weight loss. These conditions include anorexia nervosa, melancholic depression, severe psychosis, catatonia, and severe alcohol or substance dependence. In such patients a laboratory assessment is needed to determine the degree of malnutrition and starvation and to identify a potential medical emergency (e.g., due to low serum potassium). It is important to monitor vital signs and orthostatic blood pressure changes. Tests that are ordered frequently in these patients include a CBC with differential (e.g., to determine the degree of anemia, although hemoconcentration might give an artificially elevated result prior to rehydration), serum electrolytes (especially potassium and blood urea nitrogen), and a urinalysis (e.g., the specific gravity would be high in a dehydrated patient). Other tests that might be ordered include serum iron studies, serum total protein,

and albumin.

In patients with anorexia nervosa, in addition to the tests just described, an erythrocyte sedimentation rate (ESR) is often recommended. The ESR is usually low in patients with anorexia nervosa, hence this test can be somewhat useful in differentiating anorexia nervosa from other medical conditions causing anorexia. An ECG is important to assess for the impact of low potassium and starvation on the heart. Some researchers have recommended CT on MRI to exclude the presence of brain tumors. Endocrine status is frequently evaluated, including tests of thyroid function and other pituitary hormones. Stool and urine tests for laxative abuse might also be useful for patients suspected of such abuse. Certain patients might abuse appetite suppressants (note the presence of a relationship between certain appetite suppressants and pulmonary hypertension—about 23 to 46 cases per million persons per year). Bone density studies can be useful to further assess the physical impact of the patient's eating disorder.

First Episode of Psychosis Experts recommend a careful medical evaluation for a patient with a first episode of psychosis (or subsequent episode in a patient who has never had a medical workup). The evaluation should include a complete physical examination, and the core laboratory screening battery should include a urine toxicology screen for drugs of abuse, a general chemistry screen, a CBC with differential, and urinalysis. The clinician should carefully consider a range of supplemental tests as indicated, which includes a pregnancy test, ECG, brain MRI or CT, and EEG.

New Patients With Manic or Major Depressive Episodes Experts also recommend a complete physical examination, as well as a core laboratory screening battery that includes thyroid function tests (if not recently obtained), CBC, general chemistry screen, urinalysis (especially if the patient is on or might be started on lithium [Eskalith]), urine toxicology test for drugs of abuse, and ECG in patients over the age of 40 (or younger in patients with a history of cardiac disease). Serum concentrations of mood stabilizers (e.g., lithium, valproic acid [Depakene] or carbamazepine [Tegretol] are also obtained if the patient is already on any of these medications. A pregnancy test should also be ordered if appropriate. Brain imaging (e.g., MRI, CT) and EEG studies are often also employed.

Substance Abusers The laboratory has become increasingly important in the physician's assessment and monitoring of the substance-abusing patient. The laboratory is useful for detecting substances of abuse and for evaluating the impact the substance use is having on the patient's body. Often the laboratory detection of abused substances and certain diagnostic test abnormalities related to the substance abuse (e.g., abnormal liver function tests in alcohol-abusing patients) is used therapeutically to confront the denial of a patient with a substance abuse disorder and to help engage the patient in treatment.

The most commonly used specimen for the detection of drugs of abuse is urine, although toxicological analyses can also be performed on blood specimens. The period of time that the clinician can detect drugs in blood specimens is typically shorter than the length of time drugs can be detected in urine specimens because drugs and their metabolites are excreted and detectable in the urine for longer periods of time than they are detectable in blood. However, the length of time that a particular drug of abuse can be detected in the urine is somewhat variable, depending on the specific drug, the duration and amounts of the substance used, and concomitant medical problems (e.g., liver or kidney disease). Nevertheless, Table 7.7-5 provides a listing of some common drugs of abuse that can be detected in urine specimens, along with a typical length of time after recent use that the substance can be detected. Other specimens that have been studied to detect substance abuse include saliva and hair samples. A commercially available test for the measurement of alcohol in saliva exists.

Drug	Length of Time Detected in Urine
Alcohol	7–12 hours
Amphetamine	48 hours
Barbiturate	24 hours (short-acting) 3 weeks (long-acting)
Benzodiazepine	3 days
Cocaine	6–8 hours (metabolites 2–4 days)
Codeine	48 hours
Heroin	36–72 hours
Marijuana	3 days to 4 weeks (depending on use)
Methadone	3 days
Methaqualone	7 days
Morphine	48–72 hours
Phencyclidine (PCP)	8 days
Propoxyphene	6–48 hours

Table 7.7-5 Drugs of Abuse That Can Be Tested in Urine

Numerous methodologies exist for the detection of substances of abuse in the potentially substance-abusing patient. The most common strategy involves the use of a screening test and, in the context of a positive result, a more sensitive, confirmatory test (e.g., a screening enzyme-multiplied immunoassay technique [EMIT] followed up by confirmatory gas chromatography-mass spectrometry [GC-MS] testing).

Alcohol-Related Disorders In patients with alcoholism, the extent of liver enzyme elevations and abnormalities for other laboratory tests of liver function reflect the degree of liver damage in these patients. The liver enzymes examined include gamma-glutamyl transaminase (GGT), AST, and ALT. Also reflecting the degree of liver damage in these patients are abnormalities of other liver function tests (LFTs), such as reduced serum total protein and albumin, and prolonged prothrombin time (PT). Laboratory abnormalities in these patients can be used to confront their denial of their alcoholism. The clinician should note that patients with severe alcohol-related hepatic damage might no longer be able to generate liver enzyme elevations despite advanced liver disease. The alcohol-abusing patient should also be assessed for possible head trauma (e.g., subdural hematomas); hence, a CT scan might be needed (and a skull X-ray if there is evidence of skull injury).

Patients with alcohol use disorder should have a CBC to evaluate potential anemia (classically megaloblastic in nature but can be mixed megaloblastic-microcytic). Serum concentrations of magnesium, electrolytes, blood urea nitrogen (BUN), and creatinine are also important in the laboratory assessment of this patient population.

Patients with signs and symptoms of alcohol withdrawal (e.g., elevated blood pressure, pulse, tremor [6 to 8 contractions per second]) will typically have rapidly decreasing or undetectable blood alcohol concentrations. Alcohol withdrawal delirium is a medical emergency requiring careful attention to the medical needs of these patients. Hence, a negative test for alcohol in a patient with a history of alcohol abuse is not inconsistent with an ensuing medical emergency related to alcohol withdrawal.

Intravenous Substance Use A number of substances of abuse are delivered by the addict through the intravenous (IV) route (e.g., heroin, cocaine, amphetamines). The needles have often been used by other addicts and inadequately sterilized prior to use. These needles can be potentially infected with viral agents capable of causing hepatitis and acquired immune deficiency syndrome (AIDS).

Hepatitis Testing All forms of viral hepatitis (including hepatitis A, B, C, and D) have been associated with the drug-addict lifestyle. Only hepatitis B, C, and D are transmitted by the intravenous route. Hepatitis A is transmitted by the fecal-oral route, and has been associated with the poor sanitary conditions to which addicts are exposed. Serum hepatitis panels for antigens and antibodies associated with hepatitis-causing viruses are indicated in patients at high risk for these hepatitides or with evidence of hepatic damage (e.g., jaundice, elevated liver enzymes, elevated serum bilirubin, prolonged serum coagulation tests, urobilinogen on urinalysis).

HIV Testing The spread of HIV amongst the intravenous-drug–abusing population continues to be a major health care disaster. Such patients are driven by their addiction to engage in high-risk behaviors that expose them to the virus. When HIV testing is ordered, false-positive tests in a high-risk population are extremely rare. Patients undergoing HIV testing need to have appropriate pretest and posttest counseling. HIV brain infection can result in a myriad of neuropsychiatric manifestations, including dementia and psychosis.

Medical Conditions in Psychiatry Multiple medical conditions can present with psychiatric symptoms (Table 7.7-1).

Thyroid Disorders Both hyperthyroidism and hypothyroidism can mimic a wide variety of psychiatric disorders, including anxiety, depression, and psychosis. Psychiatrists are understandably interested in excluding thyroid disorder as a cause of their patients' psychiatric symptoms. Although the onset of symptoms in hyperthyroidism is often rapid, the onset of symptoms in hypothyroidism can be insidious. When “routine” screening tests are advocated for psychiatric patients, some degree of thyroid testing is usually included in the laboratory screening battery. With highly sensitive TSH assays now available, many cost-conscious clinicians and

researchers are advocating the use of a serum TSH alone for routine screening purposes in psychiatric populations. Other thyroid tests include serum thyroxine (T_4), serum triiodothyronine (T_3), T_3 resin uptake (T_3RU), free T_4, and the free thyroxine index (FTI), sometimes referred to as T_7 or T_{12}. Other thyroid tests include antithyroglobulin antibodies and antithyroid microsomal antibodies and the thyrotropin-releasing hormone stimulation test (TRHST). Patients who demonstrate goiter, ophthalmopathy, evidence of a hypermetabolic state, or have a history or symptoms suggestive of thyroid disease (e.g., heat or cold intolerance) or risk factors for thyroid problems (e.g., history of neck or chest irradiation, thyroid surgery or iodine-131 treatment, or treatment with lithium) should have a laboratory thyroid evaluation. Hyperthyroidism that results from the accidental or deliberate intake of excessive amounts of thyroid supplements is called *thyrotoxicosis factitia*. Finally, although generalized resistance to thyroid hormone has been associated with an increased incidence of attention-deficit/hyperactivity disorder, because of the rarity of the thyroid hormone disorder in children with attention-deficit/hyperactivity disorder, it is not recommended that thyroid function be routinely measured in cases of nonfamilial attention-deficit/hyperactivity disorder.

The thyroid gland can be inspected by observing the lower half of the neck in the anterior triangles and noting the presence of an ascending mass as the patient swallows. Next, the gland can be palpated from behind or in front. alpation of the gland from behind involves standing behind the patient and exploring the region behind the sternocleidomastoid muscles. The thyroid isthmus can be palpated on the anterior aspect of the tracheal rings. Next, the lower and upper poles of the lateral lobes are palpated. The inclination of the patient's head should be shifted to relax the neck muscles in addition to instructing the patient to swallow. If the thyroid gland undergoes hyperplasia and a goiter is palpated, a thyroid bruit may be auscultated from accelerated blood flow. A small diffuse goiter may be present before the menstrual period, during pregnancy, or throughout the menstrual cycle in females 12 to 20 years old. It can also be present with thyrotoxicosis. In addition to palpation of the thyroid to detect enlargement, palpation also involves a search for nodules and tenderness.

Adrenal Diseases Adrenal disease can be associated with a wide variety of psychiatric symptoms, including depression, anxiety, and psychosis. Low plasma cortisol is seen in Addison's disease (adrenal insufficiency) and elevated blood cortisol levels are seen in Cushing's disease. Evidence of hypercortisolism can be detected in urine; in some patients with major depressive disorder urinary cortisol concentrations approach or are in the range associated with Cushing's disease. An elevated urinary 17-hydroxycorticosteriod concentration has been proposed as a marker of potential suicidality by some psychiatric researchers. Patients with major depressive disorder can have alterations in the normal diurnal variation of plasma cortisol concentrations (measurable with the diurnal cortisol test [DCT], as well as a decreased suppression of serum cortisol by the exogenous administration of dexamethasone (measurable with the dexamethasone suppression test [DST]). Recent studies have reported evidence of increased adrenal gland volume in patients with major depressive disorder compared to controls. Patients with a history or physical examination suggestive of pheochromocytoma (e.g., paroxysmal or persistent hypertension, flushing, anxiety, panic attacks) might need a battery of tests including the following: a 24-hour urine for measurement of catecholamines and metabolites (such as metanephrine or vanillymandelic acid [VMA]), plasma levels of catecholamines, and a CT scan of the abdomen. Nuclear medicine scans using iodine-131-labeled meta-iodobenzy guandine are employed to locate the catecholamine-secreting tumors in this condition.

Pernicious Anemia The neuropsychiatric symptoms associated with vitamin B_{12} deficiency (e.g., dementia, depressive disorder, psychotic disorder) might not always be associated with megaloblastic anemia or other classic laboratory findings typically connected with pernicious anemia (e.g., abnormal Schilling tests). It has been suggested that elevated serum homocysteine and methylmalonic acid concentrations in patients with vitamin B_{12} deficiency might be predictive of those patients whose neuropsychiatric manifestations might respond to parenteral vitamin B_{12} therapy. Serum folate concentrations are usually measured with B_{12} concentrations because folate deficiency can result in a similar constellation of neuropsychiatric impairments. In patients with pernicious anemia, folate therapy without vitamin B_{12} administration can result in a normalization of the hematological abnormalities but continued progression of the neuropsychiatric manifestations of the disease.

Acute Intermittent Porphyria Acute intermittent porphyria can be associated with psychiatric symptoms (psychosis) even when the physical manifestations (i.e., abdominal pain, neuropathy, autonomic dysfunction) of the disorder are not present. During acute attacks there are typically elevations of uroporphyrin, urine porphobilinogen (PBG), and d-aminolevulinic acid (ALA) concentrations in the urine. Elevations of these substances are much less common during asymptomatic periods. Diminished erythrocyte uroporphyrinogen-1-synthetase can be seen during both symptomatic and asymptomatic periods of the illness.

Wilson's Disease Wilson's disease is an autosomal recessive disorder of copper metabolism that typically becomes symptomatic (with movement disorder, psychosis, personality changes) in the second to third decades of life. There is an elevation of urine copper after a 24-hour collection, decreased serum copper, and low serum ceruloplasmin. In patients with Wilson's disease it is important to monitor laboratory abnormalities related to copper deposition in the liver or kidney. Kayser-Fleischer rings adjacent to the cornea can be seen during a slit-lamp examination.

Syphilis With central nervous system (CNS) involvement, this infectious disease has classically been related to a wide variety of neuropsychiatric complications, including psychosis and dementia. The rapid plasma reagin test (RPR) or Venereal Disease Research Laboratories (VDRL) test is the most common screening test for syphilis. Positive results on these tests are followed up with fluorescent treponemal antibody absorption (FTA-ABS) tests. The test that is diagnostic of tertiary or CNS syphilis is the CSF VDRL. A positive CSF VDRL is typically associated with other CSF findings such as abnormal CSF protein and white blood cell counts.

Systemic Lupus Erythematosus This rare clinical condition can be associated with psychiatric manifestations including psychosis, delirium, depression, and dementia. It is important to detect it as the cause of psychiatric symptoms to ensure proper treatment (e.g., treatment of the lupus-associated cerebritis with steroids). Laboratory tests for lupus include the lupus prep (phenothiazines can cause false-positive results of this test) and tests for serum antinuclear and antideoxyribonucleic acid (DNA) antibodies. The antiphospholipid antibody known as lupus anticoagulant has been described in patients with lupus and rarely in patients treated with antipsychotic medications, especially chlorpromazine (Thorazine). Although the presence of lupus anticoagulant is associated with a lengthening of serum coagulation tests such as the prothrombin time, it is clinically associated with an increased incidence of thrombotic events such as stroke.

Pediatric Autoimmune Neuropsychiatric Disorder Associated With Streptococcal Infections This condition is associated with an exacerbation of neuropsychiatric symptoms (e.g., obsessions, compulsions, tics) in children and adolescents. It has been hypothesized to be associated with the development of antibodies against streptococcal infection that cross-react with basal ganglia structures; acute basal ganglia enlargement has been demonstrated in conjunction with this syndrome. The pathological process of this disorder is thought to be analogous to Sydenham's chorea. The syndrome has also been referred to as *pediatric, infection-triggered, autoimmune neuropsychiatric disorders*.

Environmental Contamination Poisoning with certain contaminants common in many workplace environments, such as heavy metals, is described as having potential neuropsychiatric manifestations. For instance, lead poisoning can result in varying degrees of lead encephalopathy, a problem that affects children and adults. Poisoning with other heavy metals, such as mercury and manganese, can also result in neuropsychiatric symptoms. Exposure to various solvents can also result in various neuropsychiatric symptoms (e.g., *solvent encephalopathy* or *painter's syndrome*). Appropriate laboratory testing for these substances is typically based on a careful occupational history.

MONITORING PSYCHOTROPIC MEDICATIONS

Antidepressant Medications The role of the laboratory for therapeutic drug monitoring (TDM) was more prominent in the previous era when tricyclic drugs were the main class of medications used to treat depression. TDM has not been established for the newer antidepressants such as the selective serotonin reuptake inhibitors (SSRIs). With these new nontricyclic antidepressants now in widespread use, the role of the laboratory in managing patients on antidepressant medications has diminished. The tricyclic drugs were also associated with a host of other potential toxicities (e.g., cardiac), which required other types of diagnostic assessments (e.g., ECG); the enhanced safety profile of the newer agents relative to the tricyclic drugs has precluded much of this other diagnostic testing as well.

Baseline Studies There are no standardized recommendations for the pretreatment evaluation of a patient about to begin antidepressant medication. It is important for the clinician to have a clear understanding of the potential adverse reactions to the antidepressant agent that is going to be used, as well as an understanding of the medical conditions and physiological vulnerabilities of the patient who will be taking the medication. For instance, a liver enzymes evaluation might be ordered in a patient with a past history of liver disease because antidepressant agents are metabolized by the liver and liver disease, as evidenced by elevated liver enzymes, might suggest extra caution when using these medications; it may also suggest the need for periodic follow-up tests of liver function to assess the effect of the antidepressant drug on liver functioning. Women who are potentially childbearing might have a pregnancy test performed so that the use of the antidepressant agent in such a person will be fully informed. An obvious aim in treating such patients is to try to expose the fetus to as few medications as possible, even to medications that are not clearly teratogenic. Furthermore, patients with a history of cardiac disease about to start treatment with a tricyclic drug should have a baseline ECG; this is especially true for patients over the age of 50. Tricyclic medications can affect intracardiac conduction and lengthen PR, QT, and QRS intervals, and patients with baseline abnormalities of these measures might need periodic follow-up ECGs. Serious and fatal arrhythmias could theoretically result from lack of attention to ECG changes that are related to the tricyclic agents used. Baseline or follow-up ECG abnormalities might suggest that the clinician choose an antidepressant medication less associated with alterations in ECG parameters. Changes in cardiac conduction induced by a tricyclic drug might be especially problematic in the following

patients: the elderly; those with pre-existing cardiac conditions; those on concomitant Type I antiarrhythmia agents such as quinidine (Cardioquin) and lidocaine (Xylocaine); those on digoxin (Lanoxin) or other cardiac glycosides that affect atrioventricular node conduction; and those with low serum potassium or magnesium.

Therapeutic Drug Monitoring Relationships between blood concentrations and therapeutic response have been established for some of the tricyclic medications. It has been recommended that blood-concentration determinations of some of these agents be employed in certain situations, such as: (1) patients with questionable medication compliance, (2) patients who are having a poor response while on a typical dose for a reasonable period of time, (3) patients who have adverse effects at very low dosages, (4) patients with medical problems (or the elderly) in whom it is important to use as low a potentially therapeutic level of the drug as possible, and (5) patients who need to obtain a potentially therapeutic blood level as rapidly as possible because of their clinical condition (e.g., if the patient is severely suicidal). Wide variations between different patients' blood levels on standard dosages of tricyclic medications have been described, presumably reflecting differences in drug absorption and metabolism. Therapeutic levels have been described for: (1) imipramine (Tofranil)—plasma imipramine plus desmethylimipramine concentrations should exceed 200 ng/mL, (2) nortriptyline (Pamelor)—a therapeutic window between 50 to 150 ng/mL), and (3) desipramine (Norpramin)—therapeutic concentrations are described as exceeding 125 ng/mL). In the literature, slightly different therapeutic concentrations are sometimes described. Clinicians should check with their laboratory for slight variations in these therapeutic concentrations that may have been established for their laboratory. Therapeutic blood concentrations for other tricyclic medications are sometimes provided (e.g., amitriptyline [Elavil], 75 to 175 ng/mL). The *therapeutic range* describes a range of blood concentrations at which it is more likely for the patient to experience a therapeutic response (although this does not preclude individual patients from experiencing antidepressant effects outside described ranges).

Clinicians should also be aware of what the toxic blood concentrations are for the tricyclic agents because higher blood concentrations of these medications are associated with greater degrees of toxicity. For the nontricyclic drug bupropion (Wellbutrin), a therapeutic blood concentration between 20 and 75 ng/mL has been described. Therapeutic blood concentrations for other antidepressant drugs (tricyclic and nontricyclic) have been less clearly established but are sometimes obtained to assess compliance, poor response to a conventional antidepressant dose, adverse effects experienced at a very low dosage of the antidepressant, and possible toxic ranges (e.g., in overdose). The utility of blood concentrations of the SSRI agent fluoxetine (Prozac) for the assessment of compliance is limited because of the long half-lives of the parent compound and its metabolite—only more dramatic cases of noncompliance would be detectable. With the monoamine oxidase inhibitors (MAOIs), when laboratory tests are sought for assessing optimal dosing reports suggest that one should try to achieve a level of inhibition of at least 80 percent of platelet monoamine oxidase activity.

In the medical assessment of the patient on tricyclic medications or MAOIs, the clinician should also be alert to clinically significant orthostatic hypotension. If clinical symptoms develop while the patient is standing (e.g., accompanied by 30 mm Hg or greater decrease in systolic and 15 mm Hg or more decrease in diastolic pressure and pulse changes greater than 20 beats per minute), a switch to a different antidepressant drug associated with less orthostatic hypotension might be indicated. Tachycardia is also associated with the more anticholinergic tricyclic drugs. Additionally, weight gain can be associated with many of the antidepressant agents, including tricyclics and MAOIs, and should be monitored in patients who appear vulnerable to such weight gain. Men with prostatic hypertrophy and patients with fecal impaction or constipation are at some risk from the anticholinergic adverse effects of the tricyclic medications. Priapism has been rarely associated with the antidepressant agent trazodone (Desyrel) and the appearance of such priapism typically represents a medical emergency. The clinician should remember that doses of buproprion above 450 mg daily are associated with an increased risk of seizure.

Monitoring of Children Various psychiatric drugs are being used in children, and monitoring of potential toxicities from these agents is important. For instance, about 30 to 60 percent of outpatients in child psychiatry fulfill criteria for major depressive disorder, and when tricyclic drugs are used, monitoring of drug concentrations in plasma plays a role in the management of these patients. Weight-corrected oral dosing of tricyclic agents in children has not been shown to reliably predict plasma levels in individual patients. Limitations to the upward adjustment of dosage of tricyclic medications include severity of “nuisance” adverse effects and significant ECG and cardiovascular changes (i.e., heart rate >130/min; PR interval >0.18 sec; QRS width >30 percent above baseline; blood pressure >140/90 mm Hg). Indeed, ECG monitoring has been shown to be an important laboratory tool for assessing compliance and assessing cardiac toxicity. A significant relationship has been shown between maintenance plasma levels of some tricyclic drugs and clinical response. For instance, for imipramine, the authors of one study recommended a therapeutic blood concentration discriminating cut-off value of 150 ng/mL. In another study with nortriptyline, plasma levels between 60 and 100 ng/mL were associated with a positive clinical response in prepubertal children with depression. However, more research is necessary to determine meaningful therapeutic blood concentrations for antidepressant medications in children. The clinical laboratory will be essential to the development of effective pharmacotherapy for prepubertal depression and management of these children. At a minimum, blood concentration tests will help to determine compliance and dosage regulation.

LITHIUM Although lithium is clearly effective in the treatment of bipolar I disorder, the therapeutic and toxic blood levels of this agent are very close to one another, and in certain individuals even seem to overlap. Additionally, lithium has effects on a number of organ systems of which the clinician should be aware. Lithium therapy is associated with a benign elevation of the white blood cell count (WBC), which can range to about 15,000 cells per mm_3. This WBC elevation can sometimes be mistaken for signs of infection, or wrongly be attributed to lithium in the context of other signs of infection (e.g., fever, cough, discomfort on urination, malaise). Furthermore, lithium can have adverse effects on electrolyte balance (especially in patients on thiazide diuretics), thyroid function, the kidney, and the heart. Hence, common lithium pretreatment tests include serum electrolytes, BUN serum creatinine, urinalysis, thyroid function tests (TFTs) (e.g., TSH, T_4, T_3RU), and an ECG. In patients with a history suggestive of possible kidney problems, a 24-hour urine test for creatinine and protein clearance is recommended, although some clinicians routinely order this test in patients about to begin lithium therapy. Some have argued that antithyroid antibody testing is helpful in assessing the potential of lithium-induced hypothyroidism. Because of the potential cardiac teratogenicity of lithium, a pregnancy test in potentially child-bearing women should be ordered. Periodic follow-up of serum electrolytes, BUN, creatinine, TFTs, ECG, and 24-hour urine for creatinine and protein clearance are recommended. The frequency and exact makeup of the follow-up testing battery should be dictated by the patient's medical condition. Suggested therapeutic blood concentrations for the lithium ion in acute mania range from 0.8 to 1.5 mEq/L, although a range where potential toxicity might be manifest is 1.2 to 1.5 mEq/L (a “warning range” where the risk of developing toxicity rises rapidly). The serum lithium concentrations of patients with lithium levels above 1.0 mEq/L should be carefully monitored. Maintenance therapeutic blood concentrations of lithium are around 0.6 to 0.9 mEq/L. Lithium concentrations for therapeutic blood-level monitoring are drawn as close to 12 hours after the last dose of lithium as possible. Steady-state concentrations in patients without renal dysfunction are reached about 5 to 8 days after initiation of lithium treatment or after a dosage change. Patients with evidence suggestive of lithium toxicity should have a concentration measured immediately. These patients might need close medical attention, including hemodialysis when the lithium levels exceed 2 to 4 mEq/L (especially in the patient in poor medical condition with poor lithium excretion).

Lithium levels are often measured every 1 to 2 weeks during the first 2 months of treatment. Unless there are indications to do otherwise, follow-up testing for patients on lithium includes lithium concentrations obtained every 3 to 6 months, yearly thyroid function testing (e.g., T_4 and TSH), serum BUN, and creatinine. Serum electrolytes are measured every 6 to 12 months, with a 24-hour urine for volume and glomerular filtration rate (GFR) in patients with suspected renal disease. Changes in lithium dosing would necessitate more frequent blood level monitoring.

Antipsychotics Except for the antipsychotic clozapine (Clozaril), no clear pretreatment and follow-up laboratory and diagnostic evaluation strategy exists. Additionally, no specific therapeutic blood levels for these agents have emerged although some suggested therapeutic blood concentrations for several antipsychotic agents exist in the psychiatric literature. For instance, some studies have suggested that a therapeutic window for treatment efficacy exists for haloperidol (Haldol), and clinically meaningful responses to clozapine have been associated with blood concentrations between 200 and 450 ng/dL; one study noted the greatest benefit with blood concentrations greater than 350 ng/dL. For haloperidol, gross toxic adverse effects, including neuroleptic malignant syndrome, confusion, seizures, or catatonia, have been associated with blood concentrations greater than 30 ng/mL; blood-level reductions were associated with a reduction in these toxic adverse effects. There is also significant dose-to-blood-level variability between individuals. Blood concentrations for antipsychotic agents have been described as useful for assessing medication noncompliance or perhaps in treatment-refractory patients who might be very rapid metabolizers of the antipsychotic agent being used. Blood concentrations testing can also be utilized to determine if a drug interaction is lowering the blood level of an antipsychotic drug. Additionally, some clinicians have advocated the use of at least a single blood level in patients who do not respond to an antipsychotic agent.

Clinicians need to be aware of the potential toxicities of the antipsychotic agents that they use, and order laboratory and diagnostic tests accordingly. For instance, clinicians using clozapine need to be aware of its potential to cause fatal agranulocytosis and seizures (although these risks exist with all antipsychotic agents, albeit to a lesser extent). With clozapine the risk of agranulocytosis (defined as an absolute neutrophil count [ANC] of less than $500/mm_3$) appears to be about 1.3 percent per year; the risk of seizures reaches approximately 5 percent of persons treated with higher dosages. Other potential adverse effects of antipsychotic medication include melanism from phenothiazines (especially chlorpromazine [Thorazine] related), abnormal lactation, and gynecomastia. It is also probably advisable to establish the childbearing status of at-risk women prior to the use of antipsychotic medications.

Serious cardiac arrhythmias have been reported associated with antipsychotic use (e.g., thioridazine [Mellaril]); hence, patients with preexisting cardiac disorder might need careful ECG follow-up when these agents are used. In patients about to start on antipsychotic agents with known cardiac effects, obtaining a baseline ECG is prudent. Note that in patients over the age of 50, the frequency of ECG abnormalities is considered significant enough to warrant such screening. ECG screening is

indicated in persons with a history of cardiac disease, regardless of age. Clinicians should also be aware that significant orthostasis can be associated with some antipsychotic agents. Patients with concomitant hepatic or renal disease require periodic monitoring of these organ systems (e.g., with periodic physicals, LFTs, BUN, and creatinine tests).

Neuroleptic Malignant Syndrome The diagnosis and follow-up of this potentially fatal adverse reaction to antipsychotic medications can be assisted by the laboratory. This disorder typically consists of varying degrees of hyperpyrexia, autonomic instability (e.g., pulse greater than 100), severe extrapyramidal dysfunction (95 percent with “lead-pipe” rigidity) and delirium. Laboratory abnormalities often include creatine phosphokinase, WBC elevations, myoglobinuria, and liver enzyme elevations. Patients with neuroleptic malignant syndrome are at risk for serious medical complications including renal failure, pneumonia, respiratory arrest, and cardiovascular collapse. Laboratory and diagnostic testing for these conditions should be ordered as indicated.

Clozapine-Induced Agranulocytosis The agranulocytosis that develops in clozapine-treated patients often occurs within the first 18 weeks of treatment. Although the drop in the WBC is usually gradual, the progression to agranulocytosis can be rapid and can occur within a few days. Fever, flu-like symptoms, sore throat, or petechiae and ecchymosis (i.e., from thrombocytopenia) on any part of the body may be a sign of granulocytopenia in patients taking clozapine. At this time there is no way to predict who will develop this potentially fatal adverse event.

Prior to initiating clozapine therapy, a WBC count should be obtained. It has been recommended that patients with a WBC count of less than 3500/mm $_3$ not be treated with clozapine. If during treatment with clozapine the WBC falls below 3500/mm $_3$, or there is a significant decrease from a higher WBC baseline that does not fall below 3500 (i.e., a single drop of 3000 or more or a cumulative drop of more than 3000 over a 3-week period), or immature white cell forms are detected, a repeat WBC with differential should be obtained immediately. If the count is between 3000-3500/mm $_3$, the ANC should be above 1500/mm$_3$ for therapy to continue (and follow-up WBC counts should be done twice weekly). WBCs below 3000/mm $_3$ or ANCs below 1500/mm$_3$ are typically indications to discontinue clozapine therapy, and WBC counts with differentials should be obtained daily. Clozapine therapy can be resumed when WBC counts are over 3000/mm $_3$ and ANC concentrations are over 1500/mm$_3$. Twice-weekly WBC counts with differentials should be obtained until the WBC reaches 3500/mm $_3$. At WBCs below 2000/mm$_3$ and ANCs below 1000/mm$_3$, bone marrow studies are recommended. It is now also recommended that patients who have total WBC counts that fall below 2000 mm $_3$ during clozapine therapy or ANCs that drop below 1000/mm$_3$ should not be rechallenged with clozapine (Table 7.7-6).

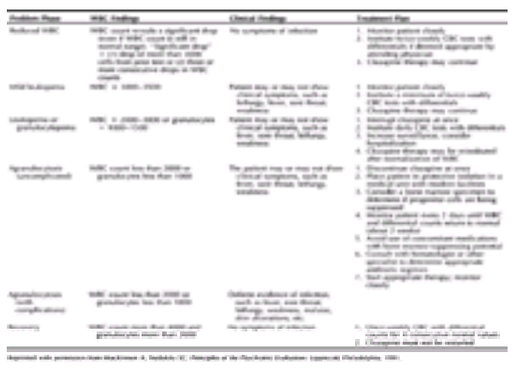

Table 7.7-6 Clinical Management of Reduced White Blood Cell (WBC) Count, Leukopenia, and Agranulocytosis in Patients Taking Clozapine

Clozapine-Related Seizures The risk of seizure from clozapine rises with increasing dosage, and reaches approximately 5 percent of persons treated with high doses of clozapine (between 600 to 900 mg a day). Although most of the clozapine-related seizure events are of the generalized tonic-clonic type, myoclonic seizures and cataplectic-like events have also been described. Before raising clozapine doses above 600 mg a day, the clinician should consider obtaining an EEG; however, according to some reports an abnormal EEG might predict therapeutic response to clozapine. In treating suspected or confirmed clozapine-related seizures, phenytoin (Dilantin) is avoided because of its ability to lower serum clozapine levels and its association with agranulocytosis. Carbamazepine can also cause agranulocytosis and should not be used in patients taking clozapine.

Anticonvulsants

Valproate Valproic acid and divalproex (Depakote) are now commonly used in the management of bipolar I disorder. They have also been used to treat agitation in patients with dementia, depression, and borderline personality disorder. In adults, serum concentrations above 45–50 µg/mL are described as the most effective in managing bipolar I disorder. Serum concentrations above 125 µg/mL are associated with a greater frequency of adverse effects, including thrombocytopenia. Acutely manic patients appear to have the greatest therapeutic response and the fewest adverse effects with valproic acid blood concentrations between about 45 and 100 µg/mL (although therapeutic concentrations up to 125 µg/mL are described). Caution should be exercised when using valproic acid and divalproex sodium in patients with liver disease. These medications are typically discontinued when liver enzyme elevations exceed three times the upper limit of normal. Serious adverse reactions that have been reported during valproic acid therapy include hepatitis, liver failure, hematological abnormalities (e.g., decreased platelets, bone marrow suppression) and acute hemorrhagic pancreatitis. Finally, these agents should not be used during the first trimester of pregnancy because of their association with birth defects.

During the first 2 months, serum valproic acid levels can be obtained as often as every 2 weeks; CBC and LFTs should be obtained monthly. During long-term use, serum valproic acid levels can be obtained every 3 to 6 months, and CBC and LFTs every 6 to 12 months. Any changes in valproic acid or divalproex dosing would necessitate more frequent monitoring of blood levels.

Carbamazepine Carbamazepine has been used as the sole or adjunctive medication in various psychiatric disorders, especially bipolar I disorder. When utilized for the treatment of psychiatric disorders, therapeutic blood levels for carbamazepine have not been clearly established. However, many clinicians aim for carbamazepine blood concentrations between 4 to 15 µg/mL (the blood concentrations with established therapeutic efficacy in the treatment of seizures). Carbamazepine has been associated with aplastic anemia in up to 1 in 10,000 patients treated with the agent, although more recent research has revised the occurrence of severe hematological adverse effects to about 1 in 125,000. However, decreases in the WBC count are common in patients taking this medication. In addition, a benign drop in the red blood cell count may occur within the first week of treatment, which reverts to normal without the drug having to be discontinued. Recommendations for the discontinuation of carbamazepine treatment have included WBC counts less than 3000 per mm $_3$, erythrocyte counts less than 4.0 × 10$_6$/mm$_3$, hemoglobin less than 11 mg/dL, platelet counts less than 100,000 per mm$_3$, or reticulocyte counts less than 0.3 percent. A conservative plan for the laboratory monitoring of patients taking carbamazepine is provided in Table 7.7-7.

Test	Frequency
1. Complete blood count	Before treatment and every 2 weeks for the first 2 months of treatment; thereafter, once every 3 months
2. Platelet count and reticulocyte count	Before treatment and yearly
3. Serum electrolytes	Before treatment and yearly
4. Electrocardiogram	Before treatment and yearly
5. AST, ALT, LDH, alkaline phosphatase	Before treatment and every month for the first 2 months of treatment; thereafter, every 3 months
6. Pregnancy test for women of childbearing age	Before treatment and as frequently as monthly in noncompliant patients

Table 7.7-7 Laboratory Monitoring of Patients Taking Carbamazepine

Other less stringent recommendations for laboratory follow-up have suggested that during the first 2 months of carbamazepine treatment, serum carbamazepine concentrations be obtained every 1 to 2 weeks, and a CBC and LFTs be obtained monthly. Clinicians should be aware that carbamazepine induces liver enzymes that increase its own metabolism and lower blood concentrations during the initial 2 to 3 weeks of its use. Hence, some clinicians recommend more careful monitoring of carbamazepine blood levels during the first month of treatment. During long-term treatment, serum concentrations can be obtained every 3 to 6 months, and CBC and LFTs every 6 months.

Carbamazepine can also have effects similar to the tricyclic antidepressant drugs on the ECG. Like valproic acid and divalproex sodium, carbamazepine is potentially teratogenic; hence, pretreatment pregnancy testing is advised in women of childbearing potential. Carbamazepine has also been reported to reduce haloperidol blood levels with clinical deterioration of the patient. Concurrent use of carbamazepine and clozapine has been associated with reductions in plasma clozapine concentrations approaching 50 percent. Finally, carbamazepine has also been associated with lowering serum sodium concentrations, potentially progressing to hyponatremia and even water intoxication (syndrome of inappropriate antidiuretic hormone secretion). Hence, some clinicians recommend a baseline serum sodium determination in patients who are going to be started on carbamazepine, as well as periodic follow-up determinations.

BRAIN IMAGING

Computed Tomography CT is used by neuropsychiatrists to exclude the presence of brain lesions in their patients. There is no evidence in support of making functional psychiatric diagnoses based on CT findings. There has been some controversy in the medical literature regarding the use of this diagnostic procedure as a screening tool. Most physicians would agree that psychiatric patients with focal neurological findings, a past history suggestive of brain insult (e.g., a history of head trauma or seizures), an abnormal EEG, or delirium should be seriously considered for a CT scan of the head. Others have proposed that CT scans should be obtained in psychiatric patients who evidence either confusion, dementia, delirium, movement disorder, anorexia nervosa, prolonged catatonia, or who are psychotic for the first time. Some also recommend a CT scan in patients over the age of 50 who show a personality change or who are having their first episode of mood disorder. A normal CT scan result oes not entirely rule out the possibility of organic brain syndrome or insult.

Magnetic Resonance Imaging MRI visualizes brain structures with remarkable clarity and offers better resolution of brain structure than CT. The indications for using MRI in a psychiatric patient are similar to those for CT scans. MRI is perhaps superior to CT scans when the suspected CNS disease process includes white matter demyelinating disease, nonmeningeal neoplasm, vascular malformation, degenerative disease such as Huntington's disease, and when a seizure focus is suspected. The MRI technique is also useful in patients unable to tolerate iodine-based contrast materials or intravenous procedures that might be needed during a CT scan evaluation. Additionally, the MRI can be used to clarify ambiguous CT scan findings.

The MRI technique is typically contraindicated in patients with pacemakers, aneurysm clips, pregnant women, and patients with potentially magnetic foreign bodies. Additionally, the CT scan is often recommended over MRI when the disease process suspected involves the pituitary gland, calcified brain lesions, meningeal tumors, and acute parenchymal infarction or hemorrhage. The clinician should be aware that a variety of anxiety reactions can occur during MRI scanning, requiring that some patients be carefully screened prior to scanning in the more claustrophobic MRI scanners and prepared for the experience (perhaps with friends and family on hand, with prescanning behavioral desensitization, or premedication with a short-acting antianxiety agent).

ELECTROPHYSIOLOGY

Electroencephalogram In patients with a possible organic CNS component to their psychiatric disturbance, an EEG can be useful. The clinician should realize that a single normal EEG result does not rule out organic pathology. Diffuse slowing is perhaps the most common EEG abnormality in psychiatric patients, constituting about 40 percent of abnormal EEGs in psychiatric populations. EEG slowing in psychiatric patients has been associated with diminished cognitive functioning, being on a larger number and higher doses of medications, increased length of hospital stay, and greater illness severity. If a seizure disorder is strongly suspected, “sampling errors” can be corrected by repeat EEGs or 24-hour ambulatory recording (often accompanied by video recordings of the patient's behavior to further document potential seizure activity). Sleep-deprived EEG recordings further increase the likelihood of unmasking latent abnormal EEG activity. Some clinicians use nasopharyngeal (NP) leads to increase the diagnostic yield. However, NP leads can be quite uncomfortable for patients and can keep them from falling asleep during EEG recording. The failure to sleep during the EEG recording can significantly diminish the usefulness of the EEG as a diagnostic tool because it is during sleep that latent abnormal EEG activity is often best detected. Clinicians should also remember that a seizure diagnosis is typically made on clinical grounds and is not entirely dependent on abnormal EEG findings. Finally, EEG monitoring is also used by some clinicians and researchers during the administration of electroconvulsive therapy (ECT). Such EEG monitoring assures the clinician that a fully therapeutic seizure has been induced.

Polysomnography This procedure is used in the evaluation of various sleep disorders (e.g., insomnia, sleep apnea, parasomnias, narcolepsy, male erectile disorder). Polysomnography involves the assessment of multiple physiological parameters while the patient sleeps (or attempts to sleep); the parameters include EEG, electro-oculogram (EOG), electromyogram (EMG), ECG, blood oxygen saturation, blood pressure, respiratory effort, and body temperature. A special daytime polysomnographic evaluation called the multiple sleep latency test is used in the evaluation of narcolepsy.

Evoked Potentials Evoked potentials refer to brain electrical activity elicited by stimuli. Exogenous, or sensory, evoked potentials (visual, auditory, and somatosensory) have great utility in detecting peripheral and central neural conduction abnormalities. Evoked potential testing can be used in the differentiation of certain organic versus functional complaints (e.g., the visual evoked potential [VEP] can be used to evaluate hystorical blindness). Other forms of evoked potential studies include the brainstem auditory evoked potential (BAEP). When neuropsychiatric symptoms of unclear etiology are present, certain evoked potential findings can be useful for detecting possible underlying neurological dysfunction (e.g., evoked potential testing might suggest an underlying demyelinating condition such as multiple sclerosis as a cause of what was previously regarded as “functional” symptoms).

Genetic Testing Clinical chromosome analysis usually takes place in the context of a prenatal analysis of genetic disorders. Possible clinical indications for ordering a cytogenetic analysis in a psychiatric patient who is not in a gynecologic or obstetric setting might include the psychiatric patient with congenital anomalies or nonspecific mental retardation. If a patient has cytogenetic analysis performed for some reason (e.g., as part of the workup of infertility, habitual abortion, amenorrhea, or ambiguous external genitalia), careful attention needs to be paid to the potential adverse psychological impact of the result on the patient and family.

AMOBARBITAL INTERVIEW

The amobarbital interview involves the slow intravenous infusion of sodium amytal, with careful attention to avoid oversedation and respiratory depression. Reports exist describing the amobarbital interview as a useful aide in differentiating certain functional versus organic conditions. For instance, in certain stuporous patients with schizophrenia or major depressive disorder, amobarbital has been described as making the patient more verbal and less guarded. Patients whose stuporous state is secondary to a neuromedical condition (e.g., brain tumor, stroke) typically become more confused, with clear deterioration on cognitive examination. An alternative medication that has been proposed as perhaps better than amobarbital for drug-assisted interviewing is the high-potency benzodiazepine midazolam (Versed); for safety, pulse oximetry has been used in conjunction with midazolam administration.

NEW CLINICAL AND RESEARCH TOOLS

Biological Markers There has been a great deal of interest in finding neurophysiological markers of psychiatric disorders. Such biological markers would not only reveal underlying pathophysiologies for psychiatric disorders, but they could also serve as diagnostic tests. Biological markers could assist in: (1) making accurate psychiatric diagnoses, (2) identifying patients at risk of developing a psychiatric disorder (e.g., so preventive steps could be implemented), and (3) predicting treatment response. Biological markers currently being investigated encompass a wide range of procedures, some of which are listed in Table 7.7-8. Difficulties that have arisen for many of the proposed markers include problems with sensitivity, specificity, reliability, and contamination from artifactual influences (e.g., concurrent medical illnesses, medication effects, and normal individual variation). None of these markers have clearly established themselves as useful for routine clinical practice. More precise biological markers for idiopathic psychiatric conditions of greater clinical and research utility will be most forthcoming when the underlying pathophysiologies of these conditions are determined. Because the etiologies and genetic contributions of psychiatric disorder largely remain unknown, biological marker research in psychiatry often takes on the character of a fishing expedition with better fishing spots suggested by earlier encouraging findings or intriguing hypotheses.

Table 7.7-8 Some Biologic Markers Under Investigation

Brain Imaging Techniques An exciting area of biological marker research involves several brain imaging techniques that have become available to neuropsychiatrists and it is understandable that tests that directly measure and image brain structure and function are of interest in psychiatry.

Electroencephalography Computerized topographic mapping of electrophysiological data represents an enhancement of conventional EEG and evoked potential (EP) testing. In this brain-imaging tool, a computer is used to amass and process large quantities of EEG and EP data from a patient. The computers analyze the data in various ways and graphically present the data as two-dimensional, typically color-coded maps of brain electrical activity. The newer technology of computerized topographic mapping of EEG and EP data has not found a clear niche in the diagnostic assessment of the psychiatric patient. There has also been the hope that the computerized EEG would help in the development of the EEG as a functional measure of the therapeutic activity of various psychiatric drugs.

Recent EEG work in patients with schizophrenia treated with clozapine has suggested that clozapine “responders” demonstrate increased EEG photic driving compared to nonresponders. The increase in photic driving was positively correlated with clinical improvement. Indeed, patients with schizophrenia who develop abnormal EEGs while on clozapine tend to evidence a better clozapine response compared to those patients whose EEGs are unaffected by clozapine. Even when not taking any psychiatric medications, patients with schizophrenia tend to display EEG changes compared to normals, such as lower alpha frequencies (which have been shown to correlate negatively with total positive symptom scores in these patients).

Sleep EEG (Polysomnography) A potentially powerful biological marker of psychiatric illness uses EEG obtained during sleep. Sleep EEG abnormalities described in major depressive disorder include an increase in the overall amount of rapid-eye movement (REM) sleep and a shortened period before the onset of REM sleep (shortened REM latency). Neuromedical conditions giving rise to psuedodepressive presentations are typically associated with decreased REM sleep (e.g., patients with dementia usually have increased amounts of non-REM sleep). In schizophrenia, decreased slow-wave sleep and increased sleep latency and fragmentation have been reported, especially during relapse. Computerized analyses of the sleep EEG, with the generation of topographic maps of sleep EEG activity, are also available.

Computed Tomography Researchers continue to study possible useful subcategories of psychiatric diagnoses that could be based on CT findings (e.g., schizophrenia with or without ventricular enlargement). For instance, there has been the suggestion that certain patients with schizophrenia who have enlarged ventricles might be more resistant to treatment with antipsychotic agents. For instance, increased prefrontal cortical sulcal widening has been associated with a poor response to clozapine. In patients with chronic alcohol dependence, a relationship between severity of frontal atrophy and negative symptoms (as measured with the Scale for the Assessment of Negative Symptoms) has been reported, although the ability of such atrophy to predict future abstinence and treatment response has not been examined. However, there is currently no evidence that supports making functional psychiatric diagnoses based on CT scan abnormalities.

Magnetic Resonance Imaging Various neuropsychiatric studies using the MRI technique have yielded some interesting findings. Patients with schizophrenia have been reported to have smaller frontal lobes, cerebrums, craniums, and hippocampi (but larger lenticular nuclei and thalami) than normal controls. Differences in the symmetries of various brain structures have also been noted when subjects with schizophrenia and normal control subjects are compared. In elderly depressed patients, MRI signal hyperintensities in subcortical gray matter have been reported to be more common than in nondepressed comparison subjects. The full utility of MRI in neuropsychiatry, with its many different scanning modes, has not yet been completely explored.

Functional MRI Although traditional MRI provides anatomical images of the brain, the functional MRI (fMRI) technique might ultimately provide the researcher and clinician images of brain activity that rival the clarity of MRI anatomical images. fMRI can be directly correlated with high-resolution, three-dimensional anatomical MRI images. In a recent fMRI study it was reported that patients with schizophrenia demonstrated less frontal lobe activation and greater temporal lobe activation on the left during a word fluency task compared to comparison subjects. The utility of this technique for informing researchers about brain functioning in psychiatric illnesses is in its infancy, but it is expected that there will be many indications for this procedure in the future.

Magnetic Resonance Spectroscopy Magnetic resonance spectroscopy (MRS) is related to MRI but uses more powerful magnetic fields to evaluate certain aspects of brain function and metabolism. Information about brain phospholipid, carbohydrate, protein, amino acid, and high-energy phosphate metabolism, brain intracellular pH, as well as information about lithium and fluorinated psychopharmacological agents, can be obtained by this technique. For instance, using phosphorus-31 nuclear magnetic resonance ($_{31}$P NMR) spectroscopy, metabolism of brain high-energy phosphate and membrane phospholipids was studied in the dorsal prefrontal cortex of drug-naive patients with schizophrenia. Significant differences were found between the patients and controls, with dorsal prefrontal cortex hypoactivity in patients suggested by decreased adenosine triphosphate and inorganic orthophosphate levels. Alterations in membrane phospholipid metabolism were suggested by lower levels of phosphomonoesters and higher levels of phosphodiesters compared to the control subjects. Technological improvements in MRS should further the contributions of this functional brain-imaging technique to neuropsychiatric research.

Positron Emission Tomography PET allows for the direct visualization of cortical and subcortical brain functioning. Depending on the type of positron-emitting isotope used, different aspects of brain functioning can be studied, including brain glucose metabolism, cerebral blood flow, brain oxygen use, and binding parameters of specific neurotransmitter receptors. PET findings include abnormalities of the anteroposterior gradient of glucose utilization and higher subcortical-to-cortical glucose metabolism ratios in patients with schizophrenia compared to normal controls. PET findings in schizophrenia, as well as in other psychiatric disorders such as bipolar I disorder, substance use disorders, obsessive-compulsive disorders, and panic disorders, have not always been replicated by other investigators. PET remains a research tool available at only a few research centers.

Single Photon Emission Computerized Tomography Like PET, SPECT visualizes both cortical and subcortical brain activity. Because of certain technical differences, the image resolution is typically not as good with SPECT as compared to state-of-the-art PET scanners. Depending on the radioisotope employed, different aspects of brain function can be studied, such as brain blood flow. SPECT may also be utilized to image the distribution of neurotransmitter receptors in vivo. SPECT scanning defects have been described in a wide variety of neuropsychiatric conditions. For instance, one study reported an average of 7.3 SPECT defects in patients with chronic fatigue syndrome versus a mean of 0.4 defects in controls. Additionally, SPECT changes were reported to correlate with changes in clinical status. Another study reported a similar number of SPECT scan defects in a group of patients with chronic fatigue syndrome and a group of patients with major depressive disorder (6.5 defects per patients versus 1.7 in healthy controls).

Magnetoencephalography Conventional and computerized EEG gather data based on measurements made of cortical brain activity. Magnetoencephalography (MEG) detects the magnetic fields associated with neuronal electrical activity in both cortical as well as deeper brain tissues. MEG is noninvasive and does not expose the patient to harmful radiation; MEG is available in only a few research centers.

Regional Cerebral Blood Flow Regional cerebral blood flow (rCBF) is a nuclear medicine technique involving the introduction of metabolically inert radioactive substances into the body. These substances arrive at the brain via the blood, and radiation emanating from the brain is picked up by detectors surrounding the skull. rCBF can delineate blood flow in cortical structures. Using rCBF, there have been reports of decreased blood flow to certain frontal regions of the brain in patients with schizophrenia as well as in patients with other neuropsychiatric disorders.

Other Neurophysiological Markers

Eye Movement Deficits (EMD) A deficit in smooth pursuit eye movement (SPEM) performance has been described in up to 85 percent of patients with schizophrenia (versus approximately 10 percent in control populations). The SPEM deficit has been proposed to be a biological marker of schizophrenia. Another EMD involves an antisaccade deficit, which has been described in a number of neuropsychiatric conditions, including in patients with frontal cortical and basal ganglia lesions, schizophrenia, and obsessive-compulsive disorder. The antisaccade performance deficit includes a decreased ability to inhibit reflexive glances toward stimuli that subjects are instructed to look away from. Schizophrenia patients with greater smooth pursuit deficit tend to show more antisaccade performance deficits. EMDs can be measured using a number of different techniques, including electrooculography (EOG) and infrared scleral reflectance techniques.

Electroretinogram The electroretinogram (ERG) measures electrical changes produced in the retina by flashes of light. ERG amplitudes are reduced in certain diseases (e.g., retinitis pigmentosa and myotonic dystrophy), and also during the prodromes for these disorders. Decreased ERG amplitude has been reported in cases of thioridazine toxicity. In neuropsychiatric conditions, ERG amplitude reductions (specifically beta-wave amplitude) have been described in some patients with autistic disorder and those with various types of dementia, such as dementia of the Alzheimer's type and Creutzfeldt-Jakob disease.

Pupillometry It has been reported that persons with dementia of the Alzheimer's type have an exaggerated pupil dilation response to the ophthalmic administration of the anticholinergic medication tropicamide (Mydriacyl) compared to persons without the disease. The pupil dilation response of individuals with forms of dementia other than of the Alzheimer's type was reported as similar to that of the healthy controls, suggesting that this pupillary marker might be more specific for Alzheimer's disease than for other forms of dementia. The pupil dilation response was also reported as more sensitive for the presence of premorbid and morbid Alzheimer's disease than conventional neuropsychological testing. However, these findings based on pupil size measures have recently been challenged. One recent report suggests that increases in pupillary oscillation might accompany prodromal mania, supporting other suggestions that pupillometry might be useful for clinical psychophysiological diagnosis and management of psychiatric patients.

Quantitative Measures of Visual Scanning Such quantitative visual scanning procedures are performed on data obtained while patients view various visual stimuli. One method of quantitative visual scanning assessment is based on eye movement research suggesting that it takes at least approximately 40 to 50 milliseconds (ms) to fully scrutinize and cognitively process a single image element. Hence, visual fixations of shorter duration are thought to subserve more automatic or preattentive cognitive processes. In schizophrenia, such quantitative assessments of eye movements while patients viewed slides of faces were reported to correlate with symptom severity. In cocaine addicts, quantitative visual scanning measures while viewing cocaine cues have been shown to correlate with measures of cocaine craving.

Endocrine Stimulation Techniques

Dexamethasone Suppression Test (DST) There was the hope that this laboratory test would prove useful for the diagnosis and management of psychiatric patients. While a version of this test is used routinely by endocrinologists in the evaluation of Cushing's disease, the test was found by research psychiatrists to be a possible marker of major depressive disorder. There was initial enthusiasm that the test would be useful in assisting with psychiatric differential diagnosis (e.g., differentiating dementia from the pseudo-dementia of depression; differentiating schizoaffective disorder from schizophrenia) and in the prediction of treatment response and suicidal risk. Although many of the research findings have proved interesting, it has been argued that overall they do not support the routine clinical use of this test. However, although pretreatment baseline DST results are of questionable value, many agree that posttreatment DST cortisol nonsuppression predicts a poor outcome in depressive disorders, with a higher risk of early relapse.

A common version of the DST as employed by psychiatrists involves the administration of a 1-mg dose of dexamethasone (Decadron) at 11 PM with a serum cortisol concentration determination prior to dexamethasone administration (to assess baseline cortisol concentrations) and other serum cortisol determinations at various points over the next 24 hours (typically 8 AM, 4 PM, and 11 PM). The DST result is considered abnormal if the postdexamethasone serum cortisol concentration exceeds about 5 µg/dL. However, the reliability of many commercial assays at about the 5 µg/dL cut-off value is questionable; hence, there is a recommendation that plasma cortisol concentrations between 4 and 7 µg/dL be interpreted cautiously. Additionally, many other limitations to the routine use of the DST have emerged, including significant potential artifactual contamination from concomitant medical conditions (e.g., diabetes mellitus), medications (e.g., carbamazepine) and the potential that the test results will direct the clinician's attention away from other more important clinical issues for the patient. If the DST is used, the psychiatrist should be attentive to the possible causes of false-positive or false-negative DST results outlined in Table 7.7-9.

False Positives	False Negatives
Cushing's syndrome	Addison's disease
Weight loss or malnutrition	Hypopituitarism
Obesity	Slow dexamethasone metabolism
Bulimia nervosa	Drugs
Pregnancy	Synthetic corticosteroids
Alcohol abuse and withdrawal	Indomethacin
Anorexia nervosa	High doses of benzodiazepines
Temporal lobe epilepsy	High doses of cyproheptadine
Dementia	
Diabetes mellitus	
Infection	
Trauma	
Recent surgery	
Advanced age	
Fever	
Carcinoma	
Renal or cardiac failure	
Renovascular hypertension	
Cerebrovascular disorder	
Antipsychotic withdrawal	
Tricyclic withdrawal	
Drugs	
High doses of estrogens	
Narcotics	
Sedative-hypnotics	
Anticonvulsants

Table 7.7-9 Causes of False-Positive or Negative Results on the Dexamethasone-Suppression Test (DST)

Thyrotropin-Releasing Hormone Stimulation Test Endocrinologists use a version of this test in the evaluation of hypothyroidism. The hypothyroid patient has an augmented TSH response to an intravenous (IV) injection of thyrotropin (Thytropar). The test has also been proposed as useful in grading different forms of hypothyroidism. In Grade 1 hypothyroidism the diagnosis is obvious based on clinical and biochemical grounds (e.g., elevated serum TSH and low serum T_4). Grade 2 hypothyroidism is less obvious and without clear clinical features of hypothyroidism (except perhaps depression), but serum TSH is elevated. Grade 3 hypothyroidism is characterized by normal baseline TSH and thyroid hormone values, but the results of the TRHST are abnormal. It has been argued that Grade 3 hypothyroidism can also present with or accompany depression in some patients, and would be missed if only the conventional serum thyroid hormone assays are used (i.e., serum TSH and T_4). Furthermore (and perhaps confusingly so) a blunted TRHST result (i.e., a result more common to hyperthyroidism) has been proposed as a biological marker of major depressive disorder with diagnostic and prognostic meaning. Although a blunted TRHST result has been reported in up to 30 percent of depressed patients, the result does not appear specific to major depressive disorder (e.g., blunted results have been reported in patients with other affective spectrum disorders such as alcoholism, panic disorder, bulimia nervosa, and borderline personality disorder).

Provocative Tests of Panic Disorder These tests challenge patients with various agents such as carbon dioxide (via inhalation), lactate (via IV infusions) or IV infusions of such substances as caffeine, isoproterenol (Isuprel) b-carboline and flumazenil (Romazicon)—all of which have been noted to be capable of inducing panic attacks in patients so predisposed (and less so in individuals without a history of panic disorder). Lactate infusion is the most extensively studied provocative test for panic disorder, and up to 72 percent of panic disorder patients have been reported as experiencing a panic attack after the IV infusion of sodium lactate. Anxiogenic responses to lactate or fenfluramine provocation have been described as greater in patients with higher panic attack frequencies. In patients with posttraumatic stress disorder, IV infusions of lactate have been demonstrated as capable of triggering flashbacks of the traumatic event, with at times dramatic affective displays in response to the flashback.

Panic attacks precipitated by IV lactate infusion have been shown to be inhibited by tricyclic antidepressant medication and alprazolam (Xanax), which are psychotherapeutic agents of demonstrated efficacy in the treatment of panic disorder. Responses to challenge tests for anxiety disorders might lead to useful subtyping paradigms for these disorders. The specificity of lactate infusions for panic disorder is unclear, as patients with primary depressive disorder with secondary panic attacks have similar rates of lactate-induced panic attacks as those patients with primary panic disorder. Simple hyperventilation procedures have also been reported as capable of precipitating panic attacks in patients so predisposed, although hyperventilation appears to be a less potent stimulus of panic attacks than IV infusions of lactate. The clinician should note that hyperventilation procedures should be used with caution because of their ability to trigger seizures. At this time, these provocative tests are more useful as research tools to study various paroxysmal anxiety disorders than they are as diagnostic tests.

Biochemical Markers From blood, CSF, and urine, the clinician and researcher can obtain many potential biochemical markers, including neurotransmitter substances and their metabolites (e.g., dopamine, homovanillic acid [HVA], norepinephrine, its metabolite 3-methoxy-4-hydroxyphenylglycol [MHPG], serotonin and its metabolite 5-hydroxyindoleacetic acid (5-HIAA), and amino acids such as tryptophan, tyrosine, glycine, and glutamate). Studies involving most of these markers and many other proposed markers have yielded mixed results. What follows are some interesting recent highlights regarding this area of research.

Plasma Homovanillic Acid The measurement of homovanillic acid in plasma (pHVA), a major acidic metabolite of dopamine, may reflect changes in the activity of dopamine in the brain. The measurement of pHVA may have a practical clinical application in the identification of schizophrenia patients responsive to antipsychotic medications. For instance, some reports suggest that responders to these drugs are characterized by antipsychotic-induced reductions in pHVA. The time-dependent decreases in pHVA in treatment responders further suggest that the ability to dampen presynaptic dopaminergic activity is related to the therapeutic efficacy of antipsychotic medications.

3-Methoxy-4-Hydroxyphenylglycol When measured in 24-hour urine collections, MHPG has been reported to be lower in patients with bipolar I disorder than in patients with bipolar II disorder. Low urine MHPG might predict imipramine (Iofranil) response in depressed patients with bipolar disorder but not in depressive disorder (unipolar) patients. High urinary MHPG concentrations have also been associated with a subtype of depressed patients more likely to show cognitive features of learned helplessness.

Low CSF MHPG (along with decreased 24-hour urinary norepinephrine-epinephrine ratios) has been proposed as a measure of a decreased noradrenergic activity that could suggest an increased predisposition to suicidal behavior.

5-Hydroxyindoleacetic Acid Associations have been reported between low CSF 5-HIAA and suicidal behavior, aggression, poor impulse control and impulsive suicidal acts, disturbed behavior in childhood, violent suicide attempts, and depression in patients with diagnoses including major depressive disorder, schizophrenia, alcohol use disorders, and adjustment disorder. Hence, although this marker might not have nosological specificity, it might mark problematic behaviors across a wide variety of psychiatric diagnoses. There have also been reports of an association between elevated CSF 5-HIAA concentrations and anxious, obsessional, or inhibited behaviors.

Markers of Alzheimer's Disease SPECT and PET are emerging as useful tools in the detection and evaluation of patients with dementia of the Alzheimer's type. When SPECT and PET are used, these patients typically show decreased perfusion in temporoparietal areas bilaterally, while patients with ischemic brain changes (vascular dementia) more often demonstrate single focal perfusion defects or multiple areas of patchy hypoperfusion.

The presence of an *Apo*E allele has also been associated with an increased risk of Alzheimer's disease. Individuals with two copies of the *Apo*E-e4 allele appear to have an especially increased risk. By late middle age, persons who are cognitively normal but who are homozygous for the e4 allele for *Apo*E have been reported to show evidence of reduced glucose metabolism on PET in the regions of the brain as do patients with dementia of the Alzheimer's type. These findings have been interpreted as being supportive of the notion that *Apo*E-e4 is a risk factor for this disorder.

A variety of other biological markers of Alzheimer's disease are currently under examination. One test for neural thread protein (NTP) from CSF is now being marketed for assisting in the diagnosis of these patients. The test measures the brain protein 21 kD NTP that is reported to be increased in patients with dementia of the Alzheimer's type as compared to normal controls. Other potential CSF tests for this disorder include measurement of CSF-tau (increased) and CSF-amyloid (decreased). One proposed biochemical marker of blood-brain barrier damage in dementia caused by cerebrovascular pathology is the CSF albumin-to-serum albumin ratio. The CSF albumin-to-serum albumin ratio is normal in patients with dementia of the Alzheimer's type but elevated in vascular dementia. The hope is that all these emerging diagnostic tests will be able to diagnose the disease early in its course. Clinicians would then be able to start drug treatments early, when such interventions would have the greatest potential of being effective. Persons with vascular dementias can be identified by CT, MRI, SPECT, or PET scan.

Inflammatory mechanisms have been implicated in the pathogenesis of dementia of the Alzheimer's type, and certain biochemical and genetic markers of inflammation may serve as diagnostic aids in the identification of persons affected with the disease or at risk of developing it. For instance, there have been reports of elevations of acute-phase reactive proteins in sera and CSF (e.g., a_1-antichymotrypsin) of patients and unaffected first-degree relatives of patients with this disorder. These markers of inflammation may become targets for novel pharmacotherapy and laboratory indices to monitor therapeutic response to treatment with anti-inflammatory medications. Additionally, knowledge of the normal handling of proteolytic products of amyloid precursor protein (APP) and factors mediating inflammation in brain of these patients may help to identify targets for novel pharmacotherapy and genetic markers of the disease. For instance, measurements of (1) apolipoprotein J and allelic variants (apolipoprotein J has been shown to be the predominant binding protein for the b-amyloid split product in CSF), (2) complexes of apoJ with soluble b-amyloid and soluble complement membrane-attack complex (MAC), and (3) low-density lipoprotein receptor (LRP-2) and allelic variants, may serve as potential risk markers for Alzheimer's disease.

Genetic Testing In theory, markers for the defective genes in the heritable neuropsychiatric disorders ultimately will be identified; these markers should prove to be powerful diagnostic tests for these diseases. At this time no functional (idiopathic) psychiatric disorder has been associated clearly with a specific chromosome or gene location. Using new molecular biology techniques, studies are beginning to suggest chromosomal loci for a host of neuropsychiatric problems.

For instance, independent groups have provided evidence for a vulnerability locus for schizophrenia and associated disorders on chromosome 8p. This vulnerability locus on 8p was likely to segregate in about 10 to 25 percent of the multiplex families studied. Data from this series have also shown potential linkage between schizophrenia and a vulnerability locus on chromosome 6p in about 10 to 30 percent of the multiplex families. Thus, there is an interesting possibility that epistasis or gene-gene interaction can take place between the 8p and 6p regions in at least some patients. Another interesting allelic marker whose absence in patients and mothers of offspring with schizophrenia may be associated with schizophrenia is the locus (DRB1*04) encoding the class II human leukocyte antigen (HLA) DR4 on chromosome 6p. There have also been reports of an association between schizophrenia and the absence of DQB1*0602, another class II HLA gene, in African-Americans and Chinese men from Singapore.

Evidence has been collected suggestive of a susceptibility gene for bipolar I disorder in the pericentrometric region of chromosome 18. Candidate genes in this region that may have some etiological or pathological association with bipolar I disorder include Golf, the a subunit of a heterotrimeric GTP-binding protein, and a corticotropin receptor gene. The lithium ion influences the affinity of the a subunit for GTP, antidepressant medications modulate expression of GTP-binding proteins, and the function of the hypothalamic-pituitary-adrenal axis is altered in mood disorders.

In Alzheimer's disease, genetic defects on chromosomes 21, 14, and 19 have been implicated. The presence of an *Apo*E allele has also been associated with an increased risk of the disease, but the presence of the allele is not considered diagnostic. *Apo*E maps to a region on chromosome 19 that has been implicated in linkage studies of the disease. Recent evidence suggests that genetic screening of mutant presenilin alleles (presenilin genes located on chromosomes 14 and 1 have been designated as *PS*1 and *PS*2, respectively) might also lead to possible diagnostic genetic tests of persons at risk. Ultimately, batteries of tests might be needed to fully determine the at-risk profile of an individual for a particular neuropsychiatric disease.

The further extension of genotypic analyses, including restriction fragmentation length polymorphism, polymerase chain reaction amplification, and sequence-specific oligonucleotide probe analysis, and specialized statistical procedures to assess linkage to complex traits will undoubtedly result in the identification of genetic risk factors for neuropsychiatric illnesses such as schizophrenia, bipolar I disorder, and dementia of the Alzheimer's type. The discovery of genetic defects responsible for neuropsychiatric disease, along with the uncovering of their roles in the diseases and biological products, will revolutionize laboratory testing of these conditions. At this time these genetic procedures and markers remain only research tools. However, there is a substantial effort to identify genes responsible for specific diseases sponsored by the federal government's human genome project, which involves the mapping of the entire human genome (composed of over 100,000 genes, of which approximately 80,000 are represented in the brain). The mapping of the human genome should enhance the clinician's ability to diagnose neuropsychiatric disease and will result in new conceptualizations of psychiatric disorders. It is hoped that this project will lead to better preventive and therapeutic measures for these disorders. Nevertheless, a host of clinical and ethical issues pertaining to the interpretation of these genetic risk factors and the counseling of patients and families will be raised by this promising area of research.

SUGGESTED CROSS-REFERENCES

Assessment is also discussed in Section 2.1, the other sections of Chapter 7, Chapter 32, Chapter 33, Chapter 34, Chapter 35, Chapter 36, Chapter 37, Chapter 38, Chapter 39, Chapter 40, Chapter 41, Chapter 42, Chapter 43, Chapter 44, Chapter 45, Chapter 46, Chapter 47, Chapter 48 and Chapter 49 on child psychiatry, and

7.8 PSYCHIATRIC RATING SCALES

DEBORAH BLACKER, M.D., SC.D.

A variety of questionnaires, interviews, checklists, outcome assessments, and other instruments are available to inform psychiatric practice, research, and administration. These instruments, which are grouped here under the term *psychiatric rating scales*, are used with increasing frequency in the practice of psychiatry. Psychiatrists must be aware of rating scales for several reasons. Most critically, many such scales are useful in practice for monitoring patients over time or for providing information that is more comprehensive than that generally obtained in a routine clinical interview. In addition, scales are sometimes required administratively to justify the need for services or to assess quality of care. Last, but equally important, these scales are used in the research that informs the practice of psychiatry, so familiarity with them provides a deeper understanding of the results of that research and the degree to which it applies to psychiatric practice.

POTENTIAL BENEFITS AND LIMITATIONS OF RATING SCALES IN PSYCHIATRY

Rating scales in psychiatry serve to standardize the information collected across time or observers. This standardization ensures a comprehensive evaluation that may aid treatment planning by establishing a diagnosis, ensuring a thorough description of symptoms, identifying comorbid conditions, and characterizing other factors affecting treatment response. In addition, it can establish a baseline for follow-up of the progress of illness over time or in response to specific interventions. This is particularly useful when several clinicians are involved, for instance in a group practice or clinic setting, or in the conduct of psychiatric research.

In addition to standardization, most rating scales also offer the user the results of a formal evaluation of their performance characteristics. This means that the clinician can know to what extent a given scale produces reproducible results (*reliability*) and how it compares with more definitive or established ways of measuring the same thing (*validity*).

Rating scales also offer some practical advantages. First, they can save valuable physician time: self-administered rating scales can be administered in the waiting room, or a nurse or technician can administer an interview prior to a session with the physician. In addition, rating scales may make it easier to obtain information about sensitive areas such as cognitive decline or sexual functioning in which direct questioning is sometimes experienced as more intrusive.

However rating scales are not a panacea. They can provide erroneous measurements because of difficulties in administration or limitations in the underlying construct. In this respect they do not differ from clinical assessments, but they may appear to provide more definitive information and thus give a spurious sense of security. At the practical level, they take time that might better be devoted to other pursuits. The critical decision about using a formal assessment tool in clinical practice is whether on balance it contributes useful information in an efficient manner. This decision depends on the specific clinical setting and goal, the practical attributes of the scale, and its psychometric properties.

TYPES OF SCALES AND WHAT THEY MEASURE

Scales are used in psychiatric research and practice to achieve a variety of goals. They also cover a broad range of areas and use a broad range of procedures and formats.

Measurement Goals Most psychiatric rating scales in common use fall into one or more of the following categories: making a diagnosis (e.g., the Structured Clinical Interview for DSM-IV [SCID] or the Diagnostic Interview Schedule for Children [DISC]); measuring severity and tracking change in specific disorders (e.g., the Hamilton Rating Scale for Anxiety [HAM-A] or the Mini-Mental State Examination [MMSE]) or general symptoms (e.g., the Symptom Checklist-90) or in overall outcome (e.g., the Behavior and Symptom Identification Scale [BASIS-32]); screening for conditions that may or may not be present (e.g., the CAGE or the Zung Self-Rating Depression Scale).

Constructs Assessed Psychiatric practitioners and investigators assess a broad range of areas, referred to as *constructs* to underscore the fact that they are not simple, direct observations of nature. These include diagnoses, signs and symptoms, severity, functional impairment, quality of life, and many others. Some of these constructs are fairly complex and are divided into two or more domains (e.g., positive and negative symptoms in schizophrenia, or mood and neurovegetative symptoms in major depression). Many scales yield separate scores, or *subscales*, for each domain. Especially when these domains are seen as substantially independent, they may be referred to as dimensions (e.g., Axis I and Axis II in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-IV], multidimensional personality traits).

Categorical Versus Continuous Classification Some constructs are viewed as *categorical*, or classifying, while others are seen as *continuous*, or measuring. Categorical constructs describe the presence or absence of a given attribute (e.g., competency to stand trial) or the category best suited to a given individual among a finite set of options (e.g., assigning a diagnosis). Continuous measures provide a quantitative assessment along a continuum of intensity, frequency, or severity. In addition to symptom severity and functional status, multidimensional personality traits, cognitive status, social support, and many other attributes are generally measured categorically.

The distinction between categorical and continuous measures is by no means absolute. *Ordinal* classification, which uses a finite, ordered set of categories (e.g., unaffected, mild, moderate, severe), stands between the two. In addition, a cutpoint is frequently used with a continuous or ordinal scale to indicate a threshold for membership in a corresponding category. For instance, individuals with Mini-mental State Examination scores below 24 may be considered to have a dementia, or those with Hamilton Rating Scale for Depression (HAM-D) scores above 8 may be considered to have an episode of major depression.

Measurement Procedures Rating scales differ in measurement methods. Issues to be considered include format, raters, and sources of information.

Format Rating scales are available in a variety of formats. Some are simply checklists or guides to observation that help the clinician achieve a standardized rating. Others are self-administered questionnaires or tests. Still others are formal interviews that may be *fully structured* (i.e., specifying the exact wording of questions to be asked) or *partly structured* (i.e., providing only some precise wording, along with suggestions for additional questions or probes). Whether fully structured or not, instruments may be written so that all questions are always included, or they may have formal skip-out sections to limit administration time.

Individual items also vary in their format. Most commonly, scales use yes-no or multiple choice questions. Often, answers are graded on a *Likert scale*, an ordinal scale with three to seven points that measures severity, intensity, frequency, or other attributes. Likert scales are most often partially or fully *anchored*, assigning a meaning to each numeric level. The same anchors can apply to all items or the instrument may provide specific anchors for each. Occasionally, questionnaires include open-ended questions, especially at the beginning, which may be used to help establish rapport. In semistructured or unstructured interviews, this information also serves to guide the rest of the interview and aids in forming a clinical impression about the patient.

Raters Some instruments are designed to be administered by doctoral-level clinicians only, while others may be administered by individuals such as psychiatric nurses or social workers with more limited clinical experience. Still other instruments are designed primarily for use by lay raters with little or no experience with psychopathology. In general, more training is required to administer less-structured scales. In addition, some scales require extensive training, even for experienced clinicians, to master the appropriate procedures and achieve a good result. Virtually all scales perform better when raters are familiar with their format and specific content.

Source of Information Instruments also vary in the source of information used to make the ratings. Information may be obtained solely from patients, who generally know the most about their condition. In some instruments, some or all of the information may be obtained from a knowledgeable informant. When the construct involves limited insight (e.g., cognitive disorders or mania) or significant social undesirability (e.g., antisocial personality, substance abuse), other informants may be preferable. Informants may also be helpful when the subject has limited ability to recall or report symptoms (e.g., delirium, dementia, or any disorder in young children). Some rating scales also allow or require inclusion of information from medical records or patient observation.

ASSESSMENT OF RATING SCALES

In clinical research, rating scales are mandatory to ensure interpretable and potentially generalizable results and are selected on the basis of coverage of the relevant constructs, expense (based on the raters, purchase price, if any, and necessary training), length and administration time, comprehensibility to the intended audience, and quality of the ratings provided. In clinical practice, one considers these factors and also whether a scale would provide more or better information than would be obtained in ordinary clinical practice or contributes to the efficiency of obtaining that information. In either case, the assessment of quality is based on *psychometric*, or mind measuring, properties.

Psychometric Properties The two principal psychometric properties of a measure are reliability and validity. Although these words are used almost interchangeably in everyday speech, in the context of evaluating rating scales they are distinct. To be useful, scales should be *reliable*, or consistent and repeatable even if performed by different raters, at different times, or under different conditions, and they should be *valid*, or accurate in representing the true state of nature.

Relation Between Reliability and Validity Establishing a measure's reliability is generally considered primary, since it is difficult to reach valid judgments without first achieving consistency. However, problems with reliability can be overcome to an extent by combining information from several assessments. Unfortunately, improved reliability does not guarantee improved validity, and some efforts to improve reliability may actually limit validity. For example, a personality disorder instrument might focus on overt behaviors rather than inner thoughts and feelings to achieve higher reliability but at the cost of losing some of the most valid information about personality. Even with clinically trained raters, it is particularly difficult to achieve reliability on items requiring subjective clinical judgment (e.g., feelings evoked in the examiner): nonetheless, when used by experienced diagnosticians, such items may contribute substantially to valid diagnoses.

Reliability Reliability refers to the consistency or repeatability of ratings and is largely empirical. In the categorical context, it refers to whether agreement can be reached on the classification of each individual. In the continuous context, it refers to whether agreement can be reached on the assignment of a given score. It can also be seen as precision; that is, whether a measure yields a ballpark estimate or a finely graded score. An instrument is more likely to be reliable if the instructions and questions are clearly and simply worded and the format is easy to understand and score. There are three standard ways to assess reliability: internal consistency, interrater, and test-retest.

INTERNAL CONSISTENCY Internal consistency assesses agreement among the individual items in a measure. This provides information about reliability because each item is viewed as a single measurement of the underlying construct; thus, the coherence of the items suggests that each of them is measuring the same thing (and hence all of them are). Internal consistency is measured most often with coefficient alpha (also known as Cronbach's alpha), which ranges between 0 and 1; values of .75 or above are considered good. However, the internal consistency of a measure depends on the internal consistency of the construct that the measure purports to assess and is higher for unidimensional constructs than those with two or more relatively independent domains.

INTERRATER AND TEST-RETEST RELIABILITY Interrater (also called *interjudge*, or *joint*) reliability is a measure of agreement between two or more observers using the same information to evaluate the same subjects. Estimates may vary with assessment conditions; for instance, estimates of interrater reliability based on videotaped interviews tend to be higher than those based on interviews conducted by one of the raters. Interrater reliability tends to be higher than *test-retest reliability*, a measure of agreement between evaluations at two points in time, in which the information obtained may differ (e.g., be associated with differences in interviewer skill, interviewer mood, room conditions, or subject's attitude). In addition, test-retest evaluations measure reliability only to the extent that the subject's true condition remains stable in the time interval, which is problematic for many conditions but virtually impossible for rapidly fluctuating conditions like state anxiety. However, because the test-retest situation more closely reflects the clinical problems associated with serial evaluations by multiple clinicians, to the extent that concerns about interval change can be eliminated, it is generally a more useful indicator of reliability in practice.

Interrater reliability and test-retest reliability of continuous constructs are measured with the intraclass correlation coefficient (ICC), while those of categorical constructs are measured with the kappa coefficient (k). A weighted version of k is available to penalize large disagreements more than small ones (e.g., between schizophrenia and psychotic depression compared with schizophrenia and schizoaffective disorder). Both k and the ICC are measures of agreement corrected for the agreement expected by chance alone and both range from 0 to 1. As a rule of thumb, a k or ICC above .8 is considered excellent, those in the .7 to .8 range are considered good, and those in the .5 to .7 range are considered fair. However, the degree of reliability required varies with the clinical purpose; extremely reliable ratings are required before administering potentially dangerous treatments, while more modest reliability may suffice for estimating rates in a population.

ISSUES IN INTERPRETING RELIABILITY DATA When interpreting reliability data, remember that reliability estimates published in the literature may not generalize to other settings. Factors to consider are the nature of the sample, the training and experience of the raters, and the test conditions. Issues regarding the sample are especially critical. In particular, reliability tends to be higher in samples with high variability, in which it is easier to discriminate among individuals. Thus, for continuous measures, reliability tends to be higher when the sample includes individuals with a wide range of scores. For categorical measures, reliability tends to be higher when the prevalence of the attribute being measured is fairly high. Reliability estimates also depend on the fraction of difficult cases (e.g., individuals near a diagnostic threshold or those resistant to being interviewed), since large numbers of these tend to diminish observed reliability.

Validity Validity refers to conformity with truth or a gold standard that can stand for truth. In the categorical context, it refers to whether an instrument can make correct classifications. In the continuous context, it refers to accuracy, or whether the score assigned represents the true state of nature. While reliability is empirical, validity is partly theoretical; many constructs measured in psychiatry have no absolute truth. Even so, some measures yield more useful and meaningful data than others. Validity assessment is generally divided into face and content validity, criterion validity, and construct validity.

FACE AND CONTENT VALIDITY *Face validity* refers to whether the items appear to assess the construct in question. Although a rating scale may purport to measure a construct of interest, a review of the items may reveal that it embodies a very different conceptualization of the construct. For instance, an “insight” scale may define insight in either psychoanalytic or neurological terms. However, items with a transparent relation to the construct may be a disadvantage when measuring socially undesirable traits such as substance abuse or malingering. *Content validity* is similar to face validity but describes whether the measure provides good balanced coverage of the construct and is less focused on whether the items give the appearance of validity. Content validity is often assessed with formal procedures such as expert consensus or factor analysis.

CRITERION VALIDITY *Criterion validity* (sometimes called predictive or concurrent validity) refers to whether or not the measure agrees with a gold standard or criterion of accuracy. Suitable gold standards include the long form of an established instrument for a new shorter version, a clinician-rated measure for a self-report form, and blood or urine tests for measures of drug use. For diagnostic interviews, the generally accepted gold standard is the longitudinal, expert, all data (LEAD) standard, which incorporates expert clinical evaluation, longitudinal data, medical records, family history, and any other sources of information.

When comparing continuous measures with a gold standard, a correlation coefficient is the statistic most often reported. For categorical variables such as diagnoses (or continuous measures with a cutpoint), sensitivity and specificity are the statistics of choice. *Sensitivity* refers to the test's ability to identify true cases, or its true positive rate. *Specificity* is the test's accuracy in identifying noncases, or one minus the false positive rate. In general, the more sensitive a test, the less specific it is. If the threshold for diagnosis, for example, is lowered, more cases are detected but at the expense of some false positives; if the threshold is raised to decrease the number of false positives, true cases are inevitably missed. The optimal threshold depends on the consequences of false positives and false negatives.

CONSTRUCT VALIDITY When an adequate gold standard is not available—a frequent state of affairs in psychiatry—or whenever additional validity data are desired, construct validity must be assessed. To accomplish this, one can compare the measure with *external validators*, attributes that bear a well-characterized relation to the construct under study but are not measured directly by the instrument. External validators used to validate psychiatric diagnostic criteria and the diagnostic instruments that aim to operationalize them include course of illness, family history, and treatment response. For example, when compared with schizophrenia measures, mania measures are expected to identify more individuals with a remitting course, a family history of major mood disorders, and a good response to lithium.

Two special cases of assessing validity using external validators have particular relevance for clinical psychiatry. One is *discriminant validity*, which examines a

measure's ability to discriminate between populations that are expected to differ on the construct of interest. For example, does a sociopathy measure correctly separate individuals in jails from those living in the community? Although such discriminations are important in clinical practice, the true test of a measure is its ability to discriminate at the margins. A study of discriminant validity is more clearly relevant if it includes the types of cases encountered in clinical practice (e.g., psychotic depression versus schizoaffective disorder) rather than more-easily discriminated populations (e.g., psychotic depression versus normal). Another special case is *sensitivity to change*; the fact that a measure shows expected changes (e.g., an improvement with an efficacious treatment or a decrement with a progressive disease) can be a strong validator.

When assessing validity in areas with few established measures and no gold standard or criterion of accuracy can be established, the assessment of the validity of the measure is limited by the validity of the construct itself. Nonetheless, by triangulating between a better definition of the construct, better ways to measure it, and better exploration of how it operates in clinical practice and research, the field moves to greater validity over time.

SELECTION OF PSYCHIATRIC RATING SCALES

The rating scales used in psychiatric practice and research presented below are grouped by topic, beginning with such general issues as diagnosis, functioning, symptom severity, and side effects and then proceeding to specific diagnostic groups, organized according to the section of DSM-IV. The selection was made on the basis of coverage of major areas and common use in clinical research, current (or potential) use in clinical practice, or both. A brief discussion of measurement issues for each area is followed by a description of each instrument, its psychometric properties, and its potential uses. Whenever possible, a brief, clinically useful instrument is provided in each area. References for each measure, organized by topic, are listed in Table 7.8-1. These references include more-detailed information about each measure and its psychometric properties and may also provide either the measure itself or instructions for obtaining a copy.

Table 7.8-1 Key References for Measures Included

Functional Status, Impairment, and General Symptom Severity The broad area of functional status, impairment, and general symptom severity cuts across a variety of diagnoses and is thus useful for grading patients by functional status or overall severity without reference to specific symptomatology. The instruments presented here have a strong mental health focus and often include items on psychiatric symptomatology. Instruments focused on more-global functioning or domains such as mobility and self-care are not generally included here.

Global Assessment of Functioning (GAF) Scale and Social and Occupational Functioning Scale (SOFAS) The GAF, shown in Table 7.8-2 was developed in the early 1990s to rate Axis V of DSM-IV and provides a measure of overall functioning related to psychiatric symptoms. The GAF is extremely similar to the Global Assessment Scale (GAS) used for the same purpose in the third edition of DSM (DSM-III) and the revised third edition (DSM-III-R), from which it was derived. A related instrument is the SOFAS, proposed as a new axis in Appendix B of DSM-IV, which focuses only on functioning and not on symptoms and does not try to discriminate between functional changes related to psychiatric and nonpsychiatric causes (Table 7.8-3). Both scales are clinician rated on a 100-point scale based on all available information, with clear descriptions of each 10-point interval. Ratings are generally made for the past week, but longer intervals (e.g., highest during the past year) can be used. Instructions for rating the GAF and SOFAS are included in DSM-IV; clinician raters do not require additional training to use these scales. The GAS has received more extensive evaluation and shows fair-to-good reliability and good validity judged against clinician ratings of the degree of impairment. GAF or GAS ratings are often required for billing purposes. In addition, the scales have been used to track change with treatment in inpatient and outpatient practice and in multiple research studies. The major criticism of the GAS and GAF is that they tend to confound symptoms and functioning, so that individuals with significant symptomatology (e.g., fixed delusional system) score low even when their social and occupational functioning is relatively spared.

Table 7.8-2 Global Assessment of Functioning (GAF) Scale

Table 7.8-3 Social and Occupational Functioning Assessment Scale (SOFAS)

Global Assessment of Relational Functioning The GARF (Table 7.8-4) was developed in the late 1980s to provide a measure of the quality of functioning in relationships analogous to the measure of individual functioning provided by the GAF or SOFAS. It was subsequently included in Appendix B of DSM-IV as an additional axis for further consideration. It provides a global rating on a 100-point scale based on a review of three major areas: problem-solving, organization, and emotional climate. Anchors are provided for each quintile of each domain. The GARF is focused on the particular needs of family and couple therapists but can be

rated by any clinician. Ratings are generally based on the present, but alternate periods (e.g., the past year, or in the period following a major stressor) can be implemented. The GARF has not been extensively evaluated, but preliminary evidence suggests that clinician and even nonclinician raters can achieve good to excellent reliability with only minimal training. The validity of the GARF is supported by expected correlations with other measures of family and couple distress and functioning. The GARF shows promise for rating relational functioning but only time will tell whether it will prove useful in clinical or research practice.

Table 7.8-4 Global Assessment of Relational Functioning (GARF)

Behavior and Symptom Identification Scale The BASIS-32 (Table 7.8-5) was developed in the early 1990s to provide a broad but brief overview of psychiatric symptoms and functional status from the patient's point of view for use in assessing the outcome of psychiatric treatment. The instrument assesses a wide range of areas, including family and work relationships; ability to complete regular tasks at home, work, or school; and symptoms of anxiety, depression, psychosis, and substance abuse. Each item is rated on a five-point scale focused on the degree of difficulty during the preceding week. BASIS-32 can be completed as a paper and pencil test (requiring 5 to 20 minutes) or the questions can be read aloud with the patient selecting the best answer from a laminated card (requiring 15 to 20 minutes). It can be scored readily by hand. A computerized scoring system is also available. BASIS-32 generates an overall score and five subscales: relation to self and others, daily living and role functioning, depression and anxiety, impulsive and addictive behavior, and psychosis. Good reliability and validity have been demonstrated. Its simple administration, brevity, and broad coverage make it well suited to its original task, and it is frequently used at baseline, during, and after treatment to monitor progress. It can provide valid ratings across a wide range of psychiatric impairment but is not generally suitable for individuals with substantial cognitive impairment. It is also not suitable for children under age 14.

Table 7.8-5 BASIS-32

Symptom Checklist-90 Revised (SCL-90-R) and Brief Symptom Inventory (BSI) The SCL-90-R was developed in the mid-1970s from the older Hopkins Symptom Checklist, a multidimensional measure of the severity of psychopathology. (*SCL-90* refers to a very similar earlier version but is frequently used to denote the current version as well.) The BSI was developed in the early 1980s as a short form of the SCL-90-R. Both cover the following domains: depression, anxiety, phobia, psychoticism, paranoia, obsessive-compulsive, hostility, somatization, and interpersonal sensitivity. Even the longer SCL-90-R fits on two sides of a single sheet of paper and can be completed in 20 minutes or less. The SCL-90-R is a self-report measure with 90 items Likert-scaled from 0 to 4 on the basis of the distress caused over the past week. The BSI is very similar, but has 53 items. Hand scoring is relatively simple, and computerized scoring is available. Both yield *t* scores based on extensive normative data for each subscale, a Global Severity Index, a Positive Symptom Distress Index, and a Positive Symptom Total. Reliability is fair to good, depending on the subscale, and most subscales appear reasonably valid when assessed against more specific measures (e.g., the depression scale against a HAM-D). The principal use of the SCL-90-R and BSI has been in characterizing psychopathology in treatment and other studies, but they have sometimes been used in primary care clinics as a screening tool for psychopathology. However, caution may be warranted in this setting because their sensitivity may be limited in some areas. In addition, the subscales bear only a modest relation to the corresponding DSM-IV disorders.

Side Effects The instruments described below are used to detect and quantify side effects from psychiatric medications, specifically motor effects of antipsychotics. Because of the focus on motor symptoms, these scales include a brief, focused physical examination as well as questions posed to the patient.

Abnormal Involuntary Movement Scale (AIMS) The AIMS (Table 7.8-6) is a clinical examination and rating scale that was developed in the 1970s to measure dyskinetic symptoms in patients taking antipsychotic drugs. The AIMS has 12 items, each of which is rated on an item-specific five-point severity scale ranging from 0 to 4. Total scores are not generally reported. Instead, changes in global severity and individual areas can be monitored over time. Ten items cover the movements themselves, divided into sections rating global severity and those related to specific body regions; two items concern dental factors that can complicate the diagnosis of dyskinesia. In the presence of extended neuroleptic exposure and the absence of other conditions causing dyskinesia, mild dyskinetic movements in two areas or moderate movements in one area suggest a diagnosis of tardive dyskinesia. The AIMS was developed for clinician raters, but lay raters can be trained to use it. It can be completed in under 10 minutes. Excellent reliability has been demonstrated, especially for experienced raters, and the instrument appears valid. In many clinical settings, the AIMS is considered standard clinical practice for patients receiving long-term neuroleptic drugs and is useful in clinical practice and research, both for monitoring patients for the development of tardive dyskinesia and for tracking changes in tardive dyskinesia over time.

Table 7.8-6 Abnormal Involuntary Movement Scale (AIMS) Examination Procedure

Simpson-Angus Rating Scale for Extrapyramidal Side Effects The Simpson-Angus scale was developed to monitor the effects of antipsychotic drugs. It has 10 items, each of which is rated on an item-specific, five-point severity scale ranging from 0 to 4. Scores are reported as the mean on all 10 items, with 0.3 considered the upper limit of normal. It is strongly focused on parkinsonian symptoms, particularly rigidity, but includes one akathisia item. It is designed for clinician use but can be administered by trained lay raters and takes about 10 minutes to administer. Good reliability has been reported, and validity is supported by the correlation of scores with antipsychotic drug dose. The scale is useful in a wide variety of clinical settings to monitor parkinsonian adverse effects and the impact of interventions to treat these effects.

Psychiatric Diagnosis Instruments assessing psychiatric diagnosis are central to psychiatric research and may have utility in clinical practice as well. However, they tend to be rather long, especially for individuals reporting many symptoms, who may require many follow-up questions. When evaluating such instruments, one must be sure that they implement current diagnostic criteria and cover the diagnostic areas of interest. For instance, few cover personality disorders (with the exception in some cases of antisocial personality), and not all cover disorders that typically begin in childhood.

Structured Clinical Interview for DSM-IV The SCID was developed in the early 1990s to provide a standardized DSM-III-R Axis I diagnosis based on an efficient but thorough clinical evaluation. It has since been updated for DSM-IV. The semistructured diagnostic interview begins with a section on demographic information and clinical background. Then there are seven diagnostic modules focused on different diagnostic groups: mood, psychotic, substance abuse, anxiety, somatoform, eating, and adjustment disorders. Both required and optional probes are provided, and skip-outs are suggested when no further questioning is warranted. All available information, including that from hospital records, informants, and patient observation, should be used to rate the SCID. The SCID is designed to be administered by experienced clinicians and is generally not recommended for use by lay interviewers. In addition, formal training in the SCID is required, and training books and videos are available to facilitate this. In individuals without symptoms, the interview takes approximately 1 hour, but it may take up to 3 hours in individuals with extensive symptomatology. Although the primary focus is research with psychiatric patients, a nonpatient version (with no reference to a chief complaint) and a more clinical version (without as much detailed subtyping) are also available. Reliability data on the SCID suggest that it performs better on more-severe disorders (e.g., bipolar I disorder, alcohol dependence) than on milder ones (e.g., dysthymia). Validity data are limited, as the SCID is more often used as the gold standard to judge other instruments. It is considered the standard interview to verify diagnosis in clinical trials and is extensively used in other forms of psychiatric research. It can also be used to ensure a systematic evaluation in psychiatric patients; for instance, on admission to an inpatient unit or at intake into an outpatient clinic. It is also used in forensic practice to ensure a formal and reproducible examination.

Diagnostic Interview Schedule (DIS) and Composite International Diagnostic Instrument (CIDI) The DIS and CIDI are fully structured diagnostic interviews designed for lay administration. The DIS was developed in the 1980s for use in the Epidemiologic Catchment Area (ECA) study in the United States, which aimed to assess rates of current and lifetime psychiatric illness according to DSM-III in a large and diverse community sample, and has since been updated for DSM-III-R and DSM-IV criteria. In 19 diagnostic modules, it covers a broad range of Axis I conditions in adults, plus several childhood disorders and antisocial personality. The most recent version also includes more information about symptoms, impairment, and treatment. The CIDI was developed from the DIS for international use and covers both ICD and DSM criteria in 11 diagnostic modules; the CIDI does not cover antisocial personality or childhood disorders. The instruments are fairly similar, and both involve verbatim reading of questions with little or no rewording allowed; only specified probes may be used for follow-up. The DIS takes 90 minutes to 2 hours; the CIDI may be somewhat shorter. Both can be scored by computer, yielding diagnoses and symptom profiles. A computerized, self-administered version of the CIDI is also available. The instruments are designed for use by lay interviewers with extensive training in their use: formal training is recommended. Reliability appears to be good for both, at least for more-severe disorders. Validity appears problematic for the DIS; studies of agreement with clinician diagnoses have yielded inconsistent results, with marked discrepancies often observed for psychotic disorders. The validity of the CIDI is still being evaluated. Both instruments have been used extensively in psychiatric research, particularly in epidemiological settings and provide valuable data. However, some caution is warranted in interpreting these data, given concerns about the instruments' validity.

Primary Care Evaluation of Mental Disorders (PRIME-MD) The PRIME-MD was developed in the mid-1990s to provide an efficient screening and evaluation tool for common mental disorders seen in the primary care setting. The instrument has two parts: a 25-item patient questionnaire that screens for a range of symptoms and a structured interview designed to follow up on any symptoms identified in the patient questionnaire or through other means. The interview has five modules covering mood, anxiety, alcohol, somatoform, and eating disorders. The patient questionnaire is very brief and can be completed in under 5 minutes. If follow-up is required, a primary care practitioner can complete the structured questionnaire in about 10 minutes. Training in the use of the instrument or careful review of the instruction manual is recommended. A self-report version of the structured interview is in development. Reliability appears to be fair to good, better for more severe diagnoses. Validity judged against psychiatrist evaluations is quite good. The screening instrument has appropriately high sensitivity, and the follow-up interview provides reasonable specificity. The PRIME-MD appears to be useful for primary care settings and may also be useful in psychiatric practice when a quick screen is desired. However, its utility for the latter purpose is limited by its lack of coverage of the more-severe psychopathology not typically seen in primary care (e.g., psychotic symptoms, mania).

Psychotic Disorders A variety of instruments are used for patients with psychotic disorders. Those reported here are symptom severity measures. A developing consensus suggests that distinguishing positive and negative symptoms in schizophrenia is worthwhile, and more-recently developed instruments implement this distinction. Because patients with psychotic disorders often lack insight and are sometimes agitated, patient observation is required in addition to direct questioning. Thus, most instruments in this domain must be administered by psychiatrists or others with clinical training.

Brief Psychiatric Rating Scale (BPRS) The BPRS (Table 7.8-7) was developed in the late 1960s as a short scale for measuring the severity of psychiatric symptomatology. Developed primarily to assess change in psychotic inpatients, it covers a broad range of areas including thought disturbance, emotional withdrawal and retardation, anxiety and depression, and hostility and suspiciousness. Its 18 items are rated on a seven-point item-specific Likert scale from 0 to 6, with the total score ranging from 0 to 108 (in some scoring systems, the lowest level for each item is 1, and the range is 18 to 126). Because the ratings include observations as well as patient reports of symptoms, the BPRS can be used to rate patients with very severe impairment. It is intended for use by experienced clinicians and can be administered in 30 minutes or less, including patient interview and observation. Reliability of the BPRS is good to excellent when raters are experienced but is more difficult to achieve without substantial training; anchored versions and a semistructured interview have been developed to increase reliability. Validity is also good as measured by correlations with other measures of symptom severity, especially those assessing schizophrenia symptomatology. The principal use of the BPRS is as an outcome measure in treatment studies of schizophrenia, and it functions well as a measure of change in this context. However, it has been largely supplanted in more-recent clinical trials by the newer measures described below. In addition, given its focus on psychosis and associated symptoms, it is only suitable for patients with fairly significant impairment. Its use in clinical practice is less well supported, in part because considerable training is required to achieve the necessary reliability.

Table 7.8-7 Brief Psychiatric Rating Scale

Positive and Negative Syndrome Scale (PANSS) The PANSS was developed in the late 1980s to remedy perceived deficits in the BPRS in the assessment of positive and negative schizophrenia and other psychotic disorders by adding additional items and providing careful anchors for each. The PANSS includes 30 items on three subscales: 7 items covering positive symptoms (e.g., hallucinations and delusions), 7 covering negative symptoms (e.g., blunted affect), and 16 covering general psychopathology (e.g., guilt, uncooperativeness). Each item is scored on a seven-point item-specific Likert scale ranging from 1 to 7; thus the positive and negative subscales each range from 7 to 49, and the general psychopathology scale from 16 to 112. The PANSS requires a clinician rater because considerable probing and clinical judgment are required. A semistructured interview guide is available. The ratings can be completed in 30 to 40 minutes. Reliability for each scale

is fairly high, with excellent internal consistency and interrater reliability. Validity also appears good based on correlation with other symptom severity measures and factor analytic validation of the subscales. The PANSS has become the standard tool for assessing clinical outcome in treatment studies of schizophrenia and other psychotic disorders and is sensitive to change with treatment. Its high reliability and good coverage of both positive and negative symptoms make it excellent for this purpose. It may also be useful for tracking severity in clinical practice, and its clear anchors make it easy to use in this setting.

Scale for the Assessment of Positive Symptoms (SAPS) and Scale for the Assessment of Negative Symptoms (SANS) The SAPS and SANS were designed to provide a detailed assessment of positive and negative symptoms of schizophrenia and may be used separately or in tandem. The domains assessed include hallucinations, delusions, bizarre behavior, and thought disorder for the SAPS and affective flattening, poverty of speech, apathy, anhedonia, and inattentiveness for the SANS. Each instrument consists of 30 fully anchored items each scored 0 to 5; thus the total score ranges from 0 to 150 for each. Each must be rated by an experienced clinician and requires approximately 30 minutes to complete. Good-to-excellent interrater reliability exists if trained interviewers are used, and each scale has high internal consistency as well. Validity is supported by correlation with other symptom severity instruments. The SAPS and SANS are principally used to monitor treatment effects in clinical research and have also been used to help characterize positive and negative symptoms in studies of schizophrenia phenomenology. The comprehensive characterization of symptomatology provided might also be useful in clinical practice, but there is little experience in this area at the present time.

Mood Disorders The domain of mood disorders includes both depressive and bipolar disorders. The issues for mania are similar to those for psychotic disorders, in that limited insight and agitation may hinder accurate symptom reporting, so clinician ratings including observational data are generally required. Rating depression, on the other hand, depends substantially on subjective assessment of mood states, so interviews and self-report instruments are both common. Because depression is common in the general population and involves significant morbidity and even mortality, screening instruments, especially those using a self-report format, are potentially quite useful in primary care and community settings.

Hamilton Rating Scale for Depression (HAM-D) The HAM-D was developed in the early 1960s to monitor the severity of major depression, with a focus on somatic symptomatology. The version in most common use has 17 items, although versions with different numbers of items, including the 24-item version (Table 7.8-8), have been used in many studies as well. Most versions do not include some of the symptoms used to diagnose depression in DSM-III and its successors, most notably increased sleep and increased appetite. Items on the HAM-D are scored 0 to 2 or 0 to 4, with total scores on the 17-item version ranging from 0 to 50: scores of 7 or less may be considered normal; 8 to 13, mild; 14 to 18, moderate; 19 to 22, severe; and 23 and above very severe. The HAM-D was designed for clinician raters but has been used by trained lay administrators as well. Ratings are completed by the examiner on the basis of patient interview and observations. A structured interview guide has been developed to improve reliability. The ratings can be completed in 15 to 20 minutes. Reliability is good to excellent, including internal consistency and interrater assessments. Validity appears good based on correlation with other depression symptom measures. The HAM-D has been used extensively to evaluate change in response to pharmacological and other interventions. It is more problematic in elderly and medically ill persons, in whom somatic symptoms may not indicate major depression.

Table 7.8-8 Hamilton Rating Scale for Depression

Beck Depression Inventory (BDI) The BDI was developed in the early 1960s to rate depression severity, with a focus on behavioral and cognitive dimensions of depression. The current version, the Beck Depression Inventory–II (Beck-II), has added more coverage of somatic symptoms to be compatible with DSM-IV and covers the most recent 2 weeks. Earlier versions focus on the past week or even shorter intervals, which may be preferable for monitoring treatment response. The BDI includes 21 self-report items, each of which has four statements describing increasing levels of severity; the total score ranges from 0 to 84. Scores of 0 to 9 are considered minimal; 10 to 16, mild; 17 to 29, moderate; and 30 to 63, severe. The scale can be completed in 5 to 10 minutes. Internal consistency has been high in numerous studies. Test-retest reliability is not consistently high, but this may reflect changes in underlying symptoms. Validity is supported by correlation with other depression measures. The principal use of the BDI is as an outcome measure in clinical trials of interventions for major depression, including psychotherapeutic interventions. Because it is a self-report instrument, it is sometimes used to screen for major depression, for instance in medical outpatients. Various cutoffs have been suggested for a diagnosis of major depression, but even a cutoff of 9 has only fair sensitivity, at a cost of considerable nonspecificity, suggesting that the instrument has limited use for screening. The instrument's strength lies in measuring the depth of depression; it is not suitable for making a diagnosis.

Zung Self-Rating Depression Scale The Zung scale was developed in the 1960s to provide a self-report measure of major depression with broad coverage of depression symptomatology. It has 20 items, each of which is scored from 1 to 4, based on the fraction of time in which it occurs. Half of the items are scored positively, and half negatively; positive items must be reversed to obtain a total severity score, which is then converted by formula to a scaled score. Scaled scores under 50 are considered normal; 50 to 59, minimal depression; 60 to 69, moderate depression; and over 70, severe depression. Most individuals can complete the Zung scale in 5 to 10 minutes. The Zung scale has been in use for many years but has not been extensively evaluated. However, reliability is good based on split-half and internal consistency studies. Validity also appears good based on correlations with other depression measures and the ability to discriminate between depressed and nondepressed outpatients. The Zung scale has been used to follow depressed patients in treatment studies; however, there is less variation in Zung scale scores than some other measures, which limits its utility as a change measure. It has also been used to screen for depression in medical outpatients or community interventions, including National Depression Screening Day, in which a threshold score of 50 was used to identify potential cases of depression requiring follow-up by a clinician.

Young Mania Rating Scale (YMRS) The YMRS is a checklist developed in the late 1970s to provide a brief but thorough evaluation of the severity of mania that could be used to monitor treatment response or detect relapse. It consists of a checklist of 11 items rated either 0 to 4 (seven items) or 0 to 8 (four items). Each item has five item-specific anchors. The total score ranges from 0 to 60. Ratings include clinical observation, so it must be rated by a clinician, but reliable ratings have been obtained by nurses on inpatient units and beginning psychiatric residents. Reliability is good, based on interrater reliability and internal consistency studies. Validity also appears good, based on correlation with other mania measures. The YMRS is useful for evaluating response to treatment in clinical research, and it is sensitive to change in this setting. It might also be used to assess treatment response or monitor for relapse in treated or untreated patients, although extensive experience with this use has not been reported.

Anxiety Disorders The anxiety disorders addressed by the measures below include panic disorder, generalized anxiety disorder, and obsessive-compulsive disorder. When examining anxiety measures, one must be aware that their definitions have changed significantly over time. Both panic and obsessive-compulsive disorder are relatively recently recognized, and the conceptualization of generalized anxiety disorder has shifted over time. Thus, older measures have somewhat less relevance for diagnostic purposes, although they may identify symptoms causing considerable distress. Whether reported during an interview or on a self-report rating scale, virtually all measures in this domain, like the measures of depression discussed above, depend on subjective descriptions of inner states.

Hamilton Rating Scale for Anxiety The HAM-A (Table 7.8-9) was developed in the late 1950s to assess anxiety symptoms, both somatic and cognitive. Because conceptualization of anxiety has changed considerably, the HAM-A provides limited coverage of “worry” required for DSM-IV diagnosis of generalized anxiety disorder and does not include the episodic anxiety found in panic disorder. There are 14 items, each of which is rated 0 to 4 on an unanchored severity scale, with the total score ranging from 0 to 56. A score of 14 has been suggested as the threshold for clinically significant anxiety, but scores of 5 or less are typical in individuals in the community. The scale is designed to be administered by a clinician, and formal training or the use of a structured interview guide is required to achieve high reliability. A computer-administered version is also available. Reliability is fairly good, based on internal consistency, interrater, and test-retest studies. However, given the lack of specific anchors, reliability should not be assumed to be high across different users in the absence of formal training. Validity appears good, based on correlation

with other anxiety scales, but is limited by the coverage of domains critical to the modern understanding of anxiety disorders. Even so, the HAM-A has been used extensively to monitor treatment response in studies of generalized anxiety disorder and may also be useful for this purpose in clinical settings.

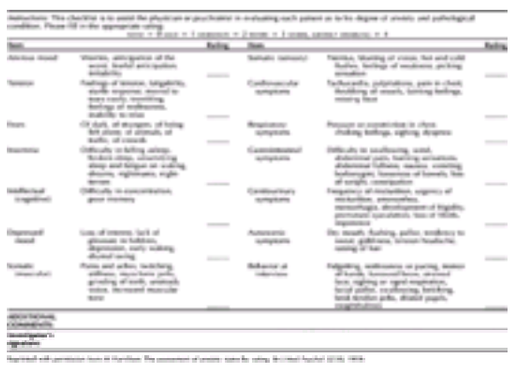

Table 7.8-9 Hamilton Rating Scale for Anxiety

Panic Disorder Severity Scale (PDSS) The PDSS is a recently developed, brief rating scale aimed at measuring the severity of panic disorder. It was based on the Yale-Brown Obsessive Compulsive Scale (YBOCS) and has seven items, each of which is rated on an item-specific five-point Likert scale. The seven items address frequency of attacks, distress associated with attacks, anticipatory anxiety, phobic avoidance, and impairment. The items are scored 0 to 4, and the total score ranges from 0 to 28. The instrument was designed for use by clinicians, but a patient-scored computerized version is in development. Reliability is excellent, based on interrater studies, but, in keeping with the small number of items and multiple dimensions, internal consistency is limited. Validity is supported by correlations with other anxiety measures, both at the total and item level, and lack of correlation with the HAM-D. Because the PDSS has been available for a fairly short period of time, there is limited experience with its use. However, it appears to be sensitive to change with treatment and is thus likely to prove useful as a change measure in clinical trials or other outcome studies for panic disorder, as well as for monitoring panic disorder in clinical practice.

Yale-Brown Obsessive Compulsive Scale (YBOCS) The YBOCS (Table 7.8-10) was developed in the late 1980s to measure the severity of symptoms in obsessive-compulsive disorder. It has 10 items rated on the basis of a semistructured interview. The first five items concern obsessions: the amount of time they consume, the degree to which they interfere with normal functioning, the distress they cause, the patient's attempts to resist them, and the patient's ability to control them. The remaining five items ask parallel questions about compulsions. Each item has a set of item-specific anchors scored 0 to 4, so total scores for obsessions and compulsions each range from 0 to 20, and overall total score ranges from 0 to 40. Typical scores for patients with obsessive-compulsive disorder are in the 16 to 30 range, and a threshold of 16 is typically used for inclusion in drug trials. The semistructured interview and ratings can be completed in 15 minutes or less. A self-administered version has recently been developed and can be completed in 10 to 15 minutes. Computerized and telephone use also provide acceptable ratings. Prior to the first use of the YBOCS, an associated 64-item checklist is administered to provide a more detailed assessment of the specific content of the patient's obsessions and delusions. Reliability studies of the YBOCS show good internal consistency, interrater reliability, and test-retest reliability over a 1-week interval. Validity appears good, although data are fairly limited in this developing field. The YBOCS has become the standard instrument for assessing obsessive-compulsive disorder severity and is used in virtually every drug trial. It may also be used clinically to monitor treatment response.

Table 7.8-10 Yale-Brown Obsessive-Compulsive Scale

Substance Use Disorders Substance use disorders include both abuse and dependence on both alcohol and drugs. These disorders, particularly those involving alcohol, are common and debilitating in the general population, so screening instruments are particularly helpful. Because these behaviors are socially undesirable, underreporting of symptoms is a significant problem. Validation against drug tests or other measures is of great value, particularly when working with patients who have known substance abuse.

CAGE The CAGE was developed in the mid-1970s to serve as a very brief screen for significant alcohol problems in a variety of settings, which could then be followed up by clinical inquiry. CAGE is an acronym for the four questions that make up the instrument: (1) Have you ever felt you should *c*ut down on your drinking?; (2) Have people *a*nnoyed you by criticizing your drinking?; (3) Have you ever felt bad or *g*uilty about your drinking?; (4) Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (*e*ye-opener)? Each "yes" answer is scored as 1, and these are summed to generate a total score. Scores of 1 or more warrant follow-up, and scores of 2 or more strongly suggest significant alcohol problems. The instrument can be administered in a minute or less either orally or on paper. Reliability has not been formally assessed. Validity has been assessed against a clinical diagnosis of alcohol abuse or dependence, and these four questions perform surprisingly well. Using a threshold score of 1, the CAGE achieves excellent sensitivity and fair to good specificity. A threshold of 2 provides still greater specificity, but at the cost of a fall in sensitivity. The CAGE performs well as an extremely brief screening instrument for use in primary care or in psychiatric practice focused on problems unrelated to alcohol. However, it has limited ability to pick up early indicators of problem drinking that might be the focus of preventive efforts.

Alcohol Use Disorders Identification Test (AUDIT) The AUDIT (Table 7.8-11) was developed by the World Health Organization in the late 1980s as a brief screening instrument designed for the early detection of hazardous (i.e., involving the risk of harm) and harmful (i.e., involving the presence of harm) alcohol use in a variety of settings. It focuses on both the past year and current drinking. It includes a 10-item core screening instrument covering alcohol consumption, drinking behaviors, and alcohol-related problems. Each item is rated using item-specific anchors scored 0 to 4 and summed for a total score of 0 to 40. The AUDIT can be administered and scored in less than 5 minutes and does not require professional training. The AUDIT also offers a Clinical Screening Procedure involving a physical examination and blood tests, which adds no more than 5 to 10 minutes to a routine medical examination. Reliability of the AUDIT appears good, based on internal consistency data. Validity judged against a clinical diagnosis of alcoholism is also good; using a threshold score of 8 is quite sensitive but somewhat nonspecific. A score of 10 is more specific but at a cost in specificity. Validity also appears good, based on correlation with other alcohol self-report measures and risk factors for alcoholism. The AUDIT provides an excellent brief screen for alcohol problems and is particularly good for detecting problem drinking at a fairly mild stage. However, its focus on early detection of hazardous and harmful drinking makes it less suited for use as a diagnostic instrument.

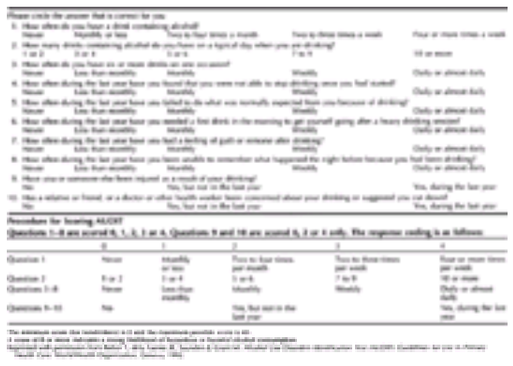

Table 7.8-11 AUDIT

Drug Abuse Screening Test (DAST) The DAST was developed in the early 1980s to serve as a screening and assessment instrument for drug abuse. The DAST is an adaptation of the Michigan Alcohol Screening Test (MAST), used to screen for alcoholism. It focuses on lifetime drug use, so it is not designed to measure changes over time. The current version of the DAST has 20 items, all of which are answered “yes” or “no,” and can be given orally or as a paper and pencil questionnaire. An earlier version had 28 items, so the 20-item version is sometimes called the Brief DAST. The positive items can be summed to form a 20-point scale. The DAST can be administered and scored in less than 10 minutes. Reliability is very good, based on internal consistency. Validity based on ability to detect drug abuse disorder also appears high, with excellent sensitivity and fairly good specificity using a threshold score of 5. The DAST is useful as a screening device for drug abuse problems in patients with other mental disorders, particularly alcohol abuse. It also provides an overview of problem severity that may be useful in guiding treatment choices.

Addiction Severity Index (ASI) The ASI was developed in the early 1980s to serve as a quantitative measure of symptoms and functional impairment caused by alcohol or drug disorders. It covers demographics, alcohol use, drug use, psychiatric status, medical status, employment, legal status, and family and social issues. Frequency, duration, and severity are assessed. It has 142 items in varying formats including yes-no, multiple choice, and scaled items. They include both subjective and objective items reported by the patient and observations made by the interviewer. In each area, the ASI yields the rater's global assessment of severity along with a computer score on a 0 to 1 scale. The 142-item version includes information on the past 30 days and lifetime status, but a shorter version is available for use at follow-up. The instrument is designed for clinician administration but has been used successfully by trained lay raters. Training is recommended, and both manuals and formal training programs are available. A computerized version is also available. The standard ASI requires 45 to 75 minutes to complete, but the follow-up version can be completed in 15 to 20 minutes. Very good to excellent reliability has been demonstrated for the overall composite score, with somewhat lower reliability for severity ratings in each area. Validity has also been demonstrated, based on correlation with other measures and discrimination of patient and nonpatient populations. Normative data are available for a range of populations of alcohol and drug abusers, including alcohol clinic patients, drug abusers, homeless persons, and prisoners. The principal use of the ASI is as an aid to treatment planning and the assessment of treatment outcome in clinical and law enforcement settings. It is relatively time consuming to administer but performs well for this purpose. It is also used in clinical research as a sensitive indicator of baseline severity and change over time, which allows comparison between clinical research and clinical practice.

Eating Disorders Eating disorders include anorexia nervosa, bulimia nervosa, and binge-eating disorder, which is included in Appendix B of DSM-IV and is gaining acceptance among eating-disorders clinicians and researchers. A wide variety of instruments, particularly self-report scales, are available. Because of the secrecy that may surround dieting, bingeing, purging, and other symptoms, validation against other indicators (e.g., body weight for anorexia, dental examination for bulimia) may be very helpful. Such validation is particularly critical for patients with anorexia, who may lack insight into their difficulties.

Eating Disorders Inventory (EDI) The EDI was developed in the early 1980s to provide a multidimensional self-report assessment of eating disorder symptomatology and related psychological attributes. The current version of the EDI, the EDI-2, has 91 items in 11 subscales: Drive for Thinness, Bulimia, Body Dissatisfaction, Ineffectiveness, Perfectionism, Interpersonal Distrust, Interoceptive Awareness, Maturity Fears, Asceticism, Impulsive Regulation, and Social Insecurity. Each item is rated on a six-point frequency-based Likert scale. The two ratings at the symptomatic end of the scale are scored 2; the middle two, scored 1; and the last two, scored 0; then the items in each subscale are added to generate a subscale score. Instrumentwide total scores may also be obtained but are not considered meaningful. Norms for each subscale are available for a variety of eating-disordered and nonclinical populations. The EDI can be completed in less than 20 minutes. Easy-reading and childhood versions are available. A computerized version is also available. Reliability data indicate very good internal consistency and test-retest reliability for virtually all EDI subscales. Validity of the EDI subscales is supported by correlation with related eating disorder measures and discrimination between patient and nonpatient samples. The EDI subscales also correlate moderately with ratings of these domains by trained clinicians. The EDI has several uses that apply in both clinical and research practice. Its principal use is in providing a range of data that may help in treatment planning. For instance, body dissatisfaction is an important predictor of prognosis and treatment response in bulimia nervosa. Some of the subscales, particularly the Bulimia scale, have also been shown to be sensitive to change with treatment and thus may be used to monitor patients over time. The EDI has also been used for screening purposes in primary care or other settings to identify individuals at high risk for eating disorders. The Drive for Thinness, Bulimia, and Body Dissatisfaction scales are probably the most useful in this regard. For instance, scores of 14 or above on the Drive for Thinness scale suggest an increased risk for anorexia nervosa and warrant further evaluation.

Bulimia Test-Revised (BULIT-R) The BULIT-R was developed in the mid-1980s to provide a categorical and continuous assessment of bulimia nervosa. The current version, while designed for DSM-III-R criteria, has been validated for DSM-IV as well. The BULIT-R has 36 self-report items, each scored on an item-specific five-point Likert scale. Of these items, 8 provide descriptive information, and the remaining 28 are summed to provide the total score, which ranges from 28 to 140. Young women with bulimia nervosa typically score above 110, while young women without disordered eating typically score below 60. The instrument can be completed in about 10 minutes. The BULIT-R shows high reliability, based on studies of internal consistency and test-retest reliability in multiple studies. Validity is supported by high correlations with other bulimia assessments. The recommended cutoff of 104 suggested to identify probable cases of bulimia shows high sensitivity and specificity for a clinical diagnosis of bulimia nervosa. Using cutoffs between 98 and 104, the BULIT-R has been used successfully to screen for bulimia nervosa. As with any screening procedure, follow-up by clinical examination is indicated for individuals scoring positive; clinical follow-up is particularly critical because the BULIT-R does not distinguish clearly between different types of eating disorders. The BULIT-R may also be useful to track symptoms over time or in response to treatment, in both clinical and research practice, although more detailed measures of the frequency and severity of bingeing and purging may be preferable in research settings.

Cognitive Disorders Dementia is becoming an increasing focus of psychiatric practice. A wide variety of measures are available. Most involve cognitive testing and provide objective, quantifiable data. However, scores vary by educational level in subjects without dementia, so these instruments tend to be most useful when the patient's baseline score is known. Other measures focus on functional status, which can be assessed on the basis of a comparison with a description of the subject's baseline function; these types of measures generally require a knowledgeable informant and may thus be more cumbersome to administer, but they tend to be less subject to educational biases.

Mini-Mental State Examination The MMSE (Table 7.8-12) is a 30-point cognitive test developed in the mid-1970s to provide a bedside assessment of a broad array of cognitive functions including orientation, attention, memory, construction, and language. It can be administered in under 10 minutes by a busy doctor or a technician and scored rapidly by hand. The MMSE has been extensively studied and shows excellent reliability. Validity appears good, based on correlations with a wide variety of more comprehensive measures of mental functioning and clinicopathological correlations. One common use of the MMSE is in screening for dementia, in both office practice and epidemiological or clinical research. For this purpose, a cutoff of 24 for identifying cases of dementia has been suggested, but it is probably more accurate to use age- and education-adjusted norms to interpret the results. For patients with extensive education, who may score 30 out of 30 despite clear evidence of functional decline, a more difficult cognitive test, full neuropsychological battery, or clinical interview may be required to detect dementia. The other principal use of the MMSE is in following the progression of dementia over time. As a rule of thumb, mild dementia ranges from a score of 20 to 24, moderate from 11 to 19, and severe from 0 to 10. However, these figures do not take the educational differences noted above into account. In addition, the MMSE does not do as well tracking progression of dementia in the lower ranges, as many patients become untestable.

Table 7.8-12 Mini-Mental State Examination

Blessed Information Memory Concentration Test (IMC) The IMC, sometimes called the Blessed IMC after its developer, was developed in the late 1960s for studies of the relationship between dementia severity and neuropathological changes. The original version of the scale, developed in Britain, had 29 items, the current American version has 26. Areas assessed include information (date, time, place, name, age, remote personal information, dates of the world wars, name of governmental leaders), memory (a name and address for 5-minute recall), and concentration (counting forward and backward from 1 to 20). A six-item version, sometimes called the short form of the Blessed or the Orientation Memory Concentration (OMC) test, is also available: it asks only the time of day, month, year, the 5-minute recall of the address, and counting backward from 20 and is highly predictive of total IMC score. IMC scores on individual items are weighted; on the 26-item IMC they range from 0 (no errors) to 33 and on the six-item version, scores range from 0 to 28. The IMC can be administered in person or over the phone by a trained clinician or lay rater. Based on internal consistency and test-retest studies in demented subjects over a 1- to 6-week interval, reliability of the 26-item and 6-item IMC both appear very good. Validity also appears good, based on clinicopathological correlations and correlations with other dementia severity measures. Studies of changes with time in patients with Alzheimer's disease show an average annual increase of 3 to 4 points on the 26-item version and 2.5 points on the 6-item version. The principal use of the IMC is assessing dementia severity over time, either through the natural course of the disease or in response to treatment interventions. The IMC is also sometimes used as a screening instrument in clinical practice or community research studies. A cutoff score of 10 has been recommended for the 6-item version, but no standard cutoff is recommended for the 26-item version. In any case, very limited population data exist, and norms are not available by age or education, which are very likely to affect test results. Because of its focus on memory items, the IMC may perform better as a severity or screening measure in patients with Alzheimer's disease than in those with other dementing illnesses.

Global Deterioration Scale (GDS), Brief Cognitive Rating Scale (BCRS), and Functional Assessment and Staging Tool (FAST) The GDS, BCRS, and FAST are a group of measures designed to provide ordinal staging of cognitive and functional status in patients with dementia, particularly those with Alzheimer's disease. The three instruments use a consistent seven-point scale. The GDS is a simple rating scale that describes seven stages from normal aging to severe dementia: (1) normal, (2) subjective complaints only, (3) subtle deficits with little or no functional decline except in very demanding tasks (e.g., managerial tasks at work, or preparing an elaborate social event like a holiday meal), (4) definitive deficits that interfere with complex activities of daily living (ADLs) (e.g., balancing a checkbook), (5) deficits that interfere with independent living in the community, (6) deficits that interfere with basic ADLs (e.g., dressing, toileting), and (7) profound deficits leading to the need for continuous assistance. The BCRS focuses on cognitive issues and describes the same seven levels in five different domains referred to as axes: (I) concentration, (II) recent memory, (III) remote memory, (IV) orientation, and (V) self-care. The FAST focuses on functional status, again in seven stages, but it adds substages within stages 6 and 7. All three scales should be completed by an individual with clinical experience (physician, psychologist, nurse, or trained technician) after a review of all available information from the patient, informants, and medical records. The FAST can generally be completed in as little as 10 to 15 minutes, but the GDS and especially the BCRS may require 30 to 45 minutes. Reliability of these scales is excellent, based on interrater and test-retest studies. Validity of all three measures is supported by correlations with other cognitive and functional status scales. GDS and BCRS stages have also been validated against neuropathological data. FAST stages correspond closely to typical progression in Alzheimer's disease. The GDS, BCRS, and FAST are useful in staging dementia, especially Alzheimer's disease, which is much more likely to follow the described ordinal stages closely. Such staging may be used to provide a concise description for patients referred to other clinicians or settings or to track changes over time or in response to treatment. The FAST is especially useful in staging severe dementia and has been used extensively to assess the need for services. The GDS and BCRS are both sensitive to change, with average declines of approximately 0.5 GDS or BCRS subscale points per year in Alzheimer's disease patients.

Personality Disorders and Personality Traits Personality may be conceptualized categorically as personality disorders or dimensionally as personality traits, which may be viewed as normal or pathological. The focus here is on personality disorders, and the traits are generally viewed as their milder forms. DSM-IV defines 10 personality disorders in three clusters, and an additional two disorders (passive-aggressive and depressive personality) are proposed in Appendix B for further study. Patients tend not to fall neatly into DSM-IV personality categories; instead, most patients who meet criteria for one personality disorder also meet criteria for one or more others, particularly within the same cluster. This and other limitations in the validity of the constructs themselves makes it difficult to achieve validity in personality measures. Personality measures include both interviews and self-report instruments. Self-report measures are appealing in that they require less time and may appear less threatening to the patient. However, they tend to overdiagnose personality disorders. Because many of the symptoms suggesting personality problems are socially undesirable, and because patients' insight tends to be limited, clinician-administered instruments, which allow for probing and patient observation, may provide more accurate data.

Structured Clinical Interview for DSM-IV Axis-II Personality Disorders (SCID-II) The SCID-II is the counterpart of the SCID for making DSM diagnoses of personality disorders. The initial version was developed for DSM-III-R in the mid-1990s, and the current version makes diagnoses according to DSM-IV. The SCID-II is organized by disorder and includes all 10 DSM-IV personality disorders plus the two proposed in Appendix B. A 119-item self-report screening questionnaire is generally given first to eliminate sections not needing further exploration: each of the items corresponds to a specific criterion for a DSM-IV personality disorder. The SCID-II proper includes one or two yes-no items for each criterion, with each affirmative answer to be followed-up by examples from the person's life. Based on these answers each criterion is scored 1 for false, 2 for subthreshold, and 3 for present, allowing criteria scores to be summed for a dimensional measure of each disorder or combined following the DSM-IV diagnostic rules for a categorical approach. The screening questionnaire can be completed by the patient in about 20 minutes; the interview generally requires about an hour. The SCID-II must be administered by doctoral-level clinicians, and training in the SCID-II is also required. A computerized administration and scoring program is available. Reliability is good for the presence or absence of any disorder but only fair for specific personality disorders; the reliability of dimensional assessment is somewhat better. Validity is somewhat harder to determine, as agreement with clinician assessment tends to be modest, but given its comprehensiveness and strict adherence to DSM-IV criteria, the SCID-II may actually be more valid. The SCID-II is most useful to provide a standardized, comprehensive assessment of personality disorders, whether in research, forensic, or clinical settings.

Personality Disorder Questionnaire (PDQ) The PDQ was developed in the late 1980s as a self-report questionnaire designed to provide categorical and dimensional assessment of DSM-III-R personality disorders and was subsequently revised for DSM-IV. An alternate version includes the two disorders in Appendix B as well. Another alternate version allows for ratings within the last few weeks and is designed to serve as a change measure. The current PDQ, the PDQ-IV, includes 85 yes-no items, designed primarily to assess the diagnostic criteria for DSM-IV personality disorders. Within the 85 items are embedded two validity scales to identify underreporting, lying, or inattention. There is also a brief clinician-administered Clinical Significance Scale to address the impact of any personality disorder identified by the self-report PDQ. The PDQ can provide categorical diagnoses with a scaled score for each or an overall index of personality disturbance based on the sum of all the diagnostic criteria. Overall scores range from 0 to 79; patients with personality disorders generally score above 30, psychotherapy outpatients without such disorders tend to score in the 20-to-30 range, and normal controls tend to score below 20. The PDQ can be completed in under 30 minutes. Computerized administration and scoring are available. Reliability is fair to good for dimensional assessment and quite variable for categorical assessment, with good reliability for obsessive-compulsive and antisocial personality, and inadequate reliability for many disorders. Validity judged against semistructured clinician-administered interviews is also variable. The PDQ, like other self-report instruments, tends to overdiagnose personality disorders, with many false positives and few false negatives. Its brevity, excellent sensitivity, and poor specificity make it most useful as a screening device, with a follow-up semistructured interview for patients screening positive.

Childhood Disorders A wide variety of instruments is available to assess mental disorders in children. Despite a rich array of instruments, the evaluation of children remains difficult for several reasons. First, the child psychiatric nosology is at an earlier stage of development, and construct validity is often problematic. Multiple changes in diagnostic criteria from DSM-III to DSM-III-R to DSM-IV complicate the choice of measures. Second, because children change markedly with age, it is virtually impossible to design a measure that covers children of all ages. Finally, because children, particularly young children, have limited ability to report their symptoms, other informants are necessary. This often creates problems because child, parent, and teacher reports of symptoms frequently disagree, and the optimal

way to combine information is unclear.

Child Behavior Checklist (CBCL) The CBCL is a family of self-rated instruments that survey a broad range of difficulties encountered in children from preschool age through adolescence. One version of the CBCL, designed for completion by parents of children aged 4 to 18, is shown in Table 7.8-13. Another version is available for parents of children ages 2 to 3. The Youth Self Report is completed by children ages 11 to 18, and the Teacher Report Form is completed by teachers regarding school age children. The scale includes not only problem behaviors, but academic and social strengths as well. Each version includes approximately 100 items scored on a 3-point Likert scale. Scoring can be done by hand or computer, and normative data are available for each of the three subscales: problem behaviors, academic functioning, and adaptive behaviors. A computerized version is also available. The CBCL does not generate diagnoses, but instead suggests cutoff scores for problems in the "clinical range." Parent, teacher, and child versions each show high reliability on the problem subscale, but the three informants frequently do not agree with one another. The CBCL may be useful in clinical settings as an adjunct to clinical evaluation: they provide a good overall view of symptomatology and may also be used to track change over time. They are used frequently for similar purposes in research involving children and thus can be compared with clinical experience. The instrument does not, however, provide diagnostic information, and its length limits its efficiency for tracking purposes.

Table 7.8-13 Child Behavior Checklist for Ages 4–18

Diagnostic Interview Schedule for Children (DISC) The DISC was originally developed in the early 1990s as a fully structured diagnostic interview for making DSM-III diagnoses in children. It has since been revised for DSM-III-R and DSM-IV. The current DISC, the DISC-IV, covers a broad range of DSM-IV diagnoses, both current and lifetime. It has nearly 3000 questions but is structured with a series of stem questions that serve as gateways to each diagnostic area, with the remainder of each section skipped if the subject answers "no." Subjects who enter each section have very few skips, so both symptom scales and diagnostic information can be obtained. Child, parent, and teacher versions are available. Computer programs are available to implement diagnostic criteria, to generate severity scales based on each version, or to combine parent and child information. A typical DISC interview may take more than an hour for a child, plus an additional hour for a parent, but because of the stem question structure, the actual time varies widely with the number of symptoms endorsed. The DISC was designed for lay interviewers. It is fairly complicated to administer, and formal training programs are highly recommended. Reliability of the DISC is only fair to good and generally is better for the combined child and parent interview. Validity judged against a clinical interview by a child psychiatrist is also fair to good, better for some diagnoses and better for the combined interview. The DISC is well tolerated by parents and children and can be used to supplement a clinical interview to ensure comprehensive diagnostic coverage. Because of its inflexibility, some clinicians find it uncomfortable to use, and its length makes it less than optimal for use in clinical practice. However, it is used frequently in a variety of research settings.

Children's Depression Inventory (CDI) The CDI is a 27-item self-report measure of mood symptoms in children aged 7 to 17. A 10-item screening version is also available. The instrument may be administered as a simple pen-and-pencil test using a special easily scored form or by computer. The CDI has a first-grade reading level, so even young children can generally complete it on their own. Good reliability has been demonstrated, and good validity is suggested by its ability to distinguish currently depressed children from those with partially remitted depression or with other psychiatric disorders, along with its correlation with other measures of childhood depression. The principal uses of the CDI are in screening for depression in psychiatric patients or epidemiological surveys: it works fairly well for this purpose but tends to miss a substantial fraction of cases because children are not always good reporters. The other use is as a change measure in office practice or clinical trials. It appears to have adequate sensitivity to change for this purpose but has not been subjected to extensive evaluation.

Conners Rating Scales The Conners Rating Scales are a family of instruments designed to measure a range of childhood and adolescent psychopathology, but are most commonly used in the assessment of attention-deficit/hyperactivity disorder. There are teacher, parent, and self-report (for adolescents) versions and both short (as few as 10 items) and long (as many as 80 items, with multiple subscales) forms. Extensive normative data drawn from an ethnically diverse population are available for each sex across a broad age range. Even the longer forms can be completed in 15 to 20 minutes, and scoring can be accomplished rapidly. Rater training is not required. Reliability data are excellent for the Conners Rating Scales. However, teacher and parent versions tend to show poor agreement. Validity data suggest that the Conners Rating Scales are excellent at discriminating attention-deficit/hyperactivity disorder patients and normal controls. It has more difficulty separating attention-deficit/hyperactivity disorder from other disruptive behavioral disorders such as conduct disorder, but this may substantially relate to the genuine clinical difficulties separating these syndromes. Newer versions of the Conners have been developed that aim to improve these discriminations, but they have not yet been subjected to extensive testing. The principal uses of the Conners Rating Scales are in screening for attention-deficit/hyperactivity disorder in school or clinic populations and following changes in symptom severity over time; sensitivity to change in response to specific therapies has been demonstrated for most versions of the Conners.

SUGGESTED CROSS-REFERENCES

Section 5.2 discusses statistics and experimental design. 7.9 COMPUTER-BASED TESTING OF THE PSYCHIATRIC PATIENT

MARVIN J. MILLER, M.D.

Twenty-five years of advances in personal computers and software have begun to affect how patients are evaluated and treated and how information about them is stored. Few clinicians have managed to avoid the impact of computers entirely.

New tools will be widely used only if they are tested, validated, confirmed, and publicized throughout the professional community. Computer applications have slowly gone through this process and have gained acceptability. Insurance and managed-care companies lead the way in implementing computers for accounting, monitoring, and practice-shaping tools. Hospitals generally introduce computers through the business office and bring them no further into the health care process.

A few computer applications, however, have gained rapid acceptance and use. The Internet is a worldwide communication network of cables, software, and computers that has rapidly gained popularity in psychiatric education, communication, and program distribution. The Internet is a decentralized tool and thus amenable to rapid growth unfettered by rigid rules and constraints. Considerable caution is therefore required on the part of the clinician because there is little regulation or supervision. Individual clinicians browsing the Internet can explore applications and Web sites of value and can benefit from them immediately if they are of demonstrated quality.

Computers equipped with appropriate cameras and software can transmit video and audio over telephone lines at low cost. This opens rich opportunities for the mental health clinician to consult with colleagues, receive education, and evaluate and treat patients. It also raises many new questions of reimbursement, supervision, licensure, and efficacy. However, the power of the technology is setting the pace and more than fifteen states have some telemedicine projects in place.

Some computerized evaluation tasks (quantitative electroencephalogram (EEG) and magnetic resonance imaging) are readily accepted as computerized tools because they would be impossible or impractical without the computational power of computers. Other tasks such as computer-based testing of patients have experienced slow but gradual acceptance. Computer education, therapy, or both of patients has proceeded even more slowly. The area of mental health computing with the most untapped potential is the computerized evaluation of patients.

COMPUTER-BASED TESTING

In the past 30 years of computerized testing in the mental health field there has been a steady increase in the quality and quantity of test instruments available and a steady decrease in the costs of these tests. The earliest computerized interviews were done at the University of Wisconsin on a LINC computer provided by the National Institute of Mental Health. The initial computerized interviews gathered a medical history that was then printed out for the physician to use. The interview was branching and would select a maximum of 320 questions out of a library of more than 500 questions in the program.

Progress in the development of computerized testing remained very slow until the arrival of the microcomputer in 1980 changed the rate of development. Individual clinicians could more easily justify the cost of the equipment and could dedicate it to a task of computer testing. The hardware capabilities available expanded rapidly to include color graphics, photos, sound, and even physiological modalities.

Early attempts at computerizing psychiatric tests involved slavish attempts to mimic the traditional tests exactly. One early investigator devised a computerized version of an intelligence test on a PDP-8 computer with a concrete replication of the original formats. When different sections of the tests were presented, drawers would open and close to present the proper test material to a patient. The same investigator also developed one of the earliest computerized therapy programs; a group of patients eager to lose weight were treated with either a computerized program, a peer group, or a control group—all lost significant amounts of weight at an equal rate.

Dimensions of Computerized Testing The gradual realization of the many advantages of computer-based testing prompted the gradual move toward computerized testing of the psychiatric patient. Answers can be gathered from the patient more quickly and more accurately by the computer. One question presented on the screen at a time helps the patient to focus and answer that question more quickly than if presented on paper. Accuracy is enhanced because there is less chance that the patient will record answers incorrectly and there is less chance that the psychometrist will record or key punch the answers incorrectly. Computer-based testing also is less threatening and encourages patients to reveal sensitive material more readily. The computer summarizes the responses to the questions more quickly and more accurately than humans do.

Interpretation of the raw data is still a difficult task. Various studies show that a combination of computerized summary and human interpretation provides the most reliable and most comprehensive evaluation of the test results. Neither the human nor the computer can do as well individually as the two combined. However, acceptance of computerized testing remains mixed. Various evaluations show that patient acceptance (even among seriously ill patients) is higher than clinician acceptance.

Some clinicians reject computer-based testing entirely. Others accept the testing results in an uncritical way, as if the computer were infallible. Proper use of computer-based testing avoids both these extremes; the use of these tests is recommended only after careful development and assessment of test results in conjunction with other tests in the battery and other clinical information gathered in more traditional ways.

Early Developments John Greist was an early pioneer in computerized testing in mental health. He developed an early program to assess suicidality that showed that patients will reveal sensitive information about suicidal impulses to the computer. The computer program could predict the probability of a suicide gesture as well as clinicians could. His group went on to develop a variety of computerized tests for diagnostic purposes and symptom assessment in a variety of areas. The first psychological test to be widely computerized was the Minnesota Multiphasic Personality Inventory (MMPI). The volume of test questions and the large number of experimental scales dictated the use of the computer as a time-saving measure for test administration and test scoring.

Ethical and Professional Concerns Computer-based testing is only one component of a professional evaluation of mental illness. The mental health professional must be the main source of quality assurance during the evaluation and needs to integrate the computer-based testing with all the other aspects of the evaluation. Psychiatrists and other professionals are bound by strict guidelines about initial specialty training, certification in the specialty, continuing medical education, and general ethical conduct. The highly trained professional signing the evaluation of a patient assumes the ultimate responsibility for the content and quality of an evaluation.

Persons constructing a computerized test need to be concerned about various aspects of reliability and validity. They need to ensure that the test will produce similar results at various points in time. Use of the computer can often enhance standardization of a test because the conditions under which the test is administered can be more precisely regulated.

The validity of a test also needs to be addressed by the test designer or developer. Tests need to demonstrate content validity by proving that adequate aspects of the topic in question are sampled. Computerized tests also need to show criterion-related validity. A test to measure attention-deficit/hyperactivity disorder should show a high correlation with an expert clinician making the same diagnosis; computer-based testing should also show predictive validity if possible. The computer evaluation of attention-deficit/hyperactivity disorder should show change and correlation with medication used to treat the disorder. The computer-based testing should also demonstrate construct validity by showing that a carefully defined theoretical construct is measured and described.

For some tests the issue of reliability can be addressed by comparing the paper-and-pencil form of the test with the computerized version; these comparisons

generally show a very high correlation. Some tests, however, are designed specifically for the computer and measure things that cannot be easily measured without a computer. Testing for reliability and validity becomes more complex for these tests.

The results of reliability and validity studies should be published in the professional literature and should be reviewed by clinicians attempting to use a specific test in their practice. Some tests enjoy wide popularity among the public and among some clinicians despite the lack of evidence in the literature of concurrent or predictive validity. Careful clinicians will ask for a bibliography regarding a test before purchasing and using that test.

Taking clinical action on a set of numbers or phrases derived from computerized testing is similar to getting numbers back from a clinical laboratory report of a blood test. The clinician must first have a measure of confidence in the clinical laboratory or the person developing the computerized test. The individual numbers, however, mean nothing unless they are evaluated within the context of the total patient condition and are integrated with other complementary or contradictory findings. The clinician's skill in using computer-based testing is the most central part of the overall ability to evaluate a patient.

Does Computerized Testing Work? Patient acceptance of computerized testing has been very rapid and clinician acceptance is gradually increasing. Studies that have compared old (usually paper-and-pencil) versions of tests with computer-based tests have generally shown very good equivalence. However, when a group of 188 psychiatric patients were given a standard verbal digit span test as well as a computerized (visual) version of the verbal digit span the patients performed more poorly on the computerized test. The State Trait Anxiety Inventory and the Beck Depression Inventory (BDI) were administered in paper-and-pencil and computerized formats. The study also evaluated the amount of computer anxiety or computer phobia present among the students and found that those with greater computer anxiety also had high BDI scores. The study was not designed to find out why the depression scores were higher or whether they more accurately revealed the amount of a depression present in the subject. A study of alcohol consumption seemed to show that patients were more willing to divulge sensitive information about alcohol consumption to the computer than they were to the human interviewer.

There are also valid questions concerning the tendency of computerized test subjects to respond in socially desirable ways. One study of 162 college students tested with the MMPI, the Research Evaluation Form, and the Drinking Habits Questionnaire supported the hypothesis that subjects reveal less damaging information to a human interviewer. Another study used the Paulhus Balanced Inventory of Desirable Responding (BIDR) on a group of 241 university students. The subscale evaluating responses in the socially desirable direction was higher in the computer-tested group as compared with the group administered this test by paper and pencil. However, a more refined version of the socially desirable subtest revealed no significant differences between computer and paper-and-pencil administration. Students who took these tests anonymously reported more pathology than they did in the nonanonymous situation.

Using a later version of the BIDR test in an effort to replicate these results in a sample of 246 naval recruits revealed similar effects for anonymity but different effects for method of administration, which supports the idea that the initial version of the social desirability scale contains some confounding factors that did not properly evaluate the question of truthful responding.

Deliberate Faking An evaluation of 100 college students taking a test by computer compared with 100 students taking the same test by paper and pencil revealed that 10 percent of the former group gave random responses and 4 percent of the latter group gave random responses. However, the random responders could be identified in both groups by inclusion of a scale that consisted of statements that could not possibly be true. Response latency also identifies faking. *Latency* is the number of milliseconds required to answer each question and the shortest response latencies are noted in random responding; this is followed by faking good responses, followed by honest responses, followed by faking bad patterns. There is a suggestion, however, that latency scores regarding questions evaluating medical problems are not as predictable.

Another effort evaluated malingering. The addition of response latency as a measure of malingering increased the correct classification of malingerers by 30 percent as compared with traditional methods of detection. An extensive evaluation of patient acceptance in computerized testing situations revealed very good acceptance. The three main dimensions of this study compared traditional testing versus keyboard testing versus touch screen testing. Three hundred and sixty-seven psychiatric patients were tested on a variable number of eight computerized tests available. The standardized test was preferred in one case and the computerized test was preferred in another. In one other test the standard approach was preferred over the keyboard approach but was no different from the touch screen approach in terms of patient preference. There were, however, frequent differences between the touch screen approach—four tests were more easily or enjoyably performed on the touch screen as compared with the keyboard and only in one situation was the keyboard preferable to the touch screen to a significant degree. The researchers concluded that computerized testing was widely accepted.

Cost Impact of Computerized Testing Potential cost savings exist in many aspects of computerized testing but surprisingly little has been done to document this. Administration of a test by a microcomputer, if amortized over the life of the computer, will probably be less than $1 per hour. This compares very favorably with what it costs when a psychometrist or a psychologist administers the same test. Test scoring by computer saves additional time and money. The computerized printout of test scores takes less time than the human typing of test results would require. Test royalties, if applicable, would be the same in both cases.

Clinicians who have computerized testing readily available tend to perform more tests and to do a broader evaluation of the patient. This does have implications for quality of care. Computerized testing can be summarized and available for the clinician to view much earlier than testing done by conventional means. In some hospital settings this can make a difference of 1 day of hospital care. More thorough assessment and more focused treatment also has the potential to reduce the length of stay for a patient or to reduce the number of outpatient visits, which can reduce total health care costs. More studies need to be done to show the potential savings. It is estimated that more than 500 computerized tests are now available for use within the mental health field.

Tests for Children and Adolescents A community center offering crisis and counseling services for children and adolescents can administer a screening battery to help with evaluation. Self-administered tests can evaluate family structure, family satisfaction, and drug use. This system can help to summarize the initial evaluation, provide a storage medium for problem lists, maintain notes of treatment sessions, and keep records for billing purposes. Diagnosing and monitoring attention-deficit disorders in children and adolescents is a very important task. Many different investigators have computerized this task and it does seem sensitive to treatment with methylphenidate (Ritalin). Some have started programs to measure these disorder via a microcomputer or on dedicated equipment.

The computerized continuance performance test has been significantly correlated with teacher ratings of school performance, subtests of the Wechsler Intelligence Scale for Children-Revised that relate to attention, and some scales from the Conner Parent and Teacher Rating Scales.

Parents of children with problems fill out the computerized version of the Child Behavior Checklist and report preferring it to the paper-and-pencil version. Respondents further displayed this preference by providing significantly more information about their child's difficulties on the computerized version.

An evaluation of the paper-and-pencil versus the computer-administered version of the Piers Harris Children's Self Concept Scale revealed no significant differences between the means of the scales derived from each version. The scale summarizing behavioral problems did show significantly more variance on the paper-and-pencil test as compared with the computerized version.

Personality Tests The Minnesota Multiphasic Personality Inventory (MMPI) are the most widely used assessments of personality and have good equivalence between the computer version and the traditional version. One study compared 80 community volunteers under one of four testing conditions: computer-computer, traditional-traditional, computer-traditional, or traditional-computer. These four sequences revealed no significant differences on any of the traditional scales and on 27 special scales. Another study used 150 college students to compare computer versus traditional administration of the MMPI. This study revealed more differences in the time of testing variable as compared with the format of testing. An evaluation of computer versus traditional testing of the MMPI in a group of 77 substance abusers also found no significant differences between formats.

The computerized version versus the paper-and-pencil version of another popular test of personality, the Personality Research Form-E, was compared and showed good test-retest stability. Surprisingly, the infrequency scale (used to detect careless responding) was the only scale that did not show good levels of reliability. The sample population of 55 subjects was quite small and probably not sufficient to warrant discarding the Infrequency scale as has been suggested.

The Jenkins Activity Survey helps to detect the type-A personality style associated with specific physiological responses to stress. Computerized and paper-and-pencil versions were compared in a group of 60 college students. There were no significant differences in the two forms when comparing method of administration or time (first or second) of testing. Reaction time for each question was also measured and was found to be significantly associated with the Speed and Impatience Scale on the second testing but not on the initial testing.

Obsessive-Compulsive Disorder Computerized tests assess the severity of symptoms of obsessive-compulsive disorder very well. The Yale-Brown Obsessive Compulsive Scale (Y-BOCS) evaluates the presence and severity of symptoms of this disorder and was computerized with high reliability results. The total Y-BOCS score correlated at $r = .88$ between the clinician-administered and the computer-administered forms and the subscales correlations were almost as high. Preference of the patient regarding form of testing was evenly split between the computer and the clinician versions. A version of the Y-BOCS has also been designed for administration by touch-tone telephone hooked up to a talking computer. This method was compared with a live telephone interview and a paper-and-pencil version. The agreement among the three methods was very high ($r = 0.99$) but more of the patients (44 percent) preferred the live interview and none preferred the talking computer.

Depression The most widely used self-rating scale for depression is the BDI. This was computerized and administered to 330 inpatients. There was no paper-and-pencil comparison group but total scores and coefficient alpha were very similar to other published studies of the BDI. The scores on the BDI also correlated strongly with the clinical diagnosis of depression. The most frequently used depression rating for use by clinicians is the Hamilton Rating Scale for Depression (HAM-D). A self-administered version of the Hamilton scale that was developed for computer administration required 37 questions to cover the original 17 items. The mean difference in total score for the total sample was only 0.1 (17.29 for the clinical version and 17.19 for the computerized version). The correlation with the BDI was $r = 0.925$. Using a cutoff score of 17, the clinician-administered version showed a specificity of 100 percent and a sensitivity of 100 percent in identifying patients with major depressive disorder whereas the computer version showed a specificity of 100 percent and a sensitivity of 94 percent.

Anxiety The Hamilton Rating Scale for Anxiety (HAM-A) has been one of the instruments most frequently used to evaluate anxiety, which is among the most frequent of the mental disorders in the United States. The HAM-A contains 14 items designed to be administered by a trained clinician. The computerized version of the HAM-A designed for self-administration contains 31 questions and was tested in a group of 292 adults including persons diagnosed as having a generalized anxiety disorder, panic disorder with or without agoraphobia, social phobia or obsessive-compulsive disorder, major depressive disorder, and community controls with no current diagnosis. The computer and the clinician versions of this test were administered in a counterbalanced form 1 week apart. The scores in the patients with anxiety disorder correlated very highly between the computer and clinician versions (coefficient alpha $r = .92$). The computer and the clinician versions of the test in a group of anxiety disorder patients were different at a significance of $P < .05$. This, however, translated to a difference of about one point in the total scale score, which may not translate to a clinically meaningful difference. On each occasion the scores on the computer were slightly higher than the scores of the clinician rater.

Neuropsychology and Psychophysiology One large category of computer programs exploits the unique abilities of the microcomputer to administer tests consistently and in a very carefully timed pattern. Neuropsychological tests are very expensive to administer, score, and interpret. The digit span test, used to evaluate attention and memory, is simple enough so that the computerized version is fairly straightforward. The digit substitution test is a more complex evaluation of logic in addition to memory and can help to evaluate the effects of research medications on cognition.

Patients with schizophrenia who were tested on a computerized version of the Tower of London test showed a slow and inefficient pattern of problem solving. The patients were slower in moving the pieces of the puzzle and required more moves to solve a particular problem. Schizophrenia patients also tend to do poorly in a specially modified version of the continuous performance test. These patients show a greater drop in performance over a 10-minute task than do normal controls.

The evaluation of memory is an important part of the psychiatric evaluation. Recently, a comparison of eight different implementations of a memory test was conducted. The Halstead category test is a test that measures abstracting ability and is very sensitive to various kinds of brain damage. The test has been successfully computerized with good replication of the traditional testing method. The Cognitive Neuromotor Testing Battery includes five different tasks designed to measure speed of processing, vigilance, memory, and visuomotor skills. This test was originally designed to measure skills needed to drive but it was also found to be sensitive to the adverse effects of medications such as those accompanying treatment with benzodiazepines. The test was found to have a good correlation with an existing neuropsychological test.

Investigators have also noted the sensitivity of computerized testing in detecting neurobehavioral toxicology and a series of computerized tests are available for this purpose and are reviewed in the literature.

Psychiatric Diagnosis The Diagnostic Interview Schedule is a diagnostic instrument used by psychiatrists and lay interviewers in several large epidemiological studies. Its reliability as a valid diagnostic tool is established and several investigators have computerized this tool. The reliability of these computerized tests has generally been modest—the kappa values for the Levitan study ranged from .17 to .92 with a mean of .46. These values show the need to regard the computerized diagnostic instrument as suitable for screening only; they also point out the need for correlation of computer testing with the remainder of the clinical evaluation.

Anorexia Nervosa A self-administered test for anorexia nervosa was computerized and is correlated highly with the standard paper-and-pencil version according to a recent sample of 47 subjects.

Posttraumatic Stress Disorder Approximately 15 to 20 percent of war veterans report this disorder; civilians who experience a severely traumatic event are also at high risk. A semi-structured clinical interview was computerized for more efficient administration; the computerized version includes 34 questions and takes about 15 minutes to administer. The kappa for diagnosis of the disorder was .90 with a sensitivity of .95 and a specificity of .95, indicating excellent validity.

Alcoholism Because treatment costs for alcohol and substance abuse problems have surpassed treatment costs for all the other mental illnesses since the mid-1980s, careful and efficient detection of these disorders of abuse is extremely important. Computerized screening and follow-up instruments have shown good validity and reliability. The self-administered Alcoholism Screening Test is a 35-item test in its long form and a 9-item test in its short form and it has demonstrated validity. The computerized version showed excellent correlation with the paper-and-pencil version. The differences in regard to format and order of administration were both nonsignificant. Agreement between the two forms was 95 percent. A follow-up instrument, the Substance Use Disorder Diagnostic Schedule, showed a similarly high agreement with the interviewer-administered format. k values were .86 for presence or absence of alcohol abuse and .86 for presence or absence of other drug abuse. These two computerized tests reported mild but nonsignificant increases in the amount of alcohol consumption as compared with reports from the interviewer-administered forms.

Vocational Testing This testing can advance the process of making a career choice by identifying particular interests and aptitudes. The array of interests can then be compared to the responses of persons in particular fields and can help to achieve a compatible career choice. Computerized batteries have been developed to test an individual's aptitudes and interests and each of these tests has shown increased efficiency and reliability in the testing process.

Behavioral Assessment Careful evaluation of potential reinforcers for a behavior therapy program conducted in a computerized evaluation was found to save time in identifying the optimal set of behavior reinforcers.

Adaptive Testing Adaptive testing consists of a computerized method for selecting the optimal questions to be presented to a patient. These consist of branching patterns that depend on a screening question to decide the particular branches taken for a particular patient. The advantages of this method are that it saves the patient testing time and energy. Application of this method to lengthy tests such as the MMPI show substantial correlation with the full administration of the MMPI. Shortening the testing time is a dubious achievement because the computer-administered testing is extremely inexpensive. Development and validation of subscales of the MMPI or other tests is also hindered when only a subset of the test is administered to any particular patient, making it very difficult to develop norms. Questions that serve to screen patients and determine the choice of branches are sometimes too brief and too superficial to make a sensitive determination of the branching, which reduces the overall validity of the test; it is therefore wise to be cautious when using adaptive testing methods.

Legal Aspects of Computerized Testing Computerized testing is similar to any other kind of psychological evaluation in the legal arena. The expert clinician on the witness stand is the one who is under scrutiny and must use these evaluation tools within the proper context and must have information about their development and validity. The expert must then consolidate all the available structured and clinical evaluation in order to form an opinion with “reasonable certainty.” Because the computerized testing can be subjected to measures of validity and reliability, the expert witness must be prepared to document knowledge of the development of a test. The clinical opinion of an expert witness is also subject to cross-examination and will almost certainly have less documented evidence of accuracy or validity.

Computer-Based Test Interpretation Simple computerized scoring of test results is rapid, precise, and efficient. Computer scoring of tests such as the MMPI-2 with its many research scales is almost a necessity and is well accepted.

Computer-based test interpretation of the test results is much more controversial. Validation of computer-based test interpretation has lagged behind the validation of

the test in question. Many computer-based test interpretation systems had attempted to generate interpretive statements for the MMPI-2. These statements were generally compared with statements by expert clinicians who looked at their own interpretation of the MMPI-2 but these were rarely compared with direct clinical observation of patients for cross-validation. Some interpretive systems make public the decision rules or the mathematical formulas that govern the generation of specific statements appearing on the interpretive summary. Other systems, however, keep the decision-making process secret and thus the clinician has no specific basis on which to judge the legitimacy of the derived interpretation, which makes it very difficult to use interpretive statements in court when the basis of those interpretations has not been revealed. Users of computer-based test interpretation products deserve to know the research underlying interpretive statements.

Legitimate arguments exist about the optimal mathematical approaches to use in modeling the process of psychiatric diagnosis. The cookbook approach used in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* is easy to understand conceptually but is too simplistic to reflect accurately how human beings actually make diagnostic decisions and act on them. Some computerized systems use the logical decision tree, the Bayesian model, cluster analysis, multiple discriminate functions, or even neural networks. In fact, different clinicians may use different models successfully. Some clinicians are able to define the models they use whereas others cannot reduce these models to specific algorithms, which helps to explain why the field of computer-based test interpretation continues to evolve and must be approached cautiously.

FUTURE DIRECTIONS

The rapid proliferation of the Internet has attracted the attention of those interested in public education and in the assessment of psychiatric illnesses. Several Internet sites now offer the public a chance to answer a select group of questions on a particular illness and receive feedback about the presence or absence of the illness in themselves. Referral sources are offered so that the individual can follow up on the situation. A recent World Wide Web search using the words “test” and “mental” found three Web sites (among the first 30 listed) offering online testing. One additional site offered a free test for depression that could be downloaded and used. Clinicians can also obtain tools to construct their own computerized questionnaires. This, along with the availability of numerous commercial testing programs, allows clinicians to use computerized testing of psychiatric patients in more extensive and comprehensive ways than ever before.

SUGGESTED CROSS-REFERENCES

Statistics and experimental design are covered in Section 5.2. Psychiatric rating scales are discussed in Section 7.8. The psychiatric report and medical record is covered in Section 7.2.

CHAPTER 8. CLINICAL MANIFESTATIONS OF PSYCHIATRIC DISORDERS

JOEL YAGER, M.D., AND MICHAEL J. GITLIN, M.D.

Like other medical disorders, psychiatric disorders express themselves in characteristic ways. Deviations from normal, from mild to severe, may occur in the intensity, duration, timing, and content of thoughts, emotions, and behaviors. Inquiring about subjective complaints and clinical symptoms and observing and eliciting the clinical signs of psychiatric disorders parallels taking a history and conducting a physical examination in general medicine. Many psychiatric complaints and disorders have to be understood in a broad context, requiring a more thorough evaluation and comprehension of the patient's interpersonal world, work role, family life, and culture than is typical in general medical practice. The nature and expression of psychiatric signs and symptoms are profoundly altered by the patient's strengths, coping capacities, and psychological defenses, so that the clinical picture ultimately represents a balance between psychopathology and psychological strengths.

The most important distinction between typical presentations of medical diseases and those of psychiatric disorders is the greater importance in psychiatric disorders of the patients' sometimes idiosyncratic descriptions of their qualitative internal states, subjective experiences that are often difficult to describe in words. Poets and novelists are often more capable than clinicians at characterizing and delineating the precise quality and experience of many psychiatric symptoms. Many patients and clinicians often find it difficult to accurately communicate a fully comprehensible and reliable description of even familiar, somewhat universal feeling states.

> An usually articulate woman, a published writer, tried to relate the differences she felt between the fatigue she associated with her disabling Lyme disease and the fatigue she experienced during a previous bout of atypical depression. Although unusually gifted in her capacity to form images in words, she found that her capacity to express exactly what she meant was not up to the task. She remained frustrated, knowing that she had not been able to adequately describe or convey the subtle but real distinctions in how she had experienced these two states.

Subjective descriptions of psychiatric symptoms are inherently less reliable, or at least less objective, than more directly measurable and quantifiable data such as blood pressure, temperature, and laboratory test results. A great deal of the research in psychiatric diagnosis over the last 25 years has been concerned with increasing the reliability of observer-rated clinical symptom assessments. In many ways this research has had the desired impact—clinicians and researchers using a variety of structured interviews can come to reasonable agreement on what symptoms patients are experiencing and whether these patients meet the criteria for most of the specific psychiatric disorders in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). However, one of the costs of this increasing reliability has, in many instances, been the narrowing of the field of clinical vision. Clinicians who rely predominantly on structured interviews and checklists may become somewhat closed-minded and risk ignoring clinical phenomena that are very important, but that may not be part of the structured interview framework or mental set. Furthermore, the quest for reliability can go only so far in describing phenomena that are difficult to express in words.

Despite these difficulties, a thorough assessment of the clinical history and description of the psychopathology and a detailed account of the patient's subjective experiences are important because:

1. Significant diagnostic distinctions are made primarily on the basis of the historical information and elicited phenomenology. The more detailed, complete, and correct the diagnosis, the more rational and precise the treatment planning and the more reliable the prognosis. Consider, for example, the importance of accurately distinguishing between antipsychotic-induced akathisia and anxiety symptoms related to psychotic thinking. On the basis of the diagnosis made, opposite therapeutic strategies may be attempted.
2. The clinician's capacity to fully hear and communicate a comprehensive understanding of a patient's internal experiences helps to diminish the patient's sense of isolation, so characteristic of many of these disorders, and fosters the growth of a therapeutic alliance, increasing the likelihood of compliance with treatment.

PREDISPOSING VULNERABILITIES

Genetic and Intrauterine Factors Genetic vulnerabilities play an important role in the expression of many psychiatric disorders. Prominent among these are dementia of the Alzheimer's type, schizophrenia, mood disorders, anxiety disorders, and alcohol dependence. For virtually all these disorders, the nature of the inherited vulnerabilities is still largely unknown.

Intrauterine processes contribute to many psychiatric disorders. For example, maternal starvation and influenza infections during the second trimester of pregnancy have been implicated in the pathogenesis of schizophrenia. Maternal smoking and low birth weight may be risk factors in the pathogenesis of attention-deficit disorders in children. Maternal alcohol abuse or dependence may lead to the fetal alcohol syndrome, a major cause of developmental disability.

Constitutional Factors Considerable research demonstrates that by birth and shortly afterward infants differ widely in temperament—in their spontaneous activity levels and thresholds, intensity, and duration of their reactions to external stimuli; the regularity or irregularity of certain biological rhythms such as sleep; tendencies to approach or withdraw from new stimuli; the speed and degree of adaptation; attention span and distractibility; the persistence of behavior; and qualities of mood. Based on such early behaviors, children may be described as having easy or difficult temperaments, as being quick or slow to warm up. Temperament, however, is not immutable. There are discontinuities over time, and the development of temperament and its lasting impact on personality development is at least in part a function of the goodness of fit with a child's family. Nevertheless, these temperamental qualities correlate somewhat with behavioral problems, especially through early childhood.

Aside from temperament, other persistent normal variations in personality development seem to be constitutionally related, and may influence subsequent resilience or vulnerability. Traits such as introversion, extroversion, and neuroticism appear to be relatively enduring and stable personality dimensions. Other temperamental qualities that endure include tenacity, novelty-seeking, and being relatively open to new experiences. Subtypes of intelligence, such as those related to conceptual, mathematical, musical, kinesthetic, and interpersonal abilities have been postulated as having separate genetic determinants and patterns of development. The type A and B personality patterns, hardy and resilient personalities, highly strung, sensitive, fussy, irritable, and pessimistic characteristics have all been described as generally lifelong qualities that originate in early childhood.

Physiological Stressors Physiological vulnerability may result from long-standing problems or from newly acquired ones. All the metabolic, toxic, infectious, and other causes of physical illness produce increased vulnerability to psychiatric disturbance. Studies have shown higher utilization of psychiatric services by those who are physically ill, and higher than expected prevalence of physical disease among the psychiatrically impaired.

Some children with prepubertal onset, obsessive-compulsive disorder and tic disorders that have an episodic symptom course have been found to have pediatric autoimmune neuropsychiatric disorders associated with streptococcal (group A b-hemolytic streptococcal) infections (PANDAS). Accompanying symptoms during episodes of exacerbation are emotional lability, separation anxiety, nightime fears and bedtime rituals, cognitive deficits, oppositional behaviors, and motoric hyperactivity. In PANDAS patients flareups of behavioral problems are commonly associated with documented group A b-hemolytic streptococcal infections or symptoms of pharyngitis and upper respiratory infections.

Human immunodeficiency virus (HIV) infection leading to seropositivity and acquired immune deficiency syndrome (AIDS) vividly illustrates the multiple and complex ways in which stressors can lead to psychiatric disturbances. These patients' psychiatric symptoms may represent organic changes that are the direct effects of the

virus on the central nervous system (CNS), producing changes in cognition, personality, and mood; understandable psychological adjustment responses of patients in response to an overwhelming life-threatening disorder; or the emergence of latent or quiescent primary psychiatric problems provoked by the psychological stress of the viral illness.

A 55-year-old successful businessman with a strong family history for unipolar depression started to feel mentally sluggish, and developed depressed mood, psychomotor retardation, and ruminative self-doubts. A medical work-up revealed high serum calcium that led to a diagnosis of hyperparathyroidism, which was ultimately treated surgically. Once the parathyroid problem was corrected, the mood disorder disappeared without further treatment.

Environmental Stressors Complex relationships exist between various life events, particularly threatening, unpredictable, and uncontrollable negative events, and the development of psychiatric symptoms. In general, such undesirable life events predispose individuals to develop psychiatric symptoms, especially if they already have a preexisting psychiatric disorder. After exposure to the same negative stressors such as a serious accident or act of violence, individuals who previously had anxiety disorders are more prone than those without such histories to subsequently develop symptoms of posttraumatic stress disorder. Although individual responses vary widely, truly catastrophic events, such as incarceration in a concentration camp, cause enduring psychiatric disturbances in a high percentage of survivors whether or not they had prior psychiatric problems. Similarly, the stress-related consequences of combat also vary widely, so that some veterans exposed to combat develop long-lasting posttraumatic stress disorder whereas others develop very few persistent symptoms. The death of a parent or spouse, divorce, and major physical injury affect some people profoundly and others hardly at all in the long run. Significant stressors are likely to be more traumatic during early development rather than later, or at certain critical developmental periods compared to other times. For example, the loss of a parent at a very young age is likely to be more traumatic and have more profound and lasting effects than the loss of a parent as an adult.

The combined impact of negative life events and poor emotional and practical social supports is important in the pathogenesis of at least some psychiatric disturbances. One British study found that women who were depressed were much more likely to have lost a parent at an early age, to be relatively housebound with three or more young children, and to lack a good confiding relationship with a spouse or other confidant. In that study biological vulnerability to depression seemed less important than the accumulation of negative life circumstances in the development of the disorder. People who are usually competent in all role functions may fall apart completely when a supportive spouse who has bolstered them and taken care of many of their needs dies suddenly. Patients presenting with a major depressive episode have experienced more uncontrollable actual and threatened losses such as the death of a spouse in the year prior to onset. Nevertheless, not all psychiatric disturbance is attributable to easily identified provoking negative life events; indeed, some major negative life events that seem to have preceded the onset of a serious psychiatric disturbance may in fact have occurred only after the psychiatric disturbance actually began. For example, someone who attributes the onset of depression to having been fired from a job several months previously may already have been functioning suboptimally and may have been fired as a consequence of a depression-induced decline in role function.

Certain environmental features can counter the effects of environmental stressors and protect against breakdowns. Stable families and friends, good financial circumstances, and supportive churches and communities offer some protection. Research has shown that individuals with psychiatric disturbances have fewer social supports than normal controls. This may be caused by friends' and relatives' withdrawal from deviant behaviors or by the disturbed individual's withdrawal from deleterious family and social relationships. In contrast, physically ill persons have more social supports than others, perhaps reflecting their ability to recruit help in times of need. The quality as well as the quantity of social supports is important too. As has been demonstrated in schizophrenia and mood disorders, for example, even in close families negative relationships may have deleterious effects in initiating and in sustaining psychiatric disturbance.

The negative impact of a physiological or environmental stressor is closely related to its personal meaning to the individual in question. For example, the loss of a spouse who has been chronically demented, disabled, and burdensome will have a very different impact than the loss of vital, supportive, loving spouse.

CHARACTERISTICS OF PSYCHIATRIC SIGNS AND SYMPTOMS

Signs and symptoms form the two major categories of clinical phenomena. Classically, as for most medical disorders, the distinction between the two is clear. *Symptoms* are subjectively experienced disturbances that are not necessarily observable by others. Patients complain of symptoms—for example, chest pain, headache, and tingling sensations. *Signs* are abnormalities that are observable by an examiner, including those that are easily evident in the course of a routine encounter with the patient as well as those elicited only through specific physical, mental status, or laboratory examinations.

In psychiatry the line between symptoms and signs is often more blurred than in general medicine. For instance, many phenomena often considered to be symptoms of psychiatric disorders may not be experienced as psychiatric problems by patients. Hearing an angel's voice may represent a manifestation of a psychotic disorder, yet the patient may vigorously dispute that the experience is a psychopathological symptom. Additionally, auditory hallucinations are often considered to be signs of a psychotic disorder even though, by their very nature, they are subjective internal experiences (symptoms). Further complicating the distinction, some psychiatric phenomena, such as the classical psychological defense mechanisms, may only be inferred from speech and behaviors but are not directly observable.

Signs and symptoms are said to be present when the limits of normal variability are surpassed. Abnormalities may manifest as alterations in amplitude (e.g., excesses or deficits), duration, intensity, timing, and modifiability of physiological events, perceptions, emotions, thoughts, and motor activities. These limits are often arbitrary. Examples include the number of hours of sleep, the intensity of anger, or the extent of mood lability. However, for other experiences the distinction between normal and abnormal is qualitative, not quantitative. However, for some phenomena, any is too much. In mainstream American culture, for instance, any experience of thoughts being broadcast out loud is considered pathological. These signs and symptoms must all be considered in context because exactly what constitutes “normal” varies from culture to culture and from situation to situation. A behavior or subjective experience that may be defined as symptomatic in one context may be perfectly acceptable and within normal bounds in another.

A phenomenon should be considered abnormal only if it seems deviant within the patient's unique culture after its full physiological and environmental context is taken into account, and if it causes personal or interpersonal impairment. Too often, phenomena prematurely mislabeled as psychopathological turn out to be perfectly understandable and nonpathological once the whole situation is appraised. Conversely, some examiners are reluctant to label certain phenomena as psychopathological even when they clearly are, for fear of stigmatizing the patient.

Within cultures, most interpersonal interactions are carefully regulated by tight sets of rules and controls, and constrained by reasonably well defined sets of expectations and acceptable limits. Even slight deviations from these acceptable limits are quickly perceived by lay persons as well as professionals, because behavioral deviances are often experienced as threats. Deviations in amplitude, duration, and intensity can occur in facial expressions, gestures, postures, vocalizations, language, and other expressions of emotion and thought. A small increase in the rate of speech, an intrusion into one person's conversation by another who does not allow proper pauses, a gesture that comes just a bit too close to a face, an excessively rigid or distant stance, or a gaze that is too staring or too avoidant—each signals social insensitivity and alerts the observer to deviant behavior.

Reliability Problems Among the core difficulties in psychiatric evaluation has been that multiple observers may note different symptoms or interpret signs differently when interviewing the same patient. These discrepancies may be caused by differences in the patient's status or in information imparted by the patient from examination to examination, in the observers' definitions of the symptoms or signs in question, and differences in perceiving and interpreting the patient's responses to general presentation or questions within the interview. These three types of reliability problems are called *information variance, criterion variance*, and *observation bias*.

Although good interrater reliability can be achieved for most symptoms of Axis I disorders, this may not hold true for personality disorders or for some specific symptoms. Furthermore, good interrater reliability may occur consistently only under optimal circumstances and may not be as common in clinical practice.

Even when simply responding to direct questions about symptoms, patients may answer differently depending on the interviewer's manner, how the questions are asked, their personal sense of trust or safety, whether they have answered these questions before, the amount of cuing that may signal the desired response fatigue, or a host of other variables.

Most clinicians still rely heavily on their own clinical intuition and subjective responses to patients as part of a diagnostic assessment. Unfortunately, whether accurate or not, these clinical judgments are often based on nonconscious assumptions, comparisons with other patients not well remembered, or distortions based on the clinician's own personal experiences. When the bases for these intuitions can be identified and described clearly, they may prove to be reliable and valid. However, intuitions are often wrong—simple trust in intuition alone is not sufficient. Thus, a clinician's sense that a patient is angry and potentially violent may result from the patient's subtle (but verifiable) body language and tone of voice—or it may represent a countertransference distortion that is not prompted by any observable patient

behavior.

Clinicians often too quickly label behaviors as inappropriate when they fail to appreciate and understand contextual or cultural considerations. Appropriateness depends heavily on context, and definitions of what is proper in a given context may also be highly subjective. Appropriate behavior or clothing in some parts of California may be inappropriate in Boston. A low intensity of emotional expression leading to a clinical description of “constricted affect” may reflect cultural norms or a psychopathological state.

Nonspecific Nature of Signs and Symptoms Until psychiatry discovers reliable diagnostic laboratory tests to define clinical syndromes, the field will continue to construct diagnostic categories based on the clustering of signs and symptoms within specific time frames. Unfortunately, pathognomically specific signs or symptoms rarely exist in psychiatry; virtually all psychiatric symptoms are nonspecific and are usually seen in a many different disorders. Depressed mood, for example, occurs in a wide variety of diagnostic groups—including major depressive disorder, schizophrenia, some personality disorders, and mood disorder due to a general medical condition. Even the so-called first-rank symptoms of schizophrenia described by Kurt Schneider are diagnostically nonspecific and are seen with some frequency in otherwise classic depressive and bipolar disorders.

In general medicine, symptoms not recognized as part of a clearly defined syndrome are often described as being of unknown origin. Thus, a fever that cannot be ascribed to a known disorder, such as pneumonia, is described as a *fever of unknown origin*. Given the nonspecific nature of psychiatric symptoms, it would seem wise to use similar conventions, referring to *hallucinations of unknown origin* or *depressed mood of unknown origin* when a symptom cannot be clearly linked to a well-described syndrome.

Even though individual signs and symptoms may be organized into syndromes and disorders, they often have courses of their own. Thus, in the appearance or the resolution of a disorder, certain associated signs and symptoms may appear very early or may persist after all the others have waned. For example, in the restricting form of anorexia nervosa, excessive exercise is often the first symptom to appear and the last to abate even after dieting has stopped. In some cases, certain signs and symptoms that are commonly associated with a given disorder may fail to appear. Each sign and symptom may have its own pattern and variable response to treatment. In the treatment of schizophrenia, for example, some patients experience rapid resolution of hallucinations but have persistent delusions without ever having any other thinking disorders, whereas others may have no residual hallucinations or delusions but still have prominent thinking disorders.

Sign and Symptom Categories Signs and symptoms have been categorized in a variety of ways: state versus trait, primary versus secondary, and form versus content. The state versus-trait distinction refers to whether the sign or symptom is an enduring characteristic of the person (‘traits”) or time-limited. Phenomena associated with specific Axis I disorders are usually state-associated phenomena. However, some enduring traits may also be symptoms. A person who always worries a great deal, chronically exhibits catastrophic thinking, and feels subjectively nervous in many different circumstances since early childhood may have *trait anxiety*. However, if such symptoms of anxiety are present only during a specific time frame, for example, over a 9-month period in conjunction with a full depressive syndrome, they are best described as *state-related symptoms*. During the acute stages of psychiatric disorders marked by dramatic state characteristics, it is unwise to infer that any of the prominent signs or symptoms are enduring traits, even those usually associated with personality. Thus, a diagnosis of dependent personality *traits* based on an acutely depressed patient's behavior is often incorrect. Similarly, manipulative behavior in the midst of a hypomanic or manic episode should not be considered evidence for enduring manipulative traits unless these behaviors are also present when the mania has clearly resolved.

Distinctions between primary and secondary symptoms have been blurred by varying definitions of these terms. The distinction may refer to causal relations between what is primary and secondary, temporal sequence between the two symptom sets, or inability to more clearly understand the origin of the various symptoms. Basing the distinction between *primary* and *secondary* upon causality implies that the terms cause and effect are clearly understood. In attention-deficit/hyperactivity disorder, for instance, the attention deficit is thought to be primary whereas the hyperactivity is thought to be secondary, caused by the inability to attend. Patients who develop severe dependent personality traits and chronic demoralization only after experiencing several incapacitating psychotic mood episodes might be described as having primary mood disorders and secondary personality disorders. Conceptual models of psychopathology in which some signs and symptoms are seen as restitutive albeit ineffective attempts to cope with more fundamental psychopathological deficits use a primary-secondary model. For example, Eugen Bleuler viewed thought disorder as a primary symptom in schizophrenia, but viewed hallucinations and delusions as secondary symptoms that developed to help the patient cope with the chaos of the primary symptoms. These models must be viewed as hypothetical constructs only and applied with great caution because in the vast majority of clinical phenomena little evidence indicates that one symptom is more primary than another.

Temporal sequence in the appearance of certain symptoms is regularly used as the basis for deciding the primacy of certain symptoms, behaviors, or disorders, such as in trying to determine what is primary and what is secondary when substance abuse occurs in conjunction with depression or anxiety. These differences are not trivial but often have strong treatment implications, because for example, treating a primary mood disorder in a substance-abusing patient (with a long course of medication) is quite different from expecting that with prolonged sobriety a secondary mood disorder will resolve on its own. Furthermore, it is becoming increasingly clear that the presence of certain preexisting psychiatric conditions, such as personality disorders, increases one's vulnerability for the subsequent development of other psychiatric disorders, such as major depressive disorders.

Unfortunately, establishing temporal sequence with any certainty is usually difficult. Although there is a high comorbidity between bulimia nervosa and major depressive disorder, in excess of 50 percent according to some studies, attempts to establish which disorder is primary have been inconclusive. Even with careful historical analysis, major depressive disorder precedes bulimia nervosa, bulimia nervosa precedes major depressive episodes, and the two conditions start concurrently in about equal percentages.

Making simple categorical distinctions between primary and secondary signs, symptoms, and disorders is less important than understanding the contribution of each element as a thread in the evolution and development of a given clinical presentation. From this perspective, each element can be viewed as dynamically affecting the appearance, manifestations, and course of the others and as exerting its own influence on the pathogenesis and treatment of the specific syndromes and associated disorders. For example, the onset, specific nature, and independent time course of sleep disturbances and insomnias may prove to be important in understanding the appearance, manifestations, and sequence of other prominent signs and symptoms of the mood disorders of which they are a part, and in their treatment.

This view is particularly important because despite the excellent conceptual contributions made by categorical diagnostic systems such as the American Psychiatric Association's DSM-IV, distinctions are often fuzzy in clinical practice and comorbidity among so-called categorically distinct disorders is often the rule rather than the exception. For example, data from the National Comorbidity Study show that 14 percent of the population experience three or more comorbid psychiatric disorders. In such individuals the dynamic interactions and mutual influences of various signs and symptoms, and their biological underpinnings, becomes impossible to disentangle.

Furthermore, the categories that currently comprise DSM-IV are not going to be the last word in the evolving history of psychiatric diagnosis. Recent studies show that psychiatric signs and symptoms may be usefully grouped into psychotic syndromes that differ in some respects from current DSM-IV categories. In a large family study of probands with broadly defined schizophrenia and affective illness and their first degree relatives, using a sophisticated statistical technique called latent class analysis Kenneth Kendler and his colleagues found six classes of psychosis including classic schizophrenia, major depression, schizophreniform disorder, bipolar-schizomania, schizodepression, and hebephrenia. While these classes bore substantial resemblance to current or historical nosological constructs, several of them differ from DSM-IV nosological constructs. In another study the three factors ordinarily associated with symptoms of schizophrenia, representing positive, negative and disorganized symptom domains, were found not to be specific to schizophrenia but were found in other schizophrenia-spectrum psychoses and in nonschizophrenia-like psychotic conditions as well.

Context Signs and symptoms are usually not static entities; depending on the context, they often vary in intensity or even in their existence. The depressed mood of a melancholic depression may persist regardless of the external situation whereas the depressed mood of milder depression may vanish completely during certain situations—including a psychiatric interview—only to reappear at other times. Signs and symptoms that occur only in specific settings or with certain internal states are referred to as *state-dependent*. For example, certain hallucinations or memories may be present only during states of drug or alcohol intoxication; in some patients, hives may erupt as a psychophysiological response only during states of anger. Interpersonal context is also important. Some persons become violent only when involved in sadomasochistic relationships or in certain group settings, such as within adolescent gangs. In gangs, social pressures for conformity and expectations for aggressive behavior may provoke or release pathological behaviors that might otherwise never be expressed by gang members individually.

Problems and Impairments Beyond the classic signs and symptoms of psychiatric disorders, recent attention has focused on the problems and impairments that psychiatric signs, symptoms, and disorders generate in affecting specific role functions and in causing social and economic burdens for the patient and others. These problems and impairments often cut across traditional sets of signs and symptoms of which categorical diagnoses are composed, affecting, for example, basic abilities to care for oneself and one's family, marital functioning, child rearing, wage earning, school performance, and social behavior. They constitute the issues with which

patients and families contend, and they need to appear on the problem lists that treatment plans and specific interventions target. Studies reveal that the impairments imposed by major depression are considerable with regard to physical functioning, role limitations, and social functioning. Problems such as violent temper outbursts, sexual aggression, or lack of job skills, which may impair role functioning in several spheres, must be directly addressed in their own right regardless of the associated DSM-IV diagnoses. These impairments enter determinations of ratings for Axis V of DSM-IV, which addresses the global assessment of functioning, and are of considerable importance in evaluating treatment outcomes. Table 8-1 lists some examples of critical impairments that have been recognized as often requiring urgent or intensive levels of care.

Anxiety
Assaultive behavior
Compulsions
Concomitant medical condition
Delusions (nonparanoid)
Delusions (paranoid)
Dissociative states
Dysphoric mood
Eating disorder
Fire setting
Hallucinations
Homicidal thought/behavior
Inadequate health care skills
Manic thought/behavior
Medical risk factor
Medical treatment noncompliance
Mood lability
Obsessions
Phobia
Physical abuse perpetrator
Psychomotor retardation
Psychotic thought or behavior
Running away
Self-mutilation
Sexual trauma perpetrator
Substance abuse
Suicidal thought or behavior

Table 8-1 Signs, Symptoms, and Impairments Requiring Immediate Care

Need for a Comprehensive Perspective A psychiatric disorder may be characterized by disturbances involving a wide variety of areas in the patient's life, including the biological, psychological, behavioral, interpersonal, and social spheres. In practice, common psychiatric syndromes often manifest in each of these dimensions. (Table 8-2). Viewing the patient from multiple perspectives, using the so-called biopsychosocial model (similar to the multiaxial approach of DSM-IV) enables clinicians to consider psychopathology and its effects on a patient's life in the broadest possible manner. To illustrate, Figure 8-1 lists some clinical hypotheses commonly used by clinicians as they link collections of signs and symptoms into syndromes and consider the treatment options that would logically follow.

Biologically derived hypotheses
1. As an organic mental disorder
2. As a mood disorder
3. As a nonaffective functional psychosis
4. In relation to the abuse of drugs or alcohol
5. As a disorder other than those listed in 1 through 4, above
Psychodynamically derived hypotheses
1. As being related to personality style
2. As being related to a precipitating event and its dynamic meaning
3. As a manifestation of unresolved grief
4. As a developmental crisis
5. As being related to ego functioning and related psychodynamic issues
Sociocultrually derived hypotheses
1. As resulting from the nature and the social effects of stressful life events
2. As being related to the extent, the nature, and the accessibility of social support
3. As being related to definitions of and responses to breakdown in the sociocultural grouping
4. As being related to the patient's motivation, treatment goals, and the dynamics of the entry process to help seeking
5. As social communication
Behaviorally derived hypotheses
1. As disordered thinking, feeling, or acting that is the result of specific antecedent events
2. As disordered thinking, feeling, or acting resulting from reinforcing consequences of the behaviors
3. As disordered thinking, feeling, or acting in response to sociocultural and biological events
4. As a deficit of behaviors (rather than as disordered behaviors) in the areas of thinking, feeling, and acting
5. By an analysis of areas of effective functioning

Table 8-2 Common Current Clinical Hypotheses Used to Assess Signs and Symptoms: Ways of Understanding the Patient's Problems

FIGURE 8-1 Biological, psychological, and social forces interact and effect the psychiatric health of a person. (Adapted from Richmond JB, Lustman SL: Total health: A conceptual visual aid. J Med Educ *29:*23, 1954.)

Because the amount of information gathered in a thorough assessment of a psychiatric disorder is potentially overwhelming, clinicians often tend to limit their fields of vision and appreciate only part of the available information; the clinician's theoretical orientation and other personal and cultural factors also limit what is perceived. Research has demonstrated that clinicians tend to perceive primarily those signs and symptoms that are most in accord with their own opinions and with the tools they have to treat psychiatric disorders, a phenomenon known as *concept-driven perception*. The theoretical biases of clinicians seem to be related both to the microcultures of their training programs and to their own personality traits. Such differences may lead one clinician to see a major mood disorder, to be treated with medication, where another sees a pervasive personality problem with dysthymic disorder, to be treated with psychotherapy, and to use different technical terms to label the same phenomenon. A psychodynamic psychiatrist might see psychomotor retardation where a neuropsychiatrist sees bradykinesia; a psychodynamicist might see depressed mood and muted speech where a neuropsychiatrist sees mask-like facies and aprosodic speech; the psychodynamicist might see ruminative thought where a neuropsychiatrist sees forced thinking; a psychodynamicist might see a grimace where a neuropsychiatrist sees a tic. Given the extent to which words themselves shape our concepts of reality, the consequences of using these different labels for very similar phenomena may be significant. Figure 8-1 illustrates concept-driven perception in which each clinician who adheres to a prominent contemporary point of view perceives only some of the potentially available phenomena related to a psychiatric disorder. Although there is overlap, each observer also perceives information that other observers do not notice. Also, some information that may be highly relevant to diagnosing or treating the disorder may be overlooked by all the observers.

The intermittent nature of many psychiatric signs and symptoms; the potential unreliability, selective recall, and false recall of patients and others in reporting symptoms and events; differing interpretations of elicited information or observations; and subjective theoretically driven biases that influence the clinician's perception of signs and symptoms, all contribute to potential errors in data collection. To help guard against misinformation and simplistic understandings and formulations, wherever possible complete assessment of a psychiatric patient requires consultation with family, friends, co-workers, and other professional observers to enrich the history and to provide supplemental observations of the patient over time.

SOMATIC MANIFESTATIONS OF PSYCHIATRIC DISORDERS

Virtually all Axis I, symptom-based disorders and most other psychiatric disorders are characterized by disturbances in at least some basic physiological functions. Although frequently nonspecific in nature, the severity of these somatic signs and symptoms provides markers as to the amount of biological disruption seen in the disorders that cause them. Furthermore, somatic symptoms can also cause exacerbations of some disorders. If untreated, these processes can create destructive feedback loops in which the disorder causes symptoms, which then exacerbates the disorder, which increases the symptoms, and so on. For example, the insomnia of manic or hypomanic episodes will, if untreated, cause a marked worsening of the mania; similarly, the weight loss of anorexia nervosa causes starvation effects such

as a preoccupation with food, thus exacerbating one of the hallmark features of the underlying disorder.

Sleep Disturbances Abnormalities of sleep may manifest in the amount, quality, and timing of sleep, as well as by the presence of abnormal events during sleep.

Insomnia is usually defined by its subjective component as the sensation of sleeping poorly. Most but not all patients complaining of insomnia will demonstrate some sleep abnormality if examined in a sleep laboratory. Insomnia is a common, often chronic symptom or sign of many different psychiatric disorders and conditions including substance abuse, depressive disorder, generalized anxiety disorder, panic attacks, manic episodes (in which the diminished sleep does not always provoke a complaint), and acute schizophrenia. It may also occur as a consequence of aging or as a symptom or disorder not associated with other psychopathology. Insomnia may also result from the ingestion of substances that alter the normal sleep-wake cycle, including alcohol or stimulants, and by the discontinuation of sedative-hypnotics. Although much attention is often paid to distinguishing patterns of insomnia, such as difficulty falling asleep versus middle or terminal insomnia (early-morning awakening), or linking specific patterns linked to specific conditions (e.g., major depressive episode with melancholic features and associated terminal insomnia) the clinical utility of these distinctions is unclear.

> A 62-year-old woman presented with new-onset primary insomnia. In spite of an extensive medical work-up by her primary physician, and equally extensive psychiatric examination, no other medical, psychiatric, iatrogenic, or substance-related problems usually causing or associated with insomnia could be identified. She was treated for her symptoms with hypnotic agents and experienced partial improvement. The insomnia persisted for more than a year before spontaneously remitting as mysteriously as it initially appeared.

Hypersomnia, characterized by either excessive nighttime sleep or excessive sleepiness during the day, is less common than insomnia. However, it too may reflect a number of different pathological states. Some depressed patients, especially those with a history of mania or hypomania, may exhibit hypersomnia. Hypersomnia may also be seen during amphetamine withdrawal, excessive use of sedatives or anxiolytics, or in conjunction with a variety of medical disorders. In *narcolepsy*, the patient has sudden attacks of irresistible sleepiness, a symptom that may be part of a broader syndrome that includes *cataplexy* (sudden attacks of generalized muscle weakness leading to physical collapse in the presence of alert consciousness), *sleep paralysis* (waking from sleep with a sensation of being totally paralyzed that may persist for minutes), and *hypnagogic hallucinations* (vivid visual hallucinations that occur at the point of falling asleep). Narcoleptic attacks are often precipitated by unusual states of arousal (e.g., cataplexy may immediately follow unrestrained laughter or orgasm). Daytime sleepiness may reflect *sleep apnea*. In this disorder, middle-aged patients demonstrate severe snoring—often first reported by their bed partners—and periods when breathing stops. The condition results from soft-palate abnormalities that cause intermittent airway obstruction throughout the night; patients awaken repeatedly to find themselves gasping for air. Associated daytime fatigue is common in sleep apnea. Periodic hypersomnia also occurs in the *Kleine-Levin syndrome*, a condition that typically affects young men, in which periods of sleepiness alternate with confusional states, ravenous hunger, and protracted sexual activity. Intervals of days, weeks, or months may pass between these episodes. *Sleep drunkenness* is characterized by excessive sleep and great difficulty awakening completely, with confusion and motor incoordination soon after arising. Excessive daytime sleepiness may also occur secondary to abnormalities to the brainstem, hypothalamus, or thalamus.

Sleepwalking disorder (somnambulism) and *sleep terror disorder* are two sleep disorders characterized, respectively, by aimless wandering with incomplete arousal, and by acute anxiety and physiological arousal without awakening. Although both disorders typically begin in childhood, sleepwalking may be also be initially precipitated by some psychotropic medications.

Nightmares are a common complaint, often associated with traumatic events, anxiety disorders, and mood disorders, but are also not uncommon as an occasional event in otherwise healthy individuals. Vivid dreams and nightmares may also be an adverse effect of medications.

> A 24-year-old Peace Corps volunteer started to experience frequent, vivid, and disturbing nightmares shortly after arriving at her placement in South America. She mentioned these symptoms to other volunteers with whom she was traveling and learned that several of them were also having similar nightmares. All had recently started courses of mefloquine (Lariam) for malarial prophylaxis, and one had been forewarned to expect vivid nightmares as a commonly occurring adverse effect of this medication.

Sensory symptoms during sleep, typically described by patients as peculiar feelings in their legs causing an irresistible need to move around, are characteristic of *restless legs syndrome*. The motor abnormality of repetitive myoclonic jerking of the legs, awakening both patients and their partners, is known as *nocturnal myoclonus*.

Appetite and Weight Disturbances Aside from the anorexia of medical illnesses, especially in their later stages, loss of appetite is most commonly seen in depressive disorders, grief, and anorexia nervosa, and is also commonly seen in conjunction with significant anxiety. Anorexia is often accompanied by changes in taste (e.g., foods begin to taste bitter or flat or have an unpleasant aroma). Patients with eating disorders may resist hunger to restrict food intake in order to achieve a physiologically unrealistic low weight. *Hyperphagia* (increased appetite) occurs in some depressed patients, both with and without a history of mania bipolar I or bipolar II disorder. Binge eating, of up to several thousand calories per episode, may occur as an attempt to self-soothe and emotionally self-regulate during times of increased tension and anxiety, and as a key feature of bulimia nervosa or of binge-eating disorder. Increased appetite may be seen, albeit rarely, in some hypothalamic disorders or in bilateral temporal lobe dysfunction, such as the Kluver-Bucy syndrome, in which it occurs in association with emotional placidity, hypersexuality, hyperorality, and other symptoms.

Other Ingestive Disturbances—Substance Abuse The use of chemicals such as alcohol, opioids, marijuana, cocaine, amphetamines, hallucinogens, and other drugs to change one's inner emotional and tensional state is well known. Used at inappropriate times and in excess, such ingestions may culminate in various syndromes of abuse and dependence and may complicate other psychiatric disorders. Use of nonnutritious substances for their presumed psychoactive effects has even been reported to occur in the wild among elephants and baboons.

Energy Disturbances Normal energy levels vary considerably among people. Some people fatigue easily and are perceived by themselves and others as having weak constitutions, whereas others appear to have almost boundless energy and much less need for sleep.

Fatigue is a common nonspecific symptom that occurs in both medical and psychiatric disorders. It is also frequently seen as an unexplained complaint in primary-care practices; in one study 24 percent of patients complaining of fatigue received no medical or psychiatric diagnosis. Historically, fatigue not caused by another disorder, typically in association with “nervousness,” has been described by terms such as *asthenia, neurocirculatory asthenia, neurasthenia*, and *psychasthenia*. Consistent with this tradition, many fatigued patients, having been labeled depressed or neurotic by their physicians, are referred to psychiatrists after routine work-up has ruled out anemia, hypothyroidism, sleep apnea, and other frequent somatic causes.

Recently, patients with primary complaints of tiredness have been most commonly diagnosed as having *chronic fatigue syndrome*, incorrectly labeled *Epstein-Barr viral syndrome*. This disorder is characterized by fatigue lasting months to years, typically beginning soon after a viral syndrome. In addition to the fatigue, chronic fatigue syndrome is characterized by myalgias and cognitive changes, such as forgetfulness and poor concentration. Although controversy still exists on the extent to which cases of chronic fatigue syndrome represent discrete postviral diagnostic syndromes, mislabeled cases of depression, or modern versions of neurasthenia, evidence continues to mount to suggest that this syndrome is a discrete postinfectious entity, and is not simply a variant of or a disguised mood or anxiety disorder.

> A highly accomplished, energetic 40-year-old woman was referred for psychiatric consultation after her physicians were unable to offer a definitive physiological diagnosis despite extensive medical work-up following the acute onset of profound fatigue occurring in the wake of a mild viral illness. This fatigue caused her to be totally incapacitated and bedridden for many months, and left her feeling helpless and distraught. Her condition was exacerbated by even small amounts of alcohol. Two independent psychiatric evaluations concluded that the patient had no psychiatric disorder. The patient developed this syndrome after jogging near Lake Tahoe. Epidemiological studies were found that reported several other cases of profound fatigue originating in this particular area after vigorous exercise. She was treated for symptoms of fatigue and gradually made an almost full recovery after about 2 years.

Disturbances in Sexual Drive As with energy, the normal range of sexual drives is great. Some individuals are naturally lusty, whereas others have limited sexual desire. Diminished sexual drive with impotence or decreased libido is seen in a wide variety of neurological, metabolic, and other somatic syndromes. Among neurological disorders, complex partial seizures are commonly associated with hyposexuality, occurring in 50 percent of patients. Psychiatric disorders known for diminished sexual drive include depressive disorders, schizophrenia, substance-related disorders, and marital conflict. Diminished libido, impotence, and anorgasmia are also common sequelae of many pharmaceutical agents, including psychotropic medications.

A 24-year-old woman, treated for depression with a selective serotonin reuptake inhibitor by her primary physician, developed profoundly diminished sexual sensation and anorgasmia in the course of treatment. In order to increase her sexual feelings as her dating and sex life resumed, she stopped taking her medication without first discussing this decision with her physician. Several months later, when her depression returned, she revealed what she had done and was effectively started on a different class of medication that lacked these adverse effects.

Increased sexual activity may be seen in some neurological, substance-induced, and psychiatric disorders. Manic patients frequently exhibit hypersexual interests and behaviors to an unusual degree compared to their euthymic interests and behaviors. Hypersexuality is occasionally seen in conjunction with epileptic syndromes or in patients who have suffered diencephalic injuries.

Altered sexuality, including fetishism, sadomasochism, and pedophilia, may be seen as isolated psychiatric syndromes. In individuals whose previous sexual behaviors were within the bounds of social propriety for their groups, inappropriate sexual behaviors may signal early brain disease or psychosis. Cross-dressing may occur in transvestites, transgenderists, transsexuals, or occasionally in psychiatric conditions such as schizophrenia.

A 36-year-old former Marine pilot became psychotic several years after being discharged from active duty. During the next several years while being successfully treated for schizophrenia, he started to cross-dress in a garish, almost cartoonish manner, and sought hormone treatment in Mexico to reduce his secondary male sex characteristics and to foster the development of breasts. Although he considered undergoing a genital amputation and having a plastic surgeon build a vagina-like vault, he hesitated to do so, describing how he really enjoyed shocking the men he took home from bars by revealing that he had a penis. On several occasions these men, outraged and humiliated, physically attacked him and hurt him badly.

Appearance Studies show that clinicians often formulate an initial psychiatric diagnosis within 30 seconds of seeing a patient. Although approximately half of such initial impressions prove to be incorrect, the remainder are validated by psychiatric history and mental status examination, revealing just how much information is communicated by appearance and body language.

Among the physical disorders whose appearance suggest coexistent psychiatric conditions are acromegaly, Cushing's disease, Down syndrome, systemic lupus erythematosus, fetal alcohol syndrome, Klinefelter's syndrome, and Wilson's disease. The general appearance of the skin may suggest the presence of occult psychiatric problems. Skin condition and tone may reveal hypervascularity and ruddiness suggestive of alcoholism, abscesses are indicative of hypodermic needle abuse, tattoos are indicative of certain group affiliations, or weathering and wasting indicative of self-neglect and malnutrition. Healed scars on the wrists and arms suggest a pattern of self-mutilation from depression, personality disturbance, or both. Patchy baldness, especially in conjunction with torn or infected cuticles, indicate *trichotillomania*, a syndrome of compulsive hairpulling. Psychophysiological symptoms reflecting psychiatric disturbance include urticarial reactions and neurodermatitis, the latter resulting in part from self-excoriation, destructive scratching secondary to compulsions, and unrelenting sensations of discomfort.

Examination of the head and neck may reveal exophthalmos or puffy eyelids suggesting thyroid disease, the marked pupillary dilation of anxiety or amphetamine abuse, the miosis of narcotic abuse, the abnormal pupillary pigments of Wilson's disease, the salivary gland enlargement of bulimia nervosa, or the necrosis of the nasal septum seen in cocaine abuse, among other signs. Frequent sighing is a common respiratory sign in depression. Simple sighing must be distinguished from respiratory dyskinesia in psychotic patients who have been treated with neuroleptic agents. The latter may occur as an acute dyskinesia resulting from antipsychotic medication or it may be a late manifestation and component of tardive dyskinesia.

Deviant appearance is quickly perceived by lay persons as well as professionals, and may contribute to the frightened and stigmatizing social withdrawal by strangers and acquaintances so often experienced by psychiatric patients. Akathisia and dystonic movements and Parkinsonian shuffling gait in patients taking neuroleptic agents, as well as the dilapidated, unkempt appearance of some psychiatric patients can immediately signal psychiatric patient status to observers. The term *Diogenes syndrome* has been used to describe old people who have a filthy personal appearance that demonstrates severe self-neglect about which they have no shame.

DISTURBANCES IN THINKING

Normal Thinking *Thinking* refers to the ideational components of mental activity, processes used to imagine, appraise, evaluate, forecast, plan, create, and will. Most thought involves complex rules that are best approximated by *fuzzy logic* decision-making algorithms that use neural net technology, increasingly applied by scientists and engineers in situations where all-or-none, black-or-white thinking does not apply, and where multifaceted, contradictory, and competing possibilities and biases are the rule. Most of what is known about thinking derives from the study of language as the product and reflection of thought; yet a great deal of thinking takes place preverbally and nonverbally. Thinking occurs in images, music, kinesthetic sensations, and in symbols other than linguistic ones. Attempts to transmit preverbal and nonverbal thought using only words are frustrating and unsatisfactory. Creative artists have considerable difficulty describing the inner states of tension and inchoate awareness from which ideas are distilled.

Ordinary thought is far from logical. Streams of conscious thought are intruded upon by competing thoughts and associations, and by outside stimuli, and attention is easily distracted. Ordinary conversation is marked by recurring asides, interruptions, delays, and the loss of ideas. Decisions are often made on the basis of very few cues and inadequate evidence: people jump to conclusions and beliefs that are not supported by evidence are zealously held. Thinking in stereotypes is more common than thinking in logical categories; from an evolutionary perspective, thinking in stereotypes and by approximation has probably been more adaptive than thinking in strictly defined categories. This tendency helps to account for clinicians' tendencies to make diagnoses by approximation and intuition based on prototypes, and to feel less comfortable using formal lists of criteria found in statistical manuals, such as DSM-IV.

Individuals vary greatly in their predominant *cognitive styles*, and a given individual's style of thinking will also shift considerably from time to time. *Cognitive style* is one's predominant manner of information processing and decision making, the particular biases and distortions that thinking processes make by means of augmenting, elaborating, or minimizing incoming information, and the extent to which careful and deliberate logic versus intuition versus thoughtless, anxiety-induced impulsivity is used to guide the decision-making process. A particular cognitive style may come to dominate a person's repertoire so completely as to interfere with the flexible, adaptive responses required to deal with the usual variety of daily needs. An *obsessional style* of thinking is marked by attention to detail and hypervigilance concerning the possible implications of a particular thought or event. This may take the form of preoccupation with strict adherence to established rules, values, or beliefs. An obsessional style may be highly adaptive in certain situations, as in professions requiring meticulous detail such as library science, computer programming, and surgery. However, excessively rigid obsessionality may be maladaptive, as when someone scrupulously sticks to the rules even when such adherence is self-destructive and short-sighted. A *hysterical* style of thinking is characterized by global, diffuse, impressionistic, emotionally laden evaluations of situations where lack of attention is given to details and nuances. This style is poorly adaptive to detail-oriented work, but may be useful in the arts, certain aspects of marketing and sales, and in some social situations.

Two brothers watched *Kramer vs. Kramer*, a film about the dissolution of a marriage and the struggles of caring for the couple's only child after the divorce. In discussing the movie afterwards, one brother, a business lawyer specializing in writing complex contracts, remembered the plot in detailed linear sequence. However, he had great difficulty explaining the underlying feelings and motivations of any of the characters. The other brother, an artist, could not remember details of the plot and confused the sequence of scenes. However, he could easily and accurately explain the relationships between the characters and their feelings.

Types of Thinking Because of the different ways in which normal and abnormal thinking expresses itself, attempts have been made to subtype thinking by the extent to which logical versus nonlogical thought is utilized. Freud's division of thought into *primary* and *secondary process thinking* is still widely used.

PRIMARY PROCESS Primary process thinking, the more primitive type, is typically seen in dreams, but also prominent in young children and in psychotic states. This type of thinking disregards logic, permits contradictions to exist simultaneously, disregards the linear notion of time, and is dominated by wish and fantasy. It uses symbol, metaphor, imagery, condensation, displacement, and concretism in its organization, creating the jumbled and incoherent style of thinking characteristic of dreams. Primary process thinking represents what has been loosely and metaphorically called *right brain thinking*, associated with visual images and creative thought.

SECONDARY PROCESS Secondary process thinking is characterized by logic. Unlike primary process thinking, the secondary process uses linear notions of time, clearly delineated abstract categories, and deductive rules of logic. The ability to think abstractly and to think in detail about future plans is characteristic of secondary process thinking. Normal secondary process thinking is also characterized by predictability, coherence, and redundancy. Words, vocal inflections, and gestures provide important contextual cues and create a sense of overall coherence to the communication. Ideas follow one another in a sequence that is understandable to

the listener.

A non-Freudian typology of thought divides thinking into three types: *fantasy thinking, imaginative thinking*, and *rational* or *conceptual thinking*. Fantasy thinking allows the person to escape from, or deny, reality, and can be seen in normal as well as pathological thinking. Everyone occasionally uses fantasy thinking when daydreaming. Some dissociative and psychotic phenomena illustrate the most pathological manifestations of fantasy thinking. Imaginative thinking merges fantasy and memory in order to generate plans for the future. Rational or conceptual thinking uses logic to solve problems.

Regardless of how one categorizes thought, people can fluidly shift from linear, secondary process or rational thought to fantasy, primary process or nonlogical thought, as in the free associative method used in psychoanalysis. During this process, individuals willfully surrender the controls that maintain secondary process thinking and switch to the less controlled modes of primary process thinking in which thoughts are loosely associated by emotional associations or based on peripheral, concrete, coincidental, loosely similar, or trivial aspects of a thought. Additionally, the fact that increases in primary process thinking can be induced in normal people under experimental conditions or with fatigue suggests that more primitive thought processes, such as those seen in psychosis, are usually inhibited by higher-order processes, and that their appearance may be release phenomena; that is, nonlinear or psychotic thinking may indicate the functional absence of those overriding control systems that ordinarily sift, evaluate, and regulate the form and flow of thought before it reaches consciousness.

THOUGHT DISTURBANCES

Flow and Form Disturbances Because the underlying processes that govern thought are not understood, current systems for classifying thought abnormalities are primarily descriptive. Conventional classification separates form and flow from the content of thought. Yet, many types of abnormal thinking include both form and content abnormalities. Thus, whereas delusions are usually classified as thought content disturbances, they are also marked by formal abnormalities such as rigidity and imperviousness of thought to external influence or to information that clearly contradicts the delusional idea. Although *formal thought disorder* typically refers to marked abnormalities in the form and flow or connectivity of thought, some clinicians use the term broadly to include any psychotic cognitive sign or symptom.

As with energy and sexuality, normal variations in the flow and form of thought are considerable. For some people, thinking appears to be effortless—rapid and productive, exhibiting linear, goal-directed thoughts and creativity, with digressions and occasional leaps but always controlled and comprehensible. For others thinking is a difficult exercise—a slow, painstaking process with low output compared to other people, or scattered, with difficulty staying with a topic or finishing a single thought. Most people experience mixtures of these extremes. Disturbances in the flow and form of thought occur with regard to rate, continuity, control, and complexity.

Thinking can be unusually slow or accelerated. Slowed (or retarded) thought, (e.g., as seen in depression), is typically goal directed but characterized by little initiative or planning. Patients experiencing retarded thought often describe feeling that even simple thought requires monumental effort, as if molasses were cluttering their thinking. These difficulties are expressed as slowness in decisionmaking and as long latency of response, increased pause times when speech is initiated and during speech. *Thought blocking*, seen in schizophrenia, is experienced as the snapping off or as a sudden break in a train of thought, as if a wall suddenly came down interrupting thinking (and speaking) in midsentence. To an outside observer, without further explanation from the patient, thought blocking may appear identical to *thought withdrawal*, a disturbance in the control of thought in which the patient feels as if some alien force has intentionally withdrawn the thoughts from consciousness. The patient's further description and explanation of the inner experience is necessary to distinguish these two symptoms.

> A 26-year-old man with paranoid schizophrenia frequently broke off his conversation in mid-sentence. To the puzzled examiner he explained that the mysterious force that controlled him with a computer chip in his brain closely monitored his thought and speech, and would shut him down whenever it was concerned that he might inadvertently say something that was classified information.

Accelerated rates of thinking, typically accompanied by fast talking, can be seen as a normal variant. Rapid rates of speech, influenced heavily by cultural and situational factors, only sometimes reflects truly rapid thought. (For example, it is not at all clear that New Yorkers, who characteristically speak more quickly than people from some other cities, actually think at a faster rate. Similarly, auctioneers and some radio and television announcers can speak with astonishing rapidity, probably reflecting both innate capacities as well as learned psychomotor skills.) *Pressure of speech*—speech that is rapid, excessive, and typically loud—is characteristic of mania (or hypomania), stimulant intoxication and, occasionally, anxiety. *Flight of ideas* occurs when the flow of thought increases to the point where the train of thought switches direction frequently and rapidly. The associative links between conceptual topics during flight of ideas are comprehensible to the listener, sometimes with considerable effort! Listening to a flight of ideas that is not overwhelmingly fast can be both a dizzying and enjoyable experience for the listener, as exemplified by the successful performance style of certain contemporary comedians, notably Robin Williams.

Continuity Disturbances in the continuity of thought may take several forms. In *circumstantiality* the flow of thought includes many digressive turns and associations, often including a great deal of unnecessary detail. Transcripts of circumstantial thought or speech are marked by multiple commas, subclauses, and parenthetical asides. Nonetheless, in circumstantial thought or speech the speaker eventually returns to the point that was initially intended without having to be prompted by the listener.

In contrast, in *tangentiality*, the person's thought wanders further and further away from the intended point, without ever returning, so that the person may not even remember what the original point was supposed to be. In *vorbeireden*, a form of tangentiality, the person talks past the point and never quite gets to the central idea. Tangentiality is a mild form of *derailment*, in which there is a breakdown in associations. *Loose associations* exemplify more severe derailment, in which the flow of ideas is no longer comprehensible to the listener because the individual thoughts seem to have no logical relation to one another. Loose associations are classically a hallmark feature of schizophrenia. In extreme cases, the associations of phrases and even individual words are incomprehensible, and syntax—the rules of grammar by which phrases are organized into sentences and words into phrases—may be disrupted. *Word salad* describes the stringing together of words that seem to have no logical association, and *verbigeration* describes the disappearance of understandable speech, replaced by strings of incoherent utterances.

Clang association refers to a sequence of thoughts stimulated by the sound of a preceding word. For example, a patient with mania said, “I'll kill with a drill or a pill—God, I'm ill—what swill.” In *echolalia* the patient repeats a sentence just uttered by the examiner. Repetition of only the last uttered word or phrase is called *palilalia*, a symptom found most often in patients with chronic schizophrenia.

Perseveration and *stereotypy* are two other associative abnormalities in which the flow of thought or speech appears to get stuck. In *perseveration*, a sentence or phrase is repeated, sometimes several times over, after it is no longer relevant; perseveration is commonly seen in delirium and other organic mental disorders. *Stereotypy* refers to the constant repetition of a phrase or a behavior in many different settings, irrespective of context.

Disturbances in the control of thought include *delusional passivity* and *obsessional thinking*. In *delusional thought passivity*, patients experience their own thoughts as being under the control of other forces. Thought passivity may take several forms: in *thought insertion* thoughts are experienced as having been placed within the patient's mind from the outside; in *thought withdrawal* thoughts are whisked out of the mind; in *thought broadcasting* patients experience their thoughts as escaping their minds to be heard by others. These experiences are often combined with specific delusions of control, seemingly to explain the passivity experiences. Several of these phenomena were included by Kurt Schneider among the first-rank symptoms of schizophrenia. Today, these symptoms are viewed more broadly as nonspecific psychotic symptoms, and are no longer considered to be pathognomonic of schizophrenia.

> A 40-year-old man who had been living in a state hospital for many years described how he was the outer shell in a set of nested beings. A homunculus-like figure in the center controlled another being surrounding him, and the patient himself was simply the outer wrapping. The inner homunculus made all the decisions, and pulled all the strings, so that the patient was simply a passive recipient of his thoughts and of the instructions that ordered him to carry out each and every act in his life.

Obsessional thinking is stereotyped, repetitive, persistent thinking that is recognized as one's own thoughts. In contrast to patients with delusional thought passivity, obsessional patients do not experience their thoughts as being controlled by outside forces. Nonetheless, they experience only partial control over the obsessional thoughts. They can, with great effort, stop thinking the obsessional thoughts but cannot prevent them from recurring. Thus, characteristic of obsessions is the subjective experience of compulsion, the resistance to it, and the preservation of insight. As bizarre as some obsessions are, patients know that these thoughts are irrational and their own. At times, obsessions may be pervasive enough to dominate the patient's consciousness. Obsessions may be simple—a sequence of words—or elaborate—such as enumerating the possible consequences of a past behavior and elaborating a cascading sequence of typically catastrophic events. Typical obsessional themes in obsessive-compulsive disorder involve preoccupations with dirt and contamination, fear of harming others, symmetry, and those related

to health and appearance.

> A 24-year-old woman was preoccupied with the fear that she would be contaminated by germs that were all around her. These thoughts were inescapable, and led her to narrow her range of activities considerably, to the point of being nearly housebound. She had to comply with a series of ritualistic acts to ward off contamination in her house.

Obsessional thoughts are usually seen in conjunction with *compulsive behaviors*, which are rituals linked to the obsessions, typically constructed to undo the effects of the thought.

The most prominent disturbance of thinking complexity is an impaired capacity to think abstractly. Abstract thinking is the ability to assume a mental set, to keep simultaneously in mind all the aspects of a complex situation, to move from feature to feature as indicated by the situation, and to abstract common properties. Complex thinking also concerns the ability to simultaneously consider many different, vague, and subtle aspects of situations; to appreciate differing and contradictory points of view; and to integrate these multiple dimensions to form opinions that are marked by differentiatedness and nuance. Normal individuals vary greatly in their abilities to engage in abstract thinking—geniuses in mathematics and theoretical physics leave most mortals far behind. *Concrete thinking* is a disturbance in the ability to form abstract concepts, generally illustrated by literal-mindedness and the inability to abstract the commonality of members of a group, for example, the fact that a flea and a tree are similar in that they are both living things. Concrete thinkers seem unable to free themselves from the literal or superficial meanings of words. Concrete thinkers may be more prone to prejudice and stereotypic thinking, more likely to manifest unidimensional or all-or-none reactions to complex situations. Concrete thinking can be seen in individuals with lower intelligence, organic mental disorders, and schizophrenia. Patients with schizophrenia may also exhibit highly selective disturbances of abstraction.

THOUGHT CONTENT

The normal content of thought, the buzzing, booming stream of consciousness that constitutes the stuff of everyday life, is composed of awareness, concerns, beliefs, preoccupations, wishes, and fantasies occurring with various degrees of clarity, vividness, differentiation, imagination, and strength. Normal thought is often illogical, containing many beliefs and prejudices that, although clearly contradictory, are nevertheless held with passion and conviction.

Belief systems are the scaffolding of thought, chains of impressions, and expectations around which plans and behaviors are organized. Belief systems may be attitudinal, setting general expectations and biases about the world that inform how incoming information is processed; examples of belief systems are optimism, pessimism, and paranoia. Some beliefs are effervescent and fleeting, whereas others are pervasive, tenacious, enduring, and influential. Some beliefs are unique and private, whereas many are shared by others.

Imaginative fantasy is an important component of normal thought. The vivid, eidetic imaginations of young children can produce fantasies in which children become fully immersed, almost as if in hypnotic states. During latency many children develop imaginary companions as playmates. In later years, imaginative thinking in which previously separate streams of thought playfully interact with one another to produce new ideas may be the essence of the creative reverie. Artists, writers, and creative scientists may retain access to these forms of thinking more readily than others. Meditative states of mind may facilitate the emergence of imaginative insights. Such thinking may also occur in dreams. Intrusive reveries are normal and common components of the usual adult stream of consciousness. During periods of specific deprivation, such as starvation or sexual deprivation, elaborate wish-fulfilling daydreams frequently occur.

Ideas are the contents of the stream of thought. Those that are consistent with one's sense of self, compatible with the individual's self image, are called *ego-syntonic*. Other thoughts that conflict with one's central values are called *ego-alien* or *ego-dystonic*. An ego-dystonic impulse to kill someone, inconsistent with one's predominant value systems, may generate a counteractive ego-syntonic thought such as, “You really don't mean it.”

Disturbances in Thought Content Abnormal beliefs and convictions form the core of thought content disturbances. Considerations of abnormality regarding beliefs and convictions must take the person's culture into account. Beliefs that may seem abnormal in one culture or subculture may be commonly accepted in another. For example, religious hallucinations, attributed to psychological or biological factors by contemporary Western societies, are routinely attributed to religious and spiritual causes by many other cultures. With regard to intensity of conviction, distorted beliefs range on a continuum from overvalued ideas to the determined, unshakable belief that is characteristic of fixed delusions. Abnormal beliefs and delusions are, in most circumstances, diagnostically nonspecific. Delusions are commonly seen in mood disorders, schizoaffective disorder, delirium, dementia, and substance-related disorders, as well as in schizophrenia and delusional disorders.

Overvalued ideas are unreasonable and sustained abnormal beliefs that are held beyond the bounds of reason. Patients with overvalued ideas have little or no insight into the fact that their ideas are very unlikely to be valid; however, the ideas themselves are not as patently unbelievable as most delusions. The distorted body images of body dysmorphic disorder exemplify overvalued ideas. Morbid jealousy and preoccupation with a spouse's possible infidelity may constitute an overvalued idea if no real evidence has ever existed to warrant such suspicion.

> A 32-year-old woman, fatigued for many months, complained of being “allergic to everything.” She initially associated her fatigue with eating certain foods, then with using certain cosmetics and soap products, then with wearing certain types of clothing, and then with being around certain types of housepaints, carpets, and draperies. These beliefs resulted in severe restrictions and functional limitations in her work and social life.

Ideas of reference are false personalized interpretations of actual events in which individuals believe that occurrences or remarks refer specifically to them, when in fact they do not. Ideas of reference may be less firmly held than delusional beliefs.

A psychotic young man came to the emergency room in a state of severe water intoxication. He had been sitting at home drinking gallons and gallons of ginger ale, after having seen a television advertisement that said “Drink Gingerale!” He believed this message was specifically addressed to him, and that dire consequences would result if he disobeyed.

Delusions *Delusions* are fixed, false beliefs, strongly held and immutable in the face of refuting evidence, that are not consonant with the person's education, social, and cultural background. Thus, delusional thoughts can only be understood or evaluated with at least some knowledge of patients' interpersonal worlds, such as their involvements with religious or political groups. One of the mind's primary functions is to generate beliefs, including myths and meaning systems. These beliefs provide the individual with a sense of personal and group identity and with ways of understanding reality. They are most noticeable when shared untestable beliefs form the basis for group cohesion as in religions and cults. Some groups adhere to their cherished beliefs despite the abundance of plausible contrary evidence, for example, some fundamentalist sects take the biblical creation story literally. In the face of contrary evidence or grave personal threat, individuals often cling to their primary beliefs as matters of faith (i.e., alternative, nonrefutable bases for understanding). The strong faith with which religious, political, and nationalistic convictions are held, even at the cost of death, shows the power that untestable beliefs can have on behavior. Potential mental health advantages of religious beliefs have been demonstrated in epidemiological studies showing that those with a sense of personal devotion report fewer depressive symptoms.

Subjectively, delusions are indistinguishable from everyday beliefs. Therefore, the subjective experience of a delusion is no different from the subjective experience of believing that the earth is round or that my spouse is the same person I married on my wedding day. Because of the identical experience of delusions and other strongly held beliefs, it is generally impossible to argue a patient out of a delusional belief. The content of delusions is highly influenced by culture. Whereas centuries ago delusions of persecution often concerned persecution by the devil and had religious connotations, persecutory delusions today often take on contemporary political and social perspectives.

> A 42-year-old Native American Vietnam veteran fled to a remote area of the Rocky Mountains to escape a world-wide conspiracy that he believed was trying to control each and every individual, including him. He was aware of this conspiracy because when he lay on the ground at night he could see countless stars and knew that they, and everything on earth, were all connected by “the Web.” Confirming this belief, he heard the murmurings of all computer messages, radio and television transmissions, phone calls, and even face-to-face conversations as part and parcel of this web.

Although delusions are diagnostically nonspecific, some specific types of delusions are more prevalent in one disorder than another. For example, although delusions of control and delusional percepts are often seen in schizophrenia, they also occur, albeit less frequently, in psychotic mood disorders. Similarly, classic

mood-congruent delusions with grandiose themes seen in mania or delusions of poverty characteristic of depression may also be seen in schizophrenia.

Table 8-3 lists some characteristics by which delusions have been classified. *Simple delusions* contain relatively few elements, whereas *complex delusions* may contain extensive elaborations of people, spirits, motives, and situations.

Sample versus complex
Complete versus partial
Systematized versus nonsystematized
Primary (autochthonous) versus secondary
How they affect behavior

Table 8-3 Characteristics of Delusions

Systematized delusions are usually restricted or circumscribed to well-delineated areas, and are ordinarily associated with a clear sensorium and absence of hallucinations. They are often isolated from other aspects of behavior. In contrast, *nonsystematized delusions* usually extend into many areas of life, and new data—new people and situations—are constantly incorporated to further support the delusion. The patient usually has concurrent mental confusion, hallucinations, and some affective lability. Whereas the patient with a closed systematized delusional system may go about life relatively unperturbed, the patient with a nonsystematized delusion frequently has poor social functioning and often behaves in response to the delusional beliefs.

Complete delusions are those held utterly without doubt. In contrast, *partial delusions* are those in which the patient entertains doubts about the delusional beliefs. Such doubts may be seen during the slow development of a delusion, as the delusion is gradually given up, or intermittently throughout its course.

Delusions have also been categorized into *primary* and *secondary* forms. Unfortunately, these terms have been used in a variety of ways, such that the distinctions are confused in the literature. According to one definition primary delusions are those that are not further understandable in terms of the patient's specific context, such as culture or mood, whereas delusional beliefs that could be understood or appreciated as an extension of a cultural belief or of a mood are secondary. In this framework, a mood-congruent psychotic delusion with themes of worthlessness or guilt would be a considered a secondary delusion. According to a different definition, a primary delusion refers to and is synonymous with an *autochthonous delusion*, one that takes form in an instant, without identifiable preceding events, as if full awareness suddenly burst forth in an unexpected flash of insight, like a bolt from the blue. These delusions may be quite elaborate.

> An 18-year-old young man from a middle-class Jewish family who had become increasingly socially isolated and withdrawn over a 2-year period presented to an emergency room in an utter panic, with his penis taped to his thigh, believing that his penis had started to shrink into his body and would disappear. No other delusional beliefs or hallucinations were evident.

Aside from the autochthonous types, three other types of delusions have been described as primary. *Delusional percept* refers to the experience of interpreting a normal perception with a delusional meaning, one which has enormous personal significance to the patient. *Delusional atmosphere* or *delusional mood* is a state of perplexity, a sense that something uncanny or odd is going on that involves the patient, but in unspecified ways. Ordinary events may take on heightened significance but the delusional interpretations are fleeting whereas the uncanny feeling lingers. Typically, after a period of time full-blown delusions develop, replacing the delusional mood. *Delusional memory* is the memory of an event that is clearly delusional. As an example, a patient “remembered” his fourth-grade teacher slipping lysergic acid diethylamide (LSD) into his apple juice; this memory served to explain his psychotic disorder. The elaboration of false memories and their subsequent fixed beliefs may assume delusional proportions.

> A young woman with schizophrenia attended a trauma group with her roommate and gradually came to believe that she had been repeatedly sexually assaulted by her father, from the time she was in the crib. What started out as vague dream-like images gradually coalesced into a series of “sensed” memories that then took on specific visual images of her father's fingers penetrating her, and of his leering down at her in the crib. Her parents were horrified by these accusations, and there was not a shred of evidence to corroborate her increasingly venomous accusations.

Patients vary considerably in the extent to which they take action in response to delusional thoughts. Just as patients can experience delusions of their thoughts being controlled *(thought passivity)*, they may similarly experience their feelings, behaviors, and will as controlled by outside forces. These *delusions of control* (or *passivity experiences*) occasionally, albeit uncommonly, result in dramatic self-destructive or aggressive behaviors, as illustrated by the murderer who called himself Son of Sam. This psychotic killer murdered several people in New York and claimed that he was the powerless agent of a force that required him to commit the acts. To defend themselves and others against delusional anticipated events, some patients may take bold and occasionally destructive actions.

> A 36-year-old man with schizophrenia was brought to the hospital after enucleating one of his eyes with a pencil. He believed that he had to sacrifice his eye in order to avert world destruction. In an elaborate delusional scheme, he was convinced that the evil he saw in the world was going to lead God to bring destruction upon all mankind, and he hoped that by sacrificing his eye God would see less of the evil in the world.

Table 8-4 lists some classic types of delusions. Although less common than those involving paranoia, grandiosity, and influence, *delusions of misidentification* are prominently reported because of their inherently intriguing nature. In *Capgras's syndrome* the patient believes that someone close to him has been replaced by an exact double. In *Fregoli's phenomenon* strangers are identified as familiar persons in the patient's life. In the *delusion of doubles*, patients believe that another person has been physically transformed into themselves.

Delusions of persecution
Delusions of grandeur
Delusions of influence
Delusion of having sinned
Nihilistic delusions
Somatic delusions
Delusion of doubles (*Doppelgänger*)
Delusional jealousy (Othello syndrome)
Delusional mood
Delusional perception
Delusional memory
Delusions of erotic attachment (Clérambault's syndrome)
Delusions of replacement of significant others (Capgras's syndrome)
Delusions of disguise (Frégoli's phenomenon)
Shared delusions (folie à deux, folie à trois, folie à famille)

Table 8-4 Some Classic Types of Delusions

Delusions are not only seen in isolated individuals. Shared delusional disorder may occur in couples *(folie a deux)* and in families *(folie en famille)*. Many psychiatrists consider group delusions to be present in some cults, however, the exact distinction between delusions and other zealous beliefs held by larger, more traditional, and

well-organized religious, political, and other groups, is arguable.

Self-Mutilatory, Suicidal, Aggressive, and Homicidal Preoccupations Other disturbances in the content of thought include maladaptive, self-destructive, and other-directed destructive thoughts. In some individuals, such thoughts occur only during times of acute distress, in reaction to specific stressful situations. In others, these thoughts may be chronically present, like background music in the stream of consciousness, varying in the frequency and intensity of their presence, in the specificity and vividness of their accompanying images, and in how compelling they are.

> A 36-year-old unemployed man with alcoholism became increasingly preoccupied with the idea that his wife was unfaithful. He accused and threatened her, stalking her whenever she left the house, filled with rage and entertaining fantasies of killing her and her presumed lover if he found them together. After months of trying to appease and reason with her husband, and after several instances of being beaten, the wife finally left him. She took their child to a shelter, hoping that he would leave them alone, but constantly feared for their safety.

Disturbances of Judgment Judgment involves a complex and diverse group of mental functions that includes analytic thinking, social and ethical action tendencies, and depth of understanding or insight. Analytic thinking includes the capacity to discriminate and to weigh the pros and cons of alternatives. Social and ethical action tendencies are closely related to culture and upbringing. The evidence for genetic factors in antisocial personality disorder (defined primarily by judgments that lead to criminal behaviors) points to the additional role of constitutional factors. Insight may reflect intelligence, learning, cognitive style, and the capacity to integrate intellectual knowledge with emotional awareness.

Impairments of judgment occur in many psychiatric disturbances. Anxiety states, intoxications, fatigue, and even group pressures may cause temporary impairments of judgment in otherwise normal individuals. Organic brain damage, cognitive disorders, and psychotic disorders may chronically impair any aspect of judgment in any person regardless of premorbid character. Poor role models and deviant social backgrounds may lead to social and ethical action tendencies quite different from those of the examiner. Thus, someone raised in a criminal environment may have superb analytic judgment and self-awareness, which are, however, put to illegal use.

Judgment may be impaired in one dimension and spared in others. Individuals may retain sound ethical judgment when their analytic capacities fail or they may retain excellent analytic abilities for nonpersonal matters while lacking insight into personal situations or behaviors. Thus, some people who can provide socially appropriate responses to traditional mental status examination questions such as what one would do in a movie theater if a fire broke out, or what one would do with a stamped and sealed addressed envelope found in the street, might at the same time be incapable of accurately assessing crucial clinical information or more personal matters specifically related to the capacity to provide informed consent, such as the pros and cons of receiving a medication or electroconvulsive therapy; or regarding judgments necessary to provide oneself with food, clothing, and shelter; or insight into one's state of health or illness. The apocryphal story about the delusional patient who was able to accurately evaluate and fix a broken-down car that had stymied the mechanics, ending with the patient's declaring “I may be crazy, but I'm not stupid” indicates the selective nature of poor judgment within psychiatric disorders.

The term *insight*, usually applied in the context of self-awareness, has been used in a variety of ways. Basic insight refers to a superficial awareness of one's situation, (e.g., that one is ill). A deeper level of insight is operating when the patient has an intellectual appreciation of what is going on (e.g., “I have hallucinations and delusions, and my doctors have told me that I have schizophrenia and must take medication”). Still deeper levels of insight reflect more complete cognitive and emotional appreciation of a situation (e.g., “I realize that I have schizophrenia, that it impairs my judgment and social function at times, and that I will have to take medications if I am to minimize my symptoms and try to make the most of my life. I feel profoundly disappointed about this affliction because it prevents me from achieving some of the goals I've always wished for. Nevertheless, I have do my best to get over my disappointment and hurt feelings so that I can get whatever I can out of life.”)

Judgment may be impaired by several factors, including cognitive clouding (as in disturbances of consciousness, such as intoxication that impairs one's usual analytic abilities), self-deception, and impulsivity.

Self-deception refers to the almost universal tendency to hide certain issues about the external world or about ourselves from various levels of one's own awareness. Self-deception functions as a coping strategy, fostering or maintaining comfortable perspectives about the world, and avoiding confrontation with issues and realities that would inevitably stir up painful conflicts or the need for difficult actions; it thereby helps an individual to preserve emotional calm. In addition, studies suggest that self-deception enables one to act and to be perceived as more convincing in the service of particular goals, as in romantic relationships or business dealings. Therefore, while kidding oneself may sometimes reflect impaired judgment, it may also yield certain important strategic advantages.

Impulsive judgment describes a tendency to avoid taking the time to fully understand and integrate all the facts and levels of awareness required for optimal decisionmaking. Impulsive judgment may occur only with certain issues or situations (such as how one picks investments), may signal an impaired state (such as substance intoxication), or may reflect a pervasive character trait.

Rapidly made judgments, and even so-called “snap” judgments, are not all maladaptively impulsive, even when they involve very important areas of life. Rapid decisions can be very accurate, highly adaptive, and even life-saving, especially if made against a background of great experience, wisdom, and forethought concerning the area requiring the decision.

Disturbances of Consciousness *Consciousness* can be defined as subjective awareness of the self and environment. Biologists increasingly believe that a continuum of consciousness exists, extending from lower animals through *Homo sapiens*. However, consciousness is subject to conflicting definitions and conceptualizations, and exactly where consciousness begins in evolution remains unclear. Philosophers agree that it is the subjectivity of experience, the so-called *qualia* of consciousness, that clearly distinguishes living consciousness from the 1990s' best versions of self-regulating automata, elegant computers, and robots. All current attempts even to approach an understanding of consciousness are very unsatisfying; consciousness remains unexplained and as yet unexplainable from a scientific point of view. Consciousness has been viewed as an emergent property of complex biological nervous systems, as a poorly understood general property of an even more mysterious and complex universe, or as a phenomenon to be understood only in religious and spiritual terms. One of the best analyses to date of possible relationships between the construction of a brain and the possibility of consciousness has been set forth by Gerald Edelman, who believes that reflective consciousness cannot occur until complex higher-order brain systems evolve whose major functions are to monitor the experiences, activities, and results of activities of those lower-order brain systems that deal directly with appraising and responding to the external and internal environments. Such higher-order meta-systems require the presence of memory, so that current and immediate impressions can be checked and compared against past experiences. These meta-systems may use a variety of sensor mechanisms to detect and signal their sensations or perceptions of various events. Some of these sensors may correspond to feeling states and some may correspond initially to preverbal thought-like mechanisms that contain the capacity to develop and recognize abstract categories, and ultimately conceptual language-based thought.

Clinically, consciousness can be considered from both qualitative as well as quantitative viewpoints. Qualitatively, consciousness does not seem to be an all-or-none phenomenon. Rather, conscious experiences may gradually and phasically shift in focus, intensity, and clarity; altered states of consciousness may occur in which some aspects of consciousness, such as sensation, perception, memory, orientation, and judgment are enhanced or impaired relative to other aspects. Quantitatively, crude divisions can be made between states depending on the relative presence, impairment, or total absence of consciousness. Even within a single individual consciousness is not a unitary phenomenon. Multiple streams of thought, operating at multiple levels of preconsciousnesses, appear to exist in all of us almost all the time, with various elements in these coexisting streams constantly shifting into higher or lower levels of conscious awareness. In pathological states, even more remarkable properties of consciousness are seen; for example, the existence of co-consciousness in humans who have had commissurotomies, and of seemingly multiple discrete consciousnesses in patients with dissociative identity disorders.

Experiments involving patients with commissurotomies of the corpus callosum have shown the existence of two virtually separate systems of consciousness that seem to operate simultaneously. For example, when in the course of an experiment the picture of a nude woman was flashed only to the right brain (the left visual field) of a commissurotomized patient, the subject verbally denied being aware of anything unusual (i.e., the left brain—the verbal brain—was unaware). However, the patient started to squirm and blush, blurting out, “Oh, you have some machine!” Similarly, when a cup was presented to the right brain (left visual field) only, the patient denied seeing anything (the left brain was unaware and the language output of the left brain indicated no awareness), but he was able to pick out the cup from an assortment of objects with his left hand (right brain control). This literal splitting of verbal awareness from visual-spatial awareness in the brain produces behavior that is at least superficially similar to that of patients who deny being consciously upset by an event, but who react with strong visceral responses. Although this formulation is simplistic, the separate consciousness for logical-verbal and for spatial-visual awareness demonstrated in split-brain experiments may be crude analogues for more highly differentiated and discrete types of awareness and modes of information processing. Furthermore, the very fact that there are separate and

even competing modes of consciousness may increase the likelihood of psychological distress, because the various modes are capable of yielding internally conflicting views of reality.

Psychological and Physiological Factors In ordinary states of alert consciousness individuals are able to pay an adequate amount of attention to their surroundings and to reflective thought. Normal people vary enormously in their ability to pay careful attention in different settings without being distracted; individual variations may reflect temperamental and cognitive style differences as well as physiological shifts within the individual. Many functions of attentive consciousness including attention, planning, and the capacity to switch appropriately between mental tasks have recently been linked to the activity of specific neurons in area 46 of the prefrontal cortex.

A sense of increased consciousness with heightened alertness, awareness, and sharper thinking may be experienced in highly aroused emotional states such as threat, sexual attraction, falling in love, or other high-stakes events such as hunting (in primitive peoples), sporting competitions, or performing in front of an important audience. High levels of arousal do not necessarily guarantee effective attention because optimal consciousness depends on optimal arousal. Too little arousal, caused by illness or fatigue, may result in insufficient stimulation and mental lethargy, diminishing the sense of alertness and attentiveness; too much arousal may result in hyperintense alertness but distractibility and scattered attention.

Consciousness involves, among other things, the experience of a continuous sense of self and of the environment, existing coherently in time and space. The experience of time and its passage may be altered by shifts in the level of awareness and by emotional states such as boredom, concentration, pain, and discomfort. The experience of time and space may be altered by hypnosis, cannabis, psychoactive and psychedelic drugs, and other events that directly affect brain physiology.

Disturbances in the Level of Consciousness Levels of consciousness (i.e., alertness, awareness, and attentiveness) may be pathologically increased or decreased. Such changes are diagnostically nonspecific and can occur in many different disorders. When levels of arousal and alertness are mildly elevated, as in hypomania or with the ingestion of small amounts of psychostimulants, subjective experiences are typically positive. In these situations the person experiences intense alertness, prolonged concentrating ability, and hyperesthesias in which perceptual vividness is heightened: colors are brighter, sounds are sharper, and touch is more intense than usual. With further increases in arousal and consciousness as seen in mania, more severe intoxications with amphetamines and cocaine, and catatonic excitement, attention deteriorates. Heightened alertness transforms into hypervigilance and paranoia, and hyperesthesias become unpleasant.

Diminished levels of consciousness can be described on a continuum. *Clouding of consciousness* is marked by diminished awareness of sensory cues and diminished attentiveness to the environment and to the self. Secondary-process thinking is most notably compromised, and more primary-process thinking emerges into consciousness. In this state, one's ability to appreciate subtleties and to think in a nuanced manner is diminished, and is replaced by more dichotomous all-or-none, stereotypic thinking. The level of consciousness may fluctuate rapidly in relation to the internal physiological state or to the degree of external stimulation. In alterations of consciousness, confusion may occur with disorientation to time, place, or person. The patient is usually highly distractible and unable to pay sustained attention to a single stimulus.

Torpor is a condition in which the patient is drowsy, falls asleep easily, and shows a narrowed range of perception and slowed thinking. *Stupor* is a state of diminished consciousness in which the patient remains mute and still although the eyes are open and may follow external objects. In the most extreme impairment of consciousness, *coma*, there is no evidence of mental activity at all. The patient appears essentially to be functioning on a decorticate or decerebrate level. In *akinetic mutism* or *coma vigil*, patients with profound brainstem lesions appear to be awake with their eyes open, but there is in fact no evidence of consciousness.

Delirium, an acute confusional state, is usually characterized by a relatively abrupt onset and a short duration of clouded, reduced, and fragmented attention; impaired memory and learning; perceptual and cognitive abnormalities such as hallucinations and delusions; disrupted sleep; and other autonomic dysfunction. The level of consciousness may be consistently diminished or may fluctuate. The electroencephalogram (EEG) usually shows diffuse slowing. Typical motor abnormalities include an increase in general restlessness, fine and coarse tremors, and myoclonic jerks. Autonomic disturbances commonly include tachycardia, fever, elevated blood pressure, diaphoresis, and pupillary dilatation. The causes of delirium are legion, including systemic medical disorders such as metabolic imbalances or infections; intracranial disorders caused by traumatic, structural, and electrical causes; and substance intoxication and withdrawal states.

Attentional difficulties are manifest by impairments in the person's ability to deploy, focus, and sustain attention. Some attentional difficulties first appear in early childhood as developmental problems of uncertain cause, and are described as *attention-deficit disorder*. Secondary attention-deficit difficulties may appear de novo in adulthood from a variety of exogenous agents, psychiatric disorders, and late-life developmental and degenerative factors.

In *narcolepsy*, which is characterized by sudden lapses into sleep, one's usual ability to stay alert and maintain consciousness is impaired. At times the onset of profound sleepiness is gradual, accompanied by hypnogogic phenomena, in which dreamlike images invade the consciousness; at other times the shift in consciousness appears to be almost instantaneous. This syndrome, occurring in about 1 in 10,000 persons, is thought to be the second most frequent cause of automobile accidents after alcohol intoxication.

Altered States of Consciousness Consciousness may also be qualitatively changed with the production of altered states. Drugs such as scopolamine (Transderm) with strong central anticholinergic properties, some seizures, and on occasion other conditions associated with delirium can induce *twilight states*, dream-like states of wakeful consciousness in which attention is poor, a mixture of primary and secondary process thinking appears, and patients fade in and out of alertness. Dream-like experiences intrude into the stream of conversation. Emotional outbursts or violent acts may occur during twilight states.

Mystical states of consciousness may occur in normal and pathological conditions. Intense meditation and peak or epiphanic experiences, reported by more than 10 percent of normal individuals in community surveys, may produce a sense that the self dissolves or expands, that the self fuses mystically with the cosmos, that time stops, and that universal meaning becomes clear. These perceptions may be accompanied by a sense of rejuvenation and renewed personal identity, ineffability, intense emotionality, and concurrent perceptual changes. Such experiences do not ordinarily last more than a few minutes. Many people have achieved these states through the use of psychedelic agents such as mescaline and LSD. Reports of a white light at the end of a tunnel, described by individuals using psychedelics and during near-death experiences, have been linked to specific neurophysiological pathways thought to be stimulated under these conditions.

Although *hypnosis* lacks a consensually accepted definition, its hallmarks are selective attention, suggestibility, and dissociation. Most people, but not all, can be hypnotized to some degree. Up to 90 percent of people are capable of achieving a light trance, whereas 10 to 20 percent are capable of entering a deep trance and exhibiting remarkable hypnotic phenomena. Hypnosis occurs when the subject is in a state of heightened, not diminished, attention. EEG studies have shown hypnotized subjects to be fully awake and alert. The heightened concentration probably accounts for the unusual levels of sensory and motor performance often seen under hypnosis and self-hypnosis.

Hypnotic phenomena include hypnotically induced hallucinations (including negative hallucinations in which the subject selectively fails to perceive sights, sounds, or other stimuli), anesthesia, sustained motor behaviors and acts of strength ordinarily beyond the individual's capacity, and distortions of memory (both hypermnesias and amnesia). Several phenomena that reveal the multiple nature of consciousness, for example, co-consciousness, are also demonstrable. Experiments have shown that even when a subject in a deep trance has achieved profound hypnotic anesthesia and can, for example, keep a hand submerged in ice water for longer periods of time than usual, part of the hypnotized subject's consciousness continues to register exactly how painful the experience actually is and can signal the researcher about the pain by finger movements without the subject having any conscious awareness or disturbance. This phenomenon, called the *hidden observer*, has also been seen in postsurgical patients who, under hypnotic trance after surgery, have been able to accurately recall conversations in the operating room that occurred while they were under general anesthesia. Dissociative and psychosomatic phenomena have also been induced with hypnosis. With posthypnotic suggestion, subjects may carry out complex actions without any hint that they are actually doing so because they were previously instructed to act that way under hypnosis. When asked why they are carrying out these activities, such subjects will usually make up reasons, while seemingly unaware of the real reasons for their actions. It has been suggested, not entirely facetiously, that many normal daily activities are conducted in a trance-like posthypnotic state, and although these activities are attributed to conscious intention, they may in fact be carried out as a result of previous suggestion. Advertisers know this well. Urticaria (hives) can be hypnotically induced and hypnotically made to disappear. Plantar warts have been successfully treated with hypnosis, and in these conditions diminished blood supplies to their bases have been demonstrated. It has recently been appreciated that yoga masters can exert remarkable control over basic bodily functions through self-hypnosis. As yet, little is known of the full extent to which heightened concentration may influence physiological regulation.

Suggestibility Pathological suggestibility may be seen in several clinical conditions. Automatic obedience has been described in *echolalia* (the automatic repetition of a sentence or phrase just uttered by another person), *echopraxia* (the automatic mimicking of a movement performed by another person), and *waxy flexibility* (maintaining for a prolonged period of time a posture in which one is placed), symptoms common in catatonic states. In situations of group delusions, and sometimes

in cults, passive individuals adopt the delusional beliefs of stronger ones. In epidemic hysteria, as described so beautifully among young women at the Salem witch trials in Arthur Miller's *The Crucible*, distorted and even delusional perceptions and beliefs may sweep over a group that has been highly aroused by a charismatic leader.

Autosuggestibility can be seen in the constructions of false memories, in which an individual progressively comes to believe that something that never happened in fact occurred. Such false memories may be held with such great conviction that they are indistinguishable from the memories of real events. Various types and degrees of self-deception may be more common in individuals who are more suggestible.

DISSOCIATIVE PHENOMENA *Dissociation* refers to the splitting off from one another of what are ordinarily closely connected behaviors, thoughts, or feelings. *Dissociative states* are those in which there is a disturbance or alteration in the normally integrated functions of identity, memory, or consciousness and include trances, fugues, blackouts, multiple personalities (*dissociative identity disorder*), and dissociative frenzies. Although dissociative states are ordinarily thought to be functional in nature, arising as an adaptive defense in individuals subjected to a great deal of trauma, particularly at early ages, they occur regularly with a variety of neurological disorders, particularly with partial complex seizures. In one series, one third of patients with complex partial seizures had dissociative phenomena including multiple personality. In these patients the dissociative phenomena were not related to the seizure activity, but to interictal alterations.

As in posthypnotic amnesia, elaborate activities can occur in dissociative states for which the subject will have no conscious memory. This amnesia is functional in nature and may be reversed by hypnosis or drug-facilitated disinhibition, for example, with amobarbital (Amytal) infusion. In many of the functional dissociative states, amnestic episodes may occur for years or decades before the patient seeks medical or psychiatric attention. *Blackouts* are periods of amnesia in alcoholism, other intoxications, or following head trauma. An alcoholic blackout period may last for hours to days, after which the person has no recollection of what transpired although other observers will attest to the fact that during this period the individual carried out multiple complicated behaviors. Although memory of the blackout is lost to the predominant consciousness, during subsequent reintoxication memories of events occurring during the previous blackout may be reawakened. This phenomenon, known as *state-dependent memory*, occurs in many other conditions as well, signifying that one's ability to retrieve specific memories may be highly influenced by specific physiological alterations caused by external intoxicants or other unusual physiological states.

When he was questioned during an initial psychiatric interview, a 28-year-old euthymic man with a history of severe bipolar I disorder could not recall the content of his thinking during any of his manic episodes. However, at the beginning of his next manic period he reminded his psychiatrist about this question, and was able to describe the grandiose delusions and hallucinations he had experienced during his previous manic states.

Dissociative fugue is characterized by prolonged periods in which individuals carry out very complex activities without having any recollection of their previous lives, identities, or even names. They often travel away from customary locales and assume entirely new identities. By definition, psychogenic fugue cannot result from a neurological disorder. In comparison, the discontinuity of experience in *dissociative amnesia* is typically more circumscribed and does not involve assuming an entirely new identity. The dissociated memories and moods often reveal themselves in disguised form as nightmares, intrusive visual images, and conversion symptoms. Typically, in psychogenic amnesia an individual may not be able to recollect what transpired during a specific period of time, for example, before the age of 9 or 10 in the context of a traumatic childhood, or catastrophic events such as traumatic, gruesome combat, or less momentous events that a person prefers to forget in order to preserve self-esteem by denying shameful, immoral, or illegal activities.

A 42-year-old man who had been in an automobile accident several months previously, without any clear report of head injury at that time, was seen in a hospital claiming that he was unable to remember any of the events of the accident or any events for a week prior to or subsequent to the accident. After several interviews conducted after he had been administered amobarbital he was able to recall that although formal police charges had never been filed against him, the accident had been his fault and that a passenger in the other car had been killed as a result of the accident. His memories evoked a great deal of psychological pain, grief, and remorse.

Dissociative identity disorder is a chronic, dissociative state in which two or more separate ongoing identities or personalities alternate in consciousness. It usually occurs in persons who as young children were severely and repeatedly brutalized. The number of identities is variable, with some cases reporting 25 or more identities. The development of dissociated alter personalities is thought to be a last-ditch, primitive psychological defense against inescapable and unbearably traumatic situations. The personalities may be of different ages and even different sexes. Typically, the presenting identity is dysphoric, anxious, and constricted, may suffer headaches and periods of blackout or amnesia, and is not aware of the other personalities. A second identity is typically vivacious and uninhibited. Another identity may know all about the other personalities and has a wise perspective on the life events leading to the problems and on possible solutions. A classic case is described in a popular book and film, *The Three Faces of Eve*. In so-called channeling, dissociated complex part-personalities are produced in trance states, in which fictitious past lives or spirit lives are created.

In *Ganser's syndrome* the patient responds to questions by giving approximate or patently ridiculous answers, for example, in response to the question “What sound does a dog make?” the patient answers “moo.” Additional features of the syndrome include alterations in consciousness, hallucinations (or pseudohallucinations), conversion phenomena, and amnesia for the episode during which these symptoms were manifest. This syndrome has most commonly been reported in prisoners, and is generally thought to be a dissociative state, although organic features may contribute.

Depersonalization refers to an alteration in one's experience and awareness of the self, leading to feelings of being unreal or detached from one's own body, of feeling like an automation; it is often accompanied by the complaint that the individual lacks all feelings and sensory experiences. Those experiencing depersonalization frequently fear that they are going crazy. Because of this fear, patients often endure depersonalization experiences for long periods of time before describing them to a mental health professional. Depersonalization is also characterized by frequent internal nonaudible dialogues between the participating self and the observing self, but with full awareness that both parties are the same person (a feature that distinguishes it from hallucinations.) Mild sensory distortions, but not hallucinations, are commonly associated with the experience. Depersonalization is seen in a variety of neurological and psychiatric disorders and is common in complex partial seizures. It may occur in the context of depression, anxiety disorders, or certain personality disorders or as an entity by itself (depersonalization disorder).

In *derealization*, individuals know themselves to be real, but feel that the world around them has suddenly become unreal. Derealization often but not always accompanies depersonalization. Transient episodes of depersonalizaiton and derealization occur frequently in normal persons, particularly during states of fatigue, sleep deprivation, or stressful situations such as bereavement, learning of a terminal diagnosis, or sudden awareness that one is about to be in an inescapable vehicle accident.

A 27-year-old man described driving in his car when he realized that he was about to be hit by a huge tractor trailer and had no way of avoiding the collision. During the seconds prior to impact, at the moment of impact itself, and for minutes following the impact when he sat, dazed and thankful to be alive, in his totally destroyed car, he felt completely estranged from events, saying to himself, “This can't be real; this isn't happening to me; I'm going to wake up and things will be normal.”

Disturbances of the Self At the most basic level, the key components of self-awareness are the reality and integrity of the self (that I am one person), the continuity of self (that I am the same person now that I was in the past and that I will be in the future), the boundaries of self (that I can distinguish between myself and the rest of the world as not-self), and activity of self (that it is *I* who is thinking, doing, feeling). Additional components of a sense of self include body image, and various self-evaluations including self-esteem and ego ideal (ideal self). *Body image* is an individual's mental representation of his or her own body. *Self-esteem* is thought to reflect how one measures up to the desired self-image. To the extent that what one sees in oneself approximates what one would like to be, elf-esteem is positive. *Ego ideals* are fantasies of the optimum person one could ever wish to be. Any of these qualities may be disturbed in psychiatric disorders.

Within each individual is a group of *social selves* composed of the roles and identities that the person assumes and that are evoked in various contexts. The presenting “self” varies depending on the persons with whom we are interacting, for example, parent, romantic partner, child, friend, or employer, and depending on what role we are assuming, for example, child, parent, colleague, or lover. Accompanying each of these “selves” are various levels of objective and subjective self-awareness and self-understanding.

Disturbances in Sense of Self Disturbances of the basic elements of self-awareness may be seen in a variety of disorders. Discontinuity phenomena are characteristic of dissociative disorders, such as dissociative amnesias and dissociative fugue. Depersonalization reflects a mild disturbance in the awareness of self as the agent of activity. More severe disturbance is characteristic of the psychotic passivity phenomena seen in schizophrenia. Boundary disturbances may be

considered characteristic of all psychotic states, regardless of diagnosis.

Disorders of self-integrity are characteristic of dissociative identity disorders as well as severe borderline personality disorders in which a person's self-concept and expression of this concept to others is erratic, leading to a sense of unstable identity. The *as-if personality* typically adopts characteristics of those who are particularly important to the individual, like a personality chameleon. In adopting these characteristics, the as-if personality does not appear to be acting, but seems to experience and manifest the assumed traits in a very genuine manner, at least for a while. A change in relationships and situations usually prompts the as-if personality to summarily discard previously held traits and to assume new ones that better fit with the new circumstances.

False self describes a persona or a faulty and limited superficial aspect of the personality that an individual builds up as a mechanism for adapting to a hostile world—to please, control, or negotiate with others and with himself or herself. However, the false self fails to incorporate, integrate, or validate important fundamental needs, wants, values, and beliefs. Through self-deception and denial the individual may consciously believe that this "self" constitutes his or her entire being. However, the false self is a relatively fragile construction that has usually warded off and denied fundamental strivings, which may include needs for autonomy, acting with integrity, expressing certain desires, beliefs or talents, or other unacknowledged aspects of the self. When these warded-off needs finally break through and demand expression at various points in development, the defective false self may collapse, leading to a period of distress and identity confusion which individuals sometimes describe as a "nervous breakdown."

Patients with pseudologia fantastica and the impostor syndrome demonstrate extreme examples of inconsistency in the sense of self. Patients with *pseudologia fantastica* compulsively spin out webs of lies, ordinarily self-aggrandizing ones, and also appear to be trying very hard to deceive themselves into believing that they are true. In the *impostor syndrome*, such fantasies are acted out by liars and impostors who seem to fervently wish that these fantasies were their reality, as if they cannot accept themselves and would be overwhelmingly ashamed to be known for who they actually are. The impostor compulsively adopts the identities of others and may, for example, show up properly attired at diplomatic functions and society galas and interact with the other guests under the assumed identity. Some famous impostors have repeatedly insinuated themselves into inner circles of high society and government.

Transsexualism is a syndrome characterized by the feeling that one was born into a body of the wrong sex and marked by the desire, starting at an early age, to be a person of the opposite sex. Male-to-female transsexualism is reported more often than female-to-male transsexualism. Both psychodynamic and biological theories have been advanced to explain these phenomena. Such persons seek procedures to change their anatomy with hormones or surgery.

Self-esteem is a measure of one's self-appraisal in relation to one's values and ego-ideals. Negative self-esteem is characteristic of depressive disorders, many personality disorders, and situational failures. Superficially inflated self-esteem may be seen in mania (or hypomania), or, in a fluctuating manner, in narcissistic and other personality disorders.

Although some individuals regard their ego-ideals as unattainable and are content to live as imperfect human beings, others strive to approximate their ideals. People who feel driven to achieve unattainable ideal goals or to become their unrealistically perfect ideal selves are likely to be chronically dysphoric and have poor self-esteem, since their attempts to become their ego-ideals are doomed to failure.

Disorders of the Will Central to the sense of self is the concept of will or volition. Psychologically, will is linked to the concepts of intentionality and of transforming awareness and knowledge into initiating action, as the bridge between desire and act. To manifest normal will, individuals must be aware and feel desires, and these desires must arise from within themselves. Concepts related to will that may become the focus of clinical attention when disturbed include motivation and decision making (i.e., the capacity to make choices).

Pathologically *heightened will*, seen primarily in manic states, is characterized by excessively intense desires and an overly facile capacity to make decisions, with complex questions being decided on in an instant. With heightened psychological energy, these individuals can start new courses of action with astonishing rapidity. Closer examination of these actions in more extreme cases, however, reveals that they share much in common with decreased will, in that the intense desires and quick decisions often reflect impulsiveness, which can be considered an escape from true willing and decision-making rather than enduring desires or thoughtful decision-making.

The term *abulia* has been used to describe the loss, lack, or impairment of the power to will or to execute what is in mind. Individuals with abulia show a diminished sense of motive or desire and impairment in making the transition from motive and desire to execution of action. Deficiencies in will may be seen in a variety of psychiatric disorders, and at the end of life when patients have surrendered their will to live and are simply waiting to die. In schizophrenia a diminished sense of will can be seen in passivity phenomena, as well as in other negative (or deficit) symptoms that may affect thoughts, feelings, and behaviors. These include lack of drive, impersistence at tasks, and a general inner flatness. Depressed patients also describe volitional disturbances, as in their general apathy and anhedonia. Patients who chronically inhale solvents (e.g., glue, gasoline, toluene), smoke marijuana very heavily, and chronically use hallucinogens have a characteristic *amotivational syndrome*. The extent to which this lack of motivation results from or contributes to the chronic substance abuse is a matter of debate.

In obsessive-compulsive disorder both the obsessional thoughts and the compulsive rituals are experienced as ego-dystonic and not consonant with the patient's conscious desires and will. Similarly, although patients with anorexia nervosa initially have the conscious experience of willing and controlling their intake of food, during the course of the disorder the sense of willfulness is replaced by passivity, of being subjugated by obsessional thoughts and compulsive behaviors that assume control of the eating behavior.

> A 35-year-old woman with chronic anorexia nervosa felt compelled to cut her food into pieces no larger than rice grains, fearing that larger pieces would make her fat, and that she might choke. She permitted herself no foods that contained any fat. Other compulsions required her to swim eight or sixteen laps in the local pool each day. Failing to do so would result in a masochistic punishment, usually burning her arm with a lit cigarette.

Disturbances of volition are among the more common complaints of patients with personality disturbances who request psychotherapy. Individuals with dependent personalities are characterized by difficulties in making decisions by themselves and often engage in courses of action contrary to their own desires. Similarly, individuals with passive-aggressive personality disorder obscure their own desires by being excessively involved in the demands made upon them by others. Their courses of action do not reflect their own decisions so much as the thwarting of others' desires. People with compulsive personalities use inflexible rules, thereby precluding courses of action based on independent evaluation, individual desires, and decisions. In other situations, they are indecisive, sometimes making impulsive decisions at the last minute when forced to decide. Finally, many individuals seek treatment because of self-designated disturbances of willing: they do not know what they want, they are unable to make choices among several options, or they procrastinate excessively. Often these problems may mask other fears—of wanting, commitment, taking initiative, hard work, success, making a mistake, being criticized, angering others, and of all the consequences related to such actions.

Disturbances of Orientation Orientation refers to one's awareness of time, place, and person. Accurate orientation requires the integrity of attention, perception, memory, and ideation. Impairments occur primarily in organic mental disorders (i.e., structural and toxic metabolic brain abnormalities) and occasionally in dissociative and psychotic states.

Normal individuals vary tremendously in their attention to the details of time, and in the extent to which their bodies automatically keep time. Some people have reliable built-in clocks by which they can awaken themselves at precise times or gauge the passage of time with uncanny accuracy, even in the absence of external cues, as during a psychotherapy session, for example. Others have difficulty making judgments about time and may develop pathological lateness or habitually schedule more activities than could ever be accomplished in the available time. Benign disorientation to time is common. After a few days in a hospital bed, most people do not know exactly what the day or date is because they are not attending to or receiving their usual cues.

Pathological time disorientation can be mild or severe, with inaccuracies of estimation ranging from days to years. The dates reported by disoriented individuals may have personal significance, such as those of important births, marriages, or deaths.

Because spatial cues are generally more available and obvious than temporal cues, disorientation to place often signifies a greater degree of cognitive impairment than disorientation to time, and therefore rarely occurs in the absence of time disorientation. Disoriented persons may know, more or less, the type of place they are in without knowing the specific place—patients may recognize that they are in *a* hospital without being able to name the hospital.

A 56-year-old former banking official with advanced Alzheimer's disease demonstrated preserved superficial social graces and was generally in a pleasant mood. When anyone asked him where he was, however, he appeared to become momentarily aware of his profound deficits and became very agitated, developing a marked tremor of his left arm and hand and fearfully looking about. This would last for a few minutes, until he was calmed and reassured that he was all right.

Disorientation to *person*, a lack of awareness of one's own identity, is typically seen only in advanced dementias, such as primary degenerative dementia of the Alzheimer's type or in dissociative states. In postconcussion amnesia, transient global amnesia, and dissociative fugue, knowledge of one's own identity may disappear and a person may remain unidentified for an indefinite period until the memory for self returns.

Disturbances of Memory Memory is not a unitary phenomenon. Capacities to remember vary for the different senses and perceptions. One person may have prodigious musical memory, with the capacity to remember and reproduce whole musical pieces after one hearing, but be incapable of remembering people's names or telephone numbers. Exceptionally detailed verbal memories have been associated with obsessional cognitive styles. When individuals with extraordinary memories complain of memory loss, ordinary memory tests may be inadequate to detect their deficits because their relative memory loss may have reduced their capacities to a point within the range of most normal people.

Memory functions have been divided into three stages: registration, retention, and recall. *Registration* or acquisition refers to the capacity to add new material to memory. The material may be sensory, perceptual, or conceptual and may come from the environment or from within the person. In order for new material to be acquired, the person must attend to the information presented, it must then be registered through the appropriate sensory channels, and then be processed or cortically organized. *Retention* is the ability to hold memories in storage. Large numbers of neurons are thought to be involved in the storage of a specific memory, and it is believed that reverberating circuits are formed in which memory traces are held by means of changes in proteins or synaptic connectivity or both. *Recall* is the capacity to return previously stored memories to consciousness.

Newly registered material is transferred incrementally from immediate to short-term memory to long-term memory. Immediate memory lasts for 15 to 20 seconds; short-term memory (or recent memory) for several minutes up to 2 days (the time involved in new learning and its early consolidation); and long-term (or remote) memory for longer periods of time. Different physiological processes mediate each of these stages of memory. Because of this, processes that affect immediate or short-term memory often spare long-term memory. The processes by which memories are transferred from short-term to long-term stores are unknown.

Cognitive scientists now refer to short-term memory as *working memory*, the system that briefly stores and processes information needed for planning and reasoning. Recent studies suggest that the working memory system consists of at least two short-term memory buffers, one for verbal and another for visual memories, plus a central executive that manipulates and coordinates information stored in the two buffers for problem-solving, planning, and organizing activities. Parallel processing systems involving specific areas of the prefrontal cortex and other brain areas appear to operate separately with respect to various processes concerned with working memory. For example, separate prefrontal areas appear to be involved in working memory functions concerned with object identity and spatial locations.

Other studies suggest that different types of memories are stored and retrieved by different brain systems, so that there is at least a dual memory system. The first system, sometimes called a *conditioned-emotional system*, or system for *implicit memory*, or *perceptual memory*, or *nondeclarative memory*, is present from birth, operational through life, and is addressable by situational, sensory, or affective cues. Past experiences are expressed through images, behaviors, or emotions. These memories need not involve any conscious memories of a past experience. Conditioned fear responses represent examples of memories elicited in this system. The second system, sometimes called *narrative-biographical memory, explicit memory, reflective memory*, or *declarative memory*, emerges during the preschool years, and includes information significant to the self. Memories are addressable through intentional retrieval efforts, apart from the original learning conditions. They are identified as representing personally experienced events, and compose the individual's life history, roughly equivalent to memory with consciousness or memory with awareness. Clinical studies suggest that in at least some amnesias implicit and explicit memory functions may become dissociated. Disturbances in memory occur through the interruption of registration, retention, or recall.

Disturbances in Registration Registration and short-term memory retention are usually impaired in disorders that affect vigilance and attention such as head trauma, delirium, intoxication, psychosis, spontaneous or induced seizures, anxiety, depression, and fatigue. A variety of other metabolic and structural brain disturbances can affect short-term memory as well, particularly lesions affecting the mammillary bodies, hippocampus, fornix, and closely associated areas. Patients with impaired attention and concentration who are able to demonstrate immediate recall may not be able to retain or recollect these items from short-term memory. Benzodiazepine use has been associated with working memory difficulties, especially in the elderly. Some short-acting high-potency benzodiazepines used as sleeping pills may be particularly troublesome in this regard.

Disturbances in Retention The retention of memories is impaired in posttraumatic amnesia as well as in a number of cognitive disorders, such as dementia of the Alzheimer's type and the Wernicke-Korsakoff syndrome. The latter, which ordinarily results from chronic thiamine deficiency seen with alcoholism, is associated with pathological alterations in the mammillary bodies and thalamus.

Disturbances in Recall Disturbances in recall can occur even when memories have been registered and are in storage. Research has shown that memories are not passively retrieved but are actively reconstructed. Each act of recollection requires an act of putting the memory together, not simply lifting it ready made from a file. Because memories are often retrieved for specific purposes to meet the individual's particular needs and agendas, this act of reconstruction is often subject to the introduction of distortions and falsification. As a result, memories may fail to truly represent past events. At times, failure to recall may signify that the memory traces themselves have disappeared and are no longer retrievable. However, difficulties in recall can occur separately, as in the everyday event of forgetting the name of a person or object, only to spontaneously remember it hours or days later. In normal forgetting, more remote events are less well remembered than recent ones, and important events are most vividly retained in memory. Some patients with dementia may lose memories for all events occurring after a specific date or event, as if the slate had been wiped clean, but retain earlier memories. Some individuals may progressively erase memories, so that they recall only earlier and earlier events.

An 80-year-old patient with Alzheimer's disease initially had no memory for events that occurred after he was 70, a few months later he was unable to recall events that had occurred after he was 60, and several years later, although he could not remember his children who had been born in his 30s, he could still recall his spouse and siblings, from earlier periods of life. At each examination it seemed as if his memories for months' or years' worth of events were simply being erased along the time line of his life.

Under usual conditions, forgotten events can be recalled with prompting, associative memories, or other forms of stimulation such as hypnosis. As described earlier, state-dependent memories are recall failures, reversed by reinstituting the context in which the memory was originally formed.

Amnestic disorders are syndromes in which short-term and long-term memory is impaired within a state of normal consciousness. Thus, memory disturbances in delirium should strictly speaking not be considered amnestic syndromes. *Anterograde amnesia* is the inability to register or learn new information (and therefore to form new memories) from a specific event onward; it typically follows head trauma, states of cerebral physiological imbalance, or drug effects. Patients who receive electroconvulsive therapy (ECT) frequently have anterograde amnesias during the course of the treatments; the amnesia gradually fades over numbers of weeks. *Retrograde amnesia* is an impairment in recalling memories that were established before a traumatic event, extending backwards in time for variable periods. As memory is regained, the more remote memories usually return first. A patient originally amnestic for the 3-month period prior to an accident may ultimately be left with amnesia for events only a day or an hour just prior to the accident. In organically caused retrograde amnesias, remote memories are usually intact while amnesia may exist for more recent events. This contrasts with *dissociative amnesia*, in which the time periods of forgotten events may be more spotty or selective.

Hyperamnesia, unusually detailed and vivid memory, may occur in gifted persons, in association with obsessive-compulsive and paranoid personality traits, and in hypnotic trances. *Intrusive memories* may occur in posttraumatic stress disorder, signaling failure of the mechanisms that usually keep unwanted memories and information out of working memory.

A 36-year-old Hispanic woman who had been brutally raped 3 years before, after which the perpetrator savagely cut her genitals and anus with a razor, experienced frequent intrusive memories of the event, associated with marked anxiety and occasional panic. These memories were most likely to intrude during times of repose, when she was trying to fall asleep, and when she was feeling anxious about other ongoing issues in her life.

Although many forgotten memories can be recalled in hypnotic trance, retrospective falsification and distortion may also occur under hypnosis. (Memories recalled under hypnosis usually are not accepted as evidence in court.) Retrospective falsification of memory, the development of false memories, is called *paramnesia*, also

known as *fausse reconnaissance. Confabulation* is another common form of paramnesia in which the patient fills in memory gaps with inaccurate information. The responses given to questions by patients who confabulate may reflect past experiences or constitute bizarre, fantastic stories. Confabulation correlates poorly with memory deficit and is thought to reflect frontal lobe dysfunction and a failure of self-monitoring. Confabulation is prominent in certain alcohol amnestic syndromes such as Wernicke-Korsakoff syndrome as well as other disorders of the mammillary bodies, thalamus, or frontal lobes.

Dêja vu is the sense that one has previously seen or experienced what is transpiring for the first time; it is a false impression that the current stream of consciousness has previously been recorded in memory. Related phenomena are *dêja entendu*, a sense that one has previously heard what is actually being heard for the first time, and *dêja pensé*, a feeling that one has at an earlier time known or understood what is being thought for the first time. Experiences of *jamais vu, jamais entendu*, and *jamais pensé* involve feelings that one has never seen, heard, or thought (respectively) things that in fact one has. These phenomena are all common in everyday life but may increase in states of fatigue or intoxication and in association with complex partial seizures or other psychopathological states.

Dementia is a syndrome in which the essential feature is an acquired impairment of short- and long-term memory with associated impairments of abstract thinking and judgment, personality changes, and other cortical disturbances. The symptoms always involve more than one sphere of function. In later stages, patients with dementia may become helpless, too confused to use a stove, and incapable of remembering the names of close relatives. They may wander into dangerous situations, oblivious of their surroundings. Dementias are caused by a variety of pathogenic processes, some of which are reversible, such as hypothyroidism and subdural hematoma; others are irreversible, such as dementia of the Alzheimer's type and vascular dementia. Although the characteristic cognitive disturbances seen in severe major depressive episodes are usually called *pseudodementias*, many neuropsychiatrists believe that profound cognitive dysfunction meeting criteria for dementia associated with depression should properly be labeled a reversible dementia syndrome.

DISTURBANCES IN PERCEPTION

Normal perception first requires that the individual be capable of receiving information as sensations. The data must then be organized to make them meaningful and comprehensible, such as distinguishing figure from ground, or focusing attention selectively on some part of the sensory field. The organized entities are called *percepts*. In states of sensory deficit such as blindness, deafness, and anesthesia perception is impaired but is still possible because individuals generally perceive information about an object through several sensory modalities concurrently. The intensity of sensation and perception is affected by vigilance and attention. Highly focused attention, as in intense concentration or hypnosis, may result in unusually acute sensation and perception—hyperesthesia, hyperacusis, or extraordinary visual acuity. Focused attention may also result in failure to sense or perceive: deep anesthesia and negative hallucinations induced by hypnosis are simply induced failures to perceive what exists in the world.

Humans usually operate in an average expectable environment in which certain types and levels of sensory input are expected, and for which the nervous system is primed. Excessive or inadequate stimulation in any sensory modality, levels of input that are extraordinarily intense, or the presentation of novel stimuli that are entirely different from anything previously experienced by the individual can provoke distorted perceptions in most normal people. For example, total sensory deprivation produced in carefully controlled artificial environments may elicit visual and auditory illusions and hallucinations.

Individuals generally exhibit *selective perception* of the world, depending on what is salient at the moment and on their individual memories, emotions, fantasies, and values. Pregnant women are more likely to perceive babies around them than are people who are not as preoccupied with childbearing.

The intensity of perceptions depends on individual sensitivities as well as on mood, anxiety, and substance use. Depressed patients often describe that colors look faded, that the world looks washed out or gray, even though their capacity to recognize specific colors is unchanged. Similarly, mania is often characterized by heightened perceptions, *hyperesthesia*. When extreme, these intense perceptions are uncomfortable. Hyperesthesia can also be seen during benzodiazepine withdrawal, hallucinogen intoxication, and occasionally as part of an epileptic aura.

The intensity of perception may vary with cognitive style and other psychological and neurological factors. Some individuals tend to be *augmenters* and others *minimizers* of bodily experiences. Chronic pain and some hypochondriacal syndromes may occur more commonly among somatic augmenters.

Selective deficits may occur in the perception of emotions. *Emotional aprosodies* have been described in which patients with specific neurological deficits or depression are selectively unable to recognize the expression of facial emotion. These have been linked by position emission tomography (PET) scan to blunted activity in the right prefrontal cortex and insula.

Illusions Perceptual distortions in estimating size, shape, and spatial relations are common even in the absence of psychiatric disorders, especially when one is fatigued or excessively aroused. *Illusions* are misinterpretations of real sensory stimuli, as when a child in a dark bedroom at night sees monsters emanating from shadows on the walls. *Pareidolias* are playful and whimsical voluntary illusions that can be seen when one looks at ambiguously defined or evanescent images, such as flames in a fireplace or clouds. Both the onset and termination of these perceptions are entirely voluntary. *Trailing*, another visual illusion, is the perception that an object moving steadily in space is followed by temporally distinct, after-images of itself. The effect is that of a series of stroboscopic photos. This phenomenon may occur with fatigue and is typically seen with marijuana and mescaline intoxication.

Hallucinations are perceptions that occur in the absence of corresponding sensory stimuli. Phenomenologically, hallucinations are ordinarily subjectively indistinguishable from normal perceptions. Hallucinations are often experienced as being private, so that others are not able to see or hear the same perceptions. The patient's explanation for this is typically delusional. Hallucinations can affect any sensory system and sometimes occur in several concurrently. When perception is altered, illusions and hallucinations, and often delusions as well, are frequently experienced together. Some studies have found that 90 percent of patients with hallucinations also have delusions, and about 35 percent of patients with delusions also have hallucinations. About 20 percent of patients have mixed sensory hallucinations (mostly auditory and visual) that may accompany functional as well as organic conditions. A given external stimulus may evoke very different perceptual distortions in different persons. For example, of three scientists who floated in sensory deprivation tanks for long periods of time one experienced a few illusions and no hallucinations; the second had many illusions and a few faint auditory and visual hallucinations; the third had vivid, dramatic, and complex visual and auditory hallucinations.

Hallucinations are experienced by many normal people under unusual conditions. It has been estimated that between 10 to 27 percent of the general population have experienced memorable hallucinations, most commonly visual hallucinations. *Hypnagogic* and *hypnopompic* hallucinations are common, predominantly visual hallucinations that occur during the moments immediately preceding falling asleep and during the transition from sleep to wakefulness, respectively. Hypnagogic and hypnopompic hallucinations both occur in normal persons and are also characteristic symptoms of narcolepsy. In acute bereavement, up to 50 percent of grieving spouses have reported hallucinating the voice or presence of the deceased, and following amputations, phantom limb hallucinations are common. Patients who become visually impaired often develop pseudohallucinations (i.e., visual hallucinations with preserved insight) with preserved cognitive status, called's *Bonnet syndrome*. These observations suggest a supersensitivity deprivation hypothesis, that when deprived of important and anticipated perceptual stimuli, the mental apparatus may overinterpret any sensory stimulation as evidence of the presence of the needed objects.

A perceptual release theory suggests that hallucinations emerge from the combined presence of intense states of internal arousal and diminished sensory input (including poor attention and poor capacity to sort out relevant from irrelevant input). Thus, diminished input from the environment (as in sensory deprivation) or reduced capacity to attend to and take in the input (as in delirious states) heighten the likelihood that internal sensations, images, and thoughts will be interpreted as originating in the outside environment.

Hallucinations vary according to sensory modality, degree of complexity of the hallucinated experience, the levels of conviction about their reality, the clarity of their contents, the location of their sources of origin, the degree of volitional control over them, and the degree to which the hallucination influences the person's behavior.

Auditory hallucinations range in complexity from hearing unstructured sounds such as whirring noises or muffled whispers to ongoing multiperson discussions about the patient. Simple auditory hallucinations are more commonly associated with organic psychoses, such as delirium, complex partial seizures, and toxic and metabolic encephalopathies. Deafness can produce hallucinations consisting of noises or of formed music. Auditory hallucinations are classically associated with schizophrenia (seen in 60 to 90 percent of patients) but are also frequently seen in mood disorders with psychotic features; 20 percent of manic patients and less than 10 percent of depressed patients experience auditory hallucinations.

Three types of auditory hallucinations commonly associated with schizophrenia (also seen less commonly in patients with psychotic depressions and mania) are: audible thoughts described as hallucinated voices that speak aloud what the patient is thinking; voices that give a running commentary on the patient's actions; and

hearing two or more voices arguing with each other, often about the patient who is referred to in the third person.

> A 23-year-old woman with schizophrenia heard several choruses of angels and “higher beings” who intermittently argued with each other about how she should be spending her time, and what she should do to hasten the arrival of the Messiah on earth. The multitudes of voices also addressed her directly, but the cacophony was often so great that she could distinguish only one or two voices, belonging to the more powerful or influential angels. She ordinarily took their advice and recommendations to heart, but she was quite perplexed by the fact that the angels often could not agree.

Although auditory hallucinations in schizophrenia are frequently mood-neutral, hallucinations in patients with mood disorders are characteristically consistent with their mood. In psychotic depression, the voices may be unrelievedly critical and sadistic; in mania the voices often refer to the patient's specialness.

> A 50-year-old former schoolteacher with bipolar disorder had characteristic auditory hallucinations during each of her episodes of mania and of melancholia. During manias she heard celestial voices praising her and instructing her to start elaborate international businesses. When melancholic she heard accusatory voices telling her that she had deeply hurt, offended, and harmed many of her students by not grading them accurately, and that as a result the FBI was searching for her and was certain to jail and torture her for the rest of her life.

Command hallucinations order patients to do things. Often the commands are benign reminders about everyday tasks: “Pick up your shoes” or “Clean the table.” However, the voices may also be frightening or dangerous, commanding acts of violence toward the self or others, such as “Jump off the roof, you're not worth anything,” or “Pick up the knife and kill your mother.” These voices vary in insistence and persistence, and patients differ in their capacities to ignore these commands. Patients with marked passivity may be helpless in the face of command hallucinations, and may feel impelled to carry out the orders. Even though one study did not find command hallucinations to be associated with a higher risk of harm to the patient or others, the presence of command hallucinations and the patient's ability to resist must be assessed carefully.

> A young man with schizophrenia heard an insistent voice ordering him to attack his mother with a kitchen knife because she was really an agent of the Devil. He was terrified, and told his mother and his psychiatrist about the voices, assuring them that he was aware that the voices were bad, and that he could resist them. When he stopped taking his medications for a few weeks, he felt that the voices become stronger, more insistent, and was less able to resist obeying them. At one point, immediately after telling his mother about his great anguish in fending off the voices, he grabbed a large kitchen knife and started to slash his own arm in an effort to deflect an attack on her. He was hospitalized and re-medicated, as a result of which the intensity of the voices abated, although they remained constantly in the background.

Visual hallucinations occur in a wide variety of neurological and psychiatric disorders, including toxic disturbances, drug withdrawal syndromes, focal CNS lesions, migraine headaches, blindness, schizophrenia, and psychotic mood disorders. Although visual hallucinations are generally assumed to characteristically reflect organic disorders, they are seen in one quarter to one half of schizophrenia patients, often but not always in conjunction with auditory hallucinations.

Visual hallucinations range from simple and elemental, consisting of flashes of light or geometric figures, to elaborate visions, such as a flock of angels.

Stimulation of one sensory modality sometimes evokes perceptual distortions in another. Marijuana and mescaline intoxication, for example, have been associated with *synesthesia*, an experience in which sensory modalities seem fused. This is also a normal experience for many people. Music may be experienced visually, the sound fusing with visual illusions; a tactile sensation may be experienced as a color (e.g., a hot surface may feel “red”).

In certain religious subcultures visual hallucinations may be experienced as normal. In one fundamentalist Pentecostal Church, worshipers danced themselves into a frenzy and, without using any drugs, several participants shared visions of the Virgin Mary at the altar.

During a period of great personal turmoil, a 24-year-old Hispanic woman with great religious conviction and cluster B personality traits, was praying in church when she noticed the Madonna and a host of female angels all smiling at her. She felt as if she were being graced, and experienced a profound sense of peace and relief. On subsequent visits to the same church, these visions returned and were always comforting to her.

Autoscopic hallucinations are hallucinations of one's own physical self. Such hallucinations may stimulate the delusion that one has a double *(Doppelgänger)*. Reports of near-death out-of-body experiences in which individuals see themselves rising to the ceiling and looking down at themselves in a hospital bed may be autoscopic hallucinations. In *Lilliputian hallucinations*, the individual sees figures in very reduced size, like midgets or dwarfs. They may be related to the perceptual distortions of *macropsia* and *micropsia*, respectively the perceptions of objects as much bigger or smaller than they actually are.

Haptic hallucinations involve touch. Simple haptic hallucinations, such as the feeling that bugs are crawling over one's skin (*formication*) are common in alcohol withdrawal syndromes and in cocaine intoxication. When unkempt and physically neglectful patients complain of these sensations, they may be caused by the presence of real physical stimuli such as lice. Some tactile hallucinations, having intercourse with God, for example, are highly suggestive of schizophrenia, but may also occur in tertiary syphilis and other conditions, and may in fact be stimulated by local genital irritation. *Olfactory* and *gustatory hallucinations*, involving smell and taste respectively, have most often been associated with organic brain disease, particularly with the uncinate fits of complex partial seizures. Olfactory hallucinations may also be seen in psychotic depression, typically as odors of decay, rotting, or death.

The term *pseudohallucination* has been used in two ways. First, pseudohallucination refers to perceptions experienced as coming from within the mind (i.e., not at the boundary or outside the mind). Using this definition, loud voices that are alien, ascribed to other beings, but that the patient knows are actually within the mind rather than out in space, are pseudohallucinations. The term has also been used to describe hallucinatory experiences whose validity the patient doubts. A better term for this second phenomenon is *partial hallucination*, analogous to *partial delusion. Functional hallucinations* are rare hallucinations that occur only in connection with a specific external perception, for example, in the presence of a sound such as running water, or a color, or a particular place. However, unlike illusions, the hallucinated sounds are not elaborations of the perception but are simply triggered only in that specific context.

> A 25-year-old farmer with schizophrenia told of a talking tree on his property. During previous episodes he had experienced a variety of auditory hallucinations that were generally well controlled with medication. However, each time he came near to this large, old tree, he would hear a profound, wise voice—as if the tree were one with the earth and the universe, and had important guidance for him. He often came to the tree when he was troubled, seeking the hallucinatory experiences.

Ictal hallucinations, occurring as part of seizure activity, are typically brief, lasting only seconds to minutes, and sterotyped. They may be simple images—such as flashes of light—or elaborate ones, such as visual recollections of past experiences. During the hallucinations the patient ordinarily experiences altered consciousness or a twilight sleep.

Migrainous hallucinations are reported by about 50 percent of patients with migraine. Most are simple visual hallucinations of geometric patterns, but fully formed visual hallucinations, sometimes with micropsia and macropsia, may also occur. This complex has been called the *Alice in Wonderland syndrome* after Lewis Carroll's descriptions of the world in *Through the Looking Glass*, which mirrored some of his own migrainous experiences. In turn, these phenomena closely resemble visual hallucinations induced by psychedelic drugs such as mescaline.

A *flashback* is an intense visual reexperience of highly charged past events, which are often replays of hallucinations. They are typically associated with heavy use of hallucinogens such as LSD and mescaline and often occur months after the last drug ingestion. The images may be simple or complex geometric patterns or they may consist of previously experienced elaborate drug-induced hallucinations. Flashback phenomena may be state-dependent. For example, visual hallucinations initially experienced with hallucinogens are more likely to be subsequently experienced as flashbacks when the subject is smoking marijuana. In posttraumatic stress disorder, some complex intrusive flashback-like images may attain an hallucinatory vividness. Images often include horrifying memories of traumatic events that may force themselves repeatedly into consciousness until they are acknowledged and worked through.

A 35-year-old man with a history of polysubstance abuse and who constantly smoked marijuana estimated that he had used hallucinogens including LSD and mescaline more than 100 times before having a series of devastatingly frightening hallucinatory experiences of devils, of his body being consumed and eaten by wild animals, and of burning in hell-fires. These were accompanied by such profound paranoia and panic attacks that he swore off “heavy drugs,” but continued to use alcohol and marijuana. Several months later, during a period of personal crisis during which he smoked an unusually large amount of powerful marijuana he suddenly reexperienced the worst devil-filled flashback; this experience lasted for several hours in spite of the efforts of several of his friends to talk him down.

Hallucinosis is a state of active hallucination occurring in someone who is alert and well oriented. This condition is seen most often in alcoholic withdrawal, but it may also occur during acute intoxications and other drug-mediated states.

A 30-year-old woman being treated for a depressive disorder with a monoamine oxidase inhibitor snorted cocaine at a party. For the next 3 days she described vivid hallucinatory experiences while in an alert state. She managed to drive her car throughout this time, although with some difficulty. In her psychiatrist's office she alternated between relating coherently to the psychiatrist and responding to her dreamlike complex visual and auditory hallucinations. These phenomena abated within 4 days.

Body Image Distortions Body image includes both perceptual and ideational components, and may reflect primarily perceptual distortions or combinations of disturbed perception and self-appraisal. Body image disturbances can occur as normal responses to abrupt changes in the body (e.g., following amputation), in brain disease, and in psychiatric disorders. Phantom-limb phenomena are classic body image problems in which an amputated limb is still felt to be present. The sensation may diminish gradually over time; the patient feels as if the phantom is receding into the stump

Agnosias, lack of awareness of some parts of the body, may accompany brain damage, most often of the nondominant parietal lobe. Patients with obvious motor or sensory deficits may deny that any deficit exists at all *(anosognosia)*, or the denial may be limited to half of the body *(hemiagnosia)*, usually the left side. In *hemidepersonalization syndromes*, a less common disorder *(hemisomatognosia)*, patients feel that one of their limbs is missing, again usually on the left side. Body image distortions in which a limb feels too heavy *(hyperschemazia)* or weightless *(hyposchemazia)* can occur as a consequence of neurological conditions such as infarction of the parietal lobe. In *duplication phenomena*, patients feel as if part or all of them has doubled (e.g., that they have two heads or two bodies). These rare phenomena may occur in schizophrenia, complex partial seizures, and migraine.

Dysmorphophobia refers to conditions in which patients distortedly perceive and intensely dislike the shape of a particular body part. As such, these symptoms are misnamed because there is no true phobic component, such as fear or avoidant behavior. Fine lines exist between perceptual distortions and realistic but unhappy appraisals of one's body, given the high social value placed on physical appearance. Dysmorphophobia may occur in the context of some personality disorders or as an isolated disorder, called *body dysmorphic disorder*. In some ways, dysmorphophobia resembles an overvalued idea. Patients may develop dysmorphophobias in relation to any body part; common concerns are hair, breasts, penis, nose, or the entire body. For some, changing the body part, as in rhinoplasty for those who do not like their noses, seems to effect a lasting positive change in body image, with patients becoming happier with themselves and feeling more attractive for years or a lifetime. Patients with severe dysmorphophobia may undergo multiple plastic surgeries and feel dissatisfied with every result. At times, the condition forms part of a larger and more pervasive syndrome, such as anorexia nervosa.

A 24-year-old engineering student from a rigid, devout, and loving home was convinced that his mild pectus excavatum condition was an atrocious deformity that accounted for his never having had a girlfriend. A mild deformity did exist, but his reaction to it was far in excess of the actual problem. He was embarrassed to take showers in the dorm, afraid that other students would see him and make fun of his deformity. He sought the services of a surgeon to fix the deformity; the surgeon sent him for psychiatric consultation prior to performing the surgery. No other psychiatric difficulties were evident, and the results of psychological testing were nonrevealing. His father, a rather literal-minded man, was in full agreement with the son's desires to have the corrective surgery. With no clear contraindication, the surgeon agreed to perform the operation. A 6-month follow-up revealed that the student was much happier, and was now dating for the first time in his life.

Hypochondriacal complaints also combine perceptual and ideational distortions. Selective hypervigilance to bodily sensations may result in a higher likelihood of perceptions of unpleasant and potentially pathological body experiences among the worried well, hypochondriacal populations, patients with somatization disorder (Briquet's syndrome), and some patients with a panic disorder.

Body image distortions may at times be severe or bizarre. Some psychotic patients with schizophrenia or depression develop somatic delusions. In depression, this often expresses itself as a delusion that part of the body or the entire body is rotting or cancerous. Some culture-bound syndromes in non-Western culture express themselves with body image distortions, such as koro, in which the man fears that his penis is shrinking into his abdomen.

DISTURBANCES OF MOOD

Defining, describing, understanding, and categorizing moods has long been among the most important and difficult tasks in psychiatry. The language of feelings is filled with terms that seem to have mostly idiosyncratic meanings as patients, phenomenologists, and psychiatrists all struggle to describe inner emotions and to correlate them with external behavior. Even basic terms such as *mood, affect, emotion*, and *feelings* lack universal definition. The most common convention, used here, defines *mood* as a sustained or prevailing subjective feeling tone or range of tones. *Affect* is the moment-to-moment feeling state, sometimes rapidly shifting in response to a variety of thoughts and situations, which the clinician can observe. *Emotions* have been defined as moods and affects that are connected to specific ideas, or to the physical concomitants of moods and affects. *Feelings* are the most poorly defined of all, leading Karl Jaspers to ultimately describe them as everything for which there is no other name. In common parlance and often professionally as well, these words are sometimes used interchangeably.

Moods, affects, and emotions can be described by a number of important qualities: intensity (shallow to deep); range (broad to narrow or flat); stability (rigid to labile); reactivity to external events (none to much); periodicity (periodic to aperiodic); congruence with thought content (congruent or appropriate to incongruent); speed of resolution (rapid to slow); and viscosity (evanescent to persistent). The individual's lifelong predominant mood is one component of temperament. Thus, for example, one may be described as having a calm, buoyant, irritable, depressive, anxious, or sensitive temperament.

Moods, affects, and emotions serve as internal and external signal systems. They signal the state of the individual to others, and often elicit the necessary help and support from the environment. A baby's face communicates its state of need, tension, or contentment, thereby recruiting appropriate parental interventions. As adults, much of the most important interpersonal communication is transmitted nonverbally through cues that signal the observer about our moods. Positive words communicated by a scowling or sullen face will lead listeners to perceive an angry message, regardless of the spoken words. Moods also have an infectious quality and serve as important ways of influencing others. A cheerful mood towards others influence their moods toward cheerfulness; they in turn are more likely to reciprocate that cheerfulness.

Internally, moods, affects, and emotions let individuals know how well or how poorly they are doing, allowing them, for instance, to gauge the distance between actual self-appraisal and desired self-expectations. For example, individuals who desire to master important goals and feel that they have a reasonably good chance of doing so will ordinarily experience pleasant emotional states in relation to these goals. If something intervenes to prevent them from reaching these goals, so that there is an insurmountable gap between their desires and the likelihood of success, they may feel hopeless. In addition to serving as signal systems, emotional states of nonspecific tension, arousal, or anger usually imply that some action will be necessary to secure their discharge or release.

Emotional states and their expression are regulated by biological, psychological, and cultural influences. For example, *emotional lability*, characterized by rapidly shifting emotions that seem unrelated to the situation, typically occurs premenstrually in some women, with varying periodicity in cyclothymic individuals and in those with cluster B personality disorders, and in relation to need states such as hunger, sleepiness, and sexual frustration. Mood shifts have also been related to environment-related physiological influences such as seasonal changes in light. Psychological regulation of emotions may be related to specific coping mechanisms and the ability to self-soothe, which are developmentally determined. Conscious and preconscious psychological mechanisms, including varieties of self-talk, may help to calm or to inflame the emotions. Cultural factors significantly regulate emotional expression. Although the facial expressions for basic emotions are similar in all cultures studied, the range and style of emotional expression permitted in relation to specific contexts varies greatly from culture to culture, and from family to family. Some cultures and families are stiff-lipped and inhibit the open expression of emotion; others encourage emotional display. Marked differences exist among cultures in the emotional expression of acute grief, fear, pain, and affection.

Depression The term *depression* has been used variously to describe an emotional state, a syndrome, and a group of specific disorders. When seen as part of a syndrome or disorder, depression has autonomic, visceral, emotional, perceptual, cognitive, and behavioral manifestations, as illustrated in Table 8-1. As a nonpathological ubiquitous mood state lasting from hours to days, but sometimes longer, feelings of depression are synonymous with feeling *sad, blue, down in the dumps, unhappy*, and *miserable*. Depressed mood is common and appropriate following a disappointment or loss. For most people, innate psychological resilience, coping options, and supportive social networks help to alleviate these brief depressive states and prevent them from becoming chronic. Some individuals suffer from chronically depressed mood, tend to view the world as a difficult place, filled with obstacles and burdens, see themselves as victimized, and lack hope for the future. The extent to which constitutional, developmental, and ongoing aversive life events contribute to this pervasive worldview is unknown. Persons who in early life were deprived and traumatized may be less resilient and more prone to chronic depressive features than are others. Repeated failures and the impact of unrelenting, uncontrollable, and unpredictable negative life events may set the stage for learned helplessness in humans just as they do in animals. A subset of chronically depressed individuals may also suffer from temperamental, biologically driven depression, often seen in conjunction with strong genetic loading for severe mood disorders.

Some depressive states are normal and common reactions to major, unwelcome, and undesirable life events. Normal *bereavement* best exemplifies this. In bereavement following major losses such as the death of a parent, spouse, or child, people experience sadness, pining, and yearning, but do not ordinarily have the feelings of guilt, unworthiness, and self-reproach that characterize depressive disorders. Feelings of helplessness and hopelessness may be temporarily present in bereavement, but they ordinarily pass with time. In uncomplicated cases, the process of bereavement takes 3 to 6 months in the acute phase, and up to a year for complete resolution. Bereaved persons are more likely to feel physically ill and seek general health care than at other times, and older widowers are more liable to die than age-matched nonbereaved controls. *Pathological grief reactions*, bereavements that last more than a year, may be seen when the surviving spouse was excessively dependent on the deceased and is unable to obtain emotional and practical (e.g., financial) support elsewhere, or when the survivor is unable to grieve fully because of markedly ambivalent feelings towards the deceased. The inadequate expression of grief because of incomplete bereavement is thought to be pathogenic in many subsequent psychiatric disorders. For example, impulsive acting-out behavior among adolescents who have lost a parent is often assumed to result from unresolved grief.

A variety of medical disorders may cause depressive syndromes. Most common among these are endocrine abnormalities such as hypothyroidism and hyperparathyroidism and CNS disorders such as cerebrovascular diseases and Parkinson's disease. Depressions are more common in strokes affecting left anterior lesions than other locations. Some medications, especially antihypertensive agents affecting adrenergic tone such as reserpine (Serpasil) and possibly beta blockers may also trigger depressions. The importance of a genetic diathesis in these iatrogenic depressions is not yet known. Depressive syndromes and disorders in general, however, are unquestionably familial and are likely to have genetic contributions, especially in depressions associated with bipolar I disorder.

Cognitive features of depression are prominent. Characterizing the exact nature of the memory impairment using standardized tests has been difficult. Cognitive tasks requiring sustained effort and elaborate cognitive processing may be more disrupted in depression than tasks that can be accomplished more automatically. The so-called *cognitive triad of depression* consists of pervasive cognitive schema related to feelings of worthlessness, helplessness, and hopelessness—expectations that no one and nothing can or is likely to help now or in the future: “I'm not OK, the world is not OK, and it's never going to get any better.” In geriatric populations the effect of depression on cognition may be so profound as to produce a true dementia syndrome, often called *pseudodementia*, a misnomer because the dementia is real but reversible.

Suicidal phenomena are of particular concern. Suicide is common in severe depressive disorders, with 15 percent of untreated depressed patients ending their lives in suicide. Depressed patients comprise the largest diagnostic group of all completed suicides. However, suicide occurs at high rates in many other conditions as well, notably substance-abuse disorders, schizophrenia, and personality disorders. Suicide may occur in these conditions with or without a diagnosable comorbid depressive disorder. Depressed patients with co-morbid alcohol abuse may be at particularly high risk for suicide.

Although consistent, useful, validated predictors of suicide do not exist, certain demographic features are associated with higher risk. These include being white, male, older, and living alone. The single most important factor in the psychiatric history is that of past suicide attempts. A history of violent behavior may also predict suicide. Murderers have a very high suicide rate, especially those who murder family members during episodes of domestic violence. Among clinical signs, hopelessness, anhedonia, and severe anxiety may predict increased suicide risk. Serious physical illness in association with other risk factors such as depression may place a patient at higher risk. A genetic predisposition towards suicidal behavior cuts across diagnostic lines and plays a role in suicide risk. This may reflect a tendency towards impulsive behavior, correlating with low CNS concentrations of 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of serotonin.

Suicidal gestures are also common among impulsive, dependent, and self-hating depressed persons, for whom they serve as tension-releasing behaviors and as cries for help that may enlist desired social support. Because such gestures have been associated with an increased risk for subsequently completed suicide, they should not be taken lightly. Nonsuicidal self-destructive behaviors such as self-mutilations and repeated unnecessary risk-taking are also common in depressive syndromes and in personality disorders. Subintentional suicide may result when suicidal gestures go awry or when reckless behavior, such as taking unnecessary risks in combat or driving while drunk, prove fatal.

Elated Moods Elated moods include euphoria, elation, exaltation, and ecstasy. They are marked by feelings of well-being and expansiveness, optimism, capability, pleasure, and grace. Such moods are normally experienced when life is going very well, when long-sought-after goals are achieved, and in states of love, religious fervor, and spiritual transcendence. Peak experiences and experiences of mystic fusion are often accompanied by feelings of exaltation and ecstasy. Sexual pleasure and some chemically mediated states of altered consciousness may also induce these feelings.

Abnormally elated moods are primarily seen as part of manic states and from the effects of certain medications and street drugs. When subtle, as in *hypomania*, the mood can be ebullient, and brimming with self-confidence, but with occasional irritability. Other characteristic symptoms of hypomania are increased energy, decreased need for sleep, rapidly flowing thoughts, excessive talking, inflated self-esteem with a demanding nature toward others, and diminished judgment. *Mania* is a more extreme state in which judgment and sleep are impaired to the point of marked functional disruption. As the mania exacerbates, irritability and anger increase, alternating rapidly with a brittle expansiveness. Cognitions become increasingly disorganized. Psychotic symptoms, usually involving themes of grandiosity or specialness, occur in 50 percent or more of patients with mania. With increasing escalation of the manic state, thinking becomes very fragmented, psychotic symptoms are more prominent, and the syndrome may appear indistinguishable from schizophrenia. These three manic states—hypomania, mania and the psychotic mania, fragmented manic state are often referred to as stage I, II, and III mania, respectively. Manic states occur in bipolar disorders, substance-induced mood disorders, and mood disorders due to a general medical condition. Such secondary manias may follow specific cerebral insults, accompany systemic disorders, or occur following ingestion of some drugs including amphetamines, antidepressants, bromocriptine (Parlodel), decongestants, isoniazid (Nydrazid), and corticosteroids. Mania is the second most common neuropsychiatric disturbance induced by steroids, occurring in 30 to 35 percent of patients who develop steroid-induced behavioral disorders. Up to 12 percent of patients treated with levodopa (Dopar) and bromocriptine for parkinsonism develop mania. Right hemispheric brain lesions are specifically associated with secondary mania.

Anxiety Like depression, the term *anxiety* refers to a number of different entities—a normal transient feeling, often with adaptive functions, a symptom seen in a wide variety of disorders, and a group of disorders in which the symptom of anxiety forms a dominant element. As a transient, disagreeable emotional state, anxiety may be adaptive, signaling anticipated or impending threat and motivating necessary action. In contrast to *fear*, the emotional state that exists when a source of threat is precise and well known, anxiety occurs when the threat is not well defined.

Patients often find it difficult to describe feelings of anxiety precisely; at its core, however, anxiety is characterized by intense negative affect, associated with an undefined threat to one's physical or psychological self. Patients will use words such as *tense, panicky, terrified, jittery, nervous, wound-up, apprehensive*, and *worried* to describe their sensations. Anxiety is additionally characterized by somatic, cognitive, behavioral, and perceptual symptoms. The somatic symptoms of anxiety are legion and often dominate the subjective symptoms: a partial list includes twitching, tremors, hot and cold flashes, sweating, palpitations, chest tightness, difficulty swallowing, nausea, diarrhea, dry mouth, and decreased libido. Cognitively, anxiety is characterized by hypervigilance, poor concentration, subjective confusion, fears of losing control or of going crazy, and catastrophic thinking. Behavioral symptoms include fearful expressions, withdrawal, irritability, immobility, and hyperventilation. Perceptual disturbances, including depersonalization, derealization, and hyperesthesia (especially hyperacusis), are also common.

Trait anxiety refers to a lifelong pattern of anxiety as a feature of temperament. Individuals with trait anxiety are skittish, hypersensitive to stimuli, and psychophysiologically more reactive than others. In contrast, *state anxiety* refers to episodes of anxiety that are tightly bound to specific situations and that do not persist after the provoking situation has abated. *Free-floating anxiety* is characterized by a persistently anxious mood in which the cause is unknown and in which large numbers of diverse thoughts and events all seem to trigger and compound the anxiety. In contrast, *situational anxiety* occurs only in relation to specific

occasions or external stimuli, as in phobias.

Anxiety symptoms can result from numerous physical conditions as well as from other psychiatric disorders. Many endocrine, autoimmune, metabolic, and toxic disorders, as well as medication adverse effects, are known to generate anxiety. The psychiatrist must differentiate the response of the patient to an underlying condition (i.e., secondary anxiety) from symptoms generated by the primary disorder itself. In psychiatric populations, anxiety symptoms are prevalent among patients with psychotic disorders, cognitive disorders, depression, and substance-related disorders, as well as in the specific anxiety disorders. In patients with schizophrenia, anxiety must be differentiated from *akathisia*, a common and often overlooked syndrome of subjective restlessness, anxiety, and agitation resulting from antipsychotic medication. The coexistence of anxiety symptoms and depression in major depressive disorder is substantial; anxiety symptoms such as anxious mood and irritability are seen in the majority of depressed patients. Additionally, half to two thirds of patients with a panic disorder will experience a major depressive episode during their lifetime. Medication and drug effects—from intoxication, adverse effects, or as part of withdrawal—are also common causes of anxiety. Many patients with severe anxiety become dependent on anxiolytic drugs (e.g., benzodiazepines, and other sedatives) or alcohol for symptom relief. During attempts to discontinue these substances and sometimes during their ongoing use, confusing admixtures of anxiety symptoms, medication effects, and withdrawal symptoms may occur. Although all the anxiety symptoms caused by drug use are also seen in primary anxiety disorders, perceptual disturbances such as depersonalization and hyperaesthesia may be more common in sedative-hypnotic withdrawal than in primary anxiety disorders.

Despite the general observation that anxious patients demonstrate increased startle responses, specific consistent differences have not been found in the physiological hyperreactivity of patients with anxiety disorder versus controls. In part, this reflects individual differences in reactivity among anxious patients; one person may respond to a specific stimulus with increased pulse and blood pressure while another might show changes in the opposite direction. Similarly, although patients who suffer panic attacks but not controls tend to experience panic attacks in response to sodium lactate infusion, other biological measures, especially those reflecting the catecholamine system and thought to reflect central noradrenergic activity, have failed to elucidate the biological underpinnings of panic attacks. Despite the lack of consistent findings, a great deal of evidence suggests that biological factors strongly contribute to the appearance of anxiety disorders.

Psychological Causes From a psychological point of view, anxiety may signal conflict between opposing desires, wishes, or beliefs on the one hand, and major disequilibria generated by negative life events on the other hand. *Role strains*, conflicts between the major social roles that form a person's identity—spouse, parent, child, wage earner, professional, community member—are common sources of anxiety. The more important the conflict and the less obvious the resolution, the greater is the associated anxiety. For example, anxiety symptoms may first emerge when an individual is confronted with an unavoidable unhappy choice, such as between sustaining a marriage or accepting a career advancement requiring a major move that is unacceptable to the spouse. At times, these conflicts may escape conscious awareness: the person may feel anxious but not know why. Anxiety disorders frequently result from a combination of several factors. A person in a work conflict facing an important deadline may try to alleviate initial anxiety symptoms by overworking or ingesting caffeine or amphetamines to keep alert, then become exhausted and fatigued, and ultimately use alcohol excessively to calm down, with each of these elements contributing separately to an anxiety state.

Certain developmental life situations are associated with anxiety: *Stranger anxiety* develops when infants 6 to 8 months old begin to recognize the difference between their mother and others. When children first go to school, mild anxiety symptoms are common; if the anxiety is excessive, *separation anxiety* or *school phobia* may result. During adult life, anxiety often centers around issues of mastery and accomplishment, both in personal and work life. *Performance anxiety*, or *stage fright*, is a specific type of pathological anxiety in which anxiety escalates to panic when public performance is required. In later life, the deterioration of one's body may engender anxiety related to feelings of helplessness and *death anxiety*.

Panic *Panic attack* is a circumscribed episode of severe state anxiety lasting minutes to hours, with symptoms escalating in a crescendo pattern. The subjective experience is one of utter terror, fears that one will die, go crazy, or lose control, accompanied by many of the somatic symptoms of anxiety mentioned above, including severe chest pains, marked shortness of breath, and exhausting fatigue. Individual isolated panic attacks are common, with up to 30 percent of the general population experiencing at least one attack each year. Panic attacks occur more regularly, and typically more severely, as part of panic disorder or in association with other anxiety disorders. Patients with other psychiatric disorders may experience limited-symptom panic attacks, with episodes characterized by less intense anxiety and by fewer and milder physical symptoms, such as isolated paresthesias or difficulty breathing. These limited-symptom attacks may represent aborted full-blown panic attacks that are not further exacerbated by secondary psychological reactions to the initial symptoms.

A 43-year-old Navy Captain began to experience episodes of severe chest pains, profound sweating, and fear that he was about to die. He had gone to the emergency room on several occasions, and each time had a normal electrocardiogram (ECG) and other tests. His capacity to work was impaired, and he started to stay at home rather than drive to work, since all his episodes began while he was driving. Although he had no prior history of significant alcohol abuse, he also began drinking large amounts of wine in an effort to stave off the attacks. The emergency room physician diagnosed panic attacks. A psychiatric interview revealed that the patient's father had died of a heart attack in his mid-40s, and that the patient had never adequately dealt with issues surrounding the death.

Although American psychiatry has segregated panic attacks from other forms of anxiety, assuming categorical, phenomenological, and biological differences, these distinctions are far from universally accepted. Some psychiatrists view panic as simply an extreme form of anxiety, to be understood as part of a continuum of intensity.

Phobias are irrational fears. In an effort to reduce the intense anxiety attached to phobic objects and situations, patients do their best to avoid the feared stimuli. Thus, phobias consist both of the fears and the avoidance components. The fear itself may include all the symptoms of extreme anxiety, up to and including panic. In *specific phobias*, persistent, irrational fears are provoked by specific stimuli. Table 8-5 lists some illustrative phobias. Common specific phobias include fear of dirt, excreta, snakes, spiders, heights, and blood.

Acrophobia	Fear of heights
Agoraphobia	Fear of open spaces
Amathophobia	Fear of dust
Apiphobia	Fear of bees
Astrapophobia	Fear of lightning
Blennophobia	Fear of slime
Claustrophobia	Fear of enclosed spaces
Cynophobia	Fear of dogs
Decidophobia	Fear of making decisions
Electrophobia	Fear of electricity
Eremophobia	Fear of being alone
Gamophobia	Fear of marriage
Gatophobia	Fear of cats
Gephyrophobia	Fear of crossing bridges
Gynophobia	Fear of women
Hydrophobia	Fear of water
Kakorraphiophobia	Fear of failure
Katagelophobia	Fear of ridicule
Keraunophobia	Fear of thunder
Musophobia	Fear of mice
Nyctophobia	Fear of night
Ochlophobia	Fear of crowds
Odynophobia	Fear of pain
Ophidiophobia	Fear of snakes
Pnigerophobia	Fear of smothering
Pyrophobia	Fear of fire
Scholionophobia	Fear of school
Sciophobia	Fear of shadows
Spheksophobia	Fear of wasps
Technophobia	Fear of technology
Thalassophobia	Fear of the ocean
Traumatophobia	Fear of the number 13
Tropophobia	Fear of moving or making changes

Table 8-5 Specific Phobias

Behavioral, psychodynamic, and biological theories have all been advanced as causes of phobias. Some well-known phobias, such as fear of animals, may result either from early traumatic events (developing along the paradigm of classical Pavlovian conditioning), or from displacements of early psychodynamic conflicts. Genetic influences may also play a role in the development of phobias. For example, some individuals with blood-injection-injury phobias, which strongly clusters among biological relatives, may be genetically predisposed by vagal responses to certain stimuli. Animal models also indicate possible biological vulnerability. Some monkeys that have never previously been exposed to snakes panic when placed in the presence of a snake. Because such fear responses obviously have adaptive value, it has been suggested that some human phobic responses also represent exaggerations of adaptive behaviors shaped by evolutionary biology.

Complex phobias, more elaborate than specific phobias, involve fears related to a broader range of situations. *Agoraphobia*, the best known, refers to a fear of open spaces. Current thinking suggests that agoraphobia is usually a secondary reaction to panic attacks. According to this view, individuals who have become terrified of having panic attacks in public retreat to the safety of their own homes, hoping to reduce the likelihood of panic attacks by avoiding places where they were once triggered and where they may feel exposed and embarrassed. Patients with *social phobia* become overwhelmingly anxious and fear situations in which they may be observed. In the limited type, only a few specific situations evoke the fear, such as speaking in public or using a public lavatory. In the general type, broad-based

fears of social situations globally hamper the person's interpersonal life.

Aggression, Hostility, Impulsiveness, and Violence The spectrum of aggressive emotions and behaviors is characterized by heightened vigilance in response to a sense of threat and enhanced readiness to attack. Physiological tone may be geared for a fight. Assertiveness, the adaptive aspect of these emotions, includes sensing that something needs to be done and feeling willing and competent to take constructive action. The manner and extent to which aggressive emotions can be expressed varies from society to society and situation to situation. These emotions are among the most carefully regulated because of their potential destructiveness. Acts of aggression may begin with verbal threats and intimidation and extend from physical bullying and assault to homocide, sometimes including acts of calculated violence and sadism.

Irritability is an unpleasant feeling state characterized by inner unease. Although minor irritability may abate when the cause is eliminated, escalating irritability has been compared to a psychic itch, begging for discharge via anger outbursts, sometimes leading to temper flareups with verbal or physical lashing out. Unlike anger, irritability does not lessen after an outburst. It is diagnostically nonspecific, seen in a variety of physiological states, anxiety, and mood disorders and as a lifelong temperamental quality. Hunger, sleepiness, sexual frustration, and pain are among the physiological triggers commonly associated with irritability.

A 36-year-old woman with bulimia nervosa but no marked mood or anxiety disorder was successfully treated with a selective serotonin reuptake inhibitor (SSRI). During a follow-up visit during which she and her husband were seen conjointly, her husband remarked about her previous irritability, particularly premenstrually, which he saw as a long-standing personality feature that had abated considerably as a result of the treatment. The patient, her husband, and her psychiatrist all attributed the decrease in irritability to the SSRI. The husband, only half-jokingly, remarked “Doc—whatever you decide to do— *never* take her off that stuff—or if you do, warn me a few days ahead of time and I'll clear out of the house!”

Individual differences in the tendency toward experiencing and expressing anger and violence are biological, developmental, and cultural in origin. Some infants are irritable from birth. Subtle early birth injuries and brain anoxia may increase the susceptibility of some persons to be violent. Furthermore, studies of EEG patterns in violent persons show increased abnormalities, especially in those with repeated violence and violence with little or no obvious motive. Soft neurological signs are also seen in violent criminals. Biochemically, low concentrations of 5-hydroxyindoleacetic acid (5-HIAA) in cerebral spinal fluid (CSF) has been associated with a variety of impulsive behaviors such as violent crimes, recurrent fire-setting, and violent suicide attempts.

In support of the hypothesis that an inverse relationship exists between central serotonergic system function and impulsive-aggressive behavior, a recent double-blind placebo-controlled trial demonstrated that pharmacological enhancement of serotonin activity with fluoxetine (Prozac), an SSRI, reduced impulsive aggressive behavior and irritability in subjects in whom such behavior was prominent.

The pathological childhood triad of bedwetting past the age of 6, setting fires, and torturing animals has been associated with subsequent violent behavior in adults. Interpersonally, studies show that violence-prone individuals require more personal space around themselves than other people do. Violent individuals feel threatened when approached too closely, particularly from the rear.

Psychological and social contributions are also strong. Violence in families breeds violence, and battered children often grow up to be battering adults. Cultural norms for the expression of violence differ considerably. In some socioeconomic and ethnic groups violent gangs organize the energies of many adolescent youth. For some, violent behavior is an adolescent socialization pattern necessary to prove one's manhood. Like other social organizations, violent gangs have detailed rules that inhibit and govern the expression of violence. Some unpredictable and unsocialized violent persons, loners, are too violent to be contained even in gangs.

Aggressive and violent behavior is diagnostically nonspecific. Violence in schizophrenia may occur as a consequence of paranoid delusions, in response to command auditory hallucinations, or secondary to passivity experiences. Manic patients and those in mixed states may be violent, often in response to minimal provocation. Violent behavior commonly occurs in patients with antisocial and borderline personality disorders; in the latter the violence is often self-directed as well as other-directed. Violent behavior may occur in epilepsy—although rarely during true ictal periods; in frontal lobe syndromes as a release phenomenon; and in association with abused substances, particularly disinhibiting sedatives such as alcohol or stimulants such as amphetamines and cocaine, which increase irritability, aggressiveness, and paranoia.

Impulsive violence may be provoked by a number of stimuli and situations. Alcohol is perhaps the most common disinhibitor of violence. Intrafamilial violence, the most common setting for homicide, is frequently related to alcohol intoxication. In *intermittent explosive disorder*, violent behaviors typically erupt after a person has ingested alcohol, a phenomenon known as *pathological intoxication*. In these often ferocious outbursts the individual may confront or provoke any potential target for violence, including total strangers and police, but girlfriends, wives, and parents are frequent victims. Patients with episodic dyscontrol commonly have histories of violent sexual behavior including rape and, often while intoxicated, speeding and reckless driving, sometimes chasing down, stopping, and attacking other motorists who they feel “get in their way.”

A 35-year-old man who had a long history of truancy and a poor school record, fighting in school, bar fights, DWIs, and being assaultive while in jail, was seen in a mental health center. Since release from jail, in spite of a diligent attempt on his part to stay out of trouble for the sake of his wife and children, he found himself getting increasingly edgy. He had acquired a job as a short-haul truck driver and had been doing well until the previous day when he felt that someone cut him off on the freeway. In a blind rage he chased down the driver of the other car, attacking him with a tire jack. Luckily, he was restrained by several bystanders and no one was physically hurt.

Temper Tantrums Immature individuals with persistent personality problems may fail to develop mechanisms to inhibit the temper tantrums they displayed as children. Particularly if childhood tantrums produced the desired result, learned tantrum behaviors may persist into adult life. Although such individuals may be pleasant and sociable when life is going well, they lack the capacity to tolerate frustration, and are easily provoked by threats to self-esteem and self-image, and by not having their own way. When frustrated or threatened they may act like bullies, glare, snarl, yell, shout, intimidate, pout, sulk, and sometimes be physically violent.

Displaced Rage When circumstances prevent the expression of rage directly against the persons or institutions provoking frustration, other outlets for aggression are often found. Acts of violence that are either calculated or wanton may result. Cruelty to animals and fire setting may persist as adult forms of destructive behavior. Rape, an act of control, intimidation, terror, and humiliation, may also displace frustrations that are not expressed more adaptively.

Sadism may occur with or without explicit sexual gratification. Calculated cruelty conducted seemingly without anger or emotional arousal may reflect inadequate development of social morality or individual conscience, as in the conduct of torturers and some cold-blooded murderers. In some societies and under specific circumstances at certain times in history, such activity has been socially sanctioned, suggesting at least that some people lack inborn inhibitions against cruelty or violence.

A 45-year-old veteran hospitalized for chronic depression and barely contained aggressive outbursts described how as a teenager he had been employed as an enforcer by a drug ring. He and his partners took pleasure in torturing and then killing men they were assigned to murder who failed to make their drug payments—as warnings to others who might try to avoid paying. What bothered him the most was that after a while he too started to enjoy participating in these activities.

Self-Mutilation For a variety of reasons, in many different cultures, and in many different disorders people commit acts of violence against themselves ranging from body piercing to cutting and burning to auto-amputation. Psychotic patients may perform extremely self-destructive acts short of actual suicide that often have symbolic import, such as enucleating their eyes or castrating themselves. Patients with borderline personality disorders may cut themselves repeatedly with broken glass or razor blades or burn their arms, legs, breasts, or other body parts with cigarettes. Patients typically deny that these acts are meant to be suicidal, but describe the need to feel external pain to mirror internal suffering, to release tension, or to counteract dissociative-like numbness.

A 25-year-old man presented to the emergency room in a deeply suicidal state. Examination revealed his arms to be riddled with cigarette burns of varying ages, from old scars to fresh burns, and he had multiple healing and healed razor and knife cuts on all his extremities. He described how these cuts were not the result of suicidal acts, which he carefully and precisely differentiated from his current mood state, but were the results of rages of self-hatred—he meant to inflict pain upon himself during periods of particular self-hate and frustration.

Trichotillomania is a syndrome of compulsive hair pulling, resulting in bald patches. It is often associated with other self-mutilatory behavior, such as picking the face, nails, or cuticles to the point of infection and bleeding. Trichotillomania may sometimes be related to obsessive-compulsive disorder.

Children with *Lesch-Nyhan syndrome*, a developmental disability syndrome caused by a congenital metabolic abnormality, bite and pick at themselves so compulsively as to do themselves great harm, and routinely require restraint. Occasionally, patients with Tourette's disorder demonstrate compulsive self-harming behavior.

Other Disturbances of Feelings Diminished levels of emotional intensity may be seen in anxiety disorders, mood disorders, and schizophrenia. Mild emotional flattening with blunted ability to feel joy is common in dysthymia. Some patients with narcissistic and borderline personality disorders complain of inner emptiness and pervasive boredom and ennui, without demonstrating diminished affect in interviews. Similarly, patients with prominent depersonalization describe numbed emotions. Pathological levels of *blunt* or *flattened affect*, indicating markedly diminished affective expression in relation to specific thought content, may be seen in chronic schizophrenia (as part of the *deficit syndrome*), some organic mental syndromes, and severe depressions. Although the term *blunted affect* is not classically used to describe the affective flatness of severe depression, it is not always easy to distinguish between schizophrenic and depressive flatness on phenomenological grounds. *Anhedonia*, the lack of pleasurable feelings from activities that ordinarily provide pleasure, is also seen as part of severe depressions or schizophrenia. Chronically psychotic patients often exhibit emotional deterioration in which affective experience and expression is entirely unrelated to thought content. *Inappropriate affect* is incongruency of affective expression and thought content. The patient may display loud and raucous laughter or giggling in relation to bland or sad thoughts, or may show grief without apparent reason. Inappropriate affect sometimes indicates that the thoughts have private meaning for the patients; the emotional expression might make better sense if the private meaning was understood. Inappropriate affect must be distinguished from affective expressions that may actually be appropriate in a given subculture or ethnic group that is unfamiliar to the observer, and from defensive affect, such as the nervous laughter used to alleviate tension or ward off crying. *Affective lability* is characterized by rapid emotional shifts, often within seconds to minutes. It is commonly seen during hypomanic states, late luteal phase dysphoric disorder (premenstrual syndrome), postpartum blues, other states of physiological instability, and in certain personality disorders.

Alexithymia is difficulty identifying, describing, and differentiating between feelings or distinguishing between feelings and physical sensations. Alexithymic individuals often have constricted imaginations and fantasies, are preoccupied with objects and events in the outside world, and have a limited private, personal internal life. When distressed, these patients are simply aware of not feeling well and usually complain of somatic symptoms, leading to frustrating interactions with their physicians who are unable to find physical causes for the presenting physical complaints. Some view alexithymia as a condition in which affect is communicated through somatic language.

DISTURBANCES IN MOTOR ASPECTS OF BEHAVIOR

Motor behavior is normally finely coordinated, purposeful, and adaptive, and necessary activities are usually carried out efficiently. In psychiatric disturbances motor abnormalities can involve generalized overactivity or underactivity or manifest in a wide range of specific disorders of movement.

Overactivity *Restlessness* and *agitation* are diffuse increases in body movement, usually noted as fidgeting, rapid and rhythmic leg- or hand-tapping, and jerky start-and-stop movements of the entire body, accompanied by inner tension. Restlessness accompanies psychiatric conditions of high emotional arousal or confusion such as toxic states, deliria, mania, agitated depressive disorders, and anxiety disorders, as well as many medical disorders such as hyperthyroidism. In some depressive states, agitation is often accompanied by pacing and hand wringing.

Generalized overactivity, in which patients seem to have increased physical energy, is distinguished from agitation by its lack of inner tension and by more purposeful movements. It is commonly seen in mania, hypomania, anorexia nervosa, and as part of attention-deficit/hyperactivity disorder.

In *catatonic* excitement, less common now than in the era before antipsychotic agents, patients exhibit disorganized and overactive behaviors including frantic jumping, thrashing of limbs, and seemingly senseless menacing or attacking behaviors. Such excitement is seen in mania, periodic catatonia, catatonic forms of schizophrenia, and some culture-bound syndromes such as *amok. Confusional excitement* is a state of restlessness and generalized purposeless activity seen in ictal states, some acute intoxications, and deliria.

Decreased Motor Activity Global reductions in motor activity—motor retardation—are seen in a variety of physical disorders such as hypothyroidism, Addison's disease, some infectious and postinfectious conditions including chronic fatigue syndrome and post-polio syndrome, and other fatiguing conditions, as well as in some organic mental disorders, intoxications, schizophrenias, and depressive disorders. Poverty of movement (*akinesia*, or more properly, *hypokinesia*) may occur in schizophrenia and as an adverse effect of antipsychotic drugs. Changes in the voice frequently accompany the reduced motor activity in schizophrenia and depression, with normal inflection replaced by monotonous tone and prolonged speech latency. In stuporous states patients remain immobile although their eyes are open and they are apparently awake.

Conversion reactions are functional, nonphysiological, psychogenic impairments in sensory or motor functions. Common motor forms include various paralyses and pareses, including limb paralyses, ataxias, and aphonias. In *globus hystericus* the patient is unable to swallow. Patients with *astasia-abasia* have marked unsteadiness of gait. Sensory conversion reactions include blindness, deafness, anesthesia, and analgesia. Some hyperesthesias and pain syndromes may also originate as conversion symptoms.

Mutism may result from a variety of peripheral muscle and CNS conditions and from functional disorders. Mutism may occur in profound depression, catatonic states, and conversion reactions. *Selective mutism* is occasionally seen in adjustment disorders and some personality disorders.

Motor Disturbances Many motor disturbances are seen in psychiatric disorders. Some form part of the core symptoms of the disorders; some occur in disorders that, by their nature, bridge neurology and psychiatry (such as Tourette's disorder); others are acute or chronic adverse effects of medications.

Tremor *Tremors*, involuntary oscillating movements of the limbs or head, may occur at rest or with movement. *Physiological tremors*, which are minimal at rest and increase with activity, are characterized by small amplitude and high frequency. They are characteristic of anxiety, fatigue, toxic or metabolic disorders such as caffeinism or hyperthyroidism, and are commonly seen in patients taking a number of different psychiatric medications including lithium (Eskalith), valproate (Depakene), and stimulating antidepressants. *Coarse tremors* with larger amplitude and lower frequency are seen in Parkinson's disease and cerebellar disease. *Asterixis* is a large-amplitude flapping tremor of the hands seen in hepatic disease.

Parkinsonism Parkinsonian symptoms and signs may be seen in psychiatric disorders, particularly in patients taking antipsychotic medications. Symptoms include akinesias with marked decrease in normally spontaneous fidgeting, stiff gait with diminished arm swing, pill-rolling nonintention tremors (which seem to be less common in neuroleptic-induced parkinsonism compared to Parkinson's disease), expressionless soft and monotonous speech, micrographic handwriting, and cogwheel rigidity.

Dystonia Although dystonic movements are seen in many neurological disorders, in psychiatric patients they are almost always secondary to the use of antipsychotic medications (neuroleptic-induced acute dystonia). Dystonic reactions consist of intermittent or sustained muscle spasms, typically of the head or neck. Common varieties include tongue spasms causing dysarthria, torticollis (neck spasm), and oculogyric crisis in which there is a forced upward gaze. Opisthotonus (spasms of paraspinal muscles leading to an arched posture) is seen less often. These reactions are most common in young males and typically occur soon after beginning or increasing the dose of a conventional antipsychotic medication.

Akathisia *Akathisia* is a syndrome of motor restlessness seen predominantly in the context of antipsychotic medications and some antidepressant drugs (neuroleptic-induced acute akathisia). It has subjective as well as motor components. Subjectively, patients experience muscle tension, difficulty finding a comfortable body position, and inability to stop moving; they feel as though they were “jumping out of their skin.” Objectively, akathisia classically manifests by rocking from foot to foot while standing, frequently crossing and uncrossing the legs when seated, and pacing. Sleep may be disturbed because of physical discomfort. Subjective components of akathisia may be difficult to distinguish from anxiety caused by the primary disorder (typically schizophrenia). Rarely, the restlessness and inner agitation becomes sufficiently uncomfortable to provoke acts of violence. In *pseudoakathisia* objective signs of akathisia are present, but the patient denies feeling restless.

A 24-year-old hospitalized man with schizophrenia was given 10 mg of haloperidol (Haldol) daily. Two days after beginning the medication, he became increasingly agitated—pacing around the ward, muttering to himself, and rapidly alternating between sitting and getting up. It was impossible to conduct an interview, in part because he would neither sit nor stand in one place. The staff thought his behavior indicated an escalation of his psychosis, and the dosage of the antipsychotic drug was doubled. Within the next few days the patient became even more agitated and told the staff that he was convinced that a motor inside him would not stop running. (Whether the motor was metaphorical or delusional was unclear.) One of the ward psychiatrists suspected akathisia, lowered the dose of the medication and prescribed anticholinergic medication and a b-adrenergic receptor antagonist to combat the akathisia. Within 2 days the patient became far more relaxed, less restless, and less psychotic.

Tardive Dyskinesia Neuroleptic–induced *tardive dyskinesia* is a movement disorder that occurs only in the context of antipsychotic medication use, occasionally after many months, more commonly after years. The abnormal movements may persist with or without continued medication use or may diminish or disappear over time. The dyskinetic movements occur at rest and can usually be temporarily suppressed volitionally or by purposeful action, distraction, or sleep. The movements are varied. In the most common type, which affects the face, especially the mouth and lips, tongue-thrusting, chewing, lip-smacking, and eye-blinking movements are seen. Another common type is characterized by choreoathetoid movements such as writhing finger motions. In the less common but more severe truncal dyskinesias, the torso moves in thrusting motions, and respiratory dyskinesia is characterized by grunting and irregular breathing patterns. Other tardive (late) syndromes include tardive akathisia and tardive dystonia in which the abnormal movements emerge late in treatment or upon medication discontinuation.

Neuroleptic Malignant Syndrome *Neuroleptic malignant syndrome*, a potentially fatal complication of antipsychotic medication, is characterized by muscle rigidity, fever, diaphoresis, delirium, mutism, and blood pressure abnormalities. Some view neuroleptic malignant syndrome as the most severe end of a spectrum that starts with neuroleptic-induced Parkinsonism, progresses to extrapyramidal syndrome with fever, and then to fulminant neuroleptic malignant syndrome.

Rabbit Syndrome This uncommon medication-induced extrapyramidal syndrome is often misdiagnosed as tardive dyskinesia. It most closely resembles a limited expression of a Parkinsonian tremor. Patients make rapid chewing movements similar to those made by rabbits, ordinarily faster and more regular than the orofacial tic of tardive dyskinesia. The tongue is spared.

Blepharospasm is a rapid and violent repetitive, spasmodic movement of the eyelids. These movements are often an adverse effect of antipsychotic or other medications but are also common in a variety of neurological disorders, including Meige's syndrome and Tourette's disorder.

Tics *Tics* are rapid, repetitive often spasmodic, jerking involuntary movements that serve no apparent purpose. The person may try to disguise or hide the tic in a seemingly purposive movement, and the movement may ultimately be shaped into a mannerism. Tics are the central feature of tic disorders, are associated with other disorders, and may occur as a consequence of stimulant (e.g., amphetamines) use.

Tourette's disorder is characterized by a chronic shifting array of motor and vocal tics. The tics may include grunts, coughs, clicks, or sniffs, while motor symptoms may include eye blinking, tongue protrusions, facial grimacing, hopping, and twitches. Complex tics may merge into complex compulsive behaviors, such as squatting, deep-knee bends, and retracing steps. *Coprolalia*, characterized by sudden verbal outbursts of obscenities, occurs in fewer than a third of Tourette's disorder patients. Mental coprolalia is an associated feature in which obscene words or phrases suddenly intrude into consciousness in an ego-dystonic manner. Obsessive-compulsive symptoms as well as attention-deficit symptoms are also common in Tourette's disorder.

Serotonin Syndrome *Serotonin syndrome* is a disorder typically caused by the combination of two or more medications with serotonergic properties. It is characterized by restlessness, myoclonus, hyperreflexia, diaphoresis, shivering, tremor, and mental status changes, such as confusion.

Motor Disturbances of Schizophrenia Many of the abnormal movements ascribed to tardive dyskinesia and other antipsychotic-induced extrapyramidal syndromes had been described in chronically psychotic patients before the introduction of antipsychotic medications. In one series of 100 patients, the large majority of whom were diagnosed as having schizophrenia, a review of medical records prior to 1955 revealed that abnormal purposive movements were found in 83 percent, mannerisms and tics in 71 percent, abnormal eye movements in 27 percent, abnormal postures or facial movements in 42 percent, and gait abnormalities in 10 percent. A recent study that comprehensively assessed hard and soft neurological signs, including motor coordination, involuntary movements, integrative sensory functions, cognitive functions, and primitive reflexes, found abnormalities in each of these areas in 67 percent of schizophrenia patients and 19 percent of their never medicated sibs but not in a matched comparison group. Levels of abnormalities were correlated in patient-sib pairs. In another study spontaneous dyskinesias were present in 12 percent of schizophrenia spectrum subjects (who met 3 of 4 criteria from the revised third edition of DSM [DSM-III-R] for paranoid, schizotypal, or schizoid personality disorder) but not in controls. These findings suggest that many patients with schizophrenia have neurological symptoms not caused by medications, and that severe psychiatric disorders may have a neurological component as well.

Catatonia refers to a broad group of movement abnormalities usually associated with schizophrenia, but also found in other disorders such as mania, depression, many neurological disorders (especially those involving the basal ganglia, limbic system, diencephalon, and frontal lobes), systemic metabolic disorders, toxic drug states, and periodic catatonia. Catatonic stupor and excitement have already been noted. *Stereotypies* are repetitious, bizarre, seemingly non-goal-directed complex organized gestures or postures that are thought to have private meanings to the patient. Examples include continuously and repeatedly crossing oneself or blessing others in a religious gesture, waving in a stylized manner, and making profane gestures. The stereotypic behaviors commonly seen in children with autistic disorder (constant spinning or rocking) may provide self-soothing, steady sensory input that help the patients reduce the degree to which they are disturbed by the ordinarily unpredictable and uncontrollable stimulation coming from the environment. *Bizarre posturing* may also be seen in catatonia. One patient with chronic catatonic schizophrenia routinely stood for hours on one leg with his arms in the air like a crane. In *echopraxia*, the patient imitates the examiner's movements, and in *echolalia* imitates speech, as if in mimicry. Some catatonic patients exhibit *waxy flexibility*, maintaining unusual postures into which they have been placed for prolonged periods of time. *Negativism* may take the form of refusing to behave in a prescribed manner, or resisting passive movement.

Gait disturbances in patients with psychiatric disorders include a variety of neurogenic gaits consistent with brain disease, intoxications, and medication adverse effects. These include the festinating gait of parkinsonism, spastic and ataxic gaits of neurological disease and psychiatric medications, waddling and reeling gaits associated with intoxications, and the nonphysiological gait disturbances seen in astasia-abasia, a form of conversion disorder. Gait mannerisms include clowning, prancing, military, and effeminate gaits.

Bruxism, chronic teeth gnashing, may occur involuntarily during tension states, or as an isolated occurrence during delta sleep in which it has sometimes been associated with benzodiazepine or alcohol use. In severe cases serious damage to dental enamel and temporomandibular joint pain may occur.

Myoclonus, characterized by focal muscle jerking, can be caused in psychiatric patients by certain medications, such as serotonin-reuptake inhibitors or monoamine oxidase inhibitors. Myoclonic jerks may be difficult to distinguish from tics, but the latter often represent larger muscle groups and more highly organized motor patterns. Myoclonus may be seen at rest but is more obvious during motor activity.

SEIZURE-LIKE BEHAVIORS In addition to the generalized, petit mal, and complex partial seizures seen in some psychiatric patients, a number of nonepileptic seizure-like behaviors must be distinguished. *Breath-holding spells*, generally innocuous impulsive and tantrumlike phenomena, usually occur in small children who hold their breaths during moments of oppositional rage, and who may faint as a result. Jerking or twitching motor movements may occur. *Temper tantrums* in young children may look like seizures, especially to the uninformed observer. The children may lie on the floor, screaming and kicking, and fail to respond to the environment. *Conversion seizures* (*hysterical seizures, pseudoseizures*) must be differentiated from genuine epileptic seizures. Patients retain consciousness, lack abnormal reflexes, and are not incontinent. However, because so many conversion seizures occur in patients who have genuine epilepsy and who know a good deal about the condition, the differential diagnosis is sometimes difficult.

COMPULSIVE BEHAVIORS Compulsive behaviors may occur in relation to everyday activities such as gambling, sexual conquest, shopping, and watching television, or in relation to substances such as alcohol, cocaine, and opioids or food. Other compulsions involve reckless risk-taking behaviors that provide stimulation and dispel dysphoric moods. Sexual compulsive perversions such as exhibitionism and sadomasochism may serve similar purposes. Compulsions are seen in a variety of psychotic and nonpsychotic psychiatric disorders. The cravings that underlie compulsive behaviors are strong motivating forces, and the compulsive behaviors may regulate emotions. As yet unknown similarities may underlie all compulsive and addictive mechanisms.

In obsessive-compulsive disorder the compulsions are ritualized, repetitive behaviors that are performed with the goal of satisfying, neutralizing, and undoing obsessional thoughts. Although intended to decrease anxiety, rituals are never more than transiently successful. The most common compulsions involve checking to make certain that gas jets and faucets have been turned off and that windows and doors are locked, hand washing, repeating certain phrases, counting objects, and

placing objects in a prescribed order.

> A 20-year-old Japanese-American man compulsively touched every electrical socket he passed, washed his hands several times each hour, and spent countless time leaving and returning to his house to check doors and windows. His mother described that these behaviors began when he was 8 or 9, and had been unrelenting ever since.

A variety of other subtle neuropsychological deficits have been reported in obsessive-compulsive disorder, including impairments on measures of spatial working memory, spatial recognition, and motor initiation and execution. In one controlled study these impairments were not seen in comparison patients with panic disorder or a depressive disorder.

LANGUAGE DISORDERS

Communication difficulties may result from disorders of thinking as previously described, abnormal speech patterns in mood disturbances and schizophrenia; or from primary speech-fluency disorders such as stuttering and stammering; disorders of the articulation and speech apparatus; and CNS disturbances involved in hearing and speech generation (aphasias).

Manic patients typically exhibit *pressured speech* in which the speed of word stream is accelerated. If severe, the speech may be garbled, imprecise, and difficult to understand. Patients with psychomotor retardation depression speak slowly, monotonously, and have a long speech latency in response to questions. Patients with schizophrenia may be difficult to understand because of their disorder or because of the dysarthric effect of antipsychotic medication.

Allusory speech is vague, imprecise, and hard to comprehend because too few cues and details are provided for the listener. Such speech may be heard from some patients with schizophrenia, certain personality disorders, or even normal individuals who wish to convey a sense of mystery by just being suggestive, whose suspiciousness causes them to be reluctant to spell things out clearly, or who believe that the listener is more aware of their private codes, meanings, and allusions than is the case.

Speech Disorders *Stuttering* and *stammering* (ordinarily synonymous), refer to disturbances in the rhythm and fluency of speech due to blocking, convulsive repetition or prolongation of sounds. This disorder affects males two to three times as often as females, and there is a high rate of familial transmission.

Aphasias *Aphasias*, impairments of language produced by brain dysfunction, are ordinarily described as being fluent and nonfluent. In *fluent aphasias*, which generally reflect dysfunction in the left temporal and parietal area, patients have a normal or even elevated verbal output, sometimes with logorrhea, but they ignore the social conventions of conversation. They produce many well-articulated phrases with normal prosody, but there is little informational content. The fluent aphasias are further divided according to the extent of comprehension by the patient and the ability of the patient to repeat what the examiner says. The principal fluent aphasias are *Wernicke's aphasia, conduction aphasia, anomic aphasia*, and *transcortical sensory aphasia*.

Nonfluent aphasias are characterized by slow and poor verbal output, difficulty with spontaneous speech, omission of grammatical connecting words, and poor prosody. Patients may produce one-word replies or very short phrases. Brain lesions that cause nonfluent aphasias typically tend to occur in the anterior left hemisphere. The principal nonfluent aphasias are *Broca's aphasia, transcortical motor aphasia, global aphasia*, and the *mixed transcortical aphasias*.

In *aprosodias* the nonverbal aspects of speech, the melody, pauses, timing, stress, accent, and intonation, are impaired. Damage to the right prefrontal region has been associated with *expressive aprosodias*, and damage to the right temporal region and insula has been associated with *receptive aprosodias* impairments in the ability to understand and interpret the prosodic communications of another person. They are analogous to *receptive aphasias*, in which the individual is unable to understand another person's words.

DISTURBANCES IN INTERPERSONAL RELATIONSHIPS

Normal interpersonal relationships include relationships with parents, children, spouses, lovers, siblings, extended-family members, friends, colleagues, coworkers, and members of the larger community. These relationships ordinarily help provide for the satisfaction of basic drives, for affiliative needs, and for finding purpose and meaning in life. Through stable and satisfying relationships, human needs are met for intimacy, including love, sex, and affection; to be cared for and nurtured, provide care, learn, play, relax, dominate, and be productive through mutual effort. Interpersonal relationships are carefully regulated by means of interpersonal signs and signals. The extent to which deviance from these patterns is tolerated in a given relationship varies from behavior to behavior, relationship to relationship, family to family, and culture to culture.

Disturbances in interpersonal relationships may be viewed as characteristics attributable to a single person or as characteristics of an interpersonal system. Individual disturbances are considered to be undesirable or maladaptive personality traits. When these traits are present to a significant extent and interfere with social functioning or cause distress, they may comprise a personality disorder. Disturbances of interpersonal relationships have also been described at a systems level (e.g., as dyadic and family patterns of system disturbance).

Personality Traits and Disorders Personality, variably defined, is the characteristic pattern of an individual's attitudes, behaviors, beliefs, feelings, thoughts, and values—the sum of a person's emotional, cognitive, and interpersonal attributes. Personality traits are the prominent and characteristic features of an individual's personality and do not imply psychopathology. Aspects of personality are present from early life, and personality traits are relatively stable from adolescence onward, consistent across different environments, and recognizable by friends and acquaintances. The term *personality disorder* should be reserved for those consistent patterns of thought, feeling, and behavior that are inflexible and maladaptive. Personality disturbances manifest primarily in interpersonal contexts and can be viewed as interpersonal behavior disorders.

The determinants of personality are multiple and varied, and include innate and early biological, developmental, and environmental factors inside and outside the home. Through learning and the environment, temperamental factors (genetic or constitutional) are shaped into character.

The dimensional approach to personality and personality pathology characterizes individuals along a continuum of traits. Five dimensions of temperament have been described which appear to be somewhat independent and to have strong genetic contributions: *Neuroticism* (highly emotional, reactive, and thin-skinned, contrasting with emotional stability), *extraversion* (contrasting with intraversion), *openness* (contrasting with discomfort with novel experiences), *agreeableness* (contrasting with contrariness), and *conscientiousness* (contrasting with fickleness). These temperamental attributes may have implications for the course of psychotherapies that cut across diagnostic categories.

Another dimension of personality not adequately dealt with in the DSM-IV concerns moral behaviors such as honesty and integrity. The extent to which individuals behave honestly and with integrity differs considerably across individuals and in different situations. Deception and lying are common behaviors that occur in benign forms (e.g., in white lies) and in pathological forms, psychiatrically important in antisocial personality disorder and sociopathic behavior, pathological liars, and malingerers. Deception and lying may be difficult to assess clinically in the absence of additional informants. Studies of nonhuman primates indicate that at least among chimpanzees, deception (equivalent to lying and dishonesty) is relatively common and in some situations adaptive.

Another recently proposed personality typology characterizes personality along three dimensions related to temperamental characteristics presumed to be strongly influenced genetically—*harm avoidance, novelty seeking*, and *reward dependence*. High scores on the three dimensions characterize inhibition and pessimism, impulsive and exploratory behavior, and dependency and sentimentality, respectively. Different personality types can be described according to patterns of scores on the three dimensions. For example, antisocial personalities are characterized by high novelty seeking, low harm avoidance, and low reward dependence, whereas dependent characters have low novelty seeking, high harm avoidance, and high reward dependence.

DSM-IV uses a categorical approach to personality. The large overlap among the DSM personality disorders and the clustering of these personality disorders into three broad groups imply a lack of clear boundaries to the currently defined categories. The three DSM-IV clusters describe odd or eccentric types (*Cluster A*); dramatic, emotional, and erratic types (*Cluster B*); and anxious and fearful types (*Cluster C*).

The odd or eccentric group includes paranoid, schizoid, and schizotypal personality disorders. Patients with these personality disorders have the core traits of being

interpersonally distant and emotionally constricted. People with paranoid personality disorder are quick to feel slighted and jealous, carry grudges, and expect to be exploited and harmed by others. People with schizoid personality disorder lack friendships or close relationships with others and are indifferent to praise or criticism by others. People with schizotypal personality disorder display odd beliefs, engage in odd and eccentric gestures and practices, and exhibit odd speech.

The dramatic, emotional, and erratic group includes borderline, histrionic, narcissistic, and antisocial personality disorders. Patients with these personality disorders characteristically have chaotic lives, emotions, and relationships. People with borderline personality disorder are impulsive, unpredictable, angry, temperamental, unstable in relationships, compulsively interpersonal, and self-damaging with regard to sex, money, and substance use. People with histrionic personality disorder are attention-seeking, exhibitionistic, seductive, and self-indulgent; exhibit exaggerated expressions of emotions; and are overconcerned with physical appearance. People with narcissistic personality disorder tend to be hypersensitive to criticism, exploitative of others, egocentric with an inflated sense of self-importance, feel entitled to special treatment, and demand constant attention. People with antisocial personality disorder are described almost exclusively in behavioral rather than affective or relational terms. They commit truancy, lie, steal, start fights, break rules, are unable to sustain work or school, and shirk day-to-day responsibilities.

The anxious and fearful group includes patients with avoidant, dependent, and obsessive-compulsive personality disorders. Patients with these disorders are characterized by constricting behaviors that serve to limit risks. People with avoidant personality disorder avoid relationships, people with dependent personality disorder avoid being responsible for decisions, and people with obsessive-compulsive personality disorder use rigid rules that preclude new behaviors. People with avoidant personality disorders are hypersensitive to rejection and are reluctant to enter close relationships in spite of strong desires for affection. Those with dependent personality disorders show excessive reliance on others to make major life decisions, stay trapped in abusive relationships for fear of being alone, have difficulty initiating projects on their own, and constantly seek reassurance and praise. Individuals with obsessive-compulsive personality disorders exhibit restricted expressions of warmth, tenderness, and generosity, and also exhibit stubbornness with a need to be right and to control decisions; indecisive at times, they often apply rules and morals too rigidly, to the point of being inflexible.

A characteristic personality disturbance seen with frontal lobe damage is referred to as *organic personality disorder* in the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), and as *personality change due to a general medical condition* in DSM-IV. Its features include irritability, inappropriate jocularity with euphoria, inappropriate socially disinhibited behavior, and impulsiveness. Other patients, with damage to different areas of the frontal lobe, in contrast, exhibit apathy and indifference.

Interpersonal Systems Couples and families have been studied as systems in their own right, and many qualities of these systems have been identified as being clinically important. A scheme for categorizing relational disorders has been proposed for future editions of DSM, but so far no single generally accepted typology of family psychopathology or interactional types has been established. However, elements of marital discord and harmony have been operationalized in several standard marital inventories. Characteristics of couples and families that have received the most attention include the rules of communication, such as those governing the directness or indirectness with which disagreement and conflict are addressed; the manner (organized or chaotic) in which communications are conducted; taboo topics and secrets about which no one can openly communicate; the nature and degree of emotional expression including affection and anger; the cohesiveness, loyalty, and compatibility of members; the nature of the members' shared identities on the one hand and their autonomous development and separateness on the other; the extent to which members treat one another respectfully or take one another for granted and use one another; the distribution of power and decision making among members; the maintenance of generational boundaries (e.g., age-appropriate performance of life roles); and the members' orientation, concurrence, and disagreement about important values involving moral, religious, intellectual, cultural, financial, occupational, and child-rearing issues, as well as aspirations, health practices, leisure activities, and other belief systems.

Despite the lack of an accepted system for describing disturbances in family systems, some common patterns have been identified. Many imbalanced relationships in which one partner largely dominates the other, may remain stable for years (*skewed* relationships). Some couples have chronically unstable relationships with constant overt conflict (*schismatic* relationships).

A characteristic family environment, called *high expressed emotion*, has been identified that defines a relapse-prone family environment in which one individual has schizophrenia, bipolar I disorder, anorexia nervosa, or major depressive disorder. This interactional pattern includes demeaning, intense personal criticism (“You are rotten and lazy”) and emotional overinvolvement with the identified patient. Aspects of overinvolvement can be measured by quantifying the numbers of hours of face-to-face contact and by the extent to which relatives' categorically assert how the patients feel without ever bothering to ask the patients.

Couple and family system difficulties are most likely to erupt during predictable stressful events in the normal family life cycle, such as during the newlywed period; pregnancy and childbearing; difficult or contentious child-rearing; difficulties with parents, in-laws, and other extended family; insurmountable and unanticipated financial or career problems; serious illness or death of a child or relative; the childrens' adolescence; departure of children from the home; infidelity; and separation.

Interpersonal Disturbances in Illness Behavior *Abnormal illness behavior (dysnosognosia)* is a persistently pathological mode of experiencing, evaluating, and responding to one's own health status despite lucid and accurate appraisal and management options provided by a health professional. These behaviors can be considered as interpersonal disorders between patients and health care professionals. Central to all of these behaviors is the adoption of the sick role by the patient, who then engages in characteristic interactions with health care providers—which typically leave both the provider and the patient dissatisfied. Patients with abnormal illness behavior typically seek repeated medical evaluations from a multitude of physicians, often undergoing a series of expensive laboratory tests. At times, the level of complaints provokes unnecessary invasive laboratory examinations or surgeries which, in turn, place the patient at genuine medical risk.

Abnormal illness behaviors may be unconscious or conscious. Unconscious abnormal illness behaviors are those in which the patient believes the symptoms reflect some genuine illness. These behaviors may occur in somatization disorder (in which multiple symptoms and organ systems are affected), conversion disorders, somatoform pain disorder (in which no cause can be found for the subjective level of pain), and hypochondriasis (in which the primary fear is of having a serious disorder). Abnormal illness behaviors in which patients act sick when they are fully aware that they are not include malingering (in which external incentives—usually financial—are the motivating factors) and factitious disorder with physical or psychological symptoms (Munchausen's syndrome). In *Munchausen's syndrome (factícious disorder with predominantly physical signs and symptoms)*, patients repeatedly and compulsively present themselves for medical care with feigned or self-induced illness. These self-induced conditions may be so serious as to ultimately cause death: some patients inject themselves with feces to cause systemic infections that then warrant hospitalization and intensive care. When the self-induced nature of the illnesses is discovered, medical staff members often become outraged at these patients. The patients rarely accept or cooperate with psychiatric care, so few have been adequately studied. Most do not appear to be psychotic, but seem to have a disturbance in personality structure. In *factícious disorder by proxy*, a caregiver, usually a parent, induces illness in a child.

FUTURE DIRECTIONS

Like psychiatric diagnostic classifications, fashions among psychiatric signs and symptoms change. Characteristics once given prominence, such as the bony protuberances of the skull studied by phrenologists a century ago, are no longer accorded much importance, whereas only in the past few decades have newly described clinical phenomena such as family-expressed emotion and alexithymia been appreciated. Because of the shifts in what is considered relevant and the current dominance of biological research, it would be easy to assume that the nuances of clinical, descriptive psychopathology are mostly of historical interest. As long as the ultimate goals of clinical psychiatry are to help patients feel better and function better, attending to patients' subjective complaints with a firm knowledge of clinical descriptors will continue to be vital aspects of the skills of psychiatry.

SUGGESTED CROSS-REFERENCES

The psychiatric interview, history, and mental status examination are discussed in Section 7.2. Additional definitions of typical signs and symptoms of psychiatric illness are included in Section 7.3. Preception and cognition are discussed in Section 3.1, memory in Section 3.4, and classification of mental disorders in Section 9.1.

9.1 CLASSIFICATION OF MENTAL DISORDERS

MICHAEL P. BOGENSCHUTZ, M.D., AND H. GEORGE NURNBERG, M.D.

Advances in scientific psychiatry are to a great extent shaped by its system of classification. Systems of classification are fundamental to all sciences, containing the concepts upon which theory is based, and influencing what can and can not be seen. The classification of illnesses *(nosology)* has always been an integral part of the theory and practice of medicine. Classification is necessary to provide a conceptual framework within which to place what is observed, to communicate efficiently about illness states, to allow decisions to be made regarding treatment, to predict outcomes to measure change, and to keep records. Medical diagnostic systems are predominantly open systems of hypothetical compound constructs that are subject to falsification and further scientific inquiry. These systems allow meaningful research questions to be posed, the answers to which in turn affect the diagnostic system.

In medical nomenclature the primary categories of interest are diagnoses. A *diagnosis* may refer to a consistent syndrome whose cause is unknown or varied, a specified disorder of structure or function whose cause remains unknown, a deviation from a specified physiological norm, or the effects of a specified etiological agent or process. This underlying ambiguity has important implications.

Psychiatry is not different from other branches of medicine in these respects; however, psychiatric classification has evolved independently of medicine. At present, the official psychiatric nosology is viewed as separate from the rest of medical nosology, with disorders conceptualized as *psychiatric* or *nonpsychiatric* although it is understood that medical illness can cause psychiatric symptoms and that psychiatric disorders can have biological bases. To the extent that mental disorders are generally typological in nature, with less emphasis on clear boundaries between disorders than on the central core of each disorder, the classification system and specialty of psychiatry are often held as less “medical” or scientific than other branches of medicine. Extensive efforts to correct this perception resulted in a paradigmatic shift from hermeneutic to empirically based approaches, and the development of a nosology intended to increase diagnostic reliability and facilitate research efforts. These changes are embodied in the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) and its current successor, the fourth edition of DSM (DSM-IV).

HISTORY

Psychiatric illnesses were widely recognized in the ancient world. Melancholia and hysteria were identified in Egypt and Sumeria as early as 2600 BC. In India a psychiatric nosology was contained within the medical classification system of the Ayur-Veda, written about 1400 BC. Both Hippocrates and Plato created systems to classify mental disorders in classical Greece. Although the Hippocratic system was based primarily on empirical observation, the Platonic system was philosophically rooted in rational idealism. However, this distinction between empiricism and rationalism is not absolute. Hippocrates' system included a humoral theory of temperament that could be considered idealist, and Plato's rational thought was partly aimed at explaining observed reality. Classification in classical Rome was based primarily on the system of Hippocrates. The Galenic, humoral system persisted into the Middle Ages in Europe.

During the European Renaissance and Enlightenment, systems of classification came to reflect the belief in the ordered and uniform character of Nature. Classification was an important part of the largely descriptive science of the day. Thomas Sydenham was a leading proponent of the notion of discrete and uniform disease categories. Carolus Linneaus and Francois Boisser de Sauvages attempted to apply the taxonomic methods of biology to medical and psychiatric illnesses, with categories based on observed signs and symptoms. In contrast, a separate current of thought in late–eighteenth-century France urged the development of a theoretical framework for medical nosology.

The tension between paradigms based on observation and theory continued in the nineteenth century. The establishment of asylums allowed more prolonged and intensive observation of patients than had previously been possible. Autopsies became increasingly common and were widely accepted, and attempts were made to find a neuropathological basis for psychiatric symptoms. Emil Kraepelin aimed to develop a “natural” classification in which cause, symptomatology, and course would converge; however, his categories were based largely on similarity of symptoms.

At the beginning of the twentieth century, no universally accepted system of psychiatric diagnosis existed in Europe or the United States, creating confusion and credibility problems. In the United States the initial impetus for developing a classification of mental disorders was the need to collect statistical information for the census. By the 1880 census, seven categories of mental illness were distinguished: mania, melancholia, monomania, paresis, dementia, dipsomania, and epilepsy. The increasing role of government in health care created a greater push for diagnostic uniformity. The first standard psychiatric nosology was produced in this country in 1918 by the American Medico-Psychological Association (forerunner of the American Psychiatric Association [APA]) and the National Commission on Mental Hygiene. It consisted of 22 disorders to be used primarily for gathering uniform statistics in all mental institutions, and was meant to be revised every 5 years. In 1935 the APA collaborated with the New York Academy of Medicine to develop a nationally acceptable psychiatric nomenclature to be incorporated in the American Medical Association's (AMA's) *Standard Classified Nomenclature of Disease*. Because the AMA system focused on severe mental illness, the U.S. military produced a broader nomenclature to incorporate outpatient presentations of World War II veterans in the 1940s. The sixth revision of *Manual of International Statistical Classification of Diseases, Injuries, and Causes of Death* (ICD-6), developed in 1948 by the World Health Organization (WHO), was not entirely satisfactory to American psychiatrists, so the APA developed a variant that was published in 1952 as the first edition of DSM (DSM-I). Heavily influenced by Adolf Meyer's psychobiological view of reactions, this was the first official manual of mental disorders to focus on clinical utility for classification. DSM-II followed in 1968 without substantial change, other than the elimination of the term *reaction* from the diagnoses.

As with DSM-I and II, the development of DSM-III was coordinated with the development of the ninth revision of *International Statistical Classification of Diseases* (ICD-9) and published in 1980 by the APA. It represented a return to a descriptive system of diagnosis, based on explicit operational diagnostic criteria, theoretically neutral, and multiaxial in format. The revised third edition of DSM (DSM-III-R) (1987) and DSM-IV (1994) refined the diagnostic categories based on available empirical data, and proceeded to make the current diagnostic system compatible with that of the current 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) system.

PSYCHOSIS, PSYCHOPATHY, AND NEUROSIS

As eighteenth-century psychiatry widened the boundaries of insanity and encouraged the development of a descriptive psychopathology, the terms *neurosis*, *psychosis*, and *psychopathic* were conflated. Although these terms have essentially disappeared from the current names of individual diagnostic categories, they reflect the intellectual underpinnings of earlier psychiatric thinking, and influenced how disturbed thinking, moods, and behaviors came to be classified. Their usage persists, and more often than not is applied incorrectly in vernacular parlance. The word “psychopathic” in particular, conjures up a range of negative applications.

Psychosis The term *psychosis* was introduced by Ernst Feuchtersleben in 1845 to describe mental illness as a complex interaction of the psychic and the physical, and to denote a subclass of the nervous diseases referred to at that time as the *neuroses*. Confusion soon arose when *psychosis*, *psychoneurosis*, and *psychopathy* all came to mean the same thing. Efforts to clarify the confusion in terminology continued over the remaining half of the nineteenth century. By the beginning of the twentieth century, under the strong influence of Kraepelin, the meanings of *neurosis* and *psychosis* had become reversed. Freud proposed a nonorganic etiology for psychoneuroses. Karl Jaspers and Kurt Schneider continued in Kraepelin's tradition in Germany, so that the psychoses came to represent severe constitutional or endogenous psychiatric illness. The neuroses and psychopathies (now called *personality disorders*) came to represent exogenous reactions or static deviations on a

continuum from normal.

Perhaps more than any other psychodiagnostic construct, the term *psychosis* has been repeatedly misused for political ends. In the social-political context of Germany in the late 1930s, this classification served the ends of the Nazi regime by providing a pseudoscientific distinction or dividing line that could be used for the eugenics program that systematically killed institutionalized patients with mental retardation, schizophrenia, and manic-depressive illness (bipolar I disorder). Soviet psychiatry would later also be used to promote political agendas based on psychiatric nosological constructs.

Although the traditional meaning of the term *psychosis* emphasized loss of reality testing and impairment of mental functioning—manifested by delusions, hallucinations, confusion, and impaired memory—two additional meanings have evolved over the past 100 years. One common use of the term *psychosis* denotes severe impairment of social and personal functioning characterized by social withdrawal and an inability to perform usual household and occupational roles. The second use of the term specifies the extent of ego regression as a criterion for psychosis. As a consequence of various and multiple meanings, the term has lost its precision in current clinical and research practice. It is possible that the term will fail to appear in future official nosological systems, following the trend set in DSM-III for the class of neuroses.

According to the glossary of the American Psychiatric Association, *psychotic* means grossly impaired in reality testing. The term may be used to describe the behavior of a person at a given time or a mental disorder in which all persons with the disorder have grossly impaired reality testing at some time during its course. Gross impairment in reality testing is defined as existing when individuals incorrectly evaluate the accuracy of their perceptions and thoughts, and make incorrect inferences about external reality, even in the face of contrary evidence. *Psychotic* does not apply to minor distortions of reality that involve matters of relative judgment. For example, depressed persons who underestimate their achievements are not described as psychotic, whereas those who incorrectly believe that they have caused actual catastrophes are so described.

Direct evidence of psychotic perceptions, thoughts, and behavior is the presence of delusions or hallucinations not accompanied by insight into their pathological nature. The term *psychotic* is also appropriate when behavior is so disorganized that it is reasonable to infer that reality testing is grossly disturbed. Examples include markedly incoherent speech without apparent awareness by the person that the speech is not understandable, and the agitated, inattentive, and disoriented behavior seen in a phencyclidine psychotic disorder.

The psychotic disorders are those that are predominantly characterized by psychosis. In DSM-IV the psychotic disorders include schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, brief psychotic disorder, shared psychotic disorder, psychotic disorder due to a general medical condition, substance-induced psychotic disorder, and psychotic disorder not otherwise specified. In addition, some severe mood disorders can have psychotic features. A person with a nonpsychotic mental disorder may exhibit transient psychotic thoughts and behaviors. For example, a person with borderline personality disorder may, when under the influence of substantial stress, loss, or substance abuse, come to believe in the reality of hearing voices, of conspiracies, or of government persecution.

Psychopathy As late as the end of nineteenth century, the adjective *psychopathic* meant psychopathological and applied to any form of mental disorder. However, Koch, Gross, Morel, and others were narrowing the concept to apply to less severe forms of pathology that would eventually evolve into the contemporary concepts of personality disorders. Kurt Schneider's publication of “Psychopathic” charted the course by moving the subject away from the realm of the nonspecific “moral” of James Cowles Prichard to abnormal personalities. He conceived of psychopathic personalities not as pathological in a medical sense, but as deviations from the mean or normal condition, although with a somatic basis that might modulate the form of psychoses. Thus, outside the disease model, they could be enduring, episodic, or reactive.

Psychopathic personality became a subclass of the larger group of abnormal personalities. In the conceptualization of discordant adaptation, Eugen Kahn used the term *psychopathic* to designate these conditions as complex states that lay intermediately between mental health and illness. Although Sigmund Freud was less interested in the issue, other psychodynamic and psychoanalytic writers like Daniel Stern and Wilhelm Reich contributed significantly to the understanding of character pathology. Carl Gustav Jung reinvigorated views of personality by shifting the focus away from archaic views of stereotyped behavioral forms to the contemporary perspective of combinations of dimensions and typologies. Ernst Kretschmer proposed typology based on biological speculation that followed Kraepelin's approach to the psychoses. These perspectives led incrementally to the current concepts of personality disorder that, like the current nosological paradigm, are primarily descriptive and directed towards neurobiological explanatory hypotheses. Although *psychopathy* does not appear in the current official nosology, a residue of the concept is retained in DSM-IV's antisocial personality disorder and ICD-10's dissocial personality disorder.

Neurosis William Cullen coined the term *neurosis* in 1784 to signify a broad category of disorders affecting the nervous system. The term is now defined as a chronic or recurrent nonpsychotic disorder, characterized mainly by anxiety, that is experienced or expressed directly, or is altered through defense mechanisms. It appears as a symptom, such as an obsession, a compulsion, a phobia, or a sexual dysfunction. Although not used in DSM-IV, the term is still found in ICD-10.

DSM-III redefined *neurotic disorder* as a mental disorder in which the predominant disturbance is a symptom or group of symptoms that is distressing to the individual and is recognized by him or her as unacceptable and alien (ego-dystonic); reality testing is grossly intact. Behavior does not actively violate gross social norms although it may be quite disabling. The disturbance is relatively enduring or recurrent without treatment, and is not limited to a transitory reaction to stressors. Earlier psychoanalytic developmental explanatory theories have been stripped from the construct. Because of DSM-III's atheoretical stance, there is no defining etiologic factor.

In ICD-10 a class called “neurotic, stress-related, and somatoform disorders” encompasses the following: phobic anxiety disorders, other anxiety disorders (including panic disorder, generalized anxiety disorder, and mixed anxiety and depressive disorder), obsessive-compulsive disorder, adjustment disorders, dissociative (conversion) disorders, and somatoform disorders. ICD-10 also includes neurasthenia as a neurotic disorder characterized by mental and physical fatigability, a sense of general instability, irritability, anhedonia, and sleep disturbances. Many cases diagnosed as neuroses outside the United States fit the descriptions of anxiety disorders as diagnosed by American psychiatrists.

There are no diagnoses called “neuroses” in DSM-IV. For those who still adhere to the term, *neurosis* encompasses a broad range of disorders with various signs and symptoms. Beyond signifying that gross reality testing is intact, neurosis has lost the precision currently necessary for a diagnostic category. In terms of an individual's functioning, it can reflect an intermediate level of impairment in a number of areas.

FEATURES OF NOSOLOGIC SYSTEMS

Nosology is the study and practice of classification in medicine. The basic purpose of classification is data reduction or condensation of information. The “natural” classification is that which predicts the maximum possible number of facts. Although seemingly straightforward, taxonomy raises a number of philosophical and methodological issues.

Nosological systems generally consist of conjectured disorders (diagnostic categories) as well as rules for making the diagnosis of each category. Because they are not isomorphic concepts, the disorder should not be confused with the diagnosis. A disorder (disease, syndrome, or complex) is a hypothetical entity with ontological status. The process of diagnosis is the attribution of the disorder to particular cases. Once this attribution has been made, the individual can be said to “have” the diagnosis but not the disorder. Unless there is a known cause or an infallible definition or both, diagnosis requires the use of a fallible rule or algorithm. Thus, one can have a disorder without having the corresponding diagnosis, and one can have a diagnosis without the corresponding disorder.

The fundamental question of the ontological status of the diagnostic categories is rarely addressed directly in psychiatry. The metatheoretical choice is between realism and nominalism. *Realism* assumes that the entity (e.g., the disorder) exists independently of its being named. *Nominalism* asserts that the entity has no reality independent of being named; diagnostic categories are cultural constructs, not independently existing entities.

Every diagnostic system, including DSM-IV, also has an explicit or implicit epistemological position. The epistemological question is, “On what is valid knowledge based?” Depending on the paradigm chosen, (e.g., empirical-descriptive or etiologically based), different answers with different implications will be given to this question.

Value judgments involved in choosing a nosological system concern the primary purposes for which the system is designed. Important considerations include the following: clinical utility; research utility; diagnostic reliability; diagnostic validity; other statistical features; administrative, political, forensic, and economic

consequences; theoretical relevance; and universal acceptability. The choice and evaluation of nosologic systems depends in large measure on the priority given these various factors. For example, a system designed solely for clinical use would emphasize convenience of use and coverage (i.e., what proportion of patients presenting clinically can be given a relevant diagnosis), whereas a system designed primarily for research purposes would place more emphasis on reliability, diagnostic validity, and theoretical relevance.

Various systems of medical diagnosis refer to constructs (i.e., syndromes, disorders, diseases) of different epistemological status. A *syndrome* is a set of signs and symptoms that co-occur at a greater than chance frequency. Diagnoses based on groups of symptoms should at minimum represent syndromes. A *disorder* represents the conjunction of a syndrome with a clinical course. At this level, something is known about the mechanism of the illness as well as its symptoms, although the underlying causes remain obscure. A *disease*, the optimal medical category, is a conjunction of etiology and pathology. In the case of a true disease, the symptoms, pathology and pathophysiology, and underlying causes are all known, as are the relations between them. In medicine, criteria used in classification belong to all three levels: symptoms, mechanisms, and causes. Causes are considered definitional and are the ultimate basis for a natural nosology. Progress in medical understanding is the process of moving from the superficial symptoms to the underlying "real" disease. A precise understanding of syndrome and course furthers the discovery of mechanisms and causes. For example, the separation of Down syndrome from the more general category of mental deficiency facilitated LeJeune's discovery of the underlying etiology: trisomy 21. A similar relation is seen between the disorder dementia paralytica and the discovery of the causative agent of the disease syphilis: *Treponema pallidum*.

The official diagnostic nomenclature in DSM-IV uses the term *disorder* because most of the entities lack the features necessary to warrant the term *disease*. Cause is not specified except for cases of posttraumatic stress disorder, mental disorders due to a general medical condition, and substance-induced mental disorders. Other than some of the dementias, even these disorders lack a specified mechanism; most psychiatric illnesses and many medical illnesses are not diseases in the strict sense of the word.

THEORY OF CLASSIFICATION

Classification Versus Typology In a traditional system of classification, *categories* are defined by a small number of individually necessary and jointly sufficient criteria that can be applied unambiguously. Any case can be determined to belong or not to belong to a given category by applying the rules defining the category to the case. Thus, the boundaries are crisply defined. Individuals within such a category are homogeneous with respect to the defining characteristics of that category. For example, all vertebrates have a spinal column; no other creature has this characteristic. *Hierarchies* are composed of clearly nested sets. All the classes of vertebrates have a backbone, but are distinguished by other characteristics (e.g., the presence of hair and mammary glands for mammals). Every mammal and bird is a vertebrate. The periodic table of elements is another example of such a hierarchical, categorical system. This system works to the extent that the classes of interest have such a structure. Ludwig Wittgenstein showed that many common object categories (e.g., "game") do not have clear defining features, which is true for many psychiatric illnesses as well.

In the typological view, cases are assigned to categories if they sufficiently resemble a typical member (or prototype) of the category. Not all characteristics of the category are necessary for membership; some may be merely correlated with membership. This view permits the existence of borderline cases and heterogeneity within the category. Hierarchical sets need not be perfectly nested; members of a subset need not have all of the (correlated) characteristics of the more inclusive set. The typal category has a clearly defined center but the boundary is indistinct, dependent in borderline cases on judgment or the use of a chosen cut-off point. Typology has been called "the opposite of true classification" because it puts similar things together rather than taking different things apart. It is argued that the prototypal model more closely resembles clinical reality in psychiatry, where borderline cases are common and present the most diagnostic difficulty; studies have shown that this is the way that clinicians conceive diagnostic categories. DSM-IV is basically a prototypal system.

Categorical and Dimensional Systems A fundamental distinction is made between categorical and dimensional systems. Modern psychiatry and medicine aspire to the categorical system of classification, that is, the disorder, and generally the diagnosis, is either present or not present. The patient has or does not have a discrete diagnosis that differs qualitatively from normal. In a pure categorical system all diagnostic criteria are necessary and sufficient to make the diagnosis. Patients with the diagnosis are a homogeneous group in respect to that entity. Categorical systems differ in the extent to which hierarchy is recognized, and the extent to which categories are allowed to overlap. Categories may overlap in two senses. Two different categories may share features (criteria) and they may share members (both diagnoses in the same individual). DSM-IV is a modified categorical system in that diagnosis is dichotomous (either present or absent), but individuals who have a given diagnosis may be quite heterogeneous with respect to the defining criteria. Both forms of category overlap occur in the current psychiatric nosology.

In a dimensional classification system, there are no discrete categories. Individuals are described in quantitative terms along continuous factors that have a (usually normal) distribution throughout the whole population. Because the dimensions are continuous, various intermediate measures between the two extreme poles of the dimensions can be expressed quantitatively. Each individual can be represented on a point in *N*-dimensional hyperspace (*N* represents the number of factors or dimensions in the model) defined by the degree to which each factor is expressed. Pathology represents a statistical deviation from the quantitatively defined mean or norm. Multidimensional systems of personality classification have been used extensively in psychology, and found to be useful in predicting external validity variables. However, because of the long-held medical tradition of conceptualizing disease entities as discrete categories, dimensional approaches have met with less clinical acceptance in psychiatry. Dimensional approaches are found in portions of DSM-IV, such as Axis V and the three clusters of Axis II personality disorders (*odd*, *dramatic*, and *anxious*).

There are other systems, such as fuzzy set theory, that combine features of categorical and dimensional systems. Fuzzy set theory allows cases to belong to sets (e.g., diagnostic categories) to varying degrees. Diagnostic groupings are maintained, but membership varies in degree (from 0 to 1).

Dimensional and categorical constructs can coexist within a system of classification. However, the structure of each needs to be recognized so that it can be used appropriately. For example, in cancer the diagnosis is either present or absent, but when present, the disease is graded along a severity dimension (staging) that has important implications for treatment and prognosis. Similarly, rating scales can be used to measure the severity or change in an illness that is conceived as categorical, for example, the Hamilton Rating Scale for Depression or Brief Psychiatric Rating Scale. Distinguishing categorical and dimensional structures is at present a major challenge for psychiatry, because categorical disease entities may be manifested dimensionally and dimensional entities may appear categorical.

Diagnostic Hierarchy Another important structural consideration pertains to diagnostic hierarchy. Are categories mutually exclusive, or may an individual simultaneously belong to more than one category? In most cases DSM-IV has abandoned the hierarchical structure of the earlier edition, but exceptions still exist. A second issue in hierarchy is whether larger categories of a superordinate level of abstraction are recognized (e.g., "affective disorder"). Such categories are analogous to the genera, families, and so on of biological classification of animal and plant species. Various diagnostic systems differ in the emphasis placed on interrelationships of the categories.

DSM-IV uses as many as three levels of grouping above the individual disorder. DSM-IV states that disorders are grouped into the larger sections "based on their shared phenomenological features in order to facilitate differential diagnosis." In many cases there are also different codes for different types of a single disorder.

Operational Methods of Diagnosis (Algorithms) In practice, illness categories are inseparable from the means of diagnosing them and the diagnostic process should reflect the true nature of the latent structure of the disorder as exactly as possible. For example, the diagnostic algorithm for a categorical construct should return a categorical diagnosis. Such a disorder is conceived as homogeneous, and the individuals assigned to the category should be homogeneous with respect to the diagnostic criteria.

The simplest and optimal diagnostic algorithm is the use of a gold standard. The gold standard is an infallible criterion or test that is pathognomonic for a disorder. For example, Klinefelter's syndrome may be diagnosed unequivocally by histological demonstration of the XXY karyotype. However, there are few true gold standards in psychiatry. Biochemical or genetic etiological markers of psychiatric illness, if found, are possible gold standards of the future.

Lacking a gold standard, categorical diagnoses are often made using a number of fallible diagnostic criteria, each one of which is thought to be correlated with the disorder. Diagnostic heterogeneity is introduced when not all, but a minimum number, of all criteria are necessary and sufficient to make the diagnosis. In a formal prototypal model of classification, the diagnosis is made if the individual represents the prototype closely enough. Although several forms of diagnostic algorithms are used in DSM-IV (Figure 9.1-1), it is predominantly a modified prototypal system. Thus, in DSM-IV's borderline personality disorder where 5 or more of 9 criteria are required to make the diagnosis, a total of 256 possible combinations of criteria can make the diagnosis. This diagnostic heterogeneity affects the validity of the diagnosis. Heterogeneity is inevitable and to be expected in research exploring heritability, biological test measures, treatment outcome, clinical course, and

comorbidity correlates of diagnoses made by such algorithms.

FIGURE 9.1-1 Differential diagnosis of psychotic disorders. (Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistic Manual of Mental Disorders*, ed 4. ©American Psychiatric Association, Washington, DC, 1994.)

This procedure can be thought of as using a scale with a certain cutoff point to make the diagnosis. In the preceding example, the criteria for borderline personality disorder can be thought of as being scored 0 (absent) or 1 (present), and the diagnosis made if the individual scores 5 or higher on the scale. When such a scale is used, by making a number of assumptions it is also possible to use the score as a dimensional measure if the diagnosis is conceptualized in dimensional terms. The score contains more information (in the mathematical sense of the word) than the categorical diagnosis (e.g., knowing that a subject has exactly 7 of 9 criteria for borderline personality disorder is more informative than knowing that he or she meets the criteria for borderline personality disorder). However, if the latent structure is actually categorical, then the dimensional score might contain considerable “noise” that could obscure the true dimensional structure. Dimensional scoring procedures can be much more complicated than this, and individuals may be scored on a number *(N)* of dimensions of interest. Such dimensional categories can always be reduced to categorical diagnoses corresponding to particular regions of *N*-dimensional space.

Psychometric Evaluation of Diagnostic Procedures Where there is a gold standard, it is possible directly to measure the relation of the results of the diagnostic test procedure to the actual presence or absence of the disorder. The *sensitivity* of the diagnosis is the probability that the diagnosis will be positive given the presence of the disorder. The *specificity* is the probability that the diagnosis will be negative given the absence of the disorder. The *predictive value positive* is the probability that the disorder is present given that the diagnosis is present. The *predictive value negative* is the probability that the disorder is absent given that the diagnosis is absent. It must be emphasized that these relationships are not inherent to the diagnostic procedure but must be measured in the context of particular populations, and can vary greatly between different populations.

Reliability refers to the degree to which the results of a diagnostic procedure remain stable across different raters and at different times. Inter-rater reliability is high when two or more raters have a high probability of reaching the same diagnosis for the same individual tested at approximately the same time. *Test-retest reliability* refers to the situation in which rater bias is not an issue (e.g., self-report questionnaires or laboratory tests), but results still may differ when the same test is repeated in the same individual. *Longitudinal reliability* is a measure of the stability of the diagnosis over time. Pearson's *r* (correlation coefficient) and k are frequently used statistical measures of reliability. One reason that reliability is important is that it is a necessary although by no means sufficient condition for diagnostic validity.

Diagnostic categories and algorithms are constructed in the hope that they will be meaningful and useful; this is true for dimensional as well as categorical measures. *Diagnostic validity*, a compound term derived from various realms of experience, is used to describe such meaningfulness. *Face validity* refers to the extent that a category appears to represent a real phenomenon, as judged by experts. *Descriptive validity* refers to the existence of reliably assessed criteria that can identify a category and distinguish it from other conditions, particularly those that are phenomenologically similar. *Predictive validity* is the ability of a conjectured entity to predict external variables. In the prevailing psychiatric epistemology, this is operationalized by the procedures described by John Feighner for establishing predictive validity. These include the study of familial transmission, course of illness, treatment response, and biologic markers for the construct in question. *Construct validity* is the ideal or hierarchically superordinate standard of diagnostic validity. It is defined as the experimental confirmation of hypotheses concerning the etiology and pathophysiology of an illness construct, demonstrating that the category represents a real and naturally occurring entity with a specific pathological mechanism. Construct validity has both convergent (sensitivity) and divergent (specificity) aspects.

Mathematical Models The development of sets of operational criteria and assessment procedures has resulted in improved diagnostic reliability. Because most of the constructs in psychiatric nosology are latent (i.e., not directly observable) and without an infallible diagnostic criterion or definition (i.e., gold standard), refinements to establish diagnostic validity must rely on statistical methods. Consequently, as computers have become more powerful, statistical and other computational models have acquired increasing popularity and acceptance as methods to identify and confirm diagnostic categories and dimensions. Methods for isolating psychiatric disorders and assigning individuals to them are promoted under the concept of numerical taxonomy, the methodological sequel to typology. Exploratory analyses use the results to suggest divisions of patients into groups or taxa. Confirmatory analyses examine the syndromal homogeneity and underlying structure of existing diagnostic groups. If the classification system developed by numerical taxonomy conforms to the existing groups, the nosology can be considered to be mathematically valid.

Numerical taxonomy involves the grouping of items according to their evaluated affinity. These procedures involve the mathematical analyses of a data matrix. *Factor analysis* used to be a common technique to identify component dimensions. It has been largely supplanted by *cluster analysis*, which is complementary and attempts to identify homogenous subgroups of individuals on the basis of some measure of similarity. Testing for multimodality or bimodality in the distribution of scores on a typological variable is another approach to distinguishing groups; for example, bimodality or a point of rarity in distribution between groups is proposed to indicate categorically distinct groups.

To overcome some of the inherent limitations of these approaches, a variety of mixture models have come forward. They essentially posit that patients come from a mathematically describable mixture of probability distributions that can be characterized as true groups. The general mixture model assumes that each subject is described by a number of measurements that are normally distributed within groups. Categorical or qualitative group distinction is demonstrated by the presence of more than one normal component distribution in the distribution of canonical coefficient scores derived from discriminant function. The latent class model is another advanced type of mixture model that assumes that the observed data reflect a mixture of distributions in which indicants are not of normal distribution. For example, grade-of-membership typology utilizes the distribution of the presence and absence of probabilistic indicants in individual subjects to identify degrees of membership in pure types.

All the numerical taxonomic methodologies produce groups or taxa on typological grounds. The critical test of their validity is their ability to predict important clinical variables in external domains of familial transmission, course of illness, treatment response, and biologic markers. Although these mathematical methods may produce taxa with strongly defined centers, further inquiry must proceed to determining clear boundaries to be ultimately compatible with the current idealized medical classification paradigm.

DEVELOPMENT OF DSM-IV

In 1988 the APA announced its decision to revise DSM-III-R, which had been published the previous year. Scheduled for 1992, DSM-IV publication was delayed until 1994. Many believed its publication was premature because there would be insufficient time to accumulate a sufficient database on which to develop DSM-IV. Objections were raised in various sectors. Clinicians and recently graduated resident trainees were resistant to changes in the criteria in which they were trained. Patient advocacy groups were concerned that there would be confusion when diagnoses were changed because of a different diagnostic system. Researchers were concerned about the implications of a new nosological system on the relevance of findings obtained with a different system. The American Psychological Association and other organizations of nonpsychiatric mental health professionals, such as social workers and psychiatric nurses, were critical because they had little, if any, input into the final product that they were required by law to adhere to.

Nevertheless, DSM-IV was published in 1994. The criticism of a lack of replicated research data on which to base DSM-IV was addressed in the introduction to the

manual. It states that the Task Force on DSM-IV conducted a three-stage empirical process prior to publication. The stages were:

1. Literature reviews, conducted to provide comprehensive and unbiased information on which to base DSM-IV diagnostic criteria. DSM-IV notes, however, that for some issues insufficient data were available, and in those cases existing data were reanalyzed.
2. Data reanalysis that consisted of “analyses of relevant unpublished data sets” of criteria included in DSM-III-R. According to the DSM-IV Task Force, this approach made it possible for work groups to “question several criteria sets that were then tested in the DSM-IV field trials.”
3. Field trials that compared DSM-III, DSM-III-R, and ICD-10, and proposed DSM-IV criteria sets. The field trials collected information on the reliability and performance characteristics of each criteria set as a whole and on specific items within each criteria set. Twelve field trials were conducted at more than 70 sites, evaluating more than 6,000 subjects. Whether that is a large enough database on which to base a revision is open to question. Many psychiatrists in various sectors (e.g., clinical, research) believe that insufficient time has elapsed between revisions of DSM to allow replicated research on which to base DSM-IV.

BASIC FEATURES OF DSM-IV

DSM-IV is the current classification of mental disorders; it is used by mental health professionals of all disciplines and is cited in insurance reimbursement, disability deliberations, statistical determinations, and forensic matters. Although there has been substantial criticism of each consecutive version of the DSM, DSM-IV is the official nomenclature and is used throughout this textbook. Table 9.1-1 lists all the disorders as they appear in DSM-IV.

Table 9.1-1 DSM-IV Classification of Mental Disorders*

DSM-IV strives to be neutral or atheoretical with regard to causes. Thus, it attempts to describe what the manifestations of the mental disorders are; only rarely does it attempt to account for how the disturbances come about. The definitions of the disorders usually consist of descriptions of the clinical features.

Specified diagnostic criteria are provided for each mental disorder. Those criteria include a list of features and, in most cases, how many must be present for the diagnosis to be made. The use of specific criteria tends to increase the reliability of the diagnostic process among clinicians.

DSM-IV also systematically describes each disorder in terms of its associated features: specific age-, culture-, and gender-related features; prevalence, incidence, and predisposing factors; course; complications; familial pattern; and differential diagnosis. In cases where many of the specific disorders share common features, that information is included in the introduction to the entire section. Laboratory findings and associated physical examination signs and symptoms are described when relevant. DSM-IV explicitly states that it is not a textbook. No mention is made of causal theories, management, or treatment; nor are the controversial issues surrounding particular diagnostic categories discussed.

DSM-IV provides explicit rules to be used when the information is insufficient (diagnosis to be deferred or provisional), or the patient's clinical presentation and history do not meet the required criteria of a prototypical category (atypical type, residual, or not otherwise specified).

Multiaxial Evaluation DSM-IV is a multiaxial system that comprises five axes and evaluates the patient along each. Axis I and Axis II comprise the entire classification of mental disorders: 17 major groupings, more than 300 specific disorders, and almost 400 categories. In many instances the patient has one or more disorders on both Axis I and II. For example, a patient may have major depressive disorder noted on Axis I and borderline and narcissistic personality disorders on Axis II. In general, multiple diagnoses on each axis are encouraged (Table 9.1-2 and Table 9.1-3).

Table 9.1-2 Multiaxial Evaluation Report Form

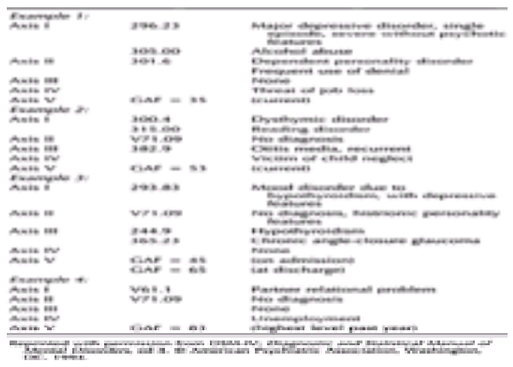

Table 9.1-3 Examples of How to Record the Results of a DSM-IV Multiaxial Evaluation

Axis I Axis I consists of all mental disorders except those listed under Axis II, and other conditions that may be a focus of clinical attention.

Axis II Axis II consists of personality disorders and mental retardation. The habitual use of a particular defense mechanism can be indicated on Axis II.

Axis III Axis III lists any physical disorder or general medical condition that is present in addition to the mental disorder. The identified physical condition may be causative (e.g., hepatic failure causing delirium), interactive (e.g., gastritis secondary to alcohol dependence), an effect (e.g., dementia and human immunodeficiency virus [HIV]-related pneumonia), or unrelated to the mental disorder. When a medical condition is causally related to a mental disorder, a mental disorder due to a general condition is listed on Axis I and the general medical condition is listed on both Axis I and III.

Axis IV Axis IV is used to code psychosocial and environmental problems that contribute significantly to the development or the exacerbation of the current disorder (Table 9.1-4). The evaluation of stressors is based on the clinician's assessment of the stress that an average person with similar sociocultural values and circumstances would experience from psychosocial stressors.

Problems with primary support group
Problems related to the social environment
Educational problems
Occupational problems
Housing problems
Economic problems
Problems with access to health care services
Problems related to interaction with the legal system/crime
Other psychosocial and environmental problems

Reprinted with permission from *DSM-IV: Diagnostic and Statistical Manual of Mental Disorders*, ed 4, © American Psychiatric Association, Washington, DC, 1994.

Table 9.1-4 Axis IV: Psychosocial and Environmental Problems

Axis V Axis V is the Global Assessment of Functioning (GAF) scale (Table 9.1-5) with which the clinician judges the patient's overall level of functioning during a particular time period (e.g., the patient's level of functioning at the time of the evaluation or the patient's highest level of functioning for at least a few months during the past year). Functioning is conceptualized as a composite of three major areas: social functioning, occupational functioning, and psychological functioning. The GAF scale, based on a continuum of severity, is a 100-point scale with 100 representing the highest level of functioning in all areas.

Table 9.1-5 Global Assessment of Functioning (GAF) Scale*

Nonaxial Format DSM-IV also allows clinicians who do not wish to use the multiaxial evaluation format to list the diagnoses serially, with the principal diagnosis listed (Table 9.1-6).

Table 9.1-6 Nonaxial Format

DSM-IV's Relation to ICD-10 The DSM-IV was designed to correspond with ICD-10, developed in 1992. There was a strong consensus that diagnostic systems used in the United States must be compatible with the International Classifications of Diseases (ICD) to ensure uniform reporting of national and international health statistics. In addition, Medicare requires that billing codes for reimbursement follow ICD.

ICD-10 is the official classification system used in Europe and many other parts of the world. All categories used in DSM-IV are found in ICD-10, but not all ICD-10 categories are in DSM-IV. In the United States, ICD-10 codes can be used on insurance forms and other documents requiring diagnoses. The codes in DSM-IV are fully compatible with ICD-10 and are listed in the appendix; however, some terms and diagnostic categories used in ICD-10 are not used in DSM-IV.

CRITIQUE OF DSM-IV

In formulating a critique of the DSM-IV, it is important at the outset to establish what the DSM-IV is and is not intended to be. The introduction of the DSM-IV states:

> The utility and credibility of the DSM-IV require that it focus on its clinical, research, and educational purposes and be supported by an extensive empirical foundation. Our highest priority has been to provide a helpful guide to clinical practice. We hoped to make DSM-IV practical and useful for clinicians by striving for brevity of criteria sets, clarity of language, and explicit statements of the constructs embodied in the diagnostic criteria. An additional goal was to facilitate research and improve communication among clinicians. We were also mindful of the use of DSM-IV for improving the collection of clinical information and as an educational tool for teaching psychopathology.

An official nomenclature must be applicable in a wide diversity of contexts. DSM-IV is used by clinicians and researchers of many different orientations (e.g.,

biological, dynamic, cognitive, behavioral, interpersonal, family, systems). It is used by psychiatrists, other physicians, psychologists, social workers, nurses, occupational and rehabilitation therapists, counselors, and other health and mental health professionals. DSM-IV must be usable across settings—inpatient, outpatient, partial hospital, consultation liaison, clinic, private practice, and primary care, and with community populations. It is also a necessary tool for collecting and communicating accurate public health statistics. Fortunately, all these many uses are compatible with one another.

These goals are similar to those of DSM-III and DSM-III-R. A strong emphasis is placed on clinical utility across a variety of settings, consensus, and utility in education and research. Although laudable goals, they are not the only ones that could have been chosen as priorities, and they are not necessarily compatible in all cases.

It is also important to note what the DSM-IV does not state as goals. It does not intend to be a definitive or permanent taxonomy. It does not claim that all the categories are necessarily valid, nor that they be clearly distinguished from each other in all cases. It uses the term *disorder* exclusively, rather than *disease*, indicating that it does not assume that the entities described are diseases.

A common criticism of DSM-IV is that it seems to place consensus and universal acceptability above validity. This is essentially a value judgment supported by the goals quoted above. Although DSM-IV remains unpopular among some clinicians (especially those who are psychodynamically oriented), it appears to have been successful in this goal as evidenced by its position as the standard nomenclature in the United States and in much of the world.

However, criticisms relating to validity remain. The rates of comorbidity, or more accurately co-occurrence, between many of the DSM-IV diagnostic categories are higher than those found in any other branch of medicine. This brings into question whether the categories actually represent discrete entities or rather different aspects of larger symptom complexes. It is also not clear whether many of the criteria sets actually represent syndromes in the statistical sense (i.e., criteria that occur together significantly more often than chance). Although the DSM-IV Task Force made a major effort to render the nosology consistent with existing empirical data, most categories lacked the adequate empirical database for that determination, even at the level of internal (face and descriptive) validity. In addition, the extensive heterogeneity allowed by the polythetic criteria sets and their algorithms limits the utility of many of the diagnoses.

Another criticism of DSM-IV concerns its atheoretical stance. Beyond the inherent paradox of such a position, should a nosological system be atheoretical (i.e., purely empirical)? The goal was to create a document that would be acceptable to health professionals regardless of theoretical outlook; explicit etiological and pathological theories are for the most part eschewed. The structure of the DSM-IV implies that mental disturbances can be characterized as disorders and categorized in a meaningful way based on signs and symptoms, particularly related to cognition and behavior. This in itself constitutes a theoretical stance. Although it may be the best that can be done at this time, the failure to involve developments in theory and cause is a significant impediment to further advances.

The categorical approach adopted by the DSM-IV is familiar and comfortable to those with medical training. However, other than an appeal to tradition, there is little evidence that such a system is more useful or valid than a dimensional or other taxometric system. There is an equally long tradition of evaluating personality traits in a dimensional fashion. Doubts have been raised regarding the categorical nature of personality disorders, psychotic disorders, and mood disorders. DSM-IV clearly acknowledges the potential contributions of the dimensional approach, and contains polythetic and dimensional as well as categorical constructs. Whether it is reasonable to apply a common form to all psychiatric disorders or whether different models, representing different structures, should be applied to different classes of illness remains an open question.

The DSM-IV multiaxial system implies the existence of qualitative differences between Axis I psychiatric disorders, Axis II personality disorders, and Axis III medical disorders but there is little evidence to support this position. The distinction of Axis I and Axis II was originally made in DSM-III to encourage use of the latter diagnoses out of concern that they could be missed because of the established hierarchical rules of the nosology. Hierarchical diagnosis was essentially abandoned in DSM-III-R, and DSM-IV follows that revision. The categorical distinction between psychiatric and medical conditions makes less and less sense as knowledge accumulates concerning the biological bases of psychiatric disorders and the effects of psychosocial variables on medical illnesses. In the absence of supporting evidence, the distinction between Axes I, II, and III appears anachronistic and possibly counterproductive.

In summary, DSM-IV is a practically-oriented, consensus system that incorporates much of current clinical belief and research data. Many of its limitations are direct consequences of its intentionally descriptive approach; others stem from an across-the-board adoption of a quasi-categorical system using polythetic criteria. To its credit, DSM-IV has achieved an acceptable level of validity, primarily in face validity and more modestly in descriptive validity, which has enabled advances to be made in external predictive realms. Most importantly, as an open system, it provides a medium of discourse for clinicians and researchers, and is intended to be replaced in the future by more definitive, research-based nosological systems that incorporate etiology and pathology.

9.2 INTERNATIONAL PSYCHIATRIC DIAGNOSIS

JUAN E. MEZZICH, M.D., FH.D., ANGEL A. OTERO-OJEDA, M.D. AND SING LEE, M.D.

The concept of “diagnosis” at any point in time, defines the field of medicine in general and psychiatry in particular. It does so by delineating the informational base necessary for clinical care. With various degrees of systematization and explicitness, diagnostic schemas, as consensual notions and formats for describing clinical conditions, have emerged since the dawn of mankind. In every case, these notions have been embedded within their time and culture.

Building on conceptual contributions over the past two centuries in various parts of the world, and having the 100-year-old International Classification of Diseases (ICD) as general reference, the emphasis for advancing psychiatric diagnosis during the past several decades has been on more-systematic and clearer formulations of psychopathology and nosology. This has led to gains in interdiagnostician agreement (diagnostic reliability) and universal communicability of diagnostic statements. These developments have been widely regarded as propitious (although not guarantees) for diagnostic validity or usefulness and for the broader advancement of the field.

Among recent efforts to update diagnostic validity, clinically and epidemiologically, are developments to enhance existing universalistic diagnostic systems by paying attention to both local realities and the uniqueness of the individual. The first type of these developments involves adaptations of the international classification system to regional or national clinical patterns and needs. The second corresponds to idiographic or personalized formulations.

CONCEPTUAL AND METHODOLOGICAL DEVELOPMENTS

Through proposals arising in different parts of the world, the following have emerged in recent decades as key conceptual and methodological developments for psychiatric diagnosis. They refer to the following major themes: systematic psychopathological description and comprehensive diagnostic formulation.

Systematic Description of Psychopathology Early roots of explicit and systematized psychopathological description can be found in nineteenth-century France when symptoms were first used as units of analysis of abnormal behavior. Current concepts of psychiatric nosology can be traced back to the end of the nineteenth century, highlighted by Valentin Magnan's notion of clinical evolution in France and Emil Kraepelin's dichotomy of the major psychoses in Germany. Other significant contributions to the nosology of severe mental disorders of recent impact on psychiatric classification are the German description of cycloid psychoses, the Scandinavian concept of psychogenic psychosis, and the French delineation of *boufée délirant*. More recently psychopathologists from Asia, Africa, and Latin America have offered informative reports on acute transient psychoses and somatically and psychologically textured characterizations of the neuroses.

The manifestations of mental disorders constitute the focus of the so-called phenomenological description of psychopathology. That approach encouraged careful observation of clinical presentations, particularly symptom profiles, while minimizing etiological inferences. Many questions remain regarding the organization of standard nosologies, for example, the number of major classes of mental disorders, the arrangement of subclasses, and the hierarchical relationships among diagnostic categories. Furthermore, etiopathogenic perspectives—from genetics, to psychodynamics, to general systems—may in the future contribute enriched and more valid formulations of mental disorders.

Explicit or operational diagnostic criteria, a mainstay of modern diagnostic methodology, were persuasively proposed by the British psychiatrist Edward Stengel as a step in dealing with the widespread confusion in classification documented in his international survey, commissioned by the World Health Organization (WHO). The actual development of operational criteria was pioneered, chronologically, by José Horwitz and Juan Marconi in Latin America, Peter Berner in Austria, and John Feighner and associates in the United States. Operationalized diagnostic criteria probably represent the most conspicuous response to the need for clarity in psychiatry and are considered essential for its progress as a scientific discipline. On the other hand, the limitations of using the criteria sets include the arbitrariness often involved in setting thresholds between cases and noncases, the cumbersomeness of their use in daily practice, and the burden they impose on meaning and usage across cultures. An approach that promises to enhance categorical definition by accommodating graded typicality and flexible boundaries involves the use of the prototypical categorization model. This is connected to mathematical *fuzzy set theory*, and its use is being explored on particularly problematic areas of psychopathology, such as personality disorders and even schizophrenia and obsessive-compulsive disorder.

Multiaxial Diagnostic Formulation Attempts to represent more fully the complexity of a patient's condition have emerged predominantly under the generic term *multiaxial approach*. Multiaxial diagnosis intends to portray the intricacies of the clinical condition through the systematic and separate assessment and formulation of highly informative aspects or domains. Standardized measurements, either typologies or dimensional scales, have been proposed with which to appraise each domain.

The first multiaxial schemata in both psychiatry and general medicine were aimed at articulating key components of an illness. Starting in 1949, the pioneers of the field who independently proposed a methodical and almost graphical assessment of syndromes and etiology were Erik Essen-Möller and Snorre Wohlfahrt in Sweden, Maurice Lecomte and associates in France, Tadeusz Bilikiewicz in Poland, and José Leme-Lopes in Brazil.

The first multiaxial schema in general medicine was the Systematized Nomenclature of Pathology, which accommodated axes on topography, morphology, etiology, and symptoms. One of the latest is the International Classification of Diseases for Oncology (ICD-O), which focuses separately on neoplastic topography and morphology (the latter including tumor behavior and differentiation).

A more recent and far-reaching purpose of the multiaxial model is to furnish a biopsychosocial description of the patient's entire clinical condition. This encompasses not only pathologies (mental and nonmental), but also psychosocial environmental factors and the consequences of illness on the individual's functioning and quality of life. The work of John Strauss, Michael Rutter, and associates in psychiatry and of Alvin Feinstein, J. S. House, and associates in general medicine are pertinent to this objective. Among the challenges for further development of the multiaxial model are the need for greater simplicity and ease of use as well as empirical appraisal of its reliability and validity across the world.

The first national diagnostic system to incorporate a multiaxial approach was the Swedish classification of mental disorders, which was based on the previously referred proposals by Essen-Möller and Wohlfahrt. More recently, the methodological developments outlined previously (phenomenological description, explicit diagnostic criteria, and multiaxial formulation) have structured the third and fourth editions of the American Psychiatric Association's (APA's) *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III and DSM-IV), as well as the WHOs 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), which has a central role for diagnosis across the world.

ICD-10

Origins of the International Classification The origins of the ICD can be traced back to the taxonomic work of the Swedish biologist Carolus Linnaeus in the eighteenth century. In *Genera Plantarum* he stated: “All the real knowledge which we possess depends on methods by which we distinguish the similar from the dissimilar ... We ought therefore by attentive and diligent observation to determine the limits of the genera, since they cannot be determined a priori. This is the great work, the important labor, for should the general be confused, all would be confusion.” Linnaeus stimulated scholars from all walks of life. For example, Francois Boissier de Sauvages and William Cullen developed formidable nosologies encompassing thousands of species of disease, organized into classes, orders, and

genera.

Bringing these leads to fruition, the first International Statistical Congress held in Brussels in 1853 commissioned the Englishman William Farr and the Italian Marc d'Espine to prepare a “uniform nomenclature of causes of death applicable to all countries” as a way to obtain comparable health status information across the world. The proposals that ensued were based primarily on either topographical or etiological principles. Accommodating both, Jacques Bertillón of Paris prepared the First International Classification of Causes of Death, adopted at the International Statistical Congress of 1893.

Since then there have been revisions of the ICD approximately every 10 years. From its foundation the WHO, created in 1948, assumed the preparation of these revisions as a constitutional responsibility. The sixth revision contained a critical expansion of the scope of the international classification by covering morbidity in addition to mortality. Correspondingly, psychiatric illness appeared for the first time in the classification with one category: mental illness and deficiency. The ninth revision had as one of its innovations the presentation of a glossary for the capsular definition of mental disorders. While modest in informational detail, this glossary signified recognition by the WHO that the intricacy of mental problems required more than the labels used in all other chapters of the ICD.

Outline of ICD-10 Work toward the preparation of ICD-10 started in 1979, the same year in which the ninth revision of *International Statistical Classification of Diseases* (ICD-9) was put into effect. Its developmental process involved the participation of the eight Collaborating Centers for the Classification of Diseases, specialty divisions (such as Mental Health) at both the headquarters and regional offices of WHO, nongovernmental organizations such as the World Psychiatric Association (WPA), and a miscellaneous panel of interested groups and individuals, all working under the coordination of the WHO Unit on the Development of Epidemiological and Health Statistical Services.

First to be noted in ICD-10 is its expanded scope, as indicated by its title, *International Statistical Classification of Diseases and Related Health Problems*. This expression continues the trend that starting with an original set of causes of death, added morbidity in its fifth revision, and more recently added problems such as disabilities and factors that influence health status, recognizing that more information is needed to deal effectively with the evolving and complex issues of health care and health promotion.

ICD-10 uses an alphanumeric code composed of a letter followed by several digits. That arrangement more than doubles the number of available categories. Splitting, rather than lumping, of categories has marked the progression of ICD revisions, which has increased the need for categorical slots. The first four characters of the code are internationally official. The fifth- and sixth-character fields are available for regional and special purpose adaptations. This arrangement maintains international communication while accommodating local diversity.

Another powerful and innovative concept is ICD-10 as a family of disease and health-related classifications. At the core of the family are the 21 main chapters coded at the official three-character and four-character levels and the short tabulation lists of causes of death and morbidity. Peripherically located are the following classifications: (1) specialty-based adaptations (e.g., for oncology) where the chief difference from the core classification lies in the further extension of the ICD codes; (2) classifications for primary care and general medical practice, characterized by the condensation of categories and emphasis on less rigorous diagnostic terminology and more immediate therapeutic utility; and (3) classifications of information outside the core ICD, such as that corresponding to disabilities and medical procedures. Also part of the family is the International Nomenclature of Diseases, which encompasses a list of recommended names for all diseases as well as their definitions. In contrast to the concept of nomenclature, a classification, in the words of the ICD pioneer Farr, “groups diseases that have considerable affinity or that are lable to be confounded with each other, and therefore is likely to facilitate the deduction of general principles.”

Main forms of human illness and related conditions constitute the 21 chapters as the core of ICD-10 (Table 9.2-1). New chapters structure the enlarged lists of disorders of the nervous system (Chapter VI), eye and adnexa (Chapter VII), and ear and mastoid process (Chapter VIII). The expanded chapter on neoplasms covers one full letter and shares another with blood disorders, which encompasses immunological conditions such as acquired immune deficiency syndrome (AIDS). Also the classification of neoplasms is multiaxial (one axis denotes topography and another morphology, i.e., histological type, and tumor invasiveness and differentiation).

Chapter	Title
I	Certain infectious and parasitic diseases
II	Neoplasms
III	Diseases of the blood and blood-forming organs and certain disorders involving the immune mechanism
IV	Endocrine, nutritional, and metabolic diseases
V	Mental and behavioral disorders
VI	Diseases of the nervous system
VII	Diseases of the eye and adnexa
VIII	Diseases of the ear and mastoid process
IX	Diseases of the circulatory system
X	Diseases of the respiratory system
XI	Diseases of the digestive system
XII	Diseases of the skin and subcutaneous tissue
XIII	Diseases of the musculoskeletal system and connective tissue
XIV	Diseases of the genitourinary system
XV	Pregnancy, childbirth, and the puerperium
XVI	Certain conditions originating in the perinatal period
XVII	Congenital malformations, deformations, and chromosomal abnormalities
XVIII	Symptoms, signs, and abnormal clinical and laboratory findings not elsewhere classified
XIX	Injury, poisoning, and certain other consequences of external causes
XX	External causes of morbidity and mortality
XI	Factors influencing health status and contact with health services

Table 9.2-1 List of Core Chapters of ICD-10

ICD-10 Classification of Mental Disorders Mental and behavioral disorders are housed within Chapter V of ICD-10 and are coded with the letter F (Table 9.2-2). The use of the sixth letter of the Gregorian alphabet to denote chapter V is explained by the assignment of two letters to a very lengthy list of conditions in chapters on infectious and parasitic diseases. After the letter F, the first digit of the Chapter V diagnostic codes denotes 10 major classes of mental and behavioral disorders: F0 through F9. The second and third digits (third and fourth characters) identify progressively finer categories. For example, the code F30.2 sequentially denotes the mental chapter, mood disorders class, manic episode, and the presence of psychotic symptoms. In this manner, 1000 four-character mental disorder categorical slots are available in ICD-10.

Table 9.2-2 ICD-10 Classification of Mental Disorders

F0-Organic, Including Symptomatic, Mental Disorders This class is etiologically based on physical disorders or conditions involving or leading to brain damage or dysfunction. The first clusters have disturbances of cognitive functions as prominent features and include the dementias (Alzheimer's, vascular, associated with other diseases, and unspecified), organic amnestic syndrome, and delirium not induced by psychoactive substances. The second cluster has as its most conspicuous manifestations alterations in perception (hallucinations), thought (delusions), mood (depressed or manic), various emotional domains (such as anxiety and dissociation), and personality.

F1-Mental and Behavioral Disorders Due to Psychoactive Substance Use In contrast to earlier classifications, this class subsumes all mental disorders related to

psychoactive substance use, from patterns of dependence and harmful use to various organic brain syndromes induced by substances. The diagnostic process and coding starts with identification of the substance involved (i.e., alcohol, opioids, cannabinoids, sedatives, or hypnotics, cocaine, other stimulants, hallucinogens, tobacco, volatile solvents, and other substances and combinations of them). Identified next in the code is the involved clinical condition: acute intoxication, harmful use (previously known as abuse and characterized by a pattern of use causing damage to physical or mental health), dependence syndrome, withdrawal state (with or without delirium), psychotic disorder, amnesic syndrome, residual and late-onset psychotic disorder, and other and unspecified mental disorders.

F2-Schizophrenia, Schizotypal, and Delusional Disorders This class has schizophrenia as its centerpiece, a disorder characterized by fundamental and distinctive distortions of thinking and perception and by inappropriate or blunted affect. The remaining categories of nonorganic, nonaffective psychoses are considered somewhat related, phenomenologically or genetically, to schizophrenia. Particularly interesting is the cluster of acute and transient psychotic disorders, which encompasses a heterogeneous set of acute-onset and relatively short-lived psychoses (polymorphic with or without schizophrenic symptoms, acute schizophrenia-like, and others) reportedly frequent in industrially developing countries (where most of the world population lives).

F3-Mood (Affective) Disorders The fundamental disturbance in this class is a change in mood or affect, usually involving depression or elation, often accompanied by a change in level of activity. Included here are manic episode, bipolar affective disorder (characterized by recurrent episodes involving both depression and elation), depressive episode, recurrent depressive disorder, persistent mood disorder (cyclothymia, dysthymia), and other and unspecified mood disorders.

F4-Neurotic, Stress-Related, and Somatoform Disorders This grouping is based on a historical concept of neurosis that presumes a substantial role played by psychological causation and that mixtures of symptoms are common, particularly in less severe forms often seen in primary care. Included in this book are phobic anxiety and other anxiety disorders, obsessive-compulsive disorder, reactions to severe stress and adjustment disorders, dissociative and conversion disorders, somatoform disorders, and other neurotic disorders (e.g., neurasthenia and depersonalization-derealization syndrome).

F5-Behavioral Syndromes Associated With Physiological Disturbances and Physical Factors Included here are eating disorders, nonorganic sleep disorders, and sexual dysfunction, mental disorders associated with the puerperium and not elsewhere classified, psychological factors influencing physical disorders, and abuse of non-dependence-producing substances (e.g., antidepressants, hormones, analgesics, and many folk remedies).

F6-Disorders of Adult Personality and Behavior This class includes clinical conditions and behavioral patterns that tend to persist and the expression of an individual's characteristic lifestyle and mode of relating to self and others. The main subclass involves personality disorders, which are deeply ingrained and enduring behavior patterns, manifesting as inflexible responses to a broad range of personal and social situations. An innovative category is that of enduring personality change, neither developmental nor attributable to brain damage or disease, and usually emerging after catastrophic experiences or another psychiatric illness. The broad class also includes impulse, gender identity, sexual preference, and sexual development and orientation disorders.

F7-Mental Retardation Mental retardation, one of the oldest in the history of psychiatric classifications, involves arrested or incomplete mental development, characterized by impaired cognitive, language, motor, and social skills evidenced during the person's formative period and contributing to the overall level of intelligence. Its subcategories correspond to various levels of severity: mild, moderate, severe, and profound mental retardation. Extent of behavioral impairment is also coded.

F8-Disorders of Psychological Development Disorders of psychological development are characterized, as a class, by the following attributes: onset during infancy or childhood, impairment or delay of functions connected to the maturation of the central nervous system, and a steady course unlike the remissions and relapses usual in many mental disorders. The functions affected most frequently include language, visuospatial skills, and motor coordination. A major subclass encompasses a variety of specific developmental disorders, classified by the abilities involved: speech and language, scholastic skills, and motor function. The other major subclass corresponds to pervasive developmental disorders, many of which are more saliently characterized by deviance rather than delay in development but always involving some degree of delay. Most conspicuous here are childhood and atypical autistic disorder and Rett's syndrome and other childhood disintegrative disorders.

F9-Behavioral and Emotional Disorders With Onset Usually Occurring in Childhood and Adolescence This complex class complements F7 and F8. Child-onset disorders included first are hyperkinetic disorders characterized by early onset, overactive and poorly modulated behavior associated with marked inattention, lack of persistent task involvement, and pervasiveness over situations and time. Conduct disorders are defined by a repetitive and persistent pattern of dissocial, aggressive, or defiant behavior. Also included in this class are emotional, social-functioning, tic, and other disorders usually starting in childhood or adolescence.

The full ICD-10 classification of mental disorders has three presentations corresponding to various degrees of definitional detail, aimed at serving different purposes and uses:

1. An abbreviated glossary containing the principal features of each disorder, for the use of statistical coders and medical librarians, published within the ICD-10 general volume
2. Clinical descriptions and diagnostic guidelines, containing widely accepted characterizations of an intermediate level of specificity, intended for regular patient care and broad clinical studies
3. Diagnostic criteria for research, characterized by more-precise and rigorous definitions

Multiaxial Presentation of ICD-10 Over the past two decades, the WHO advanced some important initiatives on multiaxial diagnosis. One was the Multiaxial Classification of Child Psychiatric Disorders, first designed in 1969 and revised and expanded several times since then. Its 1975 pentaxial version encompassed the following axes: psychiatric disorders, physical disorders, developmental disorders, intellectual level, and abnormal psychosocial situations. Another was the Triaxial Classification of Health Problems for Primary Care, which contained axes on physical, psychopathological, and social problems.

On these precedents and many others from the international literature, in the late 1980s the WHO Mental Health Division began preparing the Multiaxial Presentation of ICD-10. The conceptual bases of this development included a critical analysis of over 20 published multiaxial proposals originating in countries spanning three continents, which revealed important commonalties in the clinical domains covered. A second developmental principle was simplicity in the multiaxial schema, to enhance the prospects of its effective use across the world. The third principle was to base the instruments for axial assessment on components of the ICD-10 family of classifications, which had benefited from wide international consultations and field trials.

The Multiaxial Presentation of ICD-10 is composed of three axes: I. Clinical Diagnoses; II. Disablement; and III. Contextual Factors. The number of axes is lower than the four or five usually included in published multiaxial schemata and constitutes a condensation of those axes most frequently included in multiaxial proposals published in the international literature, which affords a measure of content validity to the schema. The value of the simplicity of the schema is enhanced by its potential for generalization beyond psychiatric practice. Information on clinical pathology, disablement, and contextual factors appears to be relevant to all health care.

Axis I—Clinical Diagnoses This axis accommodates both mental and nonmental (general medical) disorders, underlining a fundamental commonality among all illnesses. All significant disorders identifiable in a given individual are to be listed and coded according to Chapter I,Chapter II,Chapter III,Chapter IV,Chapter V,Chapter VI,Chapter VII,Chapter VIII,Chapter IX and Chapter X (the disease chapters) in the core classification of ICD-10 (Table 9.2-2).

Axis II—Disablements This axis appraises the consequences of illness in terms of impairment in the performance of basic social roles. The assessment instrument is a shortened version of the WHO Disability Assessment Scale, whose structure was condensed into four dimensions or areas: (1) personal care, (2) occupational functioning (as remunerated worker, student, or homemaker), (3) functioning with family (assessing both the regularity and quality of interactions with relatives and household members), and (4) broad social behaviors (interaction with other individuals and the community at large and leisure activities).

Axis III—Contextual Factors This axis attempts to portray the context of illness in terms of several ecological domains. These include problems related to the family or primary support group, general social environment, education, employment, housing and economic circumstances, legal issues, family history of illness, and personal life management and lifestyle. Assessment involves identifying problematic broad categories and recording specific factors. This structure is based on ICD-10 Chapter XXI (factors influencing health status and contact with health services).

Primary Health Version The ICD-10 Primary Health Version is a simple, brief classification arrangement compatible with and translatable into the ICD-10 standard classification of mental disorders (Table 9.2-3). It is linked with management aids prepared for use by primary care practitioners. The short list of categories was selected principally on the basis of importance to public health and the availability of effective and acceptable management. The centerpiece of the package is a set

of pocket-sized flip-cards, one for each selected category. One side of the flipcard exhibits assessment information, such as presenting complaints, diagnostic features, and differential diagnosis. The other side displays management guidelines, such as essential information for patient and family, specific counseling for the patient and family, medication, and specialist consultation. Additional elements of the package include flow charts, symptom indexes, and a computerized version.

F00*	Dementia
F05	Delirium
F10	Alcohol use disorders
F11*	Drug use disorders
F17.1	Tobacco use
F20*	Chronic psychotic disorders
F23*	Acute psychotic disorders
F31	Bipolar disorder
F32*	Depression
F40*	Phobic disorders
F41.0	Panic disorder
F41.1	Generalized anxiety
F41.2	Mixed anxiety and depression
F43*	Adjustment disorder
F44*	Dissociative disorder (conversion hysteria)
F45	Unexplained somatic complaints
F48.0	Neurasthenia
F50*	Eating disorders
F51*	Sleep problems
F52	Sexual disorders
F70	Mental retardation
F90	Hyperkinetic (attention deficit) disorder
F91	Conduct disorder
F98.0	Enuresis

* Means that some ICD-10 codes is included.

Table 9.2-3 ICD-10 Primary Health Care Categories

ADAPTATIONS OF ICD-10

The ICD-10 Classification of Mental and Behavioral Disorders is being accepted by most countries and by the WPA as the international standard in the field for both statistical reporting and for clinical care and research. Emerging now is the need to harmonize international communication with recognition of cultural diversity and specific local requirements. To express this perception, several national adaptations, versions, and annotations of ICD-10 are being developed and published.

The rationale and arguments for the development of local glossaries include the following:

1. Local glossaries from across the world can serve as the fundamental bases for the preparation of bottom-up international diagnostic systems.
2. Local glossaries, through its attention to various aspects of clinical reality, can facilitate the implementation of a comprehensive biopsychosocial framework, away from reductionisms of different types.
3. Local glossaries can reflect the cultural integrity of different countries and human groups and promote the value of their health-related concepts and practices.
4. Local glossaries can embody and transmit the intellectual contributions of national and regional scientists and professional leaders for the benefit of the field around the world.
5. Local glossaries can facilitate the effective use of international diagnostic systems, by adapting the various components of these systems to national patterns and needs.

The best known of these national versions is the APA's DSM-IV. In 1980 the APA published the innovative DSM-III characterized by a phenomenological emphasis on the conceptualization and organization of mental disorders, the use of explicit diagnostic criteria, and a multiaxial formulation. It acquired wide international visibility and significantly influenced the field of psychiatric classification. After preparations for ICD-10 were started by WHO, the APA initiated the development of DSM-IV, attempting this time to keep close to the international standard (which was already incorporating much of the methodological features advanced by DSM-III). Perhaps the principal attribute of DSM-IV is the scholarly emphasis in its development on the basis of critical literature reviews, reanalysis of existing databases, and focused field trials.

Cuban Glossary of Psychiatry Development of the various editions of the *Cuban Glossary of Psychiatry* started in 1975. They have attempted to reflect the realities and needs of Cuba in particular, within the general framework of Latin American culture. Emphasis on this perspective was presented first as a responsibility to the local population and second as an effort to contribute to the bottom-up building of international classification. The latter implies that carefully prepared technical contributions are as worthy of consideration for constructing an international reference as those coming from Europe, North America, or any other part of the world.

The Cuban glossaries have furthermore attempted to harmonize the general, represented by the existing ICD, with the local. Therefore, its authors consider the glossary to be the basic ICD-10 with only the changes and additions needed to ensure its applicability and usefulness for psychiatric care in Cuba.

As a broader conceptual framework for the preparation of the Cuban glossaries, their authors considered a syncretism of local historical traditions, the existing social and clinical reality of the region, and international scientific contributions. Among the many specifically Latin American contributions they were attentive to the following. Honorio Delgado, a Peruvian psychiatrist, published the influential *Curso de Psiquiatría* in the middle of this century, with a masterful presentation of psychopathological phenomenology and nosology. In 1954 in Rio de Janeiro Leme Lopes published the innovative *Dimensoes do Diagnóstico Psiquiátrico*, with a pioneering multiaxial formulation of clinical conditions. The Cuban psychiatrist José Bustamante published in 1975 with anthropologist A. Santa Cruz, what can be arguably considered the first textbook of transcultural psychiatry in the world. Carlos Alberto Seguín from Peru, with his volume on folkloric psychiatry, is emblematic of the rich Latin American contributions to the description of popular or culture-bound syndromes in the region.

Early Editions of *Cuban Glossary of Psychiatry* The Cuban glossaries of psychiatry have been the most complete and distinctive Latin American effort to annotate and adapt the existing ICD to local reality. The general principles guiding the preparation of the Cuban Glossaries of Psychiatry include the following:

1. Compatibility with ICD by incorporating modifications and additions through the fifth digits of the diagnostic code and the use of qualifying phrases
2. Consideration of all suggestions offered at provincial and national seminaries on the classification of mental disorders
3. Deliberate effort to harmonize different viewpoints
4. Systematic participation of most psychiatrists in the country and many clinical psychologists and other professionals concerned with mental health (e.g., teachers, social workers, and forensic doctors).

Its first edition (GC-1), published in 1975, constitutes an adaptation of the eighth revision of the *International Statistical Classification of Diseases, Injuries, and Causes of Death* (ICD-8). Its architect was Carlos Acosta-Nodal, professor of psychiatry at Havana University, working under the auspices of Eduardo Ordaz, director of Havana Psychiatric Hospital. The GC-1 was composed of 69 adaptations of ICD-8. The second edition of GC (GC-2), published in 1983 (Fig. 9.2-1), was an adaptation of ICD-9. Its development was again chaired by Acosta-Nodal. It contained 90 modifications of ICD-9 in addition to substantive chapters devoted to historical, theoretical, and clinical aspects of psychiatry.

FIGURE 9.2-1 Cover of the *Third Cuban Glossary of Psychiatry, 1998* (Tercer Glosario Cubano de Psiquiatria [GC-3]).

Third Edition of *Cuban Glossary of Psychiatry* The current third edition *Cuban Glossary of Psychiatry* (GC-3) was developed under the chairmanship of Angel Otero-Ojeda, from Havana University and the Havana Psychiatric Hospital. It includes a number of contributions on the diagnosis of mental disorders as experienced and presented in Cuba. These encompass both general psychiatry and child psychiatry. A basic principle in the development of GC-3 was to be similar to ICD-10, with minimal differences. In line with this, the coding system of ICD-10 was faithfully followed. Contributions and changes were incorporated through the employment of fifth digits in the diagnostic code or through the utilization of codes not used in ICD-10. The ICD-10 diagnostic guidelines for the various psychiatric disorders were also respected to the largest extent possible. In some cases, supplemental text was added. References to DSM-IV and to the ICD-10 criteria for research were often made. Of note, the GC-3 encourages diagnostic formulations based on the judicious use of all information available and allows experienced clinicians to formulate diagnoses without strictly adhering to standard diagnostic criteria.

GC-3 starts with an introductory chapter that outlines the principles of the diagnostic process and the positive aspects and problems of the current classifications. One such problem is the hospital-focus of most systems, which may limit their relevance to the emerging community-based psychiatry.

Another interesting chapter of GC-3 is that on “Syndromes of Difficult Placement” (sometimes referred to as culture-based syndromes). This includes both widely known folk syndromes such as amok, brain fag, and *rusto* as well as some syndromes and idioms of distress reported by Cuban psychiatrists. Illustrative of the latter is *abríu*, which refers to certain children believed to have the power to exercise a malign supernatural influence on their relatives, particularly siblings, who as a consequence can experience various illnesses and even die.

Additions made in the main body of GC-3 include (1) “neurotic behavior” as qualifier in broad categories such as mood disorders and neurotic, stress-related, and somatoform disorders, (2) diagnosis based on premorbid features for disorders of chronic or episodal source in broad categories such as schizophrenia and related disorders and mood disorders, (3) risky behaviors such as suicide or substance use, which are of particular relevance to community psychiatry. An illustrative deletion was dementia in children.

Some of the most innovative contributions of GC-3 involve its multiaxial schemes, which build on the standard multiaxial presentation of ICD-10. The GC-3 multiaxial scheme follows:

Axis I—Clinical Diagnosis. Both mental and nonmental disorders are included as in ICD-10's multiaxial system.

Axis II—Disabilities. Disablements in personal care, occupational functioning, functioning with family, and broader social functioning are included following the guidelines of ICD-10's multiaxial presentation.

Axis III—Psychoenvironmental Factors (Adverse). Included here are contextual problems listed under the third axis of WHO's multiaxial presentation of ICD-10.

Axis IV—Psychoenvironmental Factors (Other). Illustrative of factors considered here are to live alone and to be particularly “practical” or “romantic.”

Axis V—Maladaptive Behavior and Psychological Needs. Included here are conditions such as hypertrophic affective needs, indecisiveness, and difficulties managing hostility.

Axis VI—Other Significant Factors. Included here is miscellaneous information such as that resulting from laboratory tests and responses to therapeutic interventions.

Work on the GC-3 stimulated the Section on Diagnosis and Classification of the Latin American Psychiatric Association, under the leadership of Carlos Berganza (San Carlos University, Guatemala), Miguel Jorge (Escola Paulista de Medicina, Brazil), Otero-Ojeda (Havana University, Cuba) and Juan E. Mezzich (Mount Sinai School of Medicine in New York and Cayetano Heredia Peruvian University in Lima) to organize preparation of the first *Latin American Glossary of Psychiatry* as a Latin American annotation of ICD-10. Its components include the conceptual bases of psychiatric diagnosis, the hierarchical organization and diagnostic criteria of psychiatric nosology, culture-bound syndromes and idioms of distress, and multiaxial and comprehensive diagnostic formulations.

Chinese Classification of Mental Disorders In China attempts to classify mental disorders began around 1958. The first classificatory scheme was published in 1979 and named the *Chinese Classification of Mental Disorders*, first edition (CCMD-1) in 1981. Under the influence of the DSM and ICD systems, a number of subsequent revisions culminated in the publication of the second edition (CCMD-2) in 1989 and the revised second edition (CCMD-2-R) (Fig. 9.2-2) in 1995. For the first time in China operationalized criteria for a broad range of diagnostic categories have become available. Since China has over one fifth of the world's population, knowledge of the CCMD-2-R is central to the knowledge base of psychopathology in general. Chinese people also constitute one of the fastest growing ethnic minority groups in Western societies, so understanding the CCMD-2-R may attune clinicians to certain Chinese forms of distress in an intercultural treatment context.

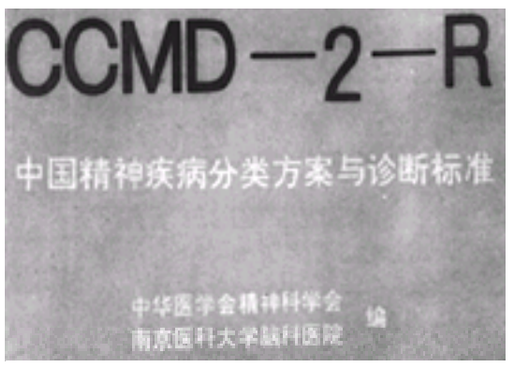

FIGURE 9.2-2 Cover of the *Chinese Classification of Mental Disorders*, ed 2, Revised, (CCM-D-R), 1995.

In devising CCMD-2-R, Chinese psychiatrists sought to harmonize with the international classification on one hand and to sustain a nosology that is useful in a huge and heterogeneous country on the other. As a result, CCMD-2-R and the ICD-10 share a broadly comparable architecture. However, inasmuch as symptom recognition and taxonomic strategy in psychiatry reflect the cultural norms and values of the society in which they are embedded, this blending is legitimately incomplete. The CCMD-2-R is a concise handbook of 238 pages that contains the equivalent or closest ICD-9 and ICD-10 codes (crosswalks) alongside the diagnostic headings. It contains a number of cross-culturally salient features, including particular additions (*gigong*-induced mental disorders, traveling psychosis), deletions (somatoform disorders, pathological gambling, a number of personality and sexual disorders), retentions (unipolar mania, neurosis), and variations (neurasthenia, depressive neurosis, anorexia nervosa) of diagnostic categories. A number of field trials have indicated adequate reliability and validity.

Addition of Culture-Specific Diagnostic Categories Both ICD-10 and DSM-IV lack a coded classification of culture-bound syndromes, which are often cited in the argument against an international classification of mental disorders. By contrast, the CCMD-2-R includes *qigong*-induced mental disorder as a culture-related mental disorder. *Qigong* is a popular trance-based healing system that consists of meditational or diverse styles of movement exercise or both. It is induced by using a culture-syntonic set of suggestions based on the Chinese concept of *qi* (vital energy). *Qigong*-induced mental disorder is believed to arise from inappropriate or excessive application of *qigong* or inability to terminate the *qigong*. This causes the flow of *qi* to deviate from the *jing luo* conduits and become *fire*, and may result in a variety of symptoms that do not fit into one coherent syndrome recognized in ICD-10 or DSM-IV. These include *qi*-related somatic discomforts, uncontrolled motor activity, anxiety, fright, weepiness, irritability, delusions, identity disturbance, hallucinations, mania, depression, and suicidal, bizarre, and violent behavior. The condition is usually brief. Treatment consists of a short course of tranquilizers and education about the proper way of practicing *qigong*. Relapse is uncommon.

In the Western psychiatric literature, psychosis related to traveling is uncommonly reported and is usually confined to air travel among subjects with a preexisting history of mental disorder. By contrast, the category of traveling psychosis arose from reports of acute psychosis developing among thousands of rural migrants who traveled in severely crammed trains over long distances in search of jobs in the richer regions of China. Its principal manifestations include an acute onset, perplexity,

disturbed consciousness, anxiety, persecutory delusions, horrifying illusions or hallucinations, motor excitement, impulsive and suicidal jumping off the train, and injuring others. In most cases, the termination of travel, rest, and renourishment lead to spontaneous recovery within a few hours to a few days. A personal or family history of mental disorder is rare. Even if traveling psychosis has an organic cause (e.g., hypercapnia, sleep deprivation, fatigue, and dehydration), its origin must be seen in the context of China's rapid market reforms, which result in marked economic regionalism and massive domestic migration. Granting traveling psychosis a special nosological status in CCMD-2-R is expected to promote research into its prevention (e.g., improved conditions for traveling and regulation of migration). It also serves judicial functions, since offenders with this diagnosis may be granted a verdict of diminished responsibility or acquittal.

Deletion of Culturally Inappropriate Categories Despite the common belief that Chinese people are prone to somatization, almost the whole block of somatoform disorder in ICD-10 and DSM-IV is excluded in the CCMD-2-R. According to ICD-10, the main features of such conditions are the repeated presentation of physical symptoms and persistent requests for medical investigations despite negative findings and reassurances by doctors that the symptoms have no physical basis. The patient usually resists attempts to discuss the possibility of psychological causation even in the presence of precipitating psychosocial stressors. This definition embodies a radical mind-body epistemology that is exotic to traditional Chinese or Ayurvedic medicine. Several factors have made it difficult for Chinese psychiatrists to apply the category of somatoform disorders. Chinese patients, if given the opportunity, readily communicate dysphoria and relate somatic symptoms to psychosocial stressors. Rather than being mutually exclusive, their somatic and emotional symptoms are highly intercorrelated. Clinically, their somatization may be considered a context-dependent strategy of engaging the concern of physicians who often work at overcrowded clinics. Moreover, the hybrid (half Greek and half Latin) word “somatoform” is a terminological puzzlement to Chinese psychiatrists, who find that neuroses (including neurasthenia) are clinically more useful categories for engaging patients in treatment.

N. S. was a 35-year-old lower social class housewife who presented to a psychiatric clinic with a mixture of symptoms associated with significant impairment. These included fullness in the head, weakness, worries, insomnia, cold intolerance, and difficulty in breathing for 2 years. She had previously worked as a clerk but quit to become a full-time housewife after marriage. Exploration revealed that she was burdened with caring for a teenage daughter and a 10-year-old son with childhood autistic disorder. She was also worried about the fidelity of her emotionally disengaged husband when he started to work in a nearby city for 1 to 2 days a week. Because of the absence of a persistently depressed or anxious mood, she did not meet the definitional thresholds for DSM-IV mood or anxiety disorders. Instead, she could be given the diagnosis of undifferentiated somatoform disorder according to DSM-IV or neurasthenia according to CCMD-2-R. During clinical interview, N. S. did not think she had major depression. She was particularly puzzled by the diagnosis of undifferentiated somatoform disorder (*weifenhua quti zhangai*), which was both unintelligible and experience-distancing to her. In her view, she merely had neurasthenia as a result of multiple stressors in the family. Although the Chinese psychiatrist wrote down the DSM-IV diagnosis in her case notes, he used the term *neurasthenia* to enhance clinical communication. N. S. declined pharmacotherapy but accepted counseling readily.

From a cultural constructionist perspective, personality disorders are based on Anglo-American conceptions of personhood and codes of appropriate behavior and owe their existence to the medicalization of disvalued social behavior. Accordingly, transformations in the values of a society determine whether they are called disease, sin, or crime. Given the disparity between the Oriental and Occidental conceptions of personhood, queries over the contextual validity of personality disorders are to be expected. Personality disorders are neither common clinical diagnoses nor popular research topics in China. Published studies indicate that a high percentage of Chinese subjects fail to fall into the subtypes recognized in DSM-IV and ICD-10. Thus, anxious (avoidant) and dependent personality disorders are excluded in CCMD-2-R. This is because many of their defining features (e.g., excessive preoccupation with being criticized or rejected in social situations, and subordination of one's own needs to those of others on whom one is dependent) are normative in the Chinese culture, which defines personhood not by autonomy and assertiveness, but by intergenerational dependence and selfeffacement. Likewise, since people who gamble immoderately and ruin their lives are considered bad rather than mad in Chinese society, the category of pathological gambling is excluded in the CCMD-2-R.

Retention of Diagnostic Categories Unipolar mania is no longer found in ICD-10 or DSM-IV, according to which a patient with two episodes of mania is assumed to have bipolar disorder. However, longitudinal studies indicate that recurrent mania continues to be seen in China and question the obligatory labeling of such Chinese patients as having bipolar disorder. The possibility that they may exhibit particular biological correlates, treatment response, and outcome supports a separate nosological status in CCMD-2-R.

The words “neurosis” and “neurotic” have completely disappeared from the DSM-IV, while the ICD-10 no longer retains neurosis as a major organizing principle. Instead, neurosis is finely partitioned into a variety of anxiety and depressive disorders, resulting in a very high prevalence of comorbidity being found in recent Western epidemiological studies. Among Chinese psychiatrists, the *neurosis (shenjing zheng)* has been used as a popular descriptive and etiological concept since the 1950s. It is therefore preserved in CCMD-2-R, which emphasizes as its main characteristics chronicity (at least 3 months), the presence of predisposing personality and social factors, and the preservation of insight.

Variation of Diagnostic Categories By tradition, Chinese psychiatrists have confined the diagnosis of mood disorder to bipolar disorder and psychotic depression. Chronic mild depression such as dysthymia is considered a form of neurosis and has been subsumed under neurasthenia and, more recently, depressive neurosis. Clinically, depressive neurosis encompasses a highly heterogeneous group of conditions that overlap with anxiety, mood, and personality disorders. Affected Chinese patients usually present with insomnia, headache, worries, and other indigenous forms of dysphoria rather than depression *(yiyu)*, which is an uncommon term in the everyday life of Chinese people. Among Chinese psychiatrists, whether depressive neurosis should be classified as a mood or neurotic disorder remains a subject of debate that is unlikely to be solved by empirical research alone.

Since CCMD-2-R has tightened the concept of neurasthenia according to Western epistemological assumptions (i.e., it should not be diagnosed if mood or other neurotic disorders are present), the use of the diagnosis is becoming less common among Chinese psychiatrists. But neurasthenia remains a common clinical diagnosis among doctors in China as a whole. According to CCMD-2-R, it is a type of neurosis composed of any three of five nonhierarchical groups of weakness, dysphoria, excitement, nervous pain, and sleep symptoms. This flexible symptom configuration is based on ample clinical experience in China and has been supported by culturally sensitive studies of the variegated illness experience of Chinese neurasthenic patients. By contrast, DSM-IV and ICD-10 representations of neurasthenia (as an undifferentiated somatoform disorder and a chronic fatigue disorder, respectively) lack contextual validity in Chinese society.

Because anorexia nervosa is still a rare condition in China, CCMD-2-R criteria for anorexia nervosa closely follow ICD-10 and DSM-IV. However, recent studies indicate that the core diagnostic construct of intense fear of fatness even when underweight is overrestrictive in a cross-cultural context. Such a fear is often absent among Chinese anorectic patients, who use other rationales (e.g., abdominal bloating, loss of appetite, or no hunger) for voluntary noneating. More culture-flexible diagnostic criteria that take account of the local meanings of food refusal will be adopted in CCMD-3.

N. F. aged 28, height 1.51 m (4 ft, 11 in), ideal body weight 47 kg (103 lb), was a single clerk who was referred to the psychiatric clinic from a gynecological unit for 6 years' history of unexplained secondary amenorrhea and weight loss from 43 kg (95 lb; body mass index, 18.9 kg/m_2) to 32 kg (70 lb; body mass index, 14.0 kg/m_2). She came from a working-class family in which the father had sexually molested her when she was 12. She experienced chronically low self-esteem and a strong sense of loss of control over her life. Since graduation from high school, she had worked continuously in a Protestant church in the hope that it would provide security for her. N. F. had always been slim and had never thought of dieting to pursue beauty. She attributed her poor food intake to loss of appetite during family dinner, when her father scolded her ruthlessly. She no longer cared how much and what she ate but sought refuge by fleeing the dining table as quickly as possible. She regarded this as a form of silent protest against him. Physical examination revealed a pubescent look and the usual signs of emaciation. Extensive investigation revealed no physical cause for the weight loss. When interviewed with the Eating Disorders module of the Structured Clinical Interview for DSM-III-R (SCID), she failed to fulfill the criteria for anorexia nervosa, while her depressive symptoms fell short of those for a major depressive episode. N. F. received individual psychotherapy for 2 years, during which family conflicts, powerlessness, and the lack of meaning in life constituted the organizing theme of her illness experience. She never mentioned the fear of fatness and sometimes challenged why the therapist, instead of understanding her lack of meaning of life, was so preoccupied with her eating behavior and body weight. She fulfilled culture-flexible diagnostic criteria for anorexia nervosa.

Regional Adaptations of ICD-10 in Other Asian Countries The ICD-10 has been tested and is increasingly used in other Asian countries such as India, Japan, and Korea. Available evidence indicates that it is a reasonably feasible scheme that promotes reliability and international comparisons across most diagnostic categories. Nonetheless, local modifications are required to enhance its contextual validity and make it user friendly. For example, the Japanese Society for International Diagnostic Criteria in Psychiatry (JSIDCP) has also decided to retain a unitary concept of neurosis, which should be connected with predisposing personality traits and life events. As in CCMD-2-R, mild depression is considered a form of neurosis rather than a mood disorder, and the term “somatoform disorder” is avoided. Further examination of the discrepancies between Asian and Western nosological systems will encourage reflective self-criticism in one hand and contribute to an internationally valid system of psychiatric classification on the other.

TOWARD COMPREHENSIVE DIAGNOSIS MODELS

While the national adaptations of the ICD represent attempts at resolving the tension between universalistic and local perspectives and needs, another emerging cluster of efforts in the field is aimed at integrating different informational domains and the perspectives of different evaluators in the construction of comprehensive diagnostic formulations.

Conceptual Framework The conceptual framework for these developments includes the articulation of previously divergent historical and philosophical traditions, new notions on health and health care being advanced by the WHO, and innovative developments in general and psychiatric epidemiology. From a historical and philosophical viewpoint, the longitudinal evolution of diagnostic systems can be seen as unfolding on three parallel lines. One is represented by a synthetic, bold, and abstract Platonic conceptualization of a disease entity as a sufficient descriptor of a patient's clinical condition. The second involves an analytical, textured, and experiential Aristotelian viewpoint. The third is an empathetic Hippocratic approach. The Platonic tradition has informed the long-standing international effort to classify illnesses as reflected in the various versions of the ICD and national versions such as DSM-IV. The Aristotelian perspective is reflected in the descriptions of the patient's contextualized clinical condition, using standardized typologies and scales, which has appeared under the term “multiaxial diagnostic evaluations” The Hippocratic tradition is related to recent efforts to focus on the individuality of the patient.

The WHO, through recent meetings of its executive board, is expanding its 50-year definition of health, proposing that it is not merely an absence of illness but a dynamic (or interactive) state of complete physical, emotional, social, and spiritual wellbeing. Additionally, WHO's explorations on the description of health status is expanding its focus from disease to functioning and other positive aspects of health. One of these is quality of life, which is to be evaluated predominantly by the individual involved. Furthermore, in the formulation of its policy in *Health for All for the 21st Century*, WHO is incorporating ethics, equity, and human rights as new, important considerations.

Epidemiology, as the basic science of public health, is undergoing a substantial conceptual revision. Newer formulations go beyond the infectious disease model and the chronic disease model, calling for approaches that incorporate multiple and interactive levels of analysis as suggested by Mervin Susser, editor of the *American Journal of Public Health*, under the term “ecological epidemiology.”

Integrating Standardized and Idiographic Formulations Building on the traditions and developments outlined above, the WPA is designing a more comprehensive diagnostic model as part of a project on international guidelines for diagnostic assessment. The model has two key components:

1. A standardized multiaxial formulation that covers nosology, disabilities, and contextual factors. The multiaxial formulation is aimed at statistically reliable measurement of key aspects of the clinical condition to facilitate sharing of diagnostic and treatment information among clinicians and across the world.
2. An idiographic or personalized formulation that focuses on the individuality of a particular patient. The idiographic formulation is aimed at providing complementary descriptive information, engaging the patient more fully in the process of clinical care and fulfilling ethical aspirations of respect to the dignity of the patient and attending to his or her expectations in dealing with health problems and enhancing quality of life.

Table 9.2-4 presents schematically the components of this diagnostic model. The standardized multiaxial formulation of this model is basically organized according to the multiaxial presentation of ICD-10.

A. Standardized multiaxial formulation
- I. Clinical diagnoses (mental and nonmental disorders)
- II. Disablements
  Difficulties in fulfilling social roles in regard to personal care, occupational functioning, functioning with family, and broader social functioning
- III. Contextual factors

B. Idiographic formulation
- I. Clinician perspectives
- II. Patient/family perspectives
- III. Integration of clinician and patient/family perspectives

Table 9.2-4 Comprehensive Diagnostic Model Incorporated Into the WPA International Guidelines for Diagnostic Assessment

A brief description of the components of the idiographic formulation follows:

I. Clinician's perspectives. This involves an effort to synthesize the information available including a summary of the patient's problems and assets, biological explanations, psychological explanations, social explanations, and biopsychosocial integration, that is, a contextualized articulation of all explanatory models pertinent to the patient's clinical condition.
II. Patient/family's perspectives. These may include a biographical history; an understanding of the nature, causes, and context of the illness experienced; self-appraisal of quality of life (e.g., physical and emotional health, functioning, social support and resources, personal and spiritual fulfillment); and attitudes and expectations toward clinical care (acute and rehabilitative treatment and preventive efforts).
III. Integration of clinician and patient or family's perspectives. This integration is expected to be based on empathetic rapport, reflecting mutual respect, interest, and human feelings between clinician and patient. The clinician and patient attempt to reach the best possible joint understanding of the patient's clinical condition in a context that includes family factors. They negotiate a care plan, considering personal issues (e.g., patient's and clinician's preferences and disposition toward treatment, sense of autonomy, time available, travel requirements), social factors (e.g., social supports, particularly availability and interest of the family), and financial circumstances (e.g., insurance and managed care constraints). Finally, they jointly monitor the progress of care and its outcome.

FUTURE DIRECTIONS

The developments on comprehensive diagnostic models and regional adaptation of ICD-10 reveal the ebullience of the diagnostic field, especially when appraised from a broad international perspective. It seems likely that the ongoing tension between universality and diversity in diagnostic systems will continue to yield innovative solutions. Emerging proposals are increasingly involving integrated assessments of health status and according pointed attention to the ethical requirements of psychiatric diagnosis. These proposals must be carefully formulated and thoughtfully and widely evaluated if they are to contribute effectively to the fulfillment of diagnosis as a conceptual and practical tool for clinical care, health promotion, and epidemiology.

SUGGESTED CROSS-REFERENCES

Section 4.1 discusses anthropology and psychiatry, while Section 4.4 discusses cross-cultural psychiatry. Psychiatric diagnosis is covered in Chapter 7, and the DSM-IV classification is covered in Section 9.1. Neurasthenia is discussed in Chapter 16 on somatoform disorders.

Textbook of Psychiatry

CHAPTER 10. DELIRIUM, DEMENTIA, AND AMNESTIC AND OTHER COGNITIVE DISORDERS

ERIC D. CAINE, M.D. AND JEFFREY M. LYNESS, M.D.

Psychiatry is in the midst of a profound transformation, at once struggling to incorporate a dynamic understanding of neuroscience and molecular biology while maintaining a view of unique persons or individuals as the central focus of therapeutic intervention. To date it has been beyond the scope of knowledge to effectively integrate research data regarding individual differences with more abstract findings regarding fundamental aspects of brain development or aging-related neurodegeneration. Discovering the bases for the major neuropsychiatric diseases can be expected to provide powerful clues for defining the nature of how neurobiological processes are expressed as emotions, thoughts, or actions, or how life events and daily experiences alter and shape brain growth and development.

Since the late 1980s, a major conceptual transition has occurred in the way clinicians and researchers view the relation between mental disorders and brain function. For much of the past century psychiatry was trapped in an either-or dilemma—either a condition was viewed as a symptomatic manifestation of structural cerebral or systemic pathology (organic), or it was considered psychological or emotional in nature (functional). However, clinicians recognized that there are no behaviors that do not involve the brain, and that the transmission of culturally derived processes from individual to individual is influenced by each person's central nervous system (CNS). Behaviors defined by some cultures as abnormal may be mediated by normal neurophysiology; in contrast, patients with damaged brains may develop compensatory strategies reflective of CNS plasticity to ameliorate the effects of disordered neural systems. The same behavior (e.g., suicide) may reflect normal or abnormal physiology. For many diseases the CNS develops normally but acquires its dysfunction later in life whereas other diseases may reflect aberrant wiring patterns or connections that function in a neurochemically or neurophysiologically normal fashion. Despite such complexity, clinicians often depended on a single criterion for defining organic disorders—either the detection of a structural lesion or, less often, the diagnosis of a known disease process; however, such an approach is no longer satisfactory.

Diagnostic decisions have depended largely on available technology. For more than a century gross postmortem examination and microscopic histopathological examination were the primary tools. Working in a tradition of clinical-pathological correlation, psychiatrists, neurologists, and others used a dichotomous approach to both diagnosis and classification—that is, a lesion was either present or absent. This approach proved heuristically limiting and became increasingly unrewarding. Indeed, histopathology is now no longer the gold standard for defining brain-based diseases. It was only marginally useful for psychiatry, and in the near future molecular biological methods will replace it for neurology. The advent of new technologies already has undermined the pseudocertainty of earlier years. Many patients with functional syndromes are found to have CNS abnormalities when studied with magnetic resonance imaging (MRI), positron emission tomography (PET), or single photon emission computed tomography (SPECT). Should these syndromes be reclassified as organic? Most would argue that such changes would be premature because the pathophysiological significance of newer findings remains obscure. Such arguments also are pertinent to the entire question of organic versus functional.

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorder* (DSM-IV) establishes a new approach to those questions. The categories of organic and functional have been abandoned. When a psychopathological syndrome is known to be a symptomatic manifestation of a systemic medical or cerebral disorder, it is designated as “due to . . .” (secondary), with a designation of the specific disease process. When it is considered to be an idiopathic psychiatric disturbance, it is designated primary. A clinician should follow a careful process of case reasoning before settling on the primary or secondary status of a disorder. To appropriately diagnose a patient as having an idiopathic (i.e., primary) condition, the clinician must necessarily exclude all definable, potentially etiological disease processes.

The clinician must exercise equal caution before diagnosing a disorder as secondary or symptomatic. To date there are no widely accepted guidelines for establishing probable causal relations between psychopathological conditions and detected cerebral abnormalities. Traditionally, such assignment of probable causality has been left to clinical judgment. DSM-IV outlines such guidelines; they have the effect of encouraging the clinician to undertake a thorough evaluation and to postulate causal connections conservatively.

DEFINITION

The primary-secondary classification, like similar classifications, reflects the thinking of its time. The change in terminology in DSM-IV from *organic* to *due to* . . . is more than cosmetic in that it captures the conceptual shift away from structure and lesion and toward active disease process and etiology. The broad group of cognitive disorders includes dementia, delirium, amnestic disorder, and other syndromes in which disordered cognition caused by known (or presumed) disease entities is the central characteristic featuret (Table 10-1). Specific secondary syndromes are scattered through the nosology, classified along with other phenomenologically similar clinical conditions (e.g., mood disorders due to general medical conditions are grouped among the mood disturbances). Such groupings are intended to foster differential diagnostic consideration; the changes in DSM-IV are intended to enhance rigorous clinical reasoning. Use of more specific designations (e.g., mood disorder due to thyroid deficiency, with major depressive-like episode) strengthens diagnostic specificity when contrasted to the previously used organic mood disorder and lays the foundation for more meaningful comparative research.

Delirium
Delirium due to a general medical condition
Substance-induced delirium
Delirium due to multiple etiologies
Delirium not otherwise specified
Dementia
Dementia of the Alzheimer's type
Vascular dementia
Dementia due to other general medical conditions
Dementia due to HIV disease
Dementia due to head trauma
Dementia due to Parkinson's disease
Dementia due to Huntington's disease
Dementia due to Pick's disease
Dementia due to Creutzfeldt-Jakob disease
Dementia due to other general medical conditions
Substance-induced persisting dementia
Dementia due to multiple etiologies
Dementia not otherwise specified
Amnestic disorders
Amnestic disorder due to a general medical condition
Substance-induced persisting amnestic disorder
Amnestic disorder not otherwise specified
Cognitive disorder not otherwise specified

Table 10-1 DSM-IV Cognitive Disorders

Throughout this chapter the term “neuropsychiatry” is used in reference to the field of medicine that considers the brain bases of mental disorders. In the United Kingdom this field is sometimes called organic psychiatry. At one time nearly all of psychiatry was neuropsychiatry; at another time, few would have chosen that label. Considering the brain substrates of behavior necessarily forces clinicians and researchers also to recognize the experiential, psychological, social, and cultural aspects of the patients and the problems they encounter.

HISTORY

The development of neuropsychiatry and the growth of general psychiatry coincided with competition and ultimately cooperation between public psychiatric asylums (now called hospitals or centers) and clinical practice in universities and private offices. Different ideologies or dogmas developed, depending on whether the clinician was seeing principally institutionalized psychotic patients, for whom there was little hope for improvement or recovery, or ambulatory patients, whose apparent psychological accessibility gave rise to therapeutic optimism. Additionally, psychiatrists in the asylums (often called alienists) had different needs than the nerve

doctors or neurointernists who saw the walking wounded in their offices.

Table 10-2 presents a brief categorization of historical periods in neuropsychiatry. It is probably not presumptuous to state that Wilhelm Griesinger (1817–1868) created neuropsychiatry with the publication of his book in 1845, crafted after practicing 2 years in Winenthal, one of the leading German asylums. An advocate of physiological medicine, Griesinger attempted to steer German medical practice away from both the romantic and somatic schools of that time. He asserted that psychiatry was part of medicine and that “psychological diseases are diseases of the brain.” He also advocated knowing one's patients well, understanding their life course, and appreciating how their mental disease affected their overall functioning. He advanced a specific notion of the ego that attempted to explain all disease under a single conceptual view based on a gradual pathological erosion of ego integrity. He supported the idea of careful neuropathological observation, although he never pursued such work in the later fashion of Theodor H. Meynert, Karl Wernicke, or Alois Alzheimer.

1845–1865	Griesinger—Integration I
1865–1900	Neuropathological and descriptive psychiatry
1900–1930	Gradual transition I
1930–1950	Ferment
1950–1965	Psychodynamic era (United States)
1965–present	Gradual transition II
The future	Integration II

Table 10-2 Historical Periods in Neuropsychiatry

Despite Griesinger's attempted integration, many of his notions now seem simplistic or misleading, especially the idea that all mental illnesses reflected one basic pathological process that could be divided into stages. The first of Griesinger's disease stages involved an assault on the ego by the basic disease, although no frank pathological disruption was apparent. In the second and third stages, ego disintegration was completed and permanent brain changes took place. Griesinger believed that therapeutic intervention would be successful only during the first stage. Griesinger and his contemporaries made no particular distinction between psychiatric and neurological problems, and patients with progressive neurological diseases were seen in asylums like Winenthal. He proposed joint psychiatry and neurology clinics, and founded one in Berlin in 1861. Most importantly he catalyzed the development of university neuropsychiatry in contrast to the asylum psychiatry that was prevalent in his day, and thus provided the means for developing academic, research-based approaches to questions that had largely been outside rigorous medical scrutiny.

Meynert (1833–1893), the next major player on the neuropsychiatric scene, steered away from Griesinger's integrative center toward an extreme of neuropathological determinism. Meynert's 1874 book, titled *Psychiatry: Diseases of the Forebrain*, largely dealt with neuroanatomy. He is probably best remembered for his histopathological studies and has deservedly been called a pioneer of neuropsychiatric pathophysiology. Meynert also consolidated within universities what proved to be both a sterile theoretical position and a form of clinical psychiatry that had little benefit for either patients in the asylum or the walking wounded. Perhaps unwittingly, Meynert and his intellectual colleagues placed neuropsychiatry in a position where it would decline. It was presumptuous to believe that all clinically significant behavioral disturbances had a demonstrable cerebral substrate, especially given available laboratory techniques. Such work took place in a context of minimal understanding of the basic aspects of neuronal or regional cerebral functioning. It was ironic that the driving investigative force, a search for pathologically defined brain abnormalities, was to become a basis for undoing the field. Psychiatry in general and neuropsychiatry in particular have been plagued by a sense of intellectual exclusivity—the either-or dilemma—in their intellectual conceptions. This sense of exclusivity and the related tendency to decry integrative (multidetermined) theoretical approaches may have reflected the ultimate conceptual complexity of the research and clinical tasks that have confronted those who would understand the cerebral bases of behavior and mental disorders: “the brain we are studying is more complex than the brain that is studying it.”

In the context of these limitations of neuropsychiatry, two fundamentally different paths emerged. The first was exemplified by the work of Emil Kraepelin (1856–1926). Although Kraepelin supported the neuropathological work of Alzheimer, he spent considerable effort developing a rigorous clinical classification of psychiatric disorders, particularly those observed in asylum settings. The classification was largely atheoretical, based as it was on form and course. Kraepelin hoped that clinical description and classification would ultimately lead to pathological correlation, a hope that has yet to be realized fully. The second path was developed by nerve doctors, neurointernists who saw their patients in offices or on the wards of neurological hospitals. Jean Martin Charcot (1825–1893) and Sigmund Freud (1856–1939) were notable among those practitioners. The idea of looking at an individual's development in the context of early life experience did not originate with Freud (Griesinger had also advocated it), but Freud pushed farthest the notion of defining the meaning of particular behaviors in terms of real and imagined life events. The different paths blazed by Freud, Kraepelin, and Meynert coexisted during the early decades of the twentieth century, with no one route of investigation clearly predominant. Clinical-pathological correlation had its greatest triumphs with the recognition of the causes of general paresis and pellagra. However, the large asylums remained full, and there were no specific therapies for clinicians to use.

In the United States, by contrast, the period from 1930 to 1950 was a time of great ferment and change, with an examination of new ideas and therapies. Shortly before World War II clinicians experimented with a variety of somatic interventions and opined about the cerebral bases of the major psychiatric disorders. New treatments, including barbiturate coma, insulin shock, and the convulsive therapies, were developed. During this time of novel therapeutics, clinicians undertook what seemed a logical step to many—ablative neurosurgical intervention, ultimately dubbed psychosurgery. Although it was based on poorly substantiated notions of cerebral functions and how they went awry in the major psychiatric disorders, frontal lobotomy spread rapidly in the United States following World War II, fueled by a desire to empty large state mental hospitals and reduce public expenditures for patients with chronic mental disorders. Psychosurgery offered the prospect of instituting a definitive medical procedure that either cured or markedly improved previously intractable syndromes. However, psychosurgery and its practitioners failed to fulfill their promises and neuropsychiatry eventually became a term of opprobrium. By the mid-1950s brain-oriented views of behavior were widely considered to offer few clinically or theoretically fruitful insights, and brain-oriented psychiatrists were seen as useless or even clinically harmful to those they treated. Juxtaposed with the 1930s' plunge into organic psychiatry and its therapies was the growth of psychoanalysis, sparked by revolutionary theories brought from Europe by analysts fleeing Adolf Hitler. Young neuropsychiatrists, neurologists, and neuroscientists proved a receptive audience for these ideas, as they discovered far greater explanatory power in the notions of Freud than in those of Charles Sherrington and the doctrine of nerve transmission. Enthusiasts found analytic insights filling unmet needs: Freud's theories and techniques supplied both tools for data collection through the free-associative interview and a coherent system to organize these findings. More importantly, these techniques directed specific interventions and provided the physician with something to do beyond watching impaired patients remain unchanged or become progressively worse.

Stanley Cobb (1887–1968) was among the leaders in the attempt to integrate psychiatry and neurology. Cobb trained in neuropathology and taught the basic neuropathology course at Harvard Medical School for several generations. A student of Adolf Meyer, he espoused a dynamic life course view. Although he maintained an appreciation for neuropathology, he moved away from a primary interest in cerebral circulation to a consideration of psychiatric disorders during the late 1920s and the 1930s. Cobb developed a conceptual pyramid as an integrative device to illustrate his views, deliberately leaving a gray, uncharted zone between pathology and clinical psychiatry. Despite subsequent advances in neuroscience, the uncharted zone seems no less opaque now than 60 years ago, when Cobb first published the conceptual pyramid in his textbooks.

The years immediately after World War II were a time of rapid change, away from neuropathology-based psychiatry and toward psychodynamic and psychoanalytic psychiatry. The growth of psychiatry departments and medical schools was spurred by federal initiative, as was the deinstitutionalization of the seriously ill. Economic motives contributed to the latter, but more important was the sense that a therapeutic triumph might be at hand. This sense was associated with the optimism following World War II of psychiatrists and psychiatrists-to-be (often physicians from other disciplines who were assigned to wartime psychiatry services), coupled with the hope for the successful use of psychoanalysis in a wide variety of disorders and the development, during the 1950s, of a more specific psychopharmacology. Notably, psychopharmacology did not reflect a greater degree of neuroscientific understanding; rather, serendipity, clinical acumen, and innovative thinking served as guiding beacons. Later developments of new compounds did result from attempts at pharmacological modeling. Indeed, more recent understandings of CNS function were catalyzed by having specific agents that could reliably alter brain activity. Central to this activity were industry-sponsored initiatives to discover and develop novel pharmacotherapeutic medications.

Formal psychiatric classification and nomenclature evolved during the post-World War II era. Prior to the adoption of the first edition of DSM (DSM-I) in 1952, psychiatric hospitals used the *Statistical Manual for the Use of Hospitals for Mental Disease*, first published under a slightly different title in 1918. Nearly all the categories in the manual were used for classifying patients with brain-related mental disturbances. As noted in DSM, that approach proved suitable for only about 10 percent of the cases seen by the Armed Forces during World War II. In contrast to the *Statistical Manual for the Use of Hospitals for Mental Disease*, DSM outlined two broad categories, one for disorders caused by or associated with impairment of brain tissue function (divided into acute and chronic), and the second for those of psychogenic origin without clearly defined physical cause or structural change in the brain. The brain disorder section classified conditions by duration and defined etiology (e.g., infection, intoxication, and tumor) with no attention to clinical phenomena whereas the psychogenic section began the move toward a more clinically specific categorization. For the latter, difficulties adjusting to internal and external stresses were the key pathogenic factors. Thus, a psychological theory officially supplanted the dominant brain view of earlier classification manuals. Despite the change in dominant explanatory theory, DSM also maintained and further codified an either-or philosophy set forth by the earlier post-Griesinger neuropsychiatrists.

A similar stance was taken in the second edition of DSM (DSM-II), with a separation of organic brain syndromes from psychoses not attributed to physical conditions listed previously. Brain syndromes were said to result from diffuse impairment of brain tissue and to be manifested by the following symptoms: impairment of orientation, memory, all intellectual functions (e.g., comprehension and calculation), and judgment, as well as lability and shallowness of affect. The organic brain syndromes were divided into psychotic and nonpsychotic conditions, the former also including senile and presenile dementia, depending solely on the severity of functional impairment. Beyond that crude separation, there were no specifying clinical features; further classification depended on defining a cause. *Acute* and *chronic* were indicated as diagnostic subcodes. Psychodynamic psychiatry was not successful in treating the more seriously impaired residents of the state hospitals, and often was found wanting among ambulatory populations. Competing approaches sprang up that claimed similar or greater effectiveness. Overall, it has been difficult to definitively demonstrate treatment success when using psychotherapeutic modalities, although recent efforts at treatment evaluation have proved both more enlightening and more promising. A neurochemically oriented biological psychiatry took hold and became pre-eminent in the research laboratory, if not always in the clinic setting. However, there has been no successful jump from synapse to behavior, integrating understanding anew. This dearth of explanation has made a fertile soil for the reemergence of neuropsychiatry.

COMPARATIVE NOSOLOGY

DSM-III and DSM-III-R The third edition of DSM (DSM-III), published in 1980, and the 1987 revised third edition (DSM-III-R) moved to discard the theoretical underpinnings based on stress-related psychological reactions and emphasized phenomenology as part of an innovative multiaxial system of classification. Nonetheless, the organic versus nonorganic dichotomy was maintained. Organic mental disorders were clearer in their clinical typology, with a greater array of subtypes and causes, related either to Axis III physical disorders or conditions or to use of psychoactive substances. Importantly, categories for mood, personality, anxiety, and hallucinatory and delusional disorders were added. These changes were made in an effort to increase recognition of clinical variations, but they lacked sufficient descriptive detail to allow reliable comparisons with idiopathic Axis I syndromes. Unfortunately, like DSM-I and DSM-II, DSM-III provided no guidelines or discussion on the question of causal connection between systemic medical or cerebral diseases and secondary psychiatric manifestations. Thus, there has been no consideration of the clinical reliability of the organic designation or of its validity.

Scientific Developments Since the 1970s a period of transition characterized by the absence of a dominant theoretical view within psychiatry has been under way. Scientific developments outside the field have profoundly shifted the direction of psychiatric thought and have come largely from behavioral neurology, clinical neuropsychology, and basic laboratory neuroscience. Challenged by the rehabilitative needs of many patients returning from World War II with focal cerebral lesions, a small number of neurologists and quantitative psychologists began to study the effects of those injuries just as psychiatrists were shifting their attention away from cerebral processes. This work quickly expanded to include patients with vascular lesions. By the late 1960s behavioral neurologists and clinical neuropsychologists were recognized specialists, although few in number, and a growing literature examined the intellectual and behavioral consequences of specific regional cerebral lesions. These writings stimulated a modern resurgence of the clinical-pathological correlative tradition first developed during the late 1800s. Since the late 1980s psychiatric researchers have drawn increasingly from the lessons of focal lesion models.

Simultaneously, basic laboratory neuroscience burgeoned, with important findings reported at a fast pace in recent years. Researchers have moved from a focus on synapses and neurons to subneuronal molecular biological processes. Investigative techniques have changed extremely quickly, facilitating the detection of variations in complex neurobiological systems while outstripping the ability to define the terms *normal* and *abnormal*.

Even as psychiatric researchers studied focal lesion syndromes with greater enthusiasm, the shortcomings of those models became more apparent. Most importantly, they involve cerebral substrates distinctly different from those of the major idiopathic psychiatric syndromes. Whereas strokes reflect vascular anatomy, major psychopathology is based on dysfunction in interacting and widespread neurochemical systems. Many clinical psychiatric disorders reflect long-term (perhaps developmental) abnormalities that affect psychological growth and interpersonal events across the life span. Focal cerebral lesions on the other hand are acquired later in life in the context of a developmentally intact CNS; thus, analogies must be drawn with caution.

Psychiatric researchers face another, more daunting obstacle when considering the brain bases of mental disorders. Since the 1970s many have chosen to compare specific diagnoses with putative CNS alterations. The exclusive use of categorical diagnoses, while beneficial for enhancing clinical rigor, has yet to prove rewarding when applied to diagnosis-brain correlative research paradigms. Although empirically defined clinical syndromes form the bedrock of modern psychopharmacology, they may not be amenable to fundamental neurobiological characterization.

The historic lessons of neuropsychiatry include the realization that a defined or unified etiology may be associated with a striking diversity of clinical presentation (e.g., general paresis and Huntington's disease); conversely, specific syndromes are often the manifestation of heterogeneous etiologies. Here again, maintenance of a rigid either-or view is likely to prove disappointing. Rather, future researchers will be required to understand how experiences in the midst of normal development permanently change the brain. Too often neuropsychiatry has viewed the universe along the trajectory of brain to behavior. It will be just as important to understand it from behavior to brain and back again. Psychiatry as a broad field, and neuropsychiatry in particular, must address an array of key questions regarding brain-behavior and behavior-brain relationships.

1. How do developmental abnormalities that occur in utero or in the early years of life lead to later emerging psychopathology? What are the genetic and environmental causes of these defects, and what are their molecular biological modes of expression?
2. How does environment and life experience change brain structure and function? In essence, what are the mechanisms of brain plasticity? How do normative and abnormally stressful life events lead to permanent changes in neural function?
3. How is brain and organism homeostasis maintained or lost? What are the neural underpinnings of cyclical or episodic changes in behavioral, emotional, and cognitive functioning?
4. What are the genetic, molecular, and environmental factors associated with brain aging and normative cognitive decline, and neurodegenerative diseases?

The limits of neuroscientific inquiry need to be recognized. Neuroscience will not improve the interviewing skills of an individual psychiatrist; moreover, it will be many years or decades before there is a clear understanding of the neural bases for individual differences: When the field progresses to the point where clinicians and scientists can merge an appreciation of a person's life story with knowledge regarding laws of the nervous system, it will finally reach a level of true integration.

DSM-IV The change in terminology in DSM-IV from *organic* to *due to* represents more than a simple semantic alteration—it emphasizes the need to define etiology, not site or structure. The term "*organic*", as used for many years pointed to defined pathological lesions and was contrasted with the term " *functional*" or physiological abnormalities that could not be detected by existing laboratory procedures. In the absence of sensitive and specific diagnostic laboratory tests, descriptive laboratory technology was often misapplied, giving a false impression of diagnostic validity. Similarly, the presence of a definable abnormality was considered sufficient to establish an organic diagnosis even though no standards were available for setting a threshold of evidence or data needed to attribute the cause of a symptom to an observed lesion.

DSM-IV takes a conservative approach to the problem. Establishing a secondary diagnosis should, whenever feasible, follow a chain of reasoning that etiologically connects a psychopathological syndrome with a systemic medical or primary cerebral disorder. The coexistence of Axis I and Axis III diagnoses in an individual case is not sufficient to infer a causal relationship, even when an apparent association or correlation is present. To more confidently determine whether an association is causal, the clinician should attempt to define the strength (relative risk), consistency of form, specificity, coherence of association, and temporal relation of clinical manifestations to the proposed disease process. Defining each attribute may not be feasible for all disorders or in every case, but it does provide stronger ground for

advancing an etiological link. When insufficient data are available to establish a causal relation, it is preferable to provide unlinked Axis I and Axis III diagnoses.

It is notable that the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) maintained “organic” as a superordinate category. Although many specific examples of syndromic diagnostic criteria are similar to those in DSM-IV, ICD-10 retained the approach favored by earlier editions of the DSM. Where DSM-IV strives to highlight steps necessary for establishing a primary general medical diagnosis, ICD-10 states: “Rather, the clinical manifestations resemble, or are identical with, those of disorders not regarded as ‘organic' in the specific sense restricted to this block of the classification. Their inclusion here is based on the hypothesis that they are directly caused by cerebral disease or dysfunction rather than resulting from either a fortuitous association. . . or a psychological reaction to its symptoms. . .”

DIAGNOSIS

Thorough clinical evaluation forms the basis for diagnosing secondary disorders. Beyond a detailed personal history and mental status examination, the clinician often must depend on supplementary laboratory evaluation, including such procedures as cerebral imaging, neuropsychological testing, and electroencephalography (EEG). Four steps form the basis for establishing a secondary (“due to . . .”) diagnosis with greater confidence: (1) definition of the specific psychopathological syndrome, (2) delineation of other manifestations of the primary disorder, (3) demonstration of active cerebral or systemic disease, and (4) demonstration of an elevated prevalence between the proposed etiological disorder and the described psychopathological picture. These steps may not always occur sequentially, as both syndrome and disease may be recognized.

Definition of the Specific Psychopathological Syndrome It is essential to describe the clinical disorder as precisely as possible. Subtyping should be undertaken when feasible, particularly with the specification of target symptoms for treatment. Use of broader or not otherwise specified terminology is available for less phenomenologically specific cases. Ideally, the clinician seeks to establish etiological relationships between definable disease processes and specific clinical presentations. The multiple presentations of general paresis, however, underscore that one pathogenic agent may cause multiple syndromic forms.

Patients with many secondary psychiatric disturbances present with symptoms that are atypical of primary (idiopathic) psychiatric disorders. Other clinical features, such as older age at onset, may serve to raise the index of suspicion. Syndrome definition involves severity as well as form. Severity implies a continuum, and the application of a diagnosis implies that the disorder has exceeded a threshold of severity. For example, although behavioral changes often arise following a cerebral lesion, a categorical diagnosis is not warranted when symptoms have not had a measurable impact on a person's functional integrity. Researchers may wish to study mildly symptomatic phenomena, but clinicians typically reserve diagnoses for conditions that cause substantially disordered behaviors, those interfering with the patient's daily life and personal well-being.

Delineation of Other Manifestations of the Primary Disorder Secondary psychopathological syndromes rarely occur alone but typically keep company with other symptoms and signs of the primary systemic or cerebral disorder. Thus, it is essential to define those cognitive, neuropsychological, peripheral, or other clinically ascertained manifestations of the disease process. For example, human immunodeficiency virus (HIV)-induced manic symptoms typically are accompanied by signs of testable cognitive impairment whereas depression due to Huntington's disease can be diagnosed with confidence only in the setting of a defined movement disorder. Identifying co-occurring manifestation provides an overall clinical context for more confidently establishing a secondary diagnosis.

Demonstration of Active Cerebral or Systemic Disease The clinician should seek nonbehavioral confirmation of the primary disease process. Such confirmation typically involves laboratory testing, including the full array of medical diagnostic procedures. One must be cautious, however, in the interpretation of many tests. An example is the use of cerebral imaging in psychiatric patients. Detection of a structural abnormality on computed tomography (CT) or MRI is not equivalent to demonstrating active cerebral disease because such imaging studies provide static (i.e., nonphysiological, nonfunctional) information in most applications. Much remains unknown regarding the link between MRI findings, definable cerebral pathology, and specific pathophysiologies or diseases.

Elevated Prevalence Rate Between Proposed Etiological Disorder and Described Pathological Picture This guideline cannot always be fulfilled, but argues for utilizing data-based conclusions that can be applied to clinical practice. Simply recording that a change in behavior occurs after the emergence of a particular cerebral disorder, for example, is insufficient proof. A specific syndrome should occur with a prevalence in association with an etiological disorder that is above the base rate in the general population.

Many clinicians recommend as the principal criterion for establishing causality the demonstration of a close temporal association of onset and course of the primary disorder and the secondary psychiatric syndrome. Although frequently useful, this criterion is not always applicable. For example, symptomatic psychosis due to epilepsy may gradually emerge 10 to 15 years after the onset of seizures. Conversely, psychiatric symptoms and signs may be the first clues to a systemic or cerebral disease, and detection of the primary pathological process may follow the emergence of psychiatric symptoms by months or longer. Many secondary psychiatric conditions also may persist after the primary disease process has resolved; examples are the secondary conditions consequent on thyroid deficiency, long-term alcohol use, or long-term exposure to neurotoxic compounds. Secondary syndromes may remit quickly, slowly, or incompletely, depending on the specific disease and whether lasting cerebral changes are present. Also, secondary syndromes may be amenable to symptomatic treatment even while the primary disorder remains without a cure.

ICD-10 recommends four criteria for classifying a syndrome as organic: (1) evidence of cerebral disease, damage, or dysfunction, or of systemic physical disease, known to be associated with one of the listed syndromes; (2) a temporal relationship (weeks or a few months) between the development of the underlying disease and the onset of the mental syndrome; (3) recovery from the mental disorder following removal or improvement of the underlying presumed cause; and (4) absence of evidence to suggest an alternative cause of the mental syndrome (such as a strong family history or precipitating stress).

ICD-10 also lists conditions known to increase the relative risk for the syndromes classified here, including epilepsy; limbic encephalitis; Huntington's disease; head trauma; brain neoplasms; extracranial neoplasms with remote CNS effects (especially carcinoma of the pancreas); vascular cerebral disease, lesions, or malformations; lupus erythematosus and other collagen diseases; endocrine disease (especially hypothyroidism and hyperthyroidism, Cushing's disease); metabolic disorders (e.g., hypoglycemia, porphyria, hypoxia); tropical infectious and parasitic diseases (e.g., trypanosomiasis); toxic effects of nonpsychotropic drugs (propranolol [Inderal], levodopa [Dopar], methyldopa [Aldomet], steroids, and antihypertensive and antimalarial agents).

Ultimately the clinician must make an informed judgment as to whether the psychiatric condition is primary or secondary. Prevalence data, for example, reflect group trends whereas the clinician has to make a decision regarding an individual. Two approaches are available. The clinical decision is relatively uncomplicated if a previously demonstrated elevated prevalence links a specific syndrome with a specific etiology, in the presence of additional supporting clinical features and consistent laboratory tests. Probabilistic reasoning in such cases leads to the conclusion that there is a cause-and-effect relation. A temporal association, when meaningfully present, further confirms the connection.

When a clinical research data base is less well established, however, it becomes even more critical to document rigorous clinical reasoning, in effect demonstrating how the detected historical, clinical, and laboratory features are not consistent with what is known about idiopathic psychiatric conditions. Again, establishing the causal connection should reflect the clinician's effort to undertake conscientious probabilistic case reasoning. Attribution of a secondary designation implies a link that is more probable than not: a standard that exceeds 50 percent is recommended, although absolute certainty may be possible. Such a standard does not require that the systemic medical or primary cerebral disease be the sole factor contributing to symptom expression; rather, *due to* . . . connotes a predominant pathogenic role. When causal probability is considered less certain (i.e., possible but not probable), the clinician should not define a syndrome as secondary in nature.

Diagnostic decisions based on incomplete data will be inevitable, and thoughtful clinical judgment remains the abiding rule. *Due to* . . . should be used conservatively; attribution of cause invites a careful consideration of the factors that contribute to disease formation. When doubt remains, the provision of a primary (idiopathic) psychiatric diagnosis will best serve the interests of the patient and avoid the premature closure of clinical evaluation.

Neuropsychiatric Assessment Neuropsychiatric assessment follows the principles of all comprehensive clinical evaluations: it is based on thorough acquisition of the current and past medical history, family history, developmental and social history, and a review of personal habits. The neuropsychiatric clinician seeks to integrate the data on unique individual development, the signs and symptoms of disease, and an understanding of behavior-brain relationships into a meaningful appraisal of functional integrity.

Clinical reasoning should entail a time-oriented view, with the clinician noting how the patient has progressed or failed to develop across his or her life course. The temporal perspective is buttressed by an understanding of normative development as well as by an appreciation of the natural history of disease processes. In

particular, the clinician should be mindful of the unique characteristics of primary cerebral disorders, whether inborn, acquired early in life, or of later onset. Fundamental to neuropsychiatric evaluation, diagnosis, and prognosis is an understanding of disease evolution at psychological and neurobiological levels of analysis. Frequently the clinician must tolerate the uncertainty of not knowing (in an absolute sense) the mechanisms by which brain diseases cause behavioral problems; the clinician then has the task of developing practical and effective solutions to problems that may not have specific scientific answers. Despite having a recognized pathological basis, most neuropsychiatric disorders do not have specific cures and continue to require empirical, symptomatic treatment approaches.

Clinicians repeatedly face a dual dilemma: etiological specificity often is related to variable clinical expression (e.g., general paresis and Huntington's disease). There is no biological law such as “one pathogen, one clinical presentation.” Clinical variability is the rule rather than the exception. Conversely, there are relatively few final common pathways for the expression of a wide variety of disease processes. These pathways include (1) alterations in arousal, attention, and concentration; (2) alterations in affective state, including both the expression of emotion and the feeling of mood; (3) alterations in perception, including ideational or physical and internal or external; (4) alterations in intellectual function (such as memory, language, or the organization of thought processes); (5) alterations in personality; and (6) alterations in motor function. Thus, behavioral abnormalities tend to be nonspecific, and despite substantial evidence from behavioral neurology that focal lesions may lead to distinctive patterns of intellectual deficit, there are insufficient data to confidently support such assertions for major psychopathological syndromes. Moreover, idiopathic or primary psychiatric disorders may mimic symptomatic psychopathological conditions that are secondary to specific systemic medical or cerebral disease processes and vice versa. What confounds the situation is that there has been insufficient research to establish how often cerebral lesions lead to discrete psychopathological syndromes or specifically how any defined psychopathological disorder is related to a particular localized cerebral abnormality.

Thus, the clinician must use an empirical method, based on careful clinical reasoning, that allows the development of a preliminary diagnosis and an initial treatment plan. The clinician should specify in advance what possible therapeutic benefits might be derived and should understand how the natural history of the disorder will unfold if proposed treatment options prove ineffective. The clinician should also be ready to undertake further evaluation if an unanticipated outcome arises. By establishing a future-oriented or outcome-oriented clinical perspective, the clinician can reduce the degree of uncertainty and establish a structural approach for systematically and self-critically scrutinizing treatment interventions.

Neuropsychiatric Case Reasoning The approach to neuropsychiatric case reasoning required for such formulation and planning entails blending the disparate traditions that developed in psychiatry in the past century. It draws from Meynert and John Hughlings Jackson (1835-1911), as well as from the behavioral neurologists of recent decades, an appreciation of brain-behavior and behavior-brain relations, with an attempt to understand the laws that govern the CNS. Such a pathobiological method, through lesion location and an appreciation of probabilistic generalities about brain function and neuropathology, in effect argues that all nervous systems are created equal. It benefits from a thoroughly documented array of case studies that seek to define the specific behavioral expression of focal cerebral lesions. It suffers from the fact that nervous systems are not identical and that personal circumstances powerfully influence the expression of disease. Nonetheless, it has taught clinicians much about what to assess and expect when dealing with disordered brain function.

The second approach to case reasoning is derived from the Kraepelinian tradition that continues to be expressed in DSM-IV. This method argues for the precise elaboration of symptoms and signs, the definition of specific syndromes, the identification of target symptoms amenable to therapeutic intervention, and the use of diagnoses for prognostic purposes. The strengths of such an approach lie in the rigorous case definition based on thorough observation and data collection, with the derived ability to generalize from one case to another. Shortcomings, akin to the problems with lesion localization, include the substantial degree of variability that exists within the boundaries of stereotypic diagnostic descriptions and the difficult-to-quantify influences of personal life circumstances.

The third method of case reasoning evolved from dynamic psychiatry and recognizes the individual as having unique personal and developmental attributes that are expressed throughout the course of life. The clinician using this method of case reasoning seeks to understand meaning as well as event and to appreciate disease process in the patient's broader social and cultural context. The neuropsychiatric clinician must view illness in all its complexity.

The different modes of case reasoning are brought together for clinical purposes through understanding how psychological meaning, symptoms, and disease process and socially defined aspects of illness each affects the patient's ability to function autonomously. Although function is not a direct measure of pathology or disease process, assessing how each person has undertaken specific developmentally important tasks is useful for appraising the interaction of those factors. Depending on the individual case, it may be possible to more clearly state which method of case reasoning is most effective for developing a treatment plan and understanding aspects of prognosis. Ultimately, the clinician is as much interested in the patient's return to prior functional integrity as in symptom remission. Treatment success cannot be proclaimed, for example, in the resolution of psychotic symptoms associated with epilepsy if the patient continues to be socially withdrawn or isolated and no longer capable of independent living.

Aging Age and its relation to the expression of illness must be recognized as a changing backdrop for all neuropsychiatric disorders. Age may be used as a convenient indicator for locating the patient in an evolving biological, psychological, and social matrix; a consideration of aging effects cannot await the last stages of the assessment, at which point aging is viewed solely as a factor modifying disease expression. Rather, thoughtful understanding of the aging-related context of a patient's illness is essential to obtaining the fullest view of the relevant life factors contributing to disordered behavior.

Data Acquisition The patient's history is an essential feature of neuropsychiatric evaluation because it provides the clinician the opportunity to develop the equivalent of a serial mental status examination across the patient's life course and to identify target symptoms that may respond to treatment. The clinician seeks to discern when, if ever, the patient functioned autonomously and effectively and to define the personal, social, psychological, symptomatic, and medical factors related to primary disease that contributed to a decline in function or to a failure of normal development. The history provides the opportunity to view the unfolding or evolution of signs and symptoms. The clinician strives to develop a variety of corollary information sources when assessing the patient's history so that the most complete view of the illness may be obtained. Corollary information sources may be particularly important for evaluating the history of patients who lack the cognitive capacity to relate their own life stories effectively and they are especially important for understanding the social and cultural context of specific symptoms.

During the history taking, the clinician seeks to elicit the functional anatomy of an illness. Subtle cognitive disorders, fluctuating symptom pictures, and progressing disease processes may be effectively tracked in a detailed rendition of changes in the patient's daily routine involving such factors as self-care, job responsibilities, and work habits; meal preparation; shopping and personal support; interactions with friends; hobbies and sports; reading interests; religious, social, and recreational activities; and ability to maintain personal finances. Understanding the fabric of life for each patient provides an invaluable source of data regarding many of the final common behavioral pathways cited previously, including attention and concentration, intellectual abilities, personality, and motor skills, and more typical symptomatic psychiatric features such as mood state and perception. The examiner seeks to find the particular pursuits that the patient has identified as most important or central to his or her lifestyle and attempts to discern how those pursuits have been affected by the emerging clinical condition. Such a method provides the opportunity to appraise both the impact of the illness and the patient-specific settings for monitoring the effects of future therapies.

Mental Status Examination Following a thorough history acquisition, the neuropsychiatrist's primary tool is the assessment of mental state. Formal mental status examination fell into disrepute when descriptive psychiatry was seen as irrelevant to the effective implementation of dynamically oriented psychotherapies. Its value is now undisputed. Like the physical examination, the mental status examination is a means of surveying predetermined functions and abilities to allow a definition of personal strengths and weaknesses. It is a repeatable, structured view of symptoms and signs; uniformity of approach assists in the reliable definition of findings and promotes effective communication between clinicians. It also establishes the basis for future comparison, essential for documenting therapeutic effectiveness, and it allows comparisons between different patients, with a generalization of findings from one to another. Table 10-3 lists the components of a comprehensive neuropsychiatric mental status examination.

Table 10-3 Neuropsychiatric Mental Status Examination

General Description Often, teachers and texts place the so-called sensorium as one of the last items for reporting when describing the mental status examination; the term is too broad, but consideration of arousal and responsiveness to the environment should be one of the first domains of assessment. If the patient has a significant disorder of attention or arousal, other aspects of the examination may be invalid. Together, attention and comprehension are the pillars of the mental status examination. Problems of arousal and inability to comprehend the fundamental aspects of the examination tend either to invalidate many findings or to warrant caution in their interpretation.

Language and Speech The clinician may use language function, particularly when assessing output, to estimate the patient's level of education and intelligence. It is essential, whenever possible, to estimate the patient's premorbid intellectual abilities. Definition of educational attainment during acquisition of the history aids in this process, but further appraisal during mental status assessment is valuable. However, this method must be used carefully because low educational attainment, a different language or cultural background, or acquired brain damage may confound any estimation.

Thought Assessment of thought processes involves appraising form and content. Thought form relates closely to language; for example, the clinician must distinguish between fluent aphasia or other disorders of word output and formal thought disorders related to psychosis (such as tangential responses or derailment). There are no ideational or perceptual manifestations that exclusively reflect neuropsychiatric disorders. Although some investigators have emphasized that olfactory hallucinations, for example, indicate brain disease specifically, such assertions have not been supported by well-designed epidemiological studies. Moreover, whereas the major primary psychiatric disorders have no known etiologies, there is no doubt that they involve abnormalities of brain functioning that result in the widest array of symptoms.

Mood and Affect When assessing affective and mood state, the examiner should appraise the congruence between expressed mood and demonstrated emotion. Patients with cerebral lesions occasionally demonstrate pseudobulbar affect or affective incontinence. The signs of pseudobulbar affect often include affective overshoot or disconnected affect, in which the patient responds to an appropriate stimulus but the expression is exaggerated or the emotional expression is unrelated to any defined mood. Although such behaviors can be observed in patients with idiopathic or primary psychiatric disorders, careful observation over an extended period often demonstrates that they are distinguishable from behaviors encountered in patients with mood disorders.

Insight and Judgment *Insight* denotes looking in while *judgment* reflects looking out. Both entail processes of appraisal or assessment, of one's own state of mind, one's motivations and actions, or one's relationships to others. Discussing the events leading to a clinical evaluation and comparing the patient's version with data gleaned from key informants (family, friends, other clinicians) provide an opportunity to define the congruity of the patient's understanding with that of others. Comparing examination-derived findings with the patient's insight (self-appraisal of mental state) serves as a direct or first-hand assessment.

Cognition When testing cognitive functions the clinician should evaluate memory; visuospatial and constructional abilities; and reading, writing, and mathematical abilities. Abstraction ability is also valuable to assess, although a patient's performance on tasks, such as proverb interpretation, may be difficult to evaluate when abnormal. Proverb interpretation may be a useful bedside projective test in some patients, but the specific interpretation may result from a variety of factors, such as poor education, low intelligence, and failure to understand the concept of proverbs, as well as a broad array of primary and secondary psychopathological disturbances. Although testing similarities are also education-sensitive, similarities may be more easily understood by patients.

A variety of standardized assessments have been developed in recent decades to assist with mental status evaluation. These include psychopathological rating scales that depend on self-report as well as examiner administration and brief evaluations of cognitive function that have proved helpful in examining individuals with developing cerebral diseases. Clinicians who use brief evaluations, however, must be cautious when interpreting their findings, which are subject to both false-negative and false-positive errors. For example, many tests use single cutoff points as thresholds for establishing abnormality. However, patients with focal lesions who experience discrete intellectual impairments may remain within the normal range of performance. Patients with idiopathic psychiatric disorders, such as major depressive disorder, may perform at abnormal levels on standardized cognitive protocols, inviting unwary clinicians to diagnose them as having dementia. Such assessments may also be susceptible to systematic differences among the elderly and are sensitive to lower educational level. Because they are tools for screening a large number of persons, bedside cognitive tests tend to be least helpful at the extremes, either when appraising highly intelligent individuals who are suffering intellectual declines but remain above the top rung of the test or when testing those who show substantial cognitive decline. The latter may continue to have residual intellectual abilities, some of which may prove helpful for maintenance care, but tests may prove insensitive to assessing those abilities.

PATHOLOGY AND LABORATORY EXAMINATION

Like all medical tests, psychiatric evaluations such as the mental status examination must be interpreted in the overall context of thorough clinical and laboratory assessment. Psychiatric and neuropsychiatric patients require careful physical examination, especially when there are issues involving etiologically related or comorbid medical conditions. When consulting internists and other medical specialists, the clinician must ask specific questions in order to focus the differential diagnostic process and use the consultation most effectively. In particular, most systemic medical or primary cerebral diseases that lead to psychopathological disturbances also manifest with a variety of peripheral or central abnormalities. Assignment of a patient's behavioral disturbance to a symptomatic or secondary status reflects, in part, the definition of other nonbehavioral manifestations of the primary disease.

An important element in the description of secondary psychiatric disorders is the use of laboratory assessment procedures to further define the characteristics of the systemic medical or cerebral process that is etiologically related to the psychiatric symptoms in question. This requires that psychiatrists understand the range of disorders that can lead to behavioral abnormalities. A screening laboratory evaluation is sought initially and may be followed by a variety of ancillary tests to increase the diagnostic specificity. Table 10-4 lists such procedures.

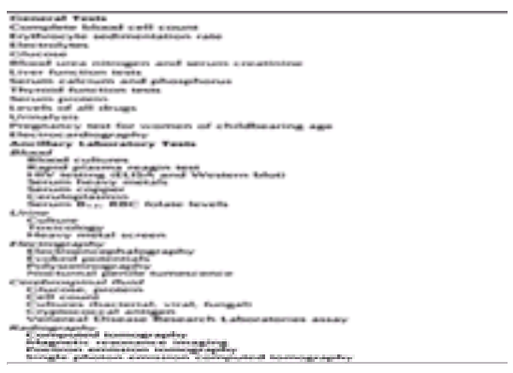

Table 10-4 Screening Laboratory Tests

A clinician requesting specific laboratory tests should be led by informed clinical suspicion as well as by an appreciation of the relative costs and benefits of each test. With the exception of low-cost screening procedures, few tests should be requested without a clearly defined rationale. Different approaches are taken for inpatients versus outpatients and for those with regular medical care versus those who have none. Repetition of recently performed tests is often without value.

Electroencephalography

EEG is an easily accessible, noninvasive test of brain dysfunction that has a high sensitivity in many disorders but relatively low specificity. Beyond its recognized uses in epilepsy, EEG's greatest utility is in detecting altered electrical rhythms associated with mild delirium, space-occupying lesions, and continuing complex partial

seizures where the patient remains conscious although behaviorally impaired. EEG is also sensitive to metabolic and toxic states, often showing a diffuse slowing of brain activity. Focal slowing, when present, may be indicative of a variety of causes such as space-occupying lesions (tumors, cerebral abscesses) or subdural hematomas. However, a superficial EEG (one that is recorded through the skull) is often insufficient for source localization and may prove insensitive to a variety of abnormal processes, necessitating nasopharyngeal recording to better define abnormalities generated by the temporal lobes or direct cortical (surface) recording to localize seizure foci. The EEG findings change with aging, with a general reduction in alpha wave activity, and with increases in the relative amounts of theta and delta wave activity. Early in the course of disorders such as Alzheimer's disease the standard EEG finding usually remains normal and therefore is often unrevealing. As part of sleep polysomnography, recent studies have suggested that the EEG may aid in the future in the distinction between elderly subjects with major depressive disorder associated with cognitive impairment and those with a primary neurodegenerative process underlying their dementia.

Computed Tomography and Magnetic Resonance Imaging

CT scanning and MRI have proved to be powerful neuropsychiatric research tools. Recent developments in MRI allow the direct measurement of structures such as the thalamus, basal ganglia, hippocampus, and amygdala, as well as temporal and apical areas of the brain and the structures of the posterior fossa. MRI has largely replaced CT as the most utilitarian and cost-effective method of imaging in neuropsychiatry. Patients with acute cerebral hemorrhages or hematomas must continue to be assessed using CT, but these patients present infrequently in psychiatric settings. MRI better discriminates the interface between gray and white matter and is useful in detecting a variety of white matter lesions in the periventricular and subcortical regions. The pathophysiological significance of such findings, designated by such terms as *rims, caps, unidentified bright objects*, and *leukoaraiosis*, remains to be defined. Such abnormalities are detected in younger patients with multiple sclerosis or HIV infection and in older patients with hypertension, vascular dementia, or dementia of the Alzheimer's type. However, their prevalence is also increased in healthy, aging individuals who have no defined disease processes. At present, those types of findings should be viewed in the same light as one would consider atrophic changes; namely, they are detected in a highly sensitive fashion but are usually nonspecific or nondiagnostic in meaning. White matter hyperintensities are more extensive and more frequent in individuals with disease, particularly those with disorders involving cognitive dysfunction, but they are too variable to contribute to the diagnosis or prognosis in an individual case. Like CT, the greatest utility of MRI when used in the evaluation of patients with dementia arises from what it may exclude (tumors, vascular disease) rather than what it can demonstrate specifically.

Because of MRI's ability to delineate brain anatomy and its sensitivity to white matter changes, these guidelines remain utilitarian when modified appropriately. Indications for ordering MRI in psychiatric patients include (1) delirium or dementia of unknown etiology; (2) a first episode of psychosis of unknown etiology; (3) a movement disorder of unknown etiology; (4) the initial evaluation of anorexia nervosa; (5) prolonged catatonia; (6) the initial onset of a major mood disorder or personality change after age 50 years; (7) the presence of unanticipated behavioral, intellectual, or functional decline in an already diagnosed psychiatric patient in whom the clinician would normally expect long-term stability or, at worst, a relapsing-remitting course with a return to baseline between episodes; and (8) the presence of any new behavioral or intellectual disorder in a patient infected with HIV.

Imaging studies have been overused in the periodic monitoring or reassessment of patients with suspected dementia of the Alzheimer's type in whom earlier examinations showed characteristic cerebral changes. Unless one suspects a missed diagnosis of normal pressure hydrocephalus, or perhaps failure to detect microinfarctions on CT when such a finding on MRI might have ruled out Alzheimer's type, repeated scans are not warranted.

Occasional patients may become agitated in the MRI tube; premedication with a benzodiazepine can minimize the problem. The magnetic field prohibits use of MRI in patients with pacemakers or metal implants, including metallic surgical clips, although many patients now receive MRI-compatible clips at surgery.

Positron Emission Tomography, Single Photon Emission Computed Tomography, and Functional Magnetic Resonance Imaging

Physiologically based techniques for imaging the brain, such as PET and SPECT, involve the injection of radioactively labeled, naturally occurring compounds or a radiopharmaceutical, with subsequent demonstration of cerebral blood flow or the incorporation of the labeled compounds into specific metabolic pathways. Such imaging methods have shown promise in studying the neurochemical and physiological bases of a variety of neuropsychiatric disorders. However, the cost of PET currently precludes its use as a routine diagnostic procedure, and there are insufficient data to project its ultimate utility for routine clinical evaluation. SPECT can be performed more readily and more cheaply, but whether it will have specific diagnostic utility in general psychiatry remains to be determined. Functional MRI (fMRI) holds great promise as a research tool to explore the physiological bases of complex behavioral processes. However, its potential utility as a clinical diagnostic tool remains to be defined.

Neuropsychological Testing

Neuropsychological testing provides a standardized, quantitative, reproducible evaluation of a patient's cognitive abilities. Such procedures may be useful for initial evaluation and periodic assessment. Tests are available that assess abilities across the broad array of cognitive domains, and many offer comparative normative groups or adjusted scores based on normative samples. The clinician seeking neuropsychological consultation should understand enough about the strengths and weaknesses of selected procedures to benefit fully from the results obtained. For example, many tests do not have appropriate aging-related norms (because they have been used primarily in young and middle-aged adults who are better educated) and therefore are less useful when used in children or the elderly. In general, clinicians should understand that a variety of distinct, competing neuropsychological schools of thought have developed different views regarding methods of individual evaluation, use of the tests, and interpretation of the data. Because neuropsychological evaluation is evolving rapidly and provides a remarkable array of tools for assaying disordered behavior, sophistication in the use and interpretation of those tests will benefit the clinician.

ETIOLOGY AND DIFFERENTIAL DIAGNOSIS

Factors Affecting Disease Presentation Neuropsychiatric evaluation and diagnosis are based on a fundamental understanding of the mechanisms by which pathobiological processes, both systemic and cerebral, express themselves through altered CNS function. The factors that influence symptom expression can be approached from several perspectives.

The first perspective relates to what might be called mode of action. Systemic disorders typically express themselves indirectly, through as yet undefined centrally active substances, defined endocrine disruptions, or fundamental metabolic alterations. Their effects tend to be generalized but often include delirium, dementia, or mood disturbance. In contrast, selective destruction of specific brain regions is more frequently associated with decrements in discrete cognitive tasks or behaviors. One must be cautious with such generalizations, however, as focal lesions in key brain regions (such as those involving brainstem structures) may cause delirious states. Moreover, the clinician may encounter substantial variability in the range of behavioral abnormalities caused by specific focal damage.

A second perspective relies on knowing the natural history of particular pathological processes. Diseases tend to progress or unfold in characteristic fashions, thus allowing for continuing differential diagnostic consideration over time. Also, meaningful prognosis depends on a thorough appreciation of natural history.

A third perspective derives from recognizing the timing of an insult within a neurodevelopmental framework, where the long-term impact of any process or event will depend in part on the compensatory or recovery capacities of the brain. Such capacities change as part of the aging process (they may be fundamental to aging), but much remains unknown.

A final perspective has to do with the types of cells and regions damaged by specific diseases. Degenerative disorders (Huntington's disease, Parkinson's disease) often lead to destruction of neurochemical systems. Hypoperfusion or pulmonary insufficiency both cause hypoxia, which in turn affects regions with especially vulnerable cell populations (such as the hippocampus) or regions near the ends of vascular trees (the so-called watershed zones, including many brain association areas). Lesions due to ischemic and hemorrhagic cerebrovascular disease reflect vascular anatomy rather than the pathoanatomy associated with degeneration of functionally significant neurochemical systems. Brain toxins may act by binding to specific neurochemical receptors, causing differential damage in direct proportion to regional variations in receptor concentration. Knowledge of the cell populations and anatomical regions affected, when integrated with the other perspectives, assists in understanding or anticipating the full effects of the primary disorder.

A variety of disorders can lead to behavioral abnormalities. They can be subsumed under the following broad categories: trauma, tumor, infection, immune and autoimmune disorders, cardiovascular disease, congenital and hereditary conditions, physiological disorders, primary psychiatric disorders, metabolic disorders, demyelinating disorders, degenerative diseases, substance-induced disorders and disorders due to toxins, and malingering.

Trauma Head trauma leading to brain injury is a possible cause for delirium, dementia, and amnestic disorder, as well as all of the secondary psychiatric syndromes.

Traumatic brain injury is largely a disease of modernity, with the majority of injuries resulting from motor vehicle accidents, gunshot wounds, or occupational mishaps. Estimates point to an annual incidence of 400 to 600 cases per 100,000 population, but such figures must be viewed with caution in light of variable definitions at the less severe (mild) end of the injury spectrum.

Pathophysiology Head trauma can cause brain injury through multiple mechanisms, both direct and indirect. Table 10-5 lists the factors that contribute to brain injury after head trauma. The clinician must recognize that brain injury from head trauma often results in pathology in areas beyond the site of direct impact. In addition, certain areas of the brain are more susceptible to injury regardless of the site of impact (Fig. 10-1). Those areas include the orbitofrontal and frontal pole convexities as well as the anterior temporal lobes, which lie close to bony skull prominences. Rotational and horizontal movements can produce shearing in areas of the brain that are relatively immobile, such as central white matter fiber pathways. Shearing forces can produce diffuse and extensive damage, also unrelated to the actual site of impact. Thus, frontal, subcortical, and limbic structures are especially vulnerable to traumatic head injury. This may explain the diversity of neuropsychiatric sequelae and the occasional occurrence of disproportionate disruptions in personality, behavior, and affect when cognitive and motor functions are largely spared. Penetrating head injuries or injuries in which the head has not been able to rotate or move may spare patients from the extensive injuries associated with indirect effects, despite significant direct damage. Bullet or penetrating missile injuries, however, may disrupt neuronal function beyond the site of impact through the effects of high-frequency vibratory waves.

Direct Effects
Contusion underlying point of trauma (coup)
Contusion linearly opposite point of trauma (contrecoup)
Compression from overlying depressed skull fracture
Compression from overlying hematoma
Indirect Effects
Diffuse impact damage
Widespread damage in cerebral white matter
Discrete lesions in corpus callosum
Discrete lesions in rostral brainstem
Common cortical contusions independent of direction of impact
Orbitofrontal
Anterior temporal
Frontopolar
Secondary cerebral processes
Cerebral edema
Increased intracranial pressure with cerebral herniation (Duret's hemorrhages)
Increased intracranial pressure with uncal herniation and posterior cerebral artery entrapment (medial occipital infarction)
Multifocal ischemic changes
Contributing secondary systemic processes
Shock (blood loss, ruptured viscera, sepsis, etc.) with hypotension
Pulmonary failure with anoxia
Long bone fracture with fat emboli

Table 10-5 Pathophysiological Mechanisms of Brain Injury After Head Trauma

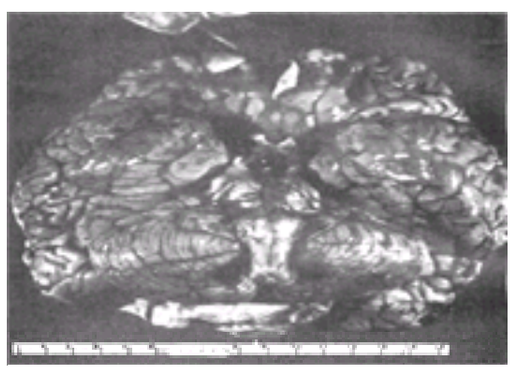

FIGURE 10-1 Severe contusion of the frontal poles has resulted in their atrophy and distortion. (Courtesy of H. M. Zimmerman, M.D.)

Psychiatric Symptoms Delirium is the acute manifestation of all head injuries that are likely to produce long-lasting sequelae. In severe head injury there is an initial loss of consciousness (coma), followed by gradual recovery, with the delirium taking the form of progressive stages of semiwakefulness, distractibility, and confusion, and finally a stable level of consciousness. The entire process may be brief or may take hours to weeks. In milder injuries there may be a brief absence of consciousness, such as momentary dazing, passing out, or transient confusion. A brief lapse or alteration of consciousness occurring after head trauma is defined as *concussion*. Table 10-6 includes frequently observed features of concussion and Table 10-7 lists common symptoms. Table 10-8 divides concussion cases into three grades of severity. Grades 2 and 3 cases require neurological evaluation; Grade 3 cases warrant immediate transport to an emergency department for assessment.

Vacant stare (befuddled facial expression)
Delayed verbal and motor responses (slow to answer questions or follow instructions)
Confusion and inability to focus attention (easily distracted and unable to follow through with normal activities)
Disorientation (walking in the wrong direction; unaware of time, date, and place)
Slurred or incoherent speech (making disjointed or incomprehensible statements)
Gross observable incoordination (stumbling, inability to walk tandem/straight line)
Emotions out of proportion to circumstances (distraught, crying for no apparent reason)
Memory deficits (exhibited by repeatedly asking a question that has already been answered, or inability to memorize and recall 3 of 3 objects in 5 minutes)
Any period of loss of consciousness (paralytic coma, unresponsiveness to arousal)

Table 10-6 Frequently Observed Features of Concussion

Early (minutes and hours):
Headache
Dizziness or vertigo
Lack of awareness of surroundings
Nausea or vomiting
Late (days to weeks):
Persistent low-grade headache
Light-headedness
Poor attention and concentration
Memory dysfunction
Easy fatigability
Irritability and low frustration tolerance
Intolerance of bright lights or difficulty focusing vision
Intolerance of loud noises, sometimes ringing in the ears
Anxiety and/or depressed mood
Sleep disturbance

Reprinted with permission from Quality Standards Committee, American Academy of Neurology (chief authors, Kelly JP, Rosenberg JH): The management of concussion in sports (summary statement). Neurology 48:581, 1997.

Table 10-7 Symptoms of Concussion

Grade 1	Transient confusion No loss of consciousness Concussion symptoms or mental status abnormalities resolve in 15 minutes
Grade 2	Transient confusion No loss of consciousness Symptoms resolve in >15 minutes
Grade 3	Any loss of consciousness

Table 10-8 Gradations of Concussion

Cognitive disorders are frequent after traumatic brain injuries. Global impairment may be seen after extensive head injury or prolonged coma, although those deficits may improve dramatically in the months following injury. Dementia or a persistence of global cognitive impairment is less common, reflecting the high mortality associated with more severe injuries. When dementia is seen, it is usually associated with hemiparesis, aphasia, or other indicators of severe and extensive injury.

Persisting dementia with gradually progressive deficits may be associated with multiple recurrent head traumas. The condition has been termed chronic traumatic encephalopathy and has been noted to occur after even minor multiple head traumas. Dementia pugilistica, or boxer's dementia, is an example. Onset usually occurs at the end of a boxer's career but chronologically earlier than the onset of the degenerative dementias. A subcortical pattern of dementia (discussed later under degenerative diseases) is typically present, with prominent parkinsonian features as well as dense memory impairment. Neuropathological studies have demonstrated global atrophy with specific involvement of the midbrain and mesial temporal lobe, presumably reflecting the direct and indirect effects of multiple injuries. Plaques and tangles are often noted, but the pathophysiological mechanism remains unknown.

Memory disturbance is nearly always present with any trauma severe enough to cause a concussion. *Posttraumatic amnesia* occurs invariably after concussive brain injury and refers to the inability to register new memory. The duration of posttraumatic amnesia, which may be very brief, is a significant indicator of severity but can be assessed only after the patient has regained a stable level of consciousness. *Retrograde amnesia* is the inability to recall events prior to the injury. It can be assessed by asking patients about their last memories before the injury. Retrograde amnesia generally shrinks with recovery whereas a postinjury memory deficit tends to remain constant; patients do not recover memories from the period of posttraumatic amnesia. Additionally, patients may suffer persisting impairment of new learning and recall (an amnestic disorder) as a result of permanent pathological changes incurred because of the traumatic event. Persisting specific deficits in the context of overall robust recovery can be disabling and frustrating for the patient, who appears normal to others although still impaired cognitively and functionally. Depending on the specific nature of any deficits, these patients would be diagnosed according to DSM-IV as having cognitive disorder not otherwise specified or amnestic disorder due to traumatic brain injury.

Postconcussional disorder is a disabling cluster of symptoms of uncertain pathophysiology. It emerges within hours to days (or a few weeks) of a mild head injury and is characterized by headache, dizziness, fatigue, poor concentration and mild memory impairment, problems sleeping, irritability, anxiety, and often significant problems with mood regulation or frank clinical depression. Diminished spontaneity, apparent apathy, and other personality changes are noted also. The cluster of symptoms is remarkably consistent from patient to patient. Table 10-9 presents the proposed research diagnostic criteria for postconcussional disorder that are included in DSM-IV.

A. A history of head trauma that has caused significant cerebral concussion.
Note: The manifestations of concussion include loss of consciousness, posttraumatic amnesia, and less commonly, posttraumatic onset of seizures. The specific method of defining this criterion needs to be established by further research.
B. Evidence from neuropsychological testing or quantified cognitive assessment of difficulty in attention (concentrating, shifting focus of attention, performing simultaneous cognitive tasks) or memory (learning or recalling information).
C. Three (or more) of the following occur shortly after the trauma and last at least 3 months.
(1) becoming fatigued easily
(2) disordered sleep
(3) headache
(4) vertigo or dizziness
(5) irritability or aggression on little or no provocation
(6) anxiety, depression, or affective lability
(7) changes in personality (e.g., social or sexual inappropriateness)
(8) apathy or lack of spontaneity
D. The symptoms in criteria B and C have their onset following head trauma or else represent a substantial worsening of preexisting symptoms.
E. The disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning. In school-age children, the impairment may be manifested by a significant worsening in school or academic performance dating from the trauma.
F. The symptoms do not meet criteria for dementia due to head trauma and are not better accounted for by another mental disorder (e.g., amnestic disorder due to head trauma, personality change due to head trauma).

Table 10-9 DSM-IV Research Criteria for Postconcussional Disorder

ICD-10 defines postconcussional syndrome as follows:

> The syndrome occurs following head trauma (usually sufficiently severe to result in loss of consciousness) and includes a number of disparate symptoms such as headache, dizziness (usually lacking the features of true vertigo), fatigue, irritability, difficulty in concentrating and performing mental tasks, impairment of memory, insomnia, and reduced tolerance to stress, emotional excitement, or alcohol. These symptoms may be accompanied by feelings of depression or anxiety, resulting from some loss of self-esteem and fear of permanent brain damage. Such feelings enhance the original symptoms and a vicious circle results. Some patients become hypochondriacal, embark on a search for diagnosis and cure, and may adopt a permanent sick role. The etiology of these symptoms is not always clear, and both organic and psychological factors have been proposed to account for them. The nosological status of this condition is thus somewhat uncertain. There is little doubt, however, that this syndrome is common and distressing to the patient.

At least three features of the syndrome are necessary for diagnosis, according to ICD-10 (Table 10-10). Laboratory tests may be helpful for corroboration. Some observers have argued that the requirement in DSM-IV to wait 3 months before a definitive postconcussional diagnosis may lead to a delay in establishing a proper diagnosis and initiating therapy for some patients. Indeed, postconcussional conditions transiently or spontaneously resolve for most affected individuals, with symptom remission during the first 3 to 6 months following injury. Although occasional individuals develop posttraumatic migraine, patients with postconcussional disorder more commonly describe symptoms reminiscent of muscle tension headaches arising frontally or posteriorally and occasionally involving temporal regions as well. Some report tenderness persisting at the site of impact, but that is less frequent and its pathophysiological basis is unknown. Major depression in the context of postconcussional disorder may not remit unless specific antidepressant treatment is initiated. Postconcussional symptoms that persist beyond 12 weeks should raise suspicions of additional brain pathology, such as an undetected subdural hematoma or a chronic cognitive impairment syndrome. A thorough evaluation is warranted. Postconcussional headaches can persist and prove disabling, and patients may benefit from the judicious use of analgesic as well as antidepressant agents. However, clinicians also must be vigilant regarding the development of headaches caused by analgesic rebound, a paradoxical but common cause of apparent chronic posttraumatic headaches. Secondary mood disorders are commonly seen with severe injury, although they may be more common after minor injury as part of the postconcussional syndrome. All forms of psychotic symptoms that are seen in idiopathic schizophrenia can be seen after traumatic injury. They are most common in the immediate delirious period but can persist once a stable level of consciousness has been obtained.

Table 10-10 ICD-10 Diagnostic Criteria for Personality and Behavioral Disorders Due to Brain Disease, Damage and Dysfunction

Personality Change Due to a General Medical Condition This disorder is a frequent concomitant of traumatic brain injury, owing to the vulnerability of the frontal lobes and the important role those structures play in the expression of personality. Two personality syndromes have been described with frontal lobe injury: the *orbitofrontal syndrome*, characterized by disinhibition, explosiveness, and jocularity; and the *frontopolar syndrome*, characterized by apathy, behavioral inertia, and indifference. Patients may appear indifferent to their incapacities or may confabulate regarding their injury and hospitalization. Less marked personality changes, such as irritability and a so-called short fuse, are common, especially as part of the postconcussional syndrome.

Adjustment disorders can occur at any point once a stable level of consciousness has been attained. Patient and family must adjust to loss of capacity, increased irritability and fatigue, a possible change in family roles, absence from work, financial constraints, and legal entanglements. As in all adverse circumstances, premorbid personality heavily influences the patient's adaptive capacities. Unfortunately, clinicians have at times seen the presence of an adjustment disorder or a prior history of maladaptive personality functioning as a reason to conclude that patients are not suffering from behavioral or cognitive impairments arising from brain injury. The evaluation and treatment of head trauma require clinical flexibility to address the broadest range of symptoms and syndromes.

Course and Prognosis The course of recovery from posttraumatic syndromes depends on the severity of the initial injury and the location of damage. The duration of coma and of posttraumatic amnesia may be useful prognostic indicators. Dramatic improvements can occur within days and continue for up to 6 months. Overall recovery may continue up to 24 months, with motor and physical improvement often preceding behavioral and cognitive restoration; less frequently, recovery continues beyond 2 years after injury. The neurobiological mechanisms leading to recovery are unknown.

Treatment There are no specific treatments for the cognitive abnormalities associated with head trauma. Life-sustaining and life-supportive short-term therapies may be needed initially, and the psychopathological conditions resulting from head trauma may warrant symptomatic therapies. Despite a boom in institutions and companies offering cognitive rehabilitation, it remains unproved scientifically whether those methods significantly augment natural recovery processes.

Litigation The high frequency of closed head injuries and posttraumatic complaints, together with the ready availability of psychiatrists, neurologists, and psychologists willing to testify as “experts,” have combined with lawyers in today's litigation-prone culture to bring postconcussional disorder center stage in American courtrooms. While there are numerous instances of claims related to bona fide cognitive, emotional, and behavioral deficits resulting from brain injury, it also is clear that many are unsubstantiated. There appear to be four often interacting factors that contribute to the latter situation: (1) Absence of concussion—Suits frequently request damages for postconcussion syndrome (or a related term) when a careful review of medical records reveals no evidence of pertinent symptoms or signs, such as altered consciousness, posttraumatic amnesia, nausea and vomiting, photophobia, or headache: (2) Nonspecific symptoms—Postconcussional disorder is diagnosed due to fatigue, headache, and dysphoria in the absence of symptoms or signs of concussion; complaints may have developed weeks or even months after an accident or injury. (3) Diagnostic mythology—Once a clinician labels a condition postconcussional without substantiation, this label is then promulgated and other clinicians accept it at face value without an independent review of all necessary data. The diagnosis soon assumes mythic proportions. (4) Lack of common sense—[A patient is diagnosed as having specific posttraumatic psychopathology or cognitive decline without the earlier medical, psychiatric, educational, and vocational records having been reviewed, which reveals the presence of the claimed symptoms or signs before the purported brain injury.]

In all litigation-related evaluations, the possibility of malingering needs to be considered. Relevant hints or clues include: a substantial discrepancy between mild clinical findings and severe or dramatic subjective complaints; relatively intact personal and vocational functioning and markedly abnormal neuropsychological test scores; vague complaints without objective test or functional correlates; disparity between complaints of vocational limitations and continued vigorous recreational activities (e.g., hunting, weight training, volleyball, or tennis); a history of legal difficulties or multiple accident claims; evidence of a clinically significant personality disorder.

An evaluator must also be vigilant to assess whether there is evidence of an undiagnosed mood disorder. Frequently an individual with severe physical injuries gradually develops complaints of dysphoria, headaches, poor concentration, and memory dysfunction. Diagnosed as suffering a postconcussional disorder, the plaintiff or patient believes he has permanent brain damage rather than an eminently treatable mood disorder.

Tumor Intracranial tumors, whether of primary CNS or metastatic origin, can cause behavioral disturbances by directly affecting brain function. They may do so by destroying or compressing brain parenchyma (from mass effect or edema), through obstructive hydrocephalus, or by disrupting brain vasculature (Fig. 10-2). The nature of the ensuing behavioral disturbance depends on factors already discussed, such as time course and injury location.

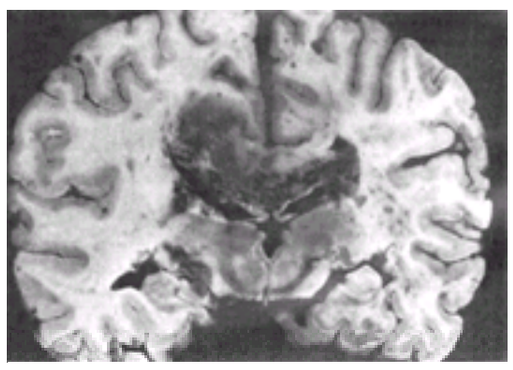

FIGURE 10-2 Glioblastoma multiforme. The massive tumor crosses the midline in the corpus callosum. (Reprinted with permission from Hirano A: *A Guide Neuropathology*. Igaku-Shoin, New York, 1981.)

Extracranial nonbrain neoplasms may indirectly alter brain function and cause psychiatric symptoms by any of several pathways. The cancer may disturb one or more organ systems known to affect brain function. For example, lung cancer may cause hypoxemia and metastatic prostate carcinoma may lead to obstructive uropathy with consequent renal failure. Paraneoplastic syndromes may lead to metabolic abnormalities (e.g., hypercalcemia) commonly associated with behavioral changes. Intriguingly, cancer may cause psychiatric symptoms without any known metabolic or other organ system disturbance; a commonly cited example is the onset of a major depressive disorder as the first clinical manifestation of occult pancreatic carcinoma. The mechanisms of such phenomena are unknown, although it has been speculated that blood-borne humoral factors secreted by the tumor are centrally active.

Infection Infections can produce any of the range of cognitive impairments or secondary syndromes that are sudden or insidious in onset. Acute infectious processes involving the CNS often produce delirium as a component of fulminant deterioration. Chronic psychopathology can result either from a chronic infectious process, such as neurosyphilis or Creutzfeldt-Jakob disease, or from persisting structural brain damage incurred as a result of an acute infection, as in the long-term sequelae

of herpes simplex encephalitis.

Syphilis Syphilis is a chronic infection resulting from inoculation with the spirochete *Treponema pallidum*. It is transmitted through sexual contact. Primary syphilis is a local disease manifested by a lesion at the site of inoculation, usually the penis, vagina, or mouth, within 2 to 3 weeks after inoculation. Secondary syphilis, manifested by a recurrent rash occurring anywhere on the body but especially on the palms and soles, has its onset 6 weeks to 6 months after initial exposure. After the rash resolves, syphilis may enter a latent stage that lasts 2 to 10 years after inoculation; serology remains positive throughout the latent stage. Tertiary syphilis may involve skin, bone, and the aorta, as well as the CNS. Neurosyphilis can occur 5 to 35 years after the initial inoculation. Neurosyphilis is divided into four stages: (1) an asymptomatic stage, without symptoms but with abnormal cerebrospinal fluid (CSF); (2) meningovascular syphilis, characterized by headache, nuchal rigidity, irritability, and delirium; (3) tabes dorsalis, with signs of posterior column degeneration, such as ataxia (due to loss of proprioception resulting in a slapping or high-stepping gait and trophic joint changes—Charcot's joints), areflexia, paraesthesias (described as lightning pains and typically involving the extremities), incontinence, impotence, and abnormal pupillary findings (the classic Argyll Robertson pupil, which accommodates but does not respond to direct light response); and (4) general paresis, also known as general paralysis of the insane, dementia paralytica, or paretic neurosyphilis, the classic neuropsychiatric disorder of tertiary syphilis (Fig. 10-3).

FIGURE 10-3 Paretic neurosyphilis. Thickening of the meninges and atrophy of the cerebral convolutions. (Reprinted with permission from Merritt HH, Adams RD, Solomon HC: *Neurosyphilis*. Oxford University Press, New York, 1946.)

General paresis has great significance for the history of psychiatry because it was one of the first instances in which severe behavioral and cognitive disturbances could be attributed directly to an etiologically definable brain disease. General paresis can present as almost any form of psychiatric disturbance or dementia syndrome. The classically described grandiose presentation has become rare whereas depressive presentations have become more common. Often a general change in personality is the initial presentation, with apathy, lability, and coarsening of behavior. Dementia is of a mixed pattern, with prominent impairment of memory, language, and judgment, as well as loss of initiative and psychomotor slowing. Neuropathologically the brain demonstrates diffuse degeneration with marked lymphocytic infiltration throughout.

Creutzfeldt-Jakob Disease *Creutzfeldt-Jakob disease* is an infection that causes a rapidly progressive cortical-pattern dementia. The infectious agent, a *prion*, is a subviral replicative protein that is now known to cause a variety of so-called spongiform diseases in animals and humans. The 1998 Nobel Prize for Medicine was awarded to Stanley Prusiner for his work describing this novel biological entity. The age at onset of Creutzfeldt-Jakob disease is usually in the sixth or seventh decade, although onset can occur at any age. The incidence is 1 in 1,000,000. The clinical symptoms vary with progression of the illness and depend on the regions of the brain that become involved. Patients may present initially with nonspecific symptoms, including lethargy, depression, and fatigue. Within weeks, however, more fulminant symptoms develop, including progressive cortical pattern dementia, myoclonus, and pyramidal and extrapyramidal signs. Although blood, CSF, and imaging studies are unremarkable, the EEG can demonstrate a characteristic pattern of diffuse symmetric rhythmic slow waves. A presentation with rapid deterioration, myoclonus, and the characteristic EEG pattern should raise suspicion of Creutzfeldt-Jakob disease. The definitive diagnosis is made by postmortem microscopic examination, which demonstrates spongiform neural degeneration and gliosis throughout the cortical and subcortical gray matter; white matter tracts are usually spared. Prion disease can incubate for decades before the emergence of clinical symptoms and subsequent rapid progression. Reported routes of transmission include invasive body contacts, such as direct tissue transplantation (e.g., corneal transplants) or hormonal extracts (e.g., human growth hormone, before synthetic supplies were developed). Familial patterns have also been reported, which suggests that there may be genetic susceptibility to infection or vertical transmission of the disease agent. No antiviral agents have been shown to be effective in retarding or slowing disease progress, although amantadine (Symmetrel) has been reported occasionally to have had some success. Death usually ensues within 6 months to 2 years of onset. During the past several years, a pathologically similar condition, bovine spongiform encephalopathy, has been described. Diagnosed primarily in the United Kingdom, this disease underscores the effects of modern animal husbandry methods on the amplification of rare diseases and the continuing threat of zenobiotic transmission of these to humans.

Viral Encephalitis Viral encephalitis varies in severity, depending on the specific etiological agents. Mild disease is more common with mumps, and enteroviral infections can be limited to headache and malaise. Severe disease is characteristic of infections such as rabies and herpes simplex. Herpes simplex encephalitis is the most common of the severe nonepidemic encephalitides. It is of interest to neuropsychiatry because of the preferential involvement of the orbitofrontal and medial-temporal regions of the brain. A typical presentation consists of severe encephalitis of rapid onset, high fever, headache, nuchal rigidity, focal neurological signs, and delirium. Rarely, a sudden, transient psychosis may herald the onset. Occasionally the onset is more insidious, with the clinical picture at presentation limited to personality change or memory impairment. Necrosis of the frontal and temporal lobes can occur rapidly. Mortality is high: approximately 70 percent. Whenever herpetic encephalitis is suspected, a definitive diagnosis should be made as rapidly as possible by brain biopsy, with the subsequent urgent initiation of antiviral therapy. Survivors may sustain deficits related to temporal and frontal lobe damage, including a dense amnesia disproportionate to the degree of other intellectual impairment; hallucinations in all spheres, including olfactory and gustatory; components of a Kluver-Bucy syndrome; partial complex seizures; aphasia; and anosmia.

Human Immunodeficiency Virus HIV-1 has created a late–twentieth-century epidemic parallel in severity and pervasiveness to the scourges of bygone eras. Acquired immune deficiency syndrome (AIDS), the later stages of HIV infection, has been recognized since the 1980s. In recent years its neuropsychiatric manifestations have become a focal point for diagnosis and therapy, as patients live longer through the use of partially effective antiviral therapies and a variety of second-line medications employed for treating opportunistic infections. The following discussion focuses on neuropsychiatric phenomena that appear to result from HIV-1 action in the brain.

Mr. Zeigler is a 55-year-old, married, Latin American businessman who is hospitalized with an 8-month history of diarrhea, fatigue, and weight loss. He has sought help from several institutions both in the United States and Europe, but his illness remains undiagnosed. A psychiatric consultation is requested because both the patient and his physician think he is depressed and wonder what role this might play in his weight loss and overall condition.

Mr. Zeigler gives a detailed history of his family's emigration from Europe when he was a child, his personal success in business, and the progressive difficulty he has been experiencing because of his weight loss and fatigue. He has lost 85 pounds over the 8 months and now has to force himself to eat. In the past, eating had been a great pleasure for him and he considered himself a gourmet cook. Although he complains of some difficulty with his memory and concentration, he continues to manage a multinational business and to conduct complex financial deals. He says he feels sad but is hopeful that the diagnosis can be made quickly. He conducts himself in the same autocratic manner in the hospital that he is accustomed to displaying in business and with his family. He has many interests, including an active sex life, which he wishes to resume once he regains his strength.

Mrs. Zeigler confirms her husband's history and speaks of his complete control of his business and of the family's financial affairs. She describes how this has created conflicts with her sons, who resent their father's unyielding control, even though they work in the family company. It is her opinion that her husband is depressed and that this is the cause of most of his symptoms. In response to questions about his activities, she agrees that his fatigue seems the only obstacle to pursuing his interests. She cannot answer any questions about his sex drive because she stopped having sex with him 10 years before this illness. He accepted this, and she presumed he frequented prostitutes.

Over the next few days Mr. Zeigler's condition deteriorates markedly, and he is thought to have had a stroke because of some slurred speech and a slight weakness of the right side of his body. He then becomes short of breath and is admitted to the intensive care unit. A chest X-ray suggests *Pneumocystis carinii* pneumonia, which is confirmed by bronchoscopy. He does not respond to co-trimoxazole (Bactrim) and is started on pentamidine (NebuPent). While in the intensive care unit Mr. Zeigler is delirious, frequently hallucinating, and often incoherent in both Spanish and English. His children fly to the United States because he is not expected to survive. This prediction proves to be incorrect, and his pneumonia resolves after several weeks of treatment. A CT scan of the brain suggests a CNS infection with toxoplasmosis, and examination of the stomach by endoscopy leads to the diagnosis of gastrointestinal *Isospora*. Surprisingly, all these infections respond to treatment.

It is now clear that Mr. Zeigler has AIDS, and his physician presents this diagnosis to him along with an inquiry about his sexual experiences. Mr. Zeigler is enraged by his doctor's implication of homosexuality and adamantly denies any homosexual activity. He discusses his adaptation to his wife's decision to cease sexual activity with him. He has frequented prostitutes in the Far East, where he traveled regularly on business. It seems impossible to him that he might have AIDS, although he admits to having contracted syphilis 4 years before his current illness. On discharge, Mr. Zeigler is given the diagnosis of AIDS, with the only clear risk factor his sexual contact with prostitutes.

Six months later Mr. Zeigler and his wife return to the United States for further evaluation of his mental status. His wife is concerned that he has become depressed because he is no longer able to handle his financial affairs. She feels his personality has undergone a radical change in that he no longer seems to care about anything, in spite of the fact that his appetite has returned to normal and he has regained much of his lost weight. Much of his time is now spent sitting idly in their garden.

When examined, Mr. Zeigler appears to be in good physical health. However, his mental condition has obviously deteriorated; it is not possible to conduct an interview in English although previously he had spoken several languages fluently. He smiles pleasantly, but is both disoriented and confused, even when speaking in Spanish. This surprises even his wife, since she had not been aware of this change in his cognitive functioning. He has poor short-term memory and cannot perform simple calculations. His remote memory is intact, although his wife feels that he has confused some historical events. Mr. Zeigler seems unaware that there are any deficits in his intellectual functioning. Medical evaluation does not reveal any active infections. (Reprinted with permission from *DSM-IV Casebook*.)

Clinicians began to recognize the variety of neuropsychiatric manifestations of HIV in the mid-1980s. Most prominent were major mood disturbances (major depressive, dysthymic, and less commonly, bipolar disorders) and a characteristic progressive cognitive impairment that was labeled AIDS dementia complex. Rarely, patients developed psychoses, at times with a schizophrenic presentation, as well as alterations of personality. Later, carefully conducted epidemiological studies revealed that persons at highest risk for HIV infection suffered elevated rates of mood and substance use disorders before contracting the disease. Intertwined with syndromes that were thought to be direct results of primary HIV infection of the CNS or secondary complications from other infections or tumors were a variety of adjustment and mood disturbances, reflecting responses to a progressive, inevitably terminal disease.

The psychopathological manifestations of HIV cover the major symptom clusters, as well as AIDS dementia complex and delirium. Clinicians have used empirical treatments, many with substantial symptomatic response. Intervention with antiviral therapies also has shown beneficial behavioral effects, especially when CSF indices of CNS infective activity have suggested that the primary disease has increased in its activity. However, there have been few carefully conducted therapeutic trials to establish the overall efficacy of any symptomatic psychopharmacotherapy.

AIDS dementia complex is characterized predominantly by a subcortical presentation, with prominent psychomotor slowing and difficulties with concentration and memory. Early associated motor deficits include ataxia, leg weakness, tremor, and loss of fine motor coordination. Patients commonly become apathetic or withdrawn. The course is steadily progressive, at times punctuated by abrupt acceleration. Like other dementing disorders, AIDS dementia complex progresses to a late stage characterized by severe dementia, mutism, incontinence, paraplegia, and in some cases, myoclonus.

During the latter part of the 1980s, controversy developed regarding the temporal sequence of the emergence of cognitive abnormalities versus other symptoms reflecting the advance of HIV infection to full-blown AIDS. There is no dispute that AIDS dementia complex may be the predominant feature of AIDS for some patients, but there is uncertainty regarding the presence of cognitive abnormalities in patients who are both clinically asymptomatic and without laboratory evidence of encroaching immune suppression. Many patients with HIV develop a mild (minor) cognitive disorder that has many of the same features of AIDS dementia complex but that is as not cognitively severe or as impairing functionally. Recently, an American Academy of Neurology AIDS Task Force developed a set of standard nomenclature for neurological manifestations of HIV-1 infection, including both cognitive and peripheral neurological findings.

In autopsy series, 75 to 90 percent of brains of patients dying from HIV infection show neuropathological alterations. In addition to changes due to secondary or opportunistic infections, there is widespread subcortical white matter pathology with relative sparing of cortical structures. Those diffuse, noninflammatory changes are now subsumed under *HIV leukoencephalopathy*. Microscopic examination also reveals foamy macrophages and multinucleated giant cells invading both white matter and subcortical nuclei, particularly basal ganglia structures. Such focal inflammatory findings are characterized as HIV encephalitis. Also, there may be pathology in the spinal cord associated with paraparesis, particularly vacuolar myelopathy. Insofar as many other patients have significant cognitive deficits in the context of relatively little pathological alterations, it is clear why investigators have encountered difficulty when attempting strict clinical-pathological correlation.

The mechanism by which HIV causes its functional effects remains unknown. Current data point to (1) neurons and supporting cellular structures, through the actions of the virus itself or from its coat proteins; (2) the undesirable effects of activated immune components (such as activated macrophages); and (3) possible excitatory neurotoxic effects of endogenous neurotransmitters that have been dumped into surrounding interstitial fluids (e.g., quinolinic acid affecting glutamate receptor subtypes, leading to the toxic accumulation of intracellular calcium).

The diagnosis of HIV-related neuropsychiatric syndromes requires a high index of suspicion and a sensitivity to possible demographic risk factors, including homosexual behavior, sexual promiscuity, intravenous substance abuse, and sexual relations with high-risk partners. In addition, there is a gradual movement of the HIV virus into the broader heterosexual population. Psychopathological changes may precede frankly defined cognitive abnormalities. The clinician also must be alert to early, subtle intellectual decline: the patient may remain within the normal range on standard neuropsychological tests but may perform at a level lower than was attained previously. In addition to neuropsychological assessment, neuroimaging may demonstrate abnormalities in subcortical periventricular and deep white matter.

AIDS dementia complex has become a major target in pharmacotherapeutic trials to cure or ameliorate the effects of HIV infection. Preventing its emergence or prolonging the time it takes to appear have become possible end points for some studies. Others are considering AIDS dementia complex as a direct target for intervention. Future antiviral pharmacotherapies may be targeted specifically to the brain to eradicate any possible reservoirs of HIV, in a fashion similar to the use of irradiation or antitumor agents in children with leukemia.

Immune and Autoimmune Disorders Three broadly defined pathophysiological mechanisms involving the immune system can be associated with neuropsychiatric

disorders: (1) hypofunction of the immune system may contribute to infectious diseases and possibly to neoplastic illnesses; (2) definite or putative autoimmune diseases may cause behavioral disturbances by affecting the function of organ systems in a way that compromises brain activity (e.g., the hyperthyroidism of Graves' disease or hepatic failure from primary biliary cirrhosis); (3) autoimmune illnesses may also affect brain function more directly by causing cerebral ischemia due to vasculitis or by direct CNS parenchymal inflammation. Some primary neurological diseases (e.g., multiple sclerosis) may involve autoimmune pathophysiology (Fig. 10-4). A major example of an autoimmune disorder involving the CNS is systemic lupus erythematosus.

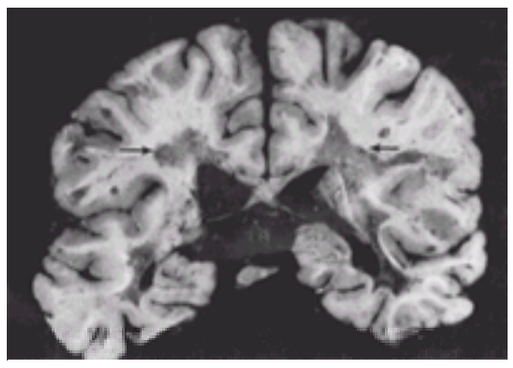

FIGURE 10-4 Multiple sclerosis. Coronal section of cerebral hemispheres showing large, sharply demarcated plaques adjacent to the bodies of the lateral ventricles (arrows). Other plaques are found adjacent to the temporal horns and smaller plaques are present in the subcortical white matter and centra semiovales. (Reprinted with permission from Golden A, Powell DE, Jennings CD: *Pathology: Understanding Human Disease*, ed 2. Williams & Wilkins, Baltimore, 1985.)

Cathy Jarvis, a 25-year-old mother with a 3-year history of systemic lupus erythematosus was admitted to a university hospital in an acute confusional state with inability to maintain attention or to carry on a coherent conversation and with marked disorientation to time and place. Before her hospitalization she had become progressively more confused over a number of days, and had started to believe that the neighbors were watching her. On the day of admission she had run out of her house and into the street in a state of uncontrollable agitation.

On admission to the hospital emergency room, Cathy was given intramuscular haloperidol (Haldol), but by the next morning her clinical picture had worsened dramatically. She was now rigid, mute, uncommunicative, and unresponsive to all questions and she exhibited facial grimacing. Her course fluctuated so that at times she became excited, screamed continuously, and seemed to be responding to auditory and visual hallucinations; at other times she was mute and rigid. She required total nursing care, with intravenous feeding, catheterization, and four-point restraint. She received frequent sedation with lorazepam (Ativan), a short-acting benzodiazepine. Because she was thought to have lupus cerebritis, intravenous methylprednisolone (Depo-Medrol), a steroid, was begun, but there was no improvement in her clinical condition.

During the next 3 weeks Cathy's condition deteriorated. She lost considerable weight, was unable to stand, and continued to require total nursing care. On day 28 she was referred for electroconvulsive therapy (ECT). After seven treatments she gradually responded, sought to feed herself and to stand, was more alert, and recognized her family. Rigidity was now only occasionally present. A lumbar puncture demonstrated the presence of immunoglobulin-G (IgG) antineuronal antibodies in high titer, consistent with a diagnosis of CNS involvement with lupus.

Over the next few weeks periods of lucidity alternated with rigidity, mutism, negativism, and staring. By day 90 of Cathy's hospitalization, a second course of ECT was begun. After 10 treatments, she was verbal, euthymic, and cooperative. (Reprinted with permission from *DSM-IV Casebook*.)

Often lupus is considered in the differential diagnosis of new-onset psychopathological syndromes. Although the etiology of lupus is not known, evidence implicates immunological mechanisms in its pathogenesis. Numerous organ systems may be involved. The disease may affect brain function (thereby producing psychiatric symptoms) indirectly, through such mechanisms as fever, renal failure, or pulmonary disease. In a minority of patients it may cause pathology directly, most likely from vasculitis affecting cerebral vessels. Patients with CNS disease may experience seizures, transverse myelopathies, or behavioral abnormalities, including delirium, psychotic syndromes, and affective lability. Clinicians evaluating patients with psychiatric symptoms of recent onset (particularly women in the second through fifth decades of life) should carefully consider the medical history, review of systems, physical examination findings, and routine laboratory screens, to look for evidence of systemic organ system involvement. The erythrocyte sedimentation rate (ESR), while nonspecific, is substantially elevated during acute CNS lupus and provides a useful screen. More specific laboratory tests (e.g., antinuclear antibody assay and antibodies to double-stranded deoxyribonucleic acid [DNA]) may be pursued when indicated. Neuroimaging scans may show cerebral infarctions but are often normal early in the disease. Glucocorticoids are the mainstay of treatment for acute CNS systemic lupus erythematosus. Psychotropic medications may be needed to treat specific behavioral symptoms (e.g., antipsychotic agents for severe agitation during delirium).

Cardiovascular Disease Because the extremely high metabolic activity of the brain is obligatorily aerobic, the brain is exquisitely sensitive to relatively minor perturbations in blood flow. Thus, alterations in cardiac function ranging from grossly obvious (cardiogenic shock) to relatively subtle (compensated congestive heart failure, chronic low-output states) often manifest with CNS dysfunction. The consequent psychiatric phenomenology may vary due to largely unknown factors, but delirium, dementia, and depressive episodes are especially common. Perfusion failure, depending on its cause, may lead to insidious, gradual changes or dramatic decrements in function. Transient profound drops in blood pressure, typically associated with major cardiac events (including surgery), may lead to mental status alterations that are difficult to pinpoint initially. Clinicians are faced with distinguishing soon-to-remit symptoms, such as postoperative delirium arising from metabolic imbalances, from subtle persisting intellectual and behavioral alterations caused by hypofusion leading to cell death.

Intrinsic cardiac illness, such as mural thrombus or valvular disease, may also be a source of embolic cerebral infarction (Fig. 10-5). Cardiovascular disease may also lead to brain dysfunction by serving as a risk factor for cerebrovascular disease. Identified risk factors for stroke include hypertension, diabetes mellitus, cigarette smoking, atrial fibrillation, left ventricular hypertrophy, and coronary artery disease.

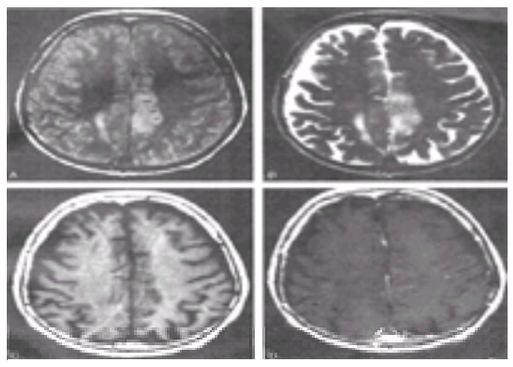

FIGURE 10-5 Acute cortical infarction. **A** and **B**, Proton-density and T2-weighted axial MRI scans show increased signal intensity within the medial cortex of left frontal and parietal lobes. Note swelling of gray matter and prominence of blood vessels within this lesion. **C** and **D** T1-weighted axial MRI scans before and after gadolinium administration demonstrate several linear foci of contrast enhancement within the area of infarction in the left frontal and parietal lobes, most consistent with enhancing arterial branches. Contrast enhancement of arterial branches is consistent with static blood flow within the infarct, and generally is seen only within the first few hours to 5 days after the onset of acute infarction. (Reprinted with permission from Rowland LP, editor: *Merritt's Textbook of Neurology*, ed 9. Williams & Wilkins, Baltimore, 1995.)

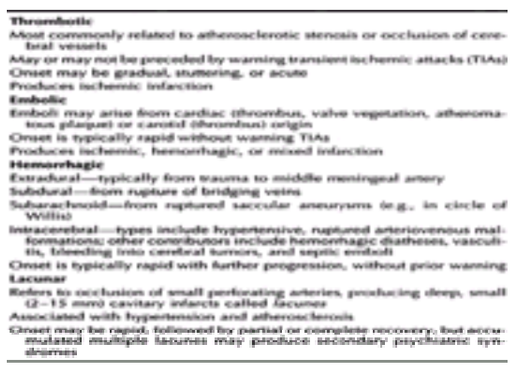
Cerebrovascular disease of any cause and pathophysiology—thrombotic, embolic, or hemorrhagic—will affect brain function. Psychiatric symptoms may develop

either suddenly (presumably in relation to abrupt neuronal losses and dysregulation) or gradually (perhaps in relation to cumulative infarcted brain tissue and to longer-term adaptations of neurochemical systems). Table 10-11 presents an overview of the variety of cerebrovascular events.



Thrombotic
Most commonly related to atherosclerotic stenosis or occlusion of cerebral vessels
May or may not be preceded by warning transient ischemic attacks (TIAs)
Onset may be gradual, stuttering, or acute
Produces ischemic infarction
Embolic
Emboli may arise from cardiac (thrombus, valve vegetation, atheromatous plaque) or carotid (thrombus) origin
Onset is typically rapid without warning TIAs
Produces ischemic, hemorrhagic, or mixed infarction
Hemorrhagic
Extradural—typically from trauma to middle meningeal artery
Subdural—from rupture of bridging veins
Subarachnoid—from ruptured saccular aneurysms (e.g., in circle of Willis)
Intracerebral—types include hypertensive, ruptured arteriovenous malformations; other contributors include hemorrhagic diatheses, vasculitis, bleeding into cerebral tumors, and septic emboli
Onset is typically rapid with further progression, without prior warning
Lacunar
Refers to occlusion of small perforating arteries, producing deep, small (2–15 mm) cavitary infarcts called *lacunes*
Associated with hypertension and atherosclerosis
Onset may be rapid, followed by partial or complete recovery, but accumulated multiple lacunes may produce secondary psychiatric syndromes

Table 10-11 Types of Cerebrovascular Events

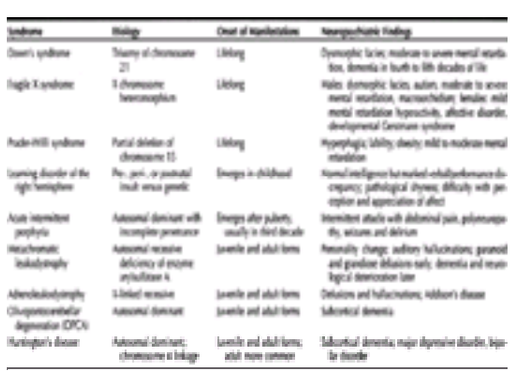
Recent data have undercut the long-held notion that vascular disease due to a vascular etiology always progresses in stair-step fashion, as has been described for the course of vascular dementia. Rather, progression appears to vary in rate and form, depending both on the type of vasculature affected (large versus small vessels) and on basic pathobiology (perfusion insufficiency versus occlusive disease).

It is important to recognize that psychiatric phenomena may manifest without other clinical evidence of a neurological event. For example, patients with right parietal infarction have presented with delirium but no other neurological symptoms or signs. Alternatively, an infarction in the distribution of the left middle cerebral artery may cause Wernicke's aphasia, characterized by fluent paraphasic or jargon-filled speech, poor comprehension and repetition, and suspicious or aggressive behavioral responses. No other signs of cerebral disease may be evident, and such patients have been misdiagnosed as having paranoid schizophrenia. It is also important to understand that pathology does not specify phenomenology. For example, patients with multiple infarcts on MRI are often labeled as having vascular dementia; however, multiple infarctions may manifest with dementia, with other behavioral syndromes (mood disorder, psychosis, anxiety, personality change), or with no definable neuropsychiatric syndrome.

Congenital and Hereditary Conditions Patients with congenital and hereditary conditions often present for psychiatric evaluation because of the frequency of associated behavioral disturbances.

> A 15-year-old boy was brought to the emergency room by his mother, who, clutching the on-call resident's arm, pleaded, “You've got to admit him; I just can't take it anymore.” The patient had been brought home from a special school by his mother 6 months previously. The mother showed the resident papers from the school that indicated that the patient's IQ was 45. He had had several placements, beginning at age 8. On visiting days, the boy always pleaded with his mother, “Mommy, take me home.” After a year or so away, the patient would be brought home by his mother, who had always been wracked by guilt because of his retardation and her inability to manage him in the home. The patient was an only child whose parents had been divorced for the past 4 years. The father had moved to another city.
>
> During the last 6 months at home, the patient had increasingly become a behavior problem. He was about 5'9" tall and weighed almost 200 pounds. He had become destructive of property at home—breaking dishes and a chair during angry tantrums—and, more recently, physically aggressive. He had hit his mother on the arm and shoulder during a recent scuffle that began when she tried to get him to stop banging a broom on the apartment floor. The mother showed her bruises to the resident and threatened to call the mayor's office if the hospital refused to admit her son.
>
> On examination, the boy was observed to have the typical signs of Down syndrome, including thick facial features, slightly protruding tongue, epicanthic fold of the eyelids, and simian crease of the palms of the hands. With indistinct and slurred speech, the boy insisted that he “didn't mean to hurt anybody.” (Reprinted with permission from *DSM-IV Casebook*.)

Congenital and hereditary conditions are of great significance in the understanding of brain-behavior relationships because they are often seen in biologically homogeneous populations with relatively specific behavioral and neuropsychiatric syndromes. Congenital conditions are caused either by genetic abnormalities affecting autosomes, sex chromosomes, or single genes or by fetal insults during the prenatal, perinatal, or immediate postnatal periods. Table 10-12 lists several developmental and hereditary disorders with significant neuropsychiatric manifestations. In DSM-IV these conditions are classified according to the age at which symptoms manifest, what symptoms are present, and whether the symptoms are progressive or static.



Syndrome	Etiology	Onset of Manifestations	Neuropsychiatric Findings
Down's syndrome	Trisomy of chromosome 21	Lifelong	Dysmorphic facies; moderate to severe mental retardation; dementia in fourth to fifth decades of life
Fragile X syndrome	X chromosome heteromorphism	Lifelong	Males: dysmorphic facies, autism, moderate to severe mental retardation, macroorchidism; females: mild mental retardation hyperactivity, affective disorder, developmental Gerstmann syndrome
Prader-Willi syndrome	Partial deletion of chromosome 15	Lifelong	Hyperphagia; lability; obesity; mild to moderate mental retardation
Learning disorder of the right hemisphere	Pre-, peri-, or postnatal insult versus genetic	Emerges in childhood	Normal intelligence but marked verbal/performance discrepancy; pathological shyness; difficulty with perception and appreciation of affect
Acute intermittent porphyria	Autosomal dominant with incomplete penetrance	Emerges after puberty, usually in third decade	Intermittent attacks with abdominal pain, polyneuropathy, seizures, and delirium
Metachromatic leukodystrophy	Autosomal recessive deficiency of enzyme arylsulfatase A	Juvenile and adult forms	Personality change; auditory hallucinations; paranoid and grandiose delusions early; dementia and neurological deterioration later
Adrenoleukodystrophy	X-linked recessive	Juvenile and adult forms	Delusions and hallucinations; Addison's disease
Olivopontocerebellar degeneration (OPCA)	Autosomal dominant	Juvenile and adult forms	Subcortical dementia
Huntington's disease	Autosomal dominant; chromosome 4 linkage	Juvenile and adult forms; adult more common	Subcortical dementia; major depressive disorder, bipolar disorder

Table 10-12 Examples of Developmental and Hereditary Disorders With Neuropsychiatric Manifestations

Down Syndrome Down syndrome results in static phenotypic abnormalities, including characteristic facies and mental retardation, and has been associated with a progressive decline in functioning beginning in the third or fourth decade of life. Alzheimerlike pathological changes are frequently detected at autopsy, even in patients who did not exhibit functional decline before death.

Fragile X Syndrome Fragile X syndrome is the second most common cause of mental retardation in men and one of the few known causes of the autism syndrome. Female heterozygotes also manifest significant psychiatric pathology, including mood disorders, difficulties with behavioral control, and a neuropsychological profile of dyscalculia, right-left disorientation, and constructional dyspraxia similar to the Gerstmann syndrome, described in patients with acquired lesions in the dominant parietal lobe. Learning disorders usually become obvious when the child begins school.

Huntington's Disease *Huntington's disease*, also known as *Huntington's chorea*, has been the focus of intensive neuropsychiatric, genetic, and pharmacological research since the 1970s. First described by George Huntington on Long Island in 1872, the disorder has received intense scrutiny, and its site on chromosome 4 has been determined. The disorder is related to an unstable trinucleotide repeat (CAG), associated with more than 36 copies of the specific sequence. Onset typically occurs in middle life, usually between ages 25 and 50 years. The juvenile form, with onset occurring during adolescence, is somewhat different phenomenologically, with a greater degree of dystonia early in the disease process and a faster rate of disease progression. A greater number of CAG trinucleotide repeats is associated with an earlier age of onset of clinical disease. Lower cognitive performance is detectable in those clinically asymptomatic at-risk individuals who have greater numbers of repeats. A greater number of repeats is associated with more severe neuronal loss in both caudate and putamen at postmortem examination, and perhaps a faster rate of pathological deterioration. Although the exact neurobiological role of the abnormal protein (*huntingtin*) encoded in Huntington's disease remains

unknown, other findings point to defects in mitochondrial energetics as a possible contributing mechanism.

Huntington's disease is not diagnosed formally until the typical movements appear, although both psychiatric and neuropsychological manifestations may precede the emergence of motor abnormalities. The psychopathology associated with Huntington's disease has a wide range of manifestations, commonly including affective presentations (typically depression, but mania as well); psychoses, often with a schizophrenic appearance; personality changes, and anxiety disorders. Some individuals, however, may proceed through the entire course of the illness with no evident psychopathology. Often the psychopathology is most florid during the early and middle stages of the disease, but as the characteristic subcortical dementia proceeds patients begin to exhibit less characteristic behavior and thus appear less symptomatic. The suicide rate is higher in patients with Huntington's disease than in the general population but suicidal ideation may be difficult to detect because patients tend to be less spontaneous and forthcoming as a result of the cognitive difficulties associated with the disorder. Interviewers must take an active or probing approach; patients who quickly pass off inquiries when presented with open-ended questions may provide more information when queried with specifically structured interview methods.

The cognitive disorder of Huntington's disease is more consistent in its presentation than the psychopathological picture, although it too evolves over the course of the disorder. Patients usually experience mild memory difficulties, and the first symptoms may be subtle problems with organizing, planning, and sequencing. Spontaneity and verbal elaboration may be diminished relatively early, although that appears to be somewhat more variable in its time of onset. As the disease progresses, psychomotor slowing progresses relatively rapidly, with concomitant difficulty with complex tasks, while recall of old knowledge and factual information remains less affected. Unlike patients with dementia of the Alzheimer's type, many patients with Huntington's disease remain insightful long into the course of their disease. Thus, their mood disturbances and potential suicidality may be tied in part to a clear realization of their situation. Indeed, even as patients respond to standard antidepressant therapy with enhanced sleep, energy, appetite, and improved overall mood state, they may remain realistically pessimistic about their long-term situation.

Patients with Huntington's disease begin to develop an apathetic appearance as the disease progresses. Early in the course, they continue to show interest and responsiveness when presented with structured situations in which they can take part; frank apathy and disinterest develop later and persist even in the context of prompted or structured assistance. Although some degree of verbal learning impairment is an early feature of the dementia, it is more prominent later in the disease course. Similarly, subtle visuospatial processing problems may occur early but do not become prominent clinically until later.

Just as the cognitive disturbance of Huntington's disease evolves slowly, so too there is a gradual change in the associated movement disorder. In most affected adults the movement disorder is typically choreiform at the outset but becomes more dystonic and bradykinetic as the disease progresses. Toward the end of the disease course, patients are bedridden, mute, and overcome by a severe dystonic state.

The pathology and neurobiology of Huntington's disease have been studied intensively in recent years (Fig. 10-6). The striatum bears the brunt of the pathology, with interruption of crucial corticostriatothalamocortical relays. Although there are no immediate, reciprocal corticostriatal connections, that multineuronal pathway similarly modulates motor function, cognition, and perhaps mood. Recent theories suggest abnormal function of excitatory neurotransmitters, most apparently acting on glutamate receptors, that serve as endogenous neurotoxins. Although efforts have been made to use symptomatic pharmacological treatments for both the psychiatric and motor symptoms, more recent pharmacotherapeutic trials have aimed at preventing progression of the disease by employing potential glutamate receptor blockers. Such efforts have provided models for similar therapeutic approaches to Parkinson's disease and Alzheimer's disease.

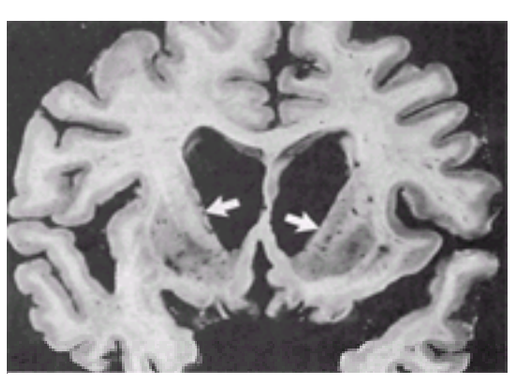


FIGURE 10-6 Huntington's chorea. There is marked atrophy of the caudate nuclei (arrows) and mild dilatation of the lateral ventricles. (Reprinted with permission from Golden A, Powell DE, Jennings CD: *Pathology: Understanding Human Disease*, ed 2. Williams & Wilkins, Baltimore, 1985.)

The mood disorders associated with Huntington's disease have proved amenable to symptomatic treatments. Standard doses of antidepressant medications may be needed, although patients often respond sensitively to rapid changes in medication and experience unwanted adverse effects. ECT has been beneficial for severe major depressive symptoms, especially in high-risk suicidal patients. The schizophrenia-like presentations of Huntington's disease appear less responsive to antipsychotic therapy than phenomenologically similar idiopathic disturbances. Patients with Huntington's–disease–related anxiety disorders have shown sufficient benefit from available medication regimens to warrant empirical trials. Psychotherapy, usually with the patient and family treated together, may lead to substantial therapeutic gains. Clinician commitment to the long haul may prove especially reassuring and stabilizing.

Like other hereditary neuropsychiatric disorders, Huntington's disease illustrates the need for all psychiatric evaluations to include a careful documentation of family history. Patients with Huntington's disease may present with mood or psychotic disturbances and no apparent abnormal involuntary movements and may be treated symptomatically with pharmacotherapeutic agents, only to evince the characteristic motor disorder later. Ignorance of the family history has led some to misinterpret that progression as evidence of tardive dyskinesia. The patient may remain incorrectly diagnosed until cognitive impairment becomes unmistakable. In the meantime, patients and families have lost the opportunity to clarify their life plans and develop support for future needs. Psychiatrists must remain vigilant in taking the family history whenever evaluating a new patient.

Other Conditions Learning disorders involving left hemisphere functions such as reading, writing, or mathematics are well known clinically. A learning disorder of the right hemisphere has been described that is characterized by intact linguistic and academic skills; left-sided soft (nonlocalizing) neurological signs; and profound impairments in functions dependent on the right hemisphere, including visuospatial skills, modulation of affect, and the paralinguistic aspects of communication. The etiology of the learning disorder is unknown, although a retrospective history of prenatal or perinatal insults is common, as is a family history of similar impairments. Acute intermittent porphyria is a hereditary disorder that is intermittent. In between episodic attacks, most patients maintain normal development. The leukodystrophies and degenerative hereditary disorders listed in Table 10-12 can produce symptoms during childhood or not until adulthood. Development until the appearance of symptoms is normal. However, in each of these disorders psychiatric symptomatology can precede other evidence of the disease process and lead to an erroneous diagnosis of an idiopathic psychiatric disorder.

Physiological Disorders—Epilepsy Epilepsy is the prototype of a physiological disease process that manifests psychiatric symptoms. It has long held the interest of neuropsychiatry and has been studied intensively, if not always fruitfully. The complexities of defining brain-behavior relationships in epilepsy merit extended discussion.

Definition Epilepsy is defined as a condition of recurrent seizures due to CNS disease or dysfunction. Seizures are behavioral alterations of abrupt onset and termination that are associated with sudden electrical discharges of the brain. Although the essential paroxysmal form remains constant and in fact defines a seizure, the content of the behavioral disturbance can vary widely. Seizures can be generally classified into two broad categories, generalized and focal. In generalized seizures the electrical abnormality usually originates from subcortical structures (primarily the brainstem) and then spreads simultaneously to all areas of the cortex. Loss of consciousness is invariable, and the seizure phenomenology is symmetrical and bilateral. Focal seizures originate from a specific brain locality, usually the temporal lobe. The abnormal electrical discharge may remain at the site of origin, proceed gradually to adjacent areas, or spread to include the entire cortex (secondary generalization). The clinical phenomenology of a focal seizure depends on the site from which that seizure originates and may be unilateral and restricted to a particular muscle group, sensation, affect, and so on. The epilepsies are classified based on the type of seizure and the inferred anatomical substrate (Table 10-13). Seizure type and phenomenology are usually constant within the course of a particular patient's disorder. The stereotyped presentation is a major feature of

evaluation, diagnosis, and assessment of treatment efficacy.

Primary generalized epilepsy
Tonic-clonic (grand mal)
Absence (petit mal)
Myoclonic
Other
Partial (focal) epilepsy
Simple (elementary) symptomatology
Focal motor
Focal sensory
Vegetative
Mixed
Complex symptomatology
Partial complex (psychomotor)
Secondary generalized
Unclassifiable

Table 10-13 Classification of the Epilepsies

Clinical Features Seizures can proceed in stages and may include a prodrome, aura, ictus, and a postictal period. Psychopathology may manifest during any of these stages as well as during the interictal (between-seizure) period (Fig. 10-7). A prodrome can be seen in generalized epilepsy, although it is more common in focal epilepsy, particularly temporal lobe epilepsy. A prodrome may consist of irritability, apprehension, sullenness, or a sense of discomfort or disease that builds up gradually over hours to days before a seizure. The prodromal state remits abruptly with the onset of the seizure. The pathophysiological basis for the prodromal state is unknown.

FIGURE 10-7 Progression of phases in epileptic seizure disorders.

Auras are focal seizures or the initial focal onset of a seizure and are associated with definable abnormal electrical discharges. Auras are abrupt in onset, last for seconds to minutes, may progress to a generalized seizure, or may terminate as the seizure ends. The type of clinical phenomenon depends on the site of origin and can include motor, sensory, autonomic, perceptual, cognitive, and affective abnormalities. Table 10-14 lists a number of common clinical manifestations of auras or focal seizures based on the anatomical site of origin. The auras accompanying seizures originating in the temporal lobe are the most varied. In general, auras may comprise a variety of symptoms and may have unique, individual-specific features, such as the crying out of a particular phrase in a particular language. Despite the great variety of auras, in any individual auras tend to be stereotyped and consistent from seizure to seizure.

Sensory	Cognitive
Headache	Transient dysphasia
Focal pain	Speech automatisms
Paresthesia	Subjective confusion
Motor	Obsessional thinking
Nystagmus	Thought blocking
Head turning	Distortion of time sense
Scanning	Affective
Posturing	Fear
Stuttering	Anxiety
Autonomic	Sadness
Facial flushing	Embarrassment
Hot flashes	Placidity
Pallor	Guilt
Dizziness	Anger
Chest pain	Joy
Tinnitus	Elation
Perceptual	Other
Micropsia, macropsia	Genital sensations
Heightened auditory acuity	Sexual behaviors
Derealization, depersonalization	
Déjà vu, jamais vu	
Hallucinations (visual, auditory, olfactory, gustatory, and tactile)	

Table 10-14 Neuropsychiatric Manifestations (in the Aura and Ictus) of Focal Epilepsy

The *ictus*, the epileptic attack, may be generalized or focal. *Primary generalized tonic-clonic epilepsy (grand mal epilepsy)* is characterized by a behavioral arrest or sudden loss of consciousness. This is followed by tonic extension of the upper and lower extremities, then clonic, rhythmic jerking of the extremities. The jerking gradually decreases in frequency, leading to muscle flaccidity. The total duration of the ictus is usually 2 to 5 minutes. Associated features may include urinary and bowel incontinence, sweating, and tachycardia. Generalized absence or petit mal epilepsy is characterized by brief lapses of consciousness lasting 3 to 30 seconds. There are no associated tonic-clonic movements, nor is there loss of postural tone. There may be a slight rhythmical twitching of the mouth. Seizures can occur numerous times during the day. Absence seizures are common and occur primarily in children ages 4 to 12 years. In both types of generalized epilepsies there is amnesia for the epileptic event. Myoclonic epilepsy is characterized by nonrhythmic, brief jerks of the limbs, trunk, and head. Myoclonic jerks are asynchronous, with body parts jerking at different times and in different sequences, and there is no loss of consciousness. Myoclonic epilepsy is frequently of familial etiology, although it may be associated with brain injury or systemic disease that affects brain function, such as chronic renal disease or hepatic insufficiency.

Partial or focal seizures are distinguished by their localized site of origin. The symptomatology can be simple (elementary) or complex, with the latter characterized by some degree of impairment of consciousness. Partial seizures with elementary symptomatology include focal motor symptoms, focal sensory symptoms, autonomic symptoms, or mixed symptomatology; consciousness is retained throughout the episode, although the seizure discharges can spread to other areas of the brain (jacksonian march) and can also develop into a generalized seizure (secondary generalization). The postictal period may be characterized by a residual focal deficit, such as motor weakness (Todd's paralysis) or dysphasia. Secondary generalization may occur rapidly, giving the false impression of an immediate generalized seizure; videotaped monitoring with simultaneous EEG may be necessary for differentiation.

Partial complex seizures, also known as psychomotor seizures, temporal lobe seizures, or temporal-limbic seizures, are perhaps of greatest interest to psychiatry. The great majority of partial complex seizures originate in the temporal lobes, but the frontal lobes and other sites have also been recorded as seizure foci. The range of presenting symptomatology varies from patient to patient and may include a broad spectrum of disturbances in behavior, cognition, and affect. Auras are frequent in partial complex seizures, representing the focal onset, and it may be difficult to distinguish the aura from the ictus. They are generally associated with clouding of consciousness but retention of posture and muscle tone. The patient may exhibit simple or complex movements, such as pulling on clothing, buttoning or unbuttoning clothing, purposeless hand movements, and fumbling with objects, or may continue with the behavior initiated prior to the seizure, such as closing a window. There may be staring, lip smacking, and wandering. The actual ictus cannot be distinguished from the aura.

Psychiatrists should be familiar with the range of symptomatology associated with partial complex or temporal lobe epilepsy because that disorder is an important diagnostic consideration in adult patients presenting with the new onset of behavioral disturbances. In light of the protean possible manifestations of partial complex epilepsy, the physician must keep in mind that there is a general consistency to the form of partial complex seizures: They have a definite and observable onset and termination; they are always associated with impairment in consciousness, such as confusion or inability to perform cognitive tasks; and they are relatively stereotyped for an individual from episode to episode.

The postictal period may also be characterized by severe disturbances of behavior. Primary generalized tonic-clonic seizures are usually followed by a period of sleep, sometimes headache, and nausea. Focal or partial seizures may have residual focal deficits of varying duration. In partial complex seizures, recovery of consciousness may lag behind recovery of motor function. Frequently automatic behavior, such as repetitive mouth movements, arm movements, and pacing, can be observed. As the postictal period is essentially a delirious state, confusion and cognitive impairment remain. Any disturbance of mood is possible, including anger, lovingness, and the epileptic furor (random, typically nondirected displays of violence and property destruction). The postictal period usually lasts only minutes, although it may last hours to days. A very rare but disturbing psychiatric postictal complication has been termed subacute postictal aggression. This is associated with directed violence that occurs in well-documented cases of epilepsy, where a patient stereotypically becomes increasingly psychotic, paranoid, and combative following a bout of uncontrolled seizures. Treatment requires both anticonvulsant and antipsychotic medications, although reported cases have occurred in patients who have poorly controlled epilepsy.

Course Epilepsy has an annual incidence of approximately 20 to 50 new cases per 100,000 population. The prevalence is 0.2 to 1.0 percent. The majority of cases of epilepsy in patients older than 15 years are of the partial or focal type. Only approximately 25 percent of adolescents or adults over the age of 15 years with seizures have generalized epilepsy. Seizures with onset in childhood are more commonly generalized, particularly absence seizures. Primary generalized tonic-clonic seizures usually occur for the first time before the age of 35 years, although they can occur at any age; absence seizures usually first manifest between the ages of 4 and 12 years. Focal seizures also have their onset commonly before the age of 20 years.

The natural history of seizure disorders has not been defined clearly. Up to one third of all seizures may remit spontaneously without treatment. Absence seizures are generally outgrown by the age of 20 years, although many patients do develop another form of generalized epilepsy as adults.

The etiological considerations for seizures vary with the age at onset. Early-onset epilepsy is usually a concomitant of genetic factors or an insult to the developing neural system in utero or in childhood; the latter can include trauma, infections, or toxic exposures. For seizures starting in adulthood, the etiological considerations include alcohol or drug withdrawal, trauma, infection, and tumors. The tumors are the primary causes of seizure disorders during the middle adult years; cerebrovascular disease is the most common etiology among the elderly.

Treatment Anticonvulsant pharmacotherapy first developed empirically, without specific knowledge of either the pathophysiology of seizures or the neurochemical mechanisms of therapeutic agents. Although the primary prescribed anticonvulsants (carbamazepine [Tegretol], phenytoin [Dilantin], valproic acid [Depakene], and phenobarbital) have remained consistent since the 1980s, recent years have seen the rapid emergence of new compounds (Table 10-15). Most medications work through one of three mechanisms of action: potentiation of g-aminobutyric acid (GABA)-mediated neuronal inhibition, inhibition of glutamate-mediated excitatory postsynaptic receptors, or control of sodium and calcium voltage-gated ion channels; Table 10-16 summarizes these actions. It is particularly important to note that anticonvulsant medications have proven to be a fruitful source of novel psychiatric compounds.

Conventional Drugs	
Phenobarbital	1912
Phenytoin	1938
Trimethadione	1946
Phensuximide	1953
Methsuximide	1957

Table 10-16 Antiepileptic Drugs

Psychopathology Psychopathology, namely disturbances in behavior, cognition, perception, or mood, can occur at any point in the seizure process. The prodrome may be characterized by a sense of irritability or apprehension. Families often report that they know when a relative is going to have a seizure on the basis of a change in temperament or disposition. Auras may include a variety of psychopathology, including dissociative experiences, hallucinations in all spheres, derealization, depersonalization, and disturbances of mood or affect. The disturbances of mood, such as a subjective sense of fear, anxiety, or depression, can be distinguished from normal expressions of the same emotion in that generally they are more crude, stereotyped, and brief emotional states. Joy, elation, or euphoria is less common. Ictal states can manifest striking changes in behavior that are likely to be coarse and disorganized. The list of ictal manifestations in Table 10-14 includes a variety of hallucinations and dissociative experiences, as well as sudden and unpredictable shifts in mood. Other sensory or psychic experiences can occur out of their usual context (a classic case is that of a woman who had spontaneous orgasms in church). The postictal state is a delirium that can display the full range of disturbances in level of arousal, ranging from stupor to hypervigilance. Partial seizures may be followed by a milder delirium that is detectable only from disorganization in behavior or difficulty with simple cognitive tasks such as registration and repetition. The issue of interictal psychopathology has been much studied and debated, in general, the psychiatric symptomatology associated with the prodrome, aura, ictus, and postictal state is remarkably broad—virtually any thought, feeling, movement, or perception that the brain can produce may be seen. The clinician must be attentive to the form and course of these symptoms whenever considering epilepsy as a possible etiological explanation for abnormal behavior.

Violence and Aggression The issue of violence or aggression as a neuropsychiatric manifestation of an ictus has provoked much controversy. In the legal arena epilepsy is occasionally invoked as a defense to mitigate culpability for a violent or even murderous act. Irritability or agitation can be a component of the prodrome, the aura and ictus can encompass angry affect and striking out, and the postictal state can manifest with fear and confusion with intact motor function. Although this might suggest the possibility of violent acts as a component of seizures, there is limited potential for such actions. Automatic acts of violence during epileptic seizures are short-lived, fragmentary, undirected, and most often occur in response to actions (such as attempts at restraint) that provoke or irritate the seizing individual. Examples include spitting, swearing, and striking out in a flailing fashion. For violence to be considered a manifestation of epilepsy, it must conform to the known

temporal sequence and symptomatology of a seizure; namely, there must be a clear onset and termination, together with other clinical signs (e.g., confusion, incontinence, and impairment of consciousness) and stereotypy. A special 1981 epilepsy task force of the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS), after studying videotapes of selected violent patients with epilepsy, recommended criteria to determine if a particular act of violence is ictal: (1) a clear diagnosis of epilepsy; (2) documented automatisms, preferably on videotape; (3) documented aggression during the automatisms that corresponds to an EEG-proved ictus; (4) demonstration that the aggressive act is characteristic of the patient's usual seizure form; and (5) clinical consensus that the act was related to the actual seizure.

People with epilepsy have long been thought to display psychopathology during the interictal period as well. Epilepsy was thought to be a subtype or complication of insanity, and so was included in most psychiatric nosologies of the past two centuries. Epilepsy patients typically were housed in asylums for the insane. In 1791 Philippe Pinel included among his recommendations for asylums the suggestion that other patients be shielded from epilepsy patients because of their “almost always incurable” status and his sense that “few objects are found to inspire so much horror and repugnance . . . than the sight of epileptic fits.” Griesinger stated that “a very great number of epileptics are in a state of chronic mental disease even during the intervals between the attacks.” Interictal psychopathology can be grouped into psychotic disorders, mood disorders, personality abnormalities, cognitive disorders, and secondary repercussions.

Psychotic Disorders Jean Etienne Esquirol, in his 1845 description of female institutionalized epilepsy patients, reported frequent psychotic symptoms, including hallucinations in all spheres:

> They have hallucinations most varied . . . they think they see luminous bodies by which they fear they might be embraced . . . they smell odors the most fetid . . . they hear sounds like the bursting of a thunderbolt, the roll of drums, the clash of arms in the din of combat. Karl Jaspers, in *General Psychopathology*, classified epilepsy as one of the three major psychoses, along with schizophrenia and manic-depressive illness. He defined *genuine epilepsy* as “convulsive disorders which are not due to any known somatic process.” Numerous studies have evaluated psychosis among epilepsy patients; unfortunately, most have been hampered by the lack of clear or standardized definitions for the symptoms being investigated. In addition, many studies have not distinguished between psychosis occurring in the context of the ictus, the prodrome, or the postictal state, and many have not indicated whether such symptoms were detected specifically during periods of interictal electrical stability. Few studies have discriminated between symptoms occurring in clear consciousness versus those occurring coincident with impaired consciousness. Nonetheless, clinicians generally encounter a higher incidence of psychosis among epilepsy patients, particularly those with temporal lobe foci, than in the general population. Some studies have specifically referred to paranoid ideation, delusions, ideas of reference, visual hallucinations, and first-rank auditory hallucinations as being common. In 1963 Eliot Slater and A.W. Beard identified an atypical schizophrenia, characterized by visual and auditory hallucinations, ideas of reference, and persecutory delusions, occurring in the context of preservation of affect and a level of social adaptation better than that of comparably psychotic schizophrenia patients. They further noted that the psychotic symptoms did not occur until many years after the onset of seizures (a mean of 14 years) and then occurred with an apparent periodicity. The occurrence of the psychotic episodes was unrelated both to the frequency of seizures and to measured anticonvulsant efficacy.

Although the true incidence or prevalence of psychotic disorders in epilepsy patients is unknown, there is general consensus that the psychotic disorder seen in epilepsy is distinct in form from idiopathic psychiatric diseases and is characterized by the features described by Slater and Beard. Other associated findings may include an association between psychosis and left hemispheric seizure focus (especially in the temporal lobe), female sex, sinistrality, or tissue abnormality (alien tissue, such as hamartomas or focal dysplasia, is more commonly found at autopsy or after surgical excision in the psychotic patients). These psychotic disturbances have been referred to as the schizophrenia-like psychosis of epilepsy and the interictal psychosis of epilepsy. Standard antipsychotic medications are beneficial symptomatically but not as efficacious as in idiopathic psychotic disorders. Some studies have noted marked improvement in the psychotic symptoms with improved seizure control following either pharmacotherapy or surgical excision of the seizure focus. A smaller number of studies have reported an increase in psychotic symptoms occurring with improved seizure control, prompting a theory of antagonism between symptoms of psychosis and seizure control.

The observation of a consistent psychotic disorder of increased prevalence in epilepsy patients has led to an intense search for the underlying mechanism in the hope of describing a more general explanation for psychotic processes. Three hypothetical mechanisms for interictal psychoses have been advanced. The first hypothesis suggests that the schizophrenia-like illness in epilepsy is epileptic in origin or related to abnormal electrical brain discharges. Kindling, an experimental animal model for the spread of epileptic foci, has been suggested as a paradigm for the development of psychosis in epilepsy. Chronic stimulation of the brain in animals can lower the electrical threshold for the development of electrical or clinical seizures. Over time, abnormal discharges develop at previously subthreshold levels of stimulation or even spontaneously. Abnormal behaviors associated with these experimentally induced brain discharges can also persist, even after stimulation has ceased and there are no motoric convulsions. It has been suggested that human kindling occurs at various brain foci, particularly the temporolimbic structures, resulting in psychotic and behavioral disturbances that may manifest only after years of seizure activity.

A second hypothesis for the development of interictal psychosis focuses on a proposed antagonistic relationship between seizure frequency (or, more accurately, EEG abnormality) and psychotic symptoms: forced normalization is the putative process by which a psychosis of sudden onset can manifest with the achievement of seizure control and associated with a normal cortical EEG. Studies of forced normalization have primarily involved case reports, and findings have been difficult to replicate. Clinical treatment regimens based on the antagonism theory, such as allowing episodic seizures or performing ECT on psychotic epilepsy patients, have proved ineffective, further weakening that proposal.

A third hypothesis to explain interictal psychosis suggests that it may not be related specifically to abnormal electrical activity but may instead reflect a common brain dysfunction that causes both epilepsy and psychosis. This hypothesis stresses the dysfunctional or broken brain inferred in epilepsy and regards the psychotic disorder as yet another symptomatic manifestation. Recent quantitative brain-imaging studies in epilepsy patients with psychotic disorders have not revealed consistent structural abnormalities within that patient group. However, specific symptom correlations have been reported, among them an increased frequency of temporal lobe structural abnormalities in epilepsy patients with auditory hallucinations. Similar findings associating specific psychotic symptoms with defined cerebral abnormalities have also been reported in other psychiatric conditions (e.g., schizophrenia). Further symptom-based research utilizing imaging and physiologically sensitive techniques may better delineate the brain regions where dysfunction can lead to particular psychotic symptoms.

Mood Disorders Affective changes can occur as part of the seizure prodrome, aura, ictus, or postictal state. Irritability is a common prodromal manifestation. Temporal lobe auras may be accompanied by mood abnormalities, most commonly fear and anxiety, although a depressive affect is possible and, more rarely, elation or euphoria. Descriptions of postictal sadness are common. All of those affective changes are generally brief, lasting minutes to hours. They differ from normally experienced vacillations in mood, in that they occur independent of any particular context, and from the pervasive and enduring affective changes found in primary mood disorders.

Mood disorders in the interictal period have not been studied as comprehensively as psychotic or personality disorders. Many authors have noted that epilepsy patients have a strong tendency to endorse items of sadness and anxiety on self-report inventories. Few studies have used clinical examinations or standardized interviews to determine the presence of mood disorders such as major depressive disorder or bipolar I disorder. One study of epilepsy patients diagnosed with major depressive disorder found that at least half of the patients had family histories of mood disorder and that no clear relation existed between severity of depression and seizure type, seizure frequency, seizure focus, or age at seizure onset. Although definitive studies of the incidence and prevalence of clinically defined mood disorders in epilepsy are needed, there is less support overall (compared with psychosis) for an elevated prevalence of mood disorders in epilepsy patient populations. Many patients do express persisting dysphoria, perhaps reflecting the dissatisfaction and maladjustment associated with a chronic disease.

Regardless of the cause of the dysphoria or dissatisfaction in epilepsy patients, there is an increased prevalence of suicide attempts and completed suicides. The incidence of suicide in patients with epilepsy is fivefold greater than in the general population. In patients with temporal lobe epilepsy the incidence of suicide increases to 25 times that of the general population, but the underlying psychopathology remains to be defined.

Personality Change There has been a long-standing misperception that an epileptic personality is distinguishable and common. Esquirol noted in his studies of 385 female epilepsy patients that “only one fifth were free from intellectual derangement, but nearly all of these were irritable, peculiar, and easily enraged.” Griesinger commented on the “dominant, suspicious, discontented, misanthropic perversion of sentiment . . . observed in many epileptics.” Eugen Bleuler spoke of the “epileptic excess of emotion . . . easily aroused, remarkably persistent . . . difficulty in abandoning any particular thought . . . fixation to a single theme . . . precise attention to detail.” Karl Jaspers described “viscosity, slowing down, explosiveness and dementia” as characteristic of epilepsy patients. These characterizations were frequently based on chronically institutionalized patient populations representing a selection of the most severely impaired patients, in whom the effects of brain injury (especially related to repeated seizures, status epilepticus, and recurrent hypoxia), the deprivations of institutionalization, and toxic treatments undoubtedly confounded clinical observation. More recent attempts at detecting a recognizable, diagnosable personality disorder in community samples of epilepsy patients resulted neither in the description of a discrete personality syndrome nor in a higher prevalence of known personality disorders.

Because standard personality inventories have not uncovered specific abnormalities in epilepsy patients some researchers have focused on particular traits or behaviors. An interictal behavior syndrome of temporal lobe epilepsy has been described that encompasses four traits or behaviors: (1) altered sexuality, usually a decreased interest in sexual matters but at times involving hypersexuality or deviant sexual interests; (2) hyperreligiosity, described as an unusually deepened interest in moral affairs and matters of global importance, with vivid case descriptions of multiple religious conversions and intrusive polemicizing; (3) hypergraphia, with patients maintaining voluminous writings, including journals, essays, and novels; and (4) viscosity or stickiness, a characteristic described for more than a century, including a preoccupation with detail, digressive or overly inclusive speech, and resulting impairments in social discourse.

Although the literature supporting such a personality syndrome is rich with clinical case histories, systematic study to define such a syndrome has been difficult to replicate. Investigators using an 18-point inventory of those behaviors found they could not distinguish patients with epilepsy from other psychiatric populations or patients with temporal lobe epilepsy from those with generalized epilepsy. Thus, the bulk of data suggests that the clinical complex of overinclusiveness in speech, interpersonal action, and writing; alteration of sexuality; and intensified emotion and cognition (hypercosmiscity) is rare and not specific for temporal lobe epilepsy. However, isolated features of this cluster may be more common among patients with temporal lobe epilepsy. When the entire picture is encountered clinically in the absence of a readily apparent seizure disorder, the clinician may wish to pursue a more intensive evaluation if the patient fails to respond to standard psychiatric therapies.

Cognitive Disorders An early view of epilepsy considered it a degenerative disorder with a progressive deterioration in cognition, similar to that seen in the degenerative dementias. Modern prospective studies, however, have disproved this belief and have demonstrated no progressive decline in cognitive skills in a general population of epilepsy patients. A subpopulation of patients with epilepsy does demonstrate a lower intelligence quotient (I.Q.) spread than the normal distribution. This probably results from a combination of factors, including the original brain damage or dysfunction responsible for the epilepsy, occasional disruption attributable to the seizure disorder, and drug effects. Numerous anticonvulsants, including ethosuximide (Zarontin), phenytoin, phenobarbital (Solfoton), and carbamazepine, have been demonstrated to lower performance on tasks of concentration, memory, and motor speed; motor speed is least impaired.) Epileptic dementia, while certainly uncommon, has been described in patients with defined CNS lesions or uncontrolled seizures. It probably reflects the cumulative effect of frequent seizure-induced hypoxic episodes and perhaps toxicity from long-standing treatment with high dosages of anticonvulsants. Phenytoin, in particular, has been demonstrated to cause cerebellar degeneration with long-term use.

Behavioral and Secondary Repercussions Despite a less glamorous research appeal, the more compelling and clinically demanding aspects of interictal function may be the behavioral, interpersonal, and social problems arising from irritability, agitation, or aggression. There are no well-defined, systematic, or tested approaches to treating those behavioral difficulties when they arise. It was long believed that maladaptive behavior, particularly aggressive behavior, as characterized by physical assaultiveness, destructiveness, and self-injury, was more common in patients with epilepsy. Recent methodologically rigorous studies, however, demonstrated that maladaptive behavior does not correlate with the presence of epilepsy when epilepsy populations are compared with appropriately matched controls. Maladaptive behavior is, however, related to the overall extent of brain damage in both types of populations. This important point cannot be overemphasized: Epilepsy is a florid manifestation of a physiologically abnormal brain, and in most instances, the fundamental CNS dysfunction that causes seizures also causes associated neuropsychiatric abnormalities.

Especially among severely afflicted epilepsy patients, obstacles to effective social functioning and personal autonomy pose the greatest therapeutic challenges for clinicians and families. Patients may not receive adequate education because seizures may interfere with daily school attendance. Patients may be restricted from many occupations owing to employers' fears of patients sustaining injury in the workplace. Limitations on driving can markedly diminish the independent functioning of these individuals and many patients are compelled to remain dependent on family, even into adulthood.

Pseudoseizures Pseudoseizures simulate the motor behavior of true seizures but do not involve abnormal electrical discharges. Pseudoseizures can be distinguished from true seizures by the form of the seizure and by the lack of the usual associated features. The form does not fit the known patterns for epileptic attacks and can consist of random flailing about. Furthermore, the form can be variable from seizure to seizure, lacking the stereotypy typical of true seizures. Incontinence and tongue biting are rare. There is minimal confusion at the conclusion of the episode, and no abnormalities are detected on neurological examination. EEG can be helpful in distinguishing pseudoseizures, especially if one can be obtained during an event and then studied for evidence of electrical discharges that would correspond with the motor behavior. An EEG obtained after a true seizure should demonstrate areas of slowing that would not be seen after a pseudoseizure. Serum prolactin levels increase markedly immediately after a seizure and can be helpful in distinguishing true seizures from pseudoseizures. Video EEG telemetry is the definitive means of determining whether an observed seizure is epileptic in origin or a pseudoseizure.

Pseudoseizures are more likely in patients who suppress emotion or express emotion through somatic means. Pseudoseizures most often are conversion disorders in which the patient does not have conscious volitional control of the behavior; rarely are pseudoseizures the result of faking or malingering. Pseudoseizures frequently occur in patients who have true epileptic disorders, confounding the diagnosis. W. Alwyn Lishman has aptly noted that the diagnostic error of interpreting epilepsy as pseudoseizures is probably much more common than the reverse and is far more detrimental to the patient's well-being. The diagnosis of pseudoseizures rests not on the presence of any particular personality traits or identifiable psychosocial stressors, but rather on the form of the seizure, associated features, and EEG confirmation.

Primary Psychiatric Disorders The presence of intellectual deficits, whether identified with bedside procedures or on standardized neuropsychological tests, does not automatically warrant the diagnosis of a cognitive impairment disorder. Neuropsychological abnormalities occur frequently in many patient populations. Once neglected or considered epiphenomena of more central emotional disturbances, cognitive processing deficits are now known to be key components of clinical disorders such as major depressive disorder (especially in the elderly), acute and chronic schizophrenia, chronic alcohol dependence, and perhaps obsessive-compulsive disorder. Cognitive impairment disorders, such as dementia or delirium, or secondary psychiatric syndromes are all caused by specific disease processes; vigilant diagnostic evaluation usually leads to detection of a primary systemic or cerebral disturbance.

Difficulties may arise when the cause is presumed but cannot be proved, as in the case of dementia of the Alzheimer's type, where the definite diagnosis must await postmortem brain examination. When a patient has both a major depressive syndrome and clinical findings consistent with incipient dementia of the Alzheimer's type, it may not be possible to determine immediately the fundamental disturbance being evaluated. Such confusing situations typically arise with the near-simultaneous onset of both symptom clusters or in patients who have experienced major depressive disorder previously. Such patients require careful definition of symptoms, initiation of therapy for all potentially treatable conditions, and serial monitoring of the patient's responses. Documentation of the longer-term course also assists in disentangling and recognizing separately contributing disease processes.

Despite careful observation and follow-up evaluation, the clinician may remain uncertain whether a syndrome is idiopathic or secondary to other detected diseases. In such instances, it is preferable to diagnose a primary psychiatric condition on Axis I, define all systemic or cerebral conditions on Axis III, and thereafter maintain a high order of vigilance while monitoring the course of the disorder longitudinally. It is important to note questions or uncertainties in the medical record for later scrutiny, for that practice avoids premature diagnostic closure.

Clinicians must also guard against willingness to provide a psychiatric diagnosis when specialists from other medical disciplines have ruled out specific disease processes after laboratory tests have been unrevealing. The failure to define an organic disease does not warrant a functional diagnosis by default. As emphasized in DSM-IV, specific clinical signs, symptoms, and course are needed to establish the presence of a primary psychiatric disorder.

Metabolic Disorders Because most systemic medical conditions can directly or indirectly affect brain function, any list of illnesses that may cause a secondary psychiatric syndrome or cognitive disorder must be incomplete. Table 10-17 lists some frequently described potential causes. The precise pathophysiological mechanisms by which the disease process alters brain function are poorly understood in most cases. More than one process may be involved. For example, a patient with acute myelogenous leukemia may have altered brain function resulting from the neoplastic process itself, anemia (with decreased oxygen delivery to the brain), brain hemorrhages (caused by thrombocytopenia), and infections.

Endocrine	
	Hypothyroidism or hyperthyroidism
	Hypoparathyroidism or hyperparathyroidism
	Sex hormones—too little, too much, or cycle-related
	Hypocorticolemia or hypercorticolemia
	Pheochromocytoma
	Diabetes mellitus
	Carcinoid syndrome
Pulmonary	
	Hypoxemia
	Hypercarbia
	Infections (pneumonia, bronchiectasis, abscess)
	Restrictive lung disease
	Obstructive lung disease
	Tumors
Hematologic	
	Anemia
	Polycythemia
	Neoplasms
Hepatic	
	Liver failure due to any etiology
Renal	
	Renal failure due to any etiology
	Infections
	Neoplasms
Nutrition	
	Marasmus
	Kwashiorkor
	Vitamin deficiencies (thiamine, niacin, B_{12}, folate)
	Dehydration
Miscellaneous	
	Hyperelectrolyte and hypoelectrolyte disturbances (especially so- dium, potassium, phosphate, calcium, magnesium)
	Hypoglycemia and hyperglycemia
	Acidemia
	Alkalemia
	Porphyria

Table 10-17 Metabolic and Other Systemic Disturbances

Secondary psychiatric syndromes may be the first, most prominent, or only clinical phenomena to call attention to the underlying condition (e.g., depression due to occult pancreatic carcinoma and cognitive deficits due to vitamin B_{12} deficiency even in the absence of other neurological or hematological signs). Secondary behavioral changes may also result from multiple etiologies, of which any one alone might or might not be sufficient to produce the psychiatric disturbance (e.g., delirium due to mild anemia, mild hyponatremia, and marginal hypoxemia). The rate of change may also be important with certain etiologies. For example, a sudden drop in serum sodium to 125 mEq/L is more likely to produce behavioral changes than a chronic hyponatremia of 125 mEq/L.

Etiologies particularly identified with specific psychiatric syndromes are discussed under each syndrome. However, most etiologies can produce more than one syndrome (e.g., hypothyroidism is most often associated with a depressive state but may also cause mania, delirium, or dementia). How a specific etiological factor causes varied behavioral changes presumably results from both trait-dependent and state-dependent brain diatheses that largely are not understood.

Demyelinating Disorders With regard to secondary psychiatric syndromes, multiple sclerosis is the most important demyelinating disorder. Although it may cause delirium, dementia, and nonaffective psychoses, mood disturbances have been described frequently. Isolated, persistent euphoria has long been noted and is thought to be physiologically related to demyelinated lesions in the limbic system, frontal lobes, and basal ganglia (Fig. 10-8). *Emotional incontinence*, also termed *pathological laughing or weeping*, is a state of labile affective expression that is apparently disconnected from underlying mood. Although pathophysiological mechanisms remain uncertain, it is speculated that interruption of pathways between the telencephalon and lower regions is responsible.

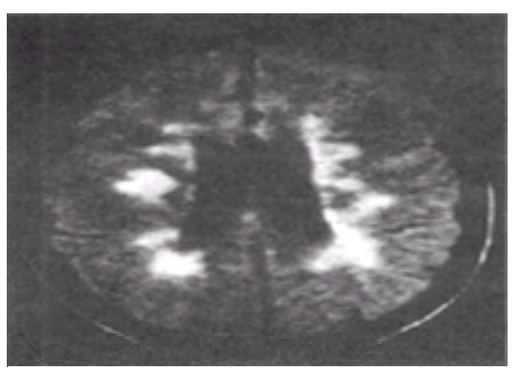

FIGURE 10-8 MRI study of the head. Extensive confluent periventricular lesions are seen in a patient with multiple sclerosis. The corresponding CT scan was normal. (Reprinted with permission from Lukes SA, Crooks LE, Aminoff MJ, Kaufman L, Panitch HS, Mills C, Norman D: Nuclear magnetic resonance imaging in multiple sclerosis. Ann Neurol *13*:596, 1983.)

Depressive syndromes are especially prevalent in patients with multiple sclerosis. Most studies have focused on major depressive disorder or have not used specific diagnostic criteria; therefore, little is known about minor or other subsyndromal depressions. Some data suggest that depressive syndromes can be caused directly by the demyelinating process in specific CNS regions; for example, patients with cerebral disease have higher rates of depression than patients with spinal multiple sclerosis. However, there is also evidence implicating psychological and social factors in the pathogenesis of depression in these patients, and it is likely that many of their depressive syndromes are not secondary to or specifically symptomatic of cerebral disease.

Bipolar disorders are less well studied, although they appear to be more prevalent in multiple sclerosis populations than in the general population. Whether bipolar disorders in multiple sclerosis patients represent true secondary bipolar disorders, mania induced by treatments with corticosteroids, or manifestations of a shared genetic diathesis is not known.

Other demyelinating disorders include variants of acute encephalomyelitis (including postinfectious encephalomyelitis and acute posttraumatic demyelinization). These disorders generally manifest initially with coma or delirium, and survivors may have lasting cognitive and behavioral disturbances.

The treatment of psychiatric syndromes in demyelinating disorders, as for most secondary syndromes, is empirical and based on target symptoms (e.g., antipsychotic agents for psychosis). Studies suggest that antidepressant medications, when used in conjunction with supportive psychotherapy, are helpful in patients with multiple sclerosis. Tricyclic drugs, and possibly other classes of antidepressant drugs, reduce emotional incontinence associated with multiple sclerosis even in the absence of a full depressive syndrome.

Degenerative Diseases Degenerative disease processes involve deterioration of brain function resulting in the loss of previously attained capacities. Some degree of CNS degeneration occurs as part of the aging process and is reflected in alterations in gross brain structure; neuronal cell number, morphology, and function; and neurotransmitter synthesis, metabolism, and function. The degeneration manifests clinically with psychometrically definable cognitive declines, particularly in secondary or long-term memory, speed of mental processing, visuospatial processing, divided attention, and cognitive flexibility. A range of decrements is associated with normal aging, and clinicians and investigators are developing neuropsychological procedures that distinguish such normative processes from those associated with degenerative diseases. Indeed, DSM-IV includes age-related cognitive decline as a clinical condition that may be a focus for clinical attention although it is not a mental disorder. It allows physicians to explain to concerned healthy patients that their aging-associated decrements in cognitive processing are distinctive from incipient dementia. Other similar conditions include problems such as borderline mental functioning or bereavement.

However, the border between normative cognitive changes and incipient dementia is ill defined. Patients who present with acquired deficits below the normal range are at higher risk statistically of developing progressive problems. However, cross-sectional cognitive tests cannot reveal time of onset, and in some individuals test results are always below normal. Conversely, people with above-average intellectual abilities may experience cognitive decline without exhibiting objective deficits because their performance remains within normal limits despite obvious functional impairments. Degenerative CNS diseases can produce disturbances in cognition, mood, behavior, personality, and motor and perceptual function. In recent years investigators have more clearly defined that the major degenerative diseases (whether hereditary or idiopathic) reflect deterioration in specific or discrete neurochemical systems where there is as well a regional specificity that reflects the location of cell bodies and their ultimate terminal zones. Such diseases are best considered neurochemical system diseases and their general pattern is one of insidious onset with a gradual progression of deficits. Dementia is the most common syndromic presentation and worsens as a reflection of the long-term progressive process; it ultimately reflects widespread CNS disease. Secondary mood, psychotic, and personality syndromes are also seen but are more likely to manifest earlier in the course, when the degeneration may be more localized.

Cortical and Subcortical Dementia Degenerative CNS diseases can be distinguished clinically from one another by the relative impairment and sparing of various cognitive and behavioral functions. Two basic clinical patterns of dementia have been characterized clinically: *cortical* and *subcortical*. The cortical pattern of

dementia is characterized by impairments in memory (primarily a storage and recall deficit) and gnostic-practic abilities (primarily involving language, visuospatial abilities, calculation, and motor praxis). Executive or managerial functions such as organization, judgment, abstraction, emotional control or modulation, and insight and social judgment are similarly affected. Fine and gross motor movements are generally preserved until later in the disease course. Personality often remains intact or displays subtle variations, with patients becoming more passive or less spontaneous, or becoming coarse and crude in their interactions. With disease progression the changes in personality become more common and pronounced. Affective expression is generally preserved, although again a coarsening may be noted in the form of emotional lability. Early in the disease, patients frequently discern and express dismay about their intellectual decline.

The subcortical pattern is characterized by a generalized slowing of mental processing. Specific cognitive skills, such as calculation, naming, or copying are less affected initially, in contrast to their early decline in the cortical degenerative processes. Verbal and visual memory impairment may be present early in the course, although such impairment more often takes the form of forgetfulness or a failure of retrieval that is initially amenable to prompting, in contrast to the more severe recall deficits of cortical dementia. Patients also show deficits in learning new motor movements or complex psychomotor procedures. Planning and organizational skills are disrupted. Abnormal movements are common and manifest as a slowing and awkwardness in normal movement or as the intrusion of such extraneous movements as chorea or tremor. In contrast to the early impairment of language function in cortical disease, language is relatively spared, although the motor production of speech may be abnormal. The personality change is often marked, with striking patterns of apathy, inertia, and diminished spontaneity. Mood disorders, including major depression and mania, occur frequently. The presenting symptoms in subcortical degenerative processes may be those of a personality change or a mood disorder at a time when cognitive impairment or motor dysfunction is not yet obvious. In the cortical processes, by contrast, the presenting symptoms more often reflect cognitive impairment, particularly memory and language dysfunction. As the dementia and the degenerative process progress, the clinical presentations of cortical and subcortical diseases become nearly indistinguishable from one another.

The term “subcortical dementia” was first used to describe the cognitive and behavioral deficits seen in patients with Huntington's disease. A similar clinical pattern was soon described for other subcortical diseases, such as progressive supranuclear palsy and Parkinson's disease. Although the term was initially used in reference to a clinical picture that could be localized to the subcortex, *subcortical dementia* is now considered a pseudoanatomical designation. It is clear from imaging and neuropathological studies that cortical dementia (e.g., dementia of the Alzheimer's type) is not restricted pathologically to the cortex; major affected cholinergic fiber pathways are subcortical in origin. Subcortical diseases similarly affect regions outside the subcortex, especially the frontal lobes, because of the brain's robust frontal-subcortical connections. Moreover, failure of subcortical nuclei that directly receive cortical efferent pathways can lead to clinical symptoms whose cerebral level of origin cannot be differentiated. Nonetheless, the cortical-subcortical distinction has been of clinical utility in defining patterns of cognitive, behavioral, mood, personality, and motor impairment, especially in the early stages of the degenerative disease process.

Alzheimer's Disease Alzheimer's disease is the prototype of a cortical degenerative disease. Alzheimer's original description in 1906 detailed most of the familiar clinical and neuropathological features. Of note, his patient suffered from paranoia in addition to cognitive decline. Currently, the diagnosis of Alzheimer's disease requires neuropathological confirmation, and the diagnosis is used clinically for cases identified antemortem. Age at onset s earlier in patients with a family history of the disease. Despite some data to suggest distinctive age-related clinical patterns, no phenomenological separation between early-onset and late-onset cases has been found consistently enough for age to substitute for detailed clinical description; however, early-onset dementia of the Alzheimer's type may have a more rapidly progressive course. A major component of the presenting symptoms is usually subjective complaints of memory difficulty, language impairment (“I can't find the word”), and dyspraxia (e.g., difficulty driving). Diagnosis at this juncture is primarily based on exclusion of other possible etiologies for dementia. No features of the physical examination or laboratory evaluation are pathognomonic for dementia of the Alzheimer's type. Some studies have apparently discriminated patients with dementia of the Alzheimer's type from patients with dementia of other etiologies and from normal controls by using techniques such as EEG, MRI, and SPECT. These studies have been difficult to replicate consistently, and at present, brain-imaging studies are best used to exclude other identifiable causes. Indeed, available technological diagnostic methods have not proved more sensitive and specific than astute clinical evaluation in comparisons of patients with dementia of the Alzheimer's type and healthy control subjects. PET holds promise but currently is too expensive for clinical diagnostic use.

A variety of diagnostic criteria sets have been developed for dementia of the Alzheimer's type. Clinical criteria have been verified prospectively in autopsy studies and have been found to be highly specific although only moderately sensitive. Implementation of the criteria requires extensive evaluation, including an informant-based history, neurological examination, neuropsychological testing, and laboratory and neuroimaging data. Studies using clinical samples collected in research centers tend to show the highest correlation between premorbid diagnosis and postmortem histopathology. In part this reflects the sophisticatmon of the evaluators; also, research cohorts can exclude subjects who show signs of other confounding conditions during the evolving disease course. Recent studies have shown substantial inter-center diagnostic variation, as well as variation when using different diagnostic criteria. Variability is greatest in population studies, in contrast to clinical samples. Factors found to be protective in epidemiological studies include higher education, larger head circumference, and cigarette smoking. The latter factor likely reflects some type of neuroprotective effect of nicotine; the former two point to a “brain reserve” hypothesis, where the unknown deleterious effects of the basic Alzheimer's disease pathobiology are mitigated by initially having either more brain substance or greater associative connections because of the stimulator effects of education.

Alzheimer's disease is characterized pathologically by generalized atrophy of the cerebral cortex (Fig. 10-9) and by neurofibrillary tangles, neuritic (amyloid) plaques, and granulovacuolar degeneration (Fig. 10-10). Although plaques and tangles may be detected in the brains of the nondemented elderly, they are more numerous in patients with dementia. In recent years investigators have attempted to circumvent the qualitative overlap in symptoms by developing stricter quantitative, age-adjusted pathological criteria for Alzheimer's disease. Controversy remains whether brains with plaques from individuals without dementia were “normal variations” or early pathological signs of incipient disease. A definitive diagnosis ultimately requires both the characteristic dementia in life and the characteristic pathology after death.

(Reprinted with permission from Golden A, Powell DE, Jennings CD: *Pathology: Understanding Human Disease*, ed 2. Williams & Wilkins, Baltimore, 1985.)

During recent years substantial effort has been devoted to the study of the molecular pathobiology of Alzheimer's disease, with the identification of at least four chromosomal loci associated with familial cases; the degeneration of central neurochemical systems, especially basal forebrain structures related to acetylcholine-mediated neurotransmission; factors associated with the formation of plaques and tangles; and exogenous (e.g., infectious and toxic) processes that may contribute to the development of sporadic cases. Molecular biologists have sought to understand the formation of the abnormal amounts of amyloid that constitute the cerebral plaques characteristic of the disease. Although amyloid itself is a normal brain product, it has been suggested that excessive amounts may be neurotoxic. Others continue to see amyloid accumulations solely as a disease byproduct. Attention has recently turned to amyloid precursor protein and the intriguing possibility of regulating amyloid production pharmacologically. The discovery of an association between apolipoprotein E4, controlled by a gene located on chromosome 19, suggests further avenues for investigating risk factors and pathogenetic mechanisms. Taken together, these recent findings point to a heterogeneous array of pathobiological processes contributing to the final clinical and histological picture known as Alzheimer's disease. The postmortem and antemortem presentations appear to be relatively generalized (i.e., nonspecific) outcomes of widely divergent etiologies.

The natural course of dementia of the Alzheimer's type, as of all the degenerative disorders, is exacerbation and progression of clinical symptomatology. Brain degeneration as measured by in vivo imaging techniques such as MRI has not been found to correlate closely with the state of clinical disease. The final common clinical picture is of a bedridden patient, wholly dependent on others for all basic functions, even for turning in bed. Nutrition can often be provided only by nasogastric or gastrointestinal tubes. Death usually results from aspiration or from infectious processes associated with prolonged recumbency.

Parkinson's Disease Described by James Parkinson in 1817, Parkinson's disease is a prototype of a subcortical degenerative disease. It is idiopathic and must be distinguished from parkinsonian syndromes that arise from a variety of causes.

Parkinson's disease is the result of the degeneration of subcortical structures, primarily the substantia nigra but also the globus pallidus, putamen, and caudate (Fig. 10-11). Cells containing dopamine are predominantly affected, although serotonergic and other systems are disrupted as well. Just as the appellation “cortical pattern” is pseudoanatomical, so in subcortical Parkinson's disease there can be significant degeneration of cortical structures. The parkinsonian syndrome manifests with structural damage that reflects the underlying process or insult. Medication-induced parkinsonism presumably involves only a dysfunction of the basal ganglia structures, without any obvious pathoanatomical abnormality. The typical age at onset of Parkinson's disease is between 50 and 60 years but may vary widely, with onset sometimes occurring one to two decades earlier. The clinical course is chronic and progressive, with severe disability attained after approximately 10 years. A smaller proportion of patients have a more rapidly progressive disease, and a yet smaller group has a slowly progressive disorder in which deterioration plateaus or remains minimal for two to three decades.

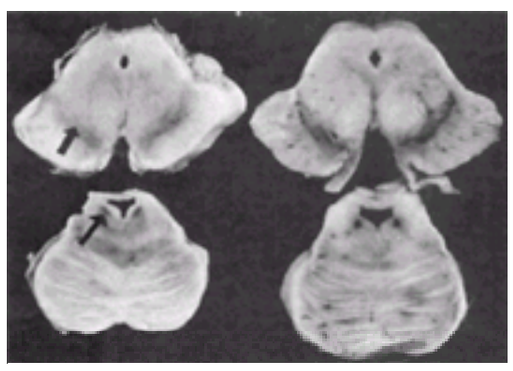

FIGURE 10-11 Parkinson's disease. Section of midbrain and pons showing depigmentation of substantia nigra and locus ceruleus in Parkinson's disease on left (arrows) and normal substantia nigra and locus ceruleus on right. In general, subcortical diseases are thought to impinge on the three Ms—movement, mentation, and mood. In Parkinson's disease all three of these areas are affected, although not always uniformly. The movement abnormalities are characterized by the triad of tremor, rigidity, and bradykinesia. The tremor and rigidity can be unilateral or bilateral. Bradykinesia is manifested by slowness in the initiation and execution of movement. The typical presentation, with a masklike facies, minimal blink, and monotonic speech, is a concomitant of the rigidity and slowness of movement. Other prominent characteristics include postural changes such as chin-to-chest flexion and gait abnormalities. The gait is characteristically slow and shuffling, and the patient has difficulty turning (en bloc turning) and trouble initiating and stopping walking. Seborrhea, sialorrhea, excessive fatigue, and constipation are also common.

Maurice Rosen was 69 when he made an appointment for a neurological evaluation. He had recently noticed that his memory was slipping and he had problems with concentration that were beginning to interfere with his work as a self-employed tax accountant. He complained of slowness and losing his train of thought. Recent changes in the tax laws were hard for him to learn, and his wife said he was becoming more withdrawn and reluctant to initiate activities. However, he was still able to take care of his personal finances and accompany his wife on visits to friends. Although mildly depressed about his disabilities, he denied other symptoms of depression, such as disturbed sleep or appetite, feelings of guilt, or suicidal ideation.

Mr. Rosen has a long history of treatment for episodes of depression, beginning in his 20s. He has taken a number of different antidepressants, and once had a course of electroconvulsive therapy. As recently as 6 months before this evaluation, he had been taking an antidepressant. Two years ago he developed an intermittent resting tremor in his left hand and a shuffling gait. Although the diagnosis of Parkinson's disease was considered by his psychiatrist, it was not confirmed by a neurologist, and therefore no additional treatment was given.

The neurologist who was now evaluating him found that his spontaneous speech was hesitant and unclear (dysarthric). Cranial nerve examination was normal. Motor tone was increased slightly in the neck and all limbs. Alternating movements of his hands were performed slowly. He had a slight intermittent tremor of the left arm at rest. Reflexes were symmetrical. A diagnosis of idiopathic Parkinson's disease was made, and he was placed on a low dose of carbidopa (Atamet), a medication that alleviates the symptoms of Parkinson's disease.

A neuropsychological examination performed 3 weeks later revealed average performance on the Wechsler Adult Intelligence Scale-Revised (full scale I.Q. = 104), but a verbal I.Q. of 118 and a performance I.Q. of 84. Memory as assessed by a 12-item, 10-trial, selective reminding task was poor, with no more than 7 items recalled on any trial, and only 3 words recalled after a 15-minute delay, although the patient could recognize the remaining words. He showed marked difficulty in drawings of overlapping figures and parallel lines. He was unable to draw three-dimensional figures. In language testing he demonstrated impaired naming. In summary, Mr. Rosen displayed evidence of impairment in memory, naming, and constructional abilities. These may have been secondary to slowness, poor planning, and perseveration. The deficits were believed to result from Parkinson's disease. Additional evaluation included an MRI, which revealed only generalized atrophy, and an EEG, which was significant for background generalized slowing. (Reprinted with permission from *DSM-IV Casebook*.)

Mentation or cognition in Parkinson's disease is an area of controversy. Most patients complain of slowed thinking, sometimes called bradyphrenia. In general, approximately 20 to 30 percent of patients with Parkinson's disease are found to have dementia, with the likelihood greater in those with late-onset disease (after age 70 years). Approximately 40 percent of nondemented patients with Parkinson's disease, however, demonstrate some neuropsychological impairment in most studies. The impairments are primarily in visuospatial capacities, as measured by copying, tracing, and tracking tasks, and in the shifting of cognitive sets, as measured by the Wisconsin Card Sorting Test or the Stroop Test. Such deficits have been noted in the absence of cognitive-based functional decline or other evidence of cognitive impairment. Controversy has emerged over whether these two patterns represent a single continuum of dementia integral to the process of Parkinson's disease or are two separate processes indicative of two distinct diseases. Neuropathologically, cases intermediate between Parkinson's disease and Alzheimer's disease exist, with the characteristic microscopic features of the latter and Lewy bodies in the substantia nigra suggesting the former. There is no clear line of division as yet between a process resembling dementia of the Alzheimer's type on which abnormal parkinsonian movements are superimposed and a clinical presentation of Parkinson's

disease in which the patient slowly develops a global progressive dementia.

Mood disorders have been frequently reported in association with Parkinson's disease. Depression is the most common; mania is virtually unreported. The mean frequency of depression is approximately 40 percent, with a reported range of 4 to 70 percent. No relation has been demonstrated between the frequency and severity of depression and the patient's current age, the age at onset of symptoms of Parkinson's disease, the duration of those symptoms, the severity of motor signs, or the response to medication. No relation has been demonstrated among mood, rigidity, bradykinesia, or tremor. Although depression has been found more commonly in patients with Parkinson's disease who display prominent gait and postural changes, the relation between mood and the severity of the disability is limited. There may be some association between depression and laterality of disease, for patients with left brain disease appear to have a higher frequency of depression than patients with right brain disease. This pattern suggests that the mood disturbance is a primary manifestation of brain deterioration and not a reactive psychological response to chronic illness and disability. Although the evidence relating lateralization to a higher frequency of depression is preliminary, it does recall data regarding poststroke depression and its putative relationship to left hemisphere localization but not to the extent of disability. The phenomenology of depression in Parkinson's disease is similar to that of idiopathic major depressive disorder, for it includes subjective dysphoria, pessimism, irritability, and suicidality, but perhaps less self-disparagement and self-blame. Some patients present with anxiety or panic attacks. Anergia, psychomotor retardation, and early-morning awakening are three symptoms that have been found to be nonspecific for depressive disorder in those patients, as they overlap considerably with the manifestations found in nondepressed patients with Parkinson's disease. Some data support the view that the depression of Parkinson's disease is associated specifically with decreased CNS serotonin concentrations. The on-off syndrome, in which patients experience severe fluctuations in mobility ranging from normal movement to a frozen state, has also been associated with changes in mood. On-off phenomena usually occur after years of chronic treatment with levodopa and can manifest as a between-dosage effect or randomly throughout the day. Many studies have reported changes in mood coincident with changes in motoric function, namely, subjective and objective dysphoria in the off period and, less frequently, abnormal elation and euphoria during the on period.

Psychosis as a concomitant of Parkinson's disease has been reported in the context of mood disorders (e.g., psychotic depression) or as a consequence of treatment. There are no reports of a specific personality change characteristic of Parkinson's disease except for the apparent apathy and lack of initiative that are often subsumed under bradykinesia and bradyphrenia.

The pharmacological treatment of Parkinson's disease addresses mood and movement because there is no known regimen for the improvement of cognition. For movement dysfunction dopamine precursors, such as levodopa or levodopa-carbidopa, (Sinemet), are a mainstay of treatment. Gait, posture, rigidity, and akinesia are generally more responsive to levodopa than is tremor. Anticholinergic agents and the dopamine agonists (bromocriptine [Parlodel] and pergolide [Permax]) are second-line agents. The monoamine oxidase (MAO) type B inhibitor selegiline (Eldepryl) has been demonstrated to apparently slow the progression of motor dysfunction, although in the low doses used it did not have significant antidepressant efficacy. Its effects on the development of cognitive impairment are unknown. Currently a new generation of dopamine receptor agonists is emerging; their long-term utility will become clear in the coming years. All symptomatic antiparkinsonian agents can cause delirium, a common iatrogenic concomitant of the disease. Levodopa has also been reported to cause visual hallucinations in some patients, even in the absence of delirium. Surgical treatments—stereotactic lesioning of the thalamus or globus pallidus—were used in the past to alleviate the motor dysfunction of Parkinson's disease. Although that approach had largely been replaced by pharmacological treatment, newer and more precise operative procedures have been developed in the past few years. Transplantation of fetal neural tissue into the caudate of the adrenal medulla also has been attempted, but no data from well-controlled studies are available regarding the effects of the procedure on mood and mentation. Recent findings suggest that fetal tissue transplantation may dramatically alleviate severe motor symptoms. Many differences exist in surgical protocols and transplantation methods, underscoring the highly experimental nature of these procedures.

Treatment of the mood disorder associated with Parkinson's disease involves the same agents that have proved valuable in treating idiopathic major depressive order. Antidepressant medication from all categories have proved efficacious. ECT is of value for treating both the mood component and the motor dysfunction; dramatic improvement in all aspects of movement has been demonstrated on standardized neurological examinations. Several studies have reported sustained improvement in motor function for as long as 6 months after treatment; however, most detected a short-lived improvement of days to weeks. ECT is recommended for patients with Parkinson's disease and the on-off syndrome, particularly when significant mood changes are present.

In summary, Parkinson's disease is a prototypical subcortical pattern degenerative disease. The overlap of clinical phenomena between a basal ganglia disease, such as Parkinson's disease, and major depressive disorder can be striking. Both are characterized by qualitatively similar impairments in the realms of movement, mentation, and mood. Differing terminologies have arisen to describe similar signs and symptoms in each. *Psychomotor slowing (psychomotor retardation)* a term used to encompass both the motoric and cognitive slowing seen in depression, is quite similar to the bradykinesia and bradyphrenia described early in the course of Parkinson's disease. A recent study that used a nonmotor measure of bradyphrenia demonstrated close correlations between cognitive slowing and severity of the mood disorder both in depressed patients with Parkinson's disease and patients with idiopathic major depressive disorder, suggesting a close phenomenological relation between the bradyphrenia of Parkinson's disease and so-called psychomotor slowing. It underscored the idea that basal ganglia disorders are fertile ground for research and insight into the neurobiological bases of idiopathic mood disorders.

Dementia With Lewy Bodies Since the late 1980s research has revealed that, beyond dementia of the Alzheimer's type and vascular dementia, a common cause of progressive dementia may be related to the presence of Lewy bodies in the brainstem and cerebral cortex. Lewy bodies—intracytoplasmic, spherical, eosinophilic neuronal inclusion bodies—are scattered through the brainstem, subcortical nuclei, limbic cortex (cingulate, entorhinal, amygdala), and neocortex (temporal > frontal = parietal). Parkinson's disease, in contrast, manifests Lewy bodies in subcortical nuclei, in addition to degeneration of dopamine cell bodies in substantia nigra. Table 10-18 lists the pathological features of dementia with Lewy bodies; Table 10-19 includes recently developed consensus guidelines for clinical diagnosis. Neuropsychiatric features, including visual hallucinations, delusions, fluctuating attention, and executive or managerial cognitive deficits, are prominent; although not specific, mood disturbances are common.

Essential for diagnosis
Lewy bodies
Associated but not essential
Lewy-related neurites
Plaques (all morphological types)
Neurofibrillary tangles
Regional neuronal loss—especially brainstem (substantia nigra and locus coeruleus) and nucleus basalis of Meynert
Microvacuolation (spongiform change) and synapse loss
Neurochemical abnormalities and neurotransmitter deficits

Table 10-18 Pathological Features Associated With Dementia With Lewy Bodies

1. The central feature required for a diagnosis of dementia with Lewy bodies is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention and of frontal-subcortical skills and visuospatial ability may be especially prominent.
2. Two of the following core features are essential for a diagnosis of probable dementia with Lewy bodies, and one is essential for possible dementia with Lewy bodies:
a. Fluctuating cognition with profound variations in attention and alertness
b. Recurrent visual hallucinations that are typically well formed and detailed
c. Spontaneous motor features of parkinsonism
3. Features supportive of the diagnosis are:
a. Repeated falls
b. Syncope
c. Transient loss of consciousness
d. Neuroleptic sensitivity
e. Systematized delusions
f. Hallucinations in other modalities
4. A diagnosis of dementia with Lewy bodies is less likely in the presence of:
a. Stroke disease, evident as focal neurologic signs or on brain imaging
b. Evidence on physical examination and investigation of any physical illness or other brain disorder sufficient to account for the clinical picture

Table 10-19 Consensus Criteria for the Clinical Diagnosis of Probable and Possible Dementia With Lewy Bodies

Substance-Induced Disorders Pharmacological compounds are potent and frequent causes of psychopathology. This effect, especially when caused by environmental and occupational neurotoxins, has been little studied; more attention has been paid to peripheral or motor effects than to the less easily quantified behavioral alterations. Although alcohol-induced neuropsychiatric syndromes have long been known of, the CNS consequences of abuse of recreational drugs received attention only in recent decades, in part because of societal disapproval of recreational drug use, disinterest among investigators, and the inherent difficulty of separating drug effects from confounding person effects.

Broadly speaking, there are four classes of chemically induced psychopathology: (1) that due to environmental contamination, both natural (e.g., venoms and poisonous foods) and human-made (e.g., gasoline contamination of well water); (2) that due to occupational exposure; (3) that due to recreational use, abuse, or dependence on substances causing transient or lasting CNS toxic effects; and (4) the iatrogenic complications of prescribed or over-the-counter medications. Compounds must be considered from the perspectives of (1) acute or immediate effects (e.g., behavioral symptoms of acute intoxication), (2) longer-term responses to persistent exposure, and (3) lasting consequences that persist after the cessation of any direct pharmacological action. The last may be especially complex because of the extremely prolonged retention (months to years) of some compounds within the body.

When considering the possibility of drug- or toxin-induced psychopathology, the clinician must undertake a careful chain of reasoning, akin to deciding on any secondary diagnosis but differing in several respects. Initially, the clinician must ascertain whether an exposure occurred and at what level; for example, an industrial hygienist may have been exposed in a possible occupational incident. Next, it is critical to understand the toxicity of a substance (especially as it might relate to different chemical forms), its mode of action (when known), its effects in various animal species, and its clinical manifestations. Typically, these issues are within the realm of toxicologists. Subsequently, the clinician seeks to define the systemic clinical manifestations of the exposure in the particular patient. Although behavioral changes may be the only exposure-related findings, more often there is a variety of consistent symptoms, signs, and laboratory findings that together make a coherent clinical picture. It is within that larger context that the clinician views any presumptively related psychopathology.

When attempting to establish a neurotoxic diagnosis, physicians also must recognize other cardinal features of toxic exposures that influence clinical reasoning: (1) neurotoxic chemicals often cause nonfocal/nonspecific syndromes; (2) standard laboratory tests may have limited diagnostic utility; (3) there usually are strong dose-response relationships; (4) a single toxin may produce multiple syndromes; (5) with a few specific exceptions (e.g., asbestos, therapeutic cerebral radiation exposure), toxin-induced illnesses occur concurrently with exposure or following a short latency period; (6) the chemical formula may not predict toxicity; (7) a compound without known neurotoxic activity can interact or potentiate the effects of known neurotoxins; and (8) neurotoxic disease often may be asymptomatic.

Ideally, one would like to know the neuropsychiatric effects of all CNS toxic compounds. In the absence of such information, the clinician must describe symptoms and signs in detail and compare them with available data. The clinician defines the temporal course of exposure and assesses how the emergence of specific psychiatric manifestations relates to known actions of the compounds in question. Simultaneously, the clinician must consider the form of the disorder and establish whether it suggests a pathological CNS process or is more consistent with primary (idiopathic) psychopathology. The clinician must decide whether the syndrome in question might reflect other unrelated disease processes as well. Any measurable clinical and laboratory manifestations of CNS disease should be identified. Although no single measurement can be considered proof, taken together such measurements offer the possibility of establishing a diagnosis with a high degree of clinical certainty.

The array of environmental and occupational compounds to which people may be exposed is large. Except for patients exposed to recreational and iatrogenic agents, until recently most psychiatrists did not treat patients with toxic exposures. This is changing rapidly as a result of late twentieth-century technology and increasing societal awareness. The clinician should remember that toxic exposures are used by some patients to explain a pantheon of personal ills, many of a psychiatric nature. It is neither appropriate to treat those complaints lightly nor clinically sound to accept such pathogenic explanations without firm clinical support.

Recreational drugs may be used or abused intentionally to cause dose-dependent behavioral changes, including anxiolysis with nicotine, intoxication with alcohol or marijuana, or psychosis with mescaline. There may be additional unwanted psychiatric phenomena with drug intoxication. Unwanted secondary syndromes commonly described include anxiety and insomnia due to caffeine; paranoid psychosis with cocaine; mood alterations (dysphoria, anxiety, euphoria) accompanying the perceptual disturbances induced by hallucinogenic substances; agitated (often violent) psychotic states with phencyclidine (PCP); and depressive symptoms and seemingly paradoxical disinhibition of aggressive impulses with sedative-hypnotic agents. However, there may be considerable variability and therefore lack of specificity in syndromic association with particular substances. Also, many substances in sufficient doses can cause delirium, which may itself have associated psychiatric symptoms ranging from mood disturbance to psychosis.

Withdrawal syndromes are also commonly encountered with drugs of abuse and tend to be characteristic of the class of drug. Withdrawal from nicotine may produce anxiety or irritability; withdrawal from stimulants produces a hypersomnic dysphoric crash; and withdrawal from opiates produces a well-described state that includes malaise, anxiety and irritability, drug craving, insomnia, psychomotor agitation, anorexia, and a variety of physical symptoms (e.g., diarrhea, piloerection, mydriasis, hypertension, and tachycardia). Delirium often follows withdrawal from alcohol and sedative-hypnotic medications but is not a component of other drug withdrawal syndromes (e.g., opioid-related).

Numerous medications have been implicated in causing psychiatric phenomena. Prescription drugs and over-the-counter preparations may cause physiologically induced behavioral changes, either through intoxication (which may involve use at therapeutic or supratherapeutic levels) or withdrawal. As with other causes of secondary psychiatric disorders, combinations of medications and medical illnesses may cause behavioral changes even when each medication or illness alone does not.

Among prescribed medications, psychotropic drugs are designed to effect behavioral changes. Unwanted psychiatric syndromes, such as antipsychotic-induced depressive syndromes or the delirium of lithium toxicity, occur often. Countless medications have been implicated in secondary psychiatric syndromes; it is rare indeed for a medication to be listed in the *Physicians' Desk Reference* without an accompanying description of some potential neuropsychiatric adverse effect. However, this information must be interpreted with caution. Behavioral adverse effects are also noted with placebos; therefore, distinguishing physiological from psychological symptoms may be difficult. Psychiatric symptoms may also reflect the clinical manifestations of the primary illness being treated (e.g., delirium in a patient receiving a new parenteral antibiotic may be due to the antibiotic or the targeted infection). Finally, numerous other factors may complicate the process of establishing the etiological significance of a particular medication. For example, b-adrenergic-receptor antagonists have been postulated for many years to cause depressive syndromes, yet a recent large study, carefully controlled for patient demographics, medical illness, medications, and other factors, was unable to find a significant independent association between b-adrenergic receptor antagonists and depression. Despite these caveats, many medications clearly can cause secondary psychiatric syndromes.

COGNITIVE DISORDERS

Delirium Delirium, a transient disorder of brain function manifested by global cognitive impairment and other behavioral phenomena, is a common disease state that has been described for centuries. Nevertheless, it is frequently missed or misdiagnosed, with the potential for substantial attendant morbidity and mortality. Recognition and appropriate evaluation and treatment of delirium should be an imperative, not just for psychiatrists but for all physicians.

Definition DSM-IV includes delirium under cognitive disorders. Delirium is a syndrome, with core features of impairment of consciousness with attentional deficit, other cognitive alterations, and a relatively rapid onset of the disorder with a characteristically fluctuating course. Frequently there are other associated clinical phenomena, which may appear more prominent to the uneducated observer than the core features.

History

Physicians have long recognized states of altered behavior, including changes in level of consciousness, of acute onset that were associated with fever, poisons, or other medical or neurological diseases. There are references to such presentations in the writings of Hippocrates and in much subsequent Greco-Roman literature. Descriptions of the syndrome similar to modern definitions appear from the late Middle Ages through the eighteenth century. The history, however, is obscured by an etymological web that to this day impedes communication and education about the disorder. Numerous terms have been used to describe the syndrome of delirium, including *phrenitis, frenzy*, and *febrile insanity*; conversely, the term “delirium” has also been applied to other psychiatric states that led to insanity.

By the nineteenth century emphasis was placed on disordered consciousness as the hallmark of delirium. The phrase “clouding of consciousness” dates to that time

and is still used in many quarters today despite lack of clarity as to what it means. Similarly, the term “confusion” was used frequently, despite the lack of a specific relation to delirium.

The work of George Engel and John Romano in the 1940s, summarized by them in publications from the 1950s, indicated that attentional and other cognitive disturbances were best viewed as the core features of the syndrome and that the state was associated with acute brain failure, as demonstrated by slowing on the EEG. Subsequent work on the pathophysiology of delirium has been relatively scant. Zbigniew Jerzy Lipowski, beginning in the 1960s and continuing to the present, has been instrumental in raising clinical and research awareness of delirium, defining the syndrome according to strict criteria and popularizing (especially in the psychiatric community) the use of the term “delirium.” Recent years have seen alterations in diagnostic criteria, as evidenced by the removal of associated clinical features such as psychomotor changes from the required criteria. There has also been increasing study of epidemiology, clinical course, and risk factors for onset or poor outcome.

Unfortunately, etymological confusion remains. Numerous synonyms remain in common use, especially in nonpsychiatric medical fields; some of them are encephalopathy, acute confusional state, and acute organic brain syndrome. Some neurologists maintain a distinction between delirium, which they reserve to describe extremely agitated delirious states with frank thought process disorganization, perceptual disturbances, and autonomic hyperactivity, and acute confusional states, which they use to describe all other, often less severe delirious states. Most psychiatrists, and many other workers in the field, believe that such distinctions are premature at best (because of a lack of evidence of differing causes or pathophysiologies between the two) and misleading at worst, obscuring the commonality of core clinical features, potential etiologies, and management approaches.

Epidemiology There have been relatively few studies of the incidence and prevalence of delirium. Little is known about the epidemiology of delirium in community or other nonpatient, noninstitutionalized populations. An estimated 10 to 15 percent of general medical inpatients are delirious at any given time, and studies indicate that as many as 30 to 50 percent of acutely ill geriatric patients become delirious at some point during their hospital stay. Rates of delirium in psychiatric and nursing home populations are not well established but are clearly substantial. Risk factors for the development of delirium include increased severity of physical illness, older age, and baseline cognitive impairment (e.g., due to dementia).

Delirium is frequently unrecognized by treating physicians. Because of its wide array of associated symptoms, it may be detected but misdiagnosed as depression, schizophrenia, or other psychiatric disorder. Delirium is a frequent cause for psychiatric consultation in the general hospital but often is not recognized as such by the referring physician.

Etiology The syndrome of delirium reflects brain dysfunction that is almost always due to identifiable systemic or cerebral disease or to drug intoxication or withdrawal. A partial list of frequently encountered causes is given in Table 10-20. Often delirium is due to multiple simultaneous causes, each one of which may or may not be enough to cause delirium by itself. On rare occasions a syndrome nearly indistinguishable from delirium may manifest as part of the course of another Axis I disorder such as bipolar I disorder.

Drug intoxication
Anticholinergics
Lithium
Antiarrhythmics (e.g., lidocaine)
H_2-receptor blockers
Sedative-hypnotics
Alcohol
Drug withdrawal
Alcohol
Sedative-hypnotics
Tumor
Primary cerebral
Trauma
Cerebral contusion (as an example)
Subdural hematoma
Infection
Cerebral (e.g., meningitis, encephalitis, HIV, syphilis)
Systemic (e.g., sepsis, urinary tract infection, pneumonia)
Cardiovascular
Cerebrovascular (e.g., infarcts, hemorrhage, vasculitis)
Cardiovascular (e.g., low-output states, congestive heart failure, shock)
Physiological or metabolic
Hypoxemia, electrolyte disturbances, renal or hepatic failure, hypo- or hyperglycemia, postictal states (as examples)
Endocrine
Thyroid or glucocorticoid disturbances (as examples)
Nutritional
Thiamine or vitamin B_{12} deficiency, pellagra (as examples)

Table 10-20 Causes of Delirium

Diagnosis and Clinical Features The syndrome of delirium is almost always caused by one or more systemic or cerebral derangements that affect brain function.

A 74-year-old African-American woman, Ms. Richardson, was brought to a city hospital emergency room by the police. She is unkempt, dirty, and foul smelling. She does not look at the interviewer and is apparently confused and unresponsive to most of his questions. She knows her name and address, but not the day or the month. She is unable to describe the events that led to her admission.

The police reported that they were called by neighbors because Ms. Richardson had been wandering around the neighborhood and not taking care of herself. The medical center mobile crisis unit went to her house twice, but could not get in and presumed she was not home. Finally, the police came and broke into the apartment, where they were met by a snarling German shepherd. They shot the dog with a tranquilizing gun, and then found Ms. Richardson hiding in the corner, wearing nothing but a bra. The apartment was filthy, the floor was littered with dog feces. The police found a gun, which they took into custody.

The following day, while Ms. Richardson was awaiting transfer to a medical unit for treatment of her out-of-control diabetes, the supervising psychiatrist attempted to interview her. Her facial expression was still mostly unresponsive, and she still didn't know the month and couldn't say what hospital she was in. She reported that the neighbors had called the police because she was “sick,” and indeed she had felt sick and weak, with pains in her shoulder; in addition, she had not eaten for 3 days. She remembered that the police had shot her dog with a tranquilizer, and said the dog was not in “the shop” and would be returned to her when she got home. She refused to give the name of a neighbor who was a friend, saying, “he's got enough troubles of his own.” She denied ever being in a psychiatric hospital or hearing voices, but acknowledged that she had at one point seen a psychiatrist “near Lincoln Center” because she couldn't sleep. He had prescribed medication that was too strong, so she didn't take it. She didn't remember the name, so the interviewer asked if it was Thorazine. She said no, it was “allal.” “Haldol?” asked the interviewer. She nodded. The interviewer was convinced that was the drug, but other observers thought she might have said yes to anything that sounded remotely like it, such as “Elavil.” When asked about the gun, she denied, with some annoyance, that it was real and said it was a toy gun that had been brought to the house by her brother, who had died 8 years ago. She was still feeling weak and sick, complained of pains in her shoulder, and apparently had trouble swallowing. She did manage to smile as the team left her bedside. (Reprinted with permission from *DSM-IV Casebook*.)

DSM-IV gives separate diagnostic criteria for delirium due to a general medical condition (Table 10-21), for delirium related to systemic medical conditions or primary cerebral conditions, substance intoxication delirium (Table 10-22), substance withdrawal delirium (Table 10-23), delirium due to multiple etiologies (Table 10-24), and delirium not otherwise specified (Table 10-25) for a delirium of unknown cause or due to causes not listed, such as sensory deprivation. However, the core syndrome is the same, regardless of cause.

A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a pre-existing, established, or evolving dementia.
C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition.
Coding note: Include the name of the general medical condition on Axis I, e.g., delirium due to hepatic encephalopathy; also code the general medical condition on Axis III.

Table 10-21 DSM-IV Diagnostic Criteria for Delirium Due to a General Medical Condition

A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a pre-existing, established, or evolving dementia.
C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
D. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):
(1) the symptoms in criteria A and B developed during substance intoxication
(2) medication use is etiologically related to the disturbance
Note: This diagnosis should be made instead of a diagnosis of substance intoxication only when the cognitive symptoms are in excess of those usually associated with the intoxication syndrome and when the symptoms are sufficiently severe to warrant independent clinical attention.
Note: The diagnosis should be recorded as substance-induced delirium if related to medication use.
Code: (Specific substance) intoxication delirium (Alcohol; amphetamine (or amphetamine-like substance); cannabis; cocaine; hallucinogen; inhalant; opioid; phencyclidine (or phencyclidine-like substance); sedative, hypnotic, or anxiolytic; other (or unknown) substance (e.g., cimetidine, digitalis, benztropine))

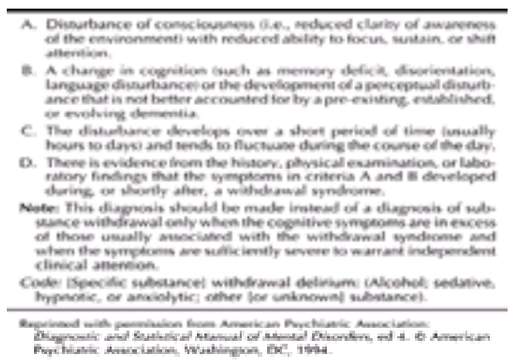
Table 10-22 DSM-IV Diagnostic Criteria for Substance Intoxication Delirium



A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a pre-existing, established, or evolving dementia.
C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
D. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):
(1) the symptoms in criteria A and B developed during, or shortly after, a withdrawal syndrome.
(2) medication use is etiologically related to the disturbance
Note: This diagnosis should be made instead of a diagnosis of substance withdrawal only when the cognitive symptoms are in excess of those usually associated with the withdrawal syndrome and when the symptoms are sufficiently severe to warrant independent clinical attention.
Code: (Specific substance) withdrawal delirium; (Alcohol); sedative, hypnotic, or anxiolytic; other (or unknown) substance).

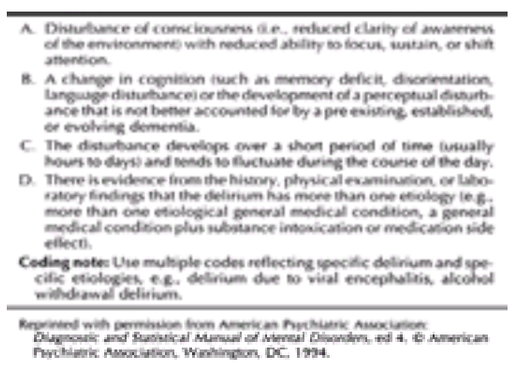
Table 10-23 DSM-IV Diagnostic Criteria for Substance Withdrawal Delirium



A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a pre existing, established, or evolving dementia.
C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
D. There is evidence from the history, physical examination, or laboratory findings that the delirium has more than one etiology (e.g., more than one etiological general medical condition, a general medical condition plus substance intoxication or medication side effect).
Coding note: Use multiple codes reflecting specific delirium and specific etiologies, e.g., delirium due to viral encephalitis, alcohol withdrawal delirium.

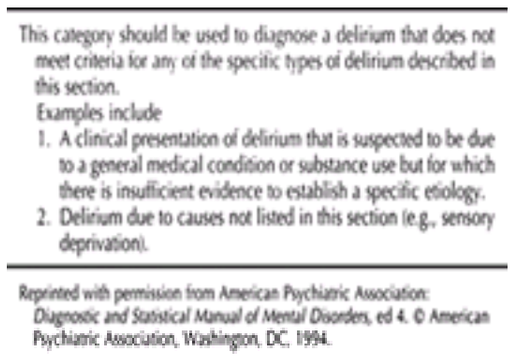
Table 10-24 DSM-IV Diagnostic Criteria for Delirium Due to Multiple Etiologies



This category should be used to diagnose a delirium that does not meet criteria for any of the specific types of delirium described in this section.
Examples include
1. A clinical presentation of delirium that is suspected to be due to a general medical condition or substance use but for which there is insufficient evidence to establish a specific etiology.
2. Delirium due to causes not listed in this section (e.g., sensory deprivation).

Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 10-25 DSM-IV Diagnostic Criteria for Delirium Not Otherwise Specified

The core features of delirium include altered consciousness, such as decreased level of consciousness; altered attention, which may include diminished ability to focus, sustain, or shift attention; impairment in other realms of cognitive function, which may manifest as disorientation (especially to time and space) and decreased memory; relatively rapid onset (usually hours to days); brief duration (usually days to weeks); and often marked, unpredictable fluctuations in severity and other clinical manifestations during the course of the day, sometimes worse at night (sundowning), which may range from periods of lucidity to quite severe cognitive impairment and disorganization.

Associated clinical features are often present and may be prominent. They may include disorganization of thought processes (ranging from mild tangentiality to frank incoherence), perceptual disturbances such as illusions and hallucinations, psychomotor hyperactivity and hypoactivity, disruption of the sleep-wake cycle (often manifested as fragmented sleep at night, with or without daytime drowsiness), mood alterations (from subtle irritability to obvious dysphoria, anxiety, or even euphoria), and other manifestations of altered neurological function (e.g., autonomic hyperactivity or instability, myoclonic jerking, and dysarthria). The EEG usually shows diffuse slowing of background activity, although patients with delirium due to alcohol or sedative-hypnotic withdrawal have low-voltage fast activity.

ICD-10 takes a somewhat different approach to establishing the diagnosis of delirium (Table 10-26). It requires the concurrent presence of disturbances in consciousness and attention, perception, thinking, psychomotor behavior, emotion, and the sleep-wake cycle. All features must be present to some degree for a definite diagnosis, thus making for a more restrictive classification than DSM-IV. The key to diagnosing delirium is to maintain a heightened suspicion for the syndrome whenever a patient experiences a relatively rapid change in or the new onset of any psychiatric symptom or sign. Once the diagnosis is suspected, the history (usually obtained from informants such as family, nursing staff, and prior treaters) and mental status examination can elucidate the cognitive disturbances at the core of the syndrome and uncover associated clinical phenomena that may affect management or suggest the etiology.

Table 10-26 ICD-10 Diagnostic Criteria for Delirium, Not Induced by Alcohol and Other Psychoactive Substances

The presence of delirium should prompt careful investigation for contributing causes. Delirium may be the first, most prominent, or only clinical manifestation of the new onset of a medical condition or the worsening of a previously diagnosed illness. A careful medical history (including medication and drug history), physical examination, and neurological examination must be undertaken, and various laboratory tests, neuroimaging procedures, lumbar puncture, and EEG may be useful. In searching for cause, physicians should remember that relatively minor abnormalities (e.g., a mild anemia plus slight hyponatremia plus slight hypercalcemia) may additively produce delirium even if each abnormality alone would not normally do so. Sometimes the search for an etiology does not yield a clear cause of the delirium; the patient still has the syndrome of delirium, however, and vigilance for clinical contributing factors must be maintained. Physicians should avoid the common mistake of believing delirium to be ruled out by the lack of obvious etiology, thereby proving that the behavioral disturbance is functional in origin. EEG may be helpful in such cases by demonstrating diffuse brain dysfunction, although that in itself does not demonstrate etiology.

Current understanding of the pathophysiology of delirium is limited. Dysfunction of the reticular activating system has been speculated, given its role in arousal. There is evidence for hypofunction of cholinergic systems, particularly in the basal forebrain and pons. There is some evidence for dysfunction of several other neurochemical systems, including noradrenergic, GABAergic, and serotonergic; more undoubtedly await investigation. Earlier speculation about globally decreased cerebral metabolism has not been confirmed, but also has not been carefully studied in delirium despite the availability of techniques such as PET and SPECT. Even more obscure is the pathophysiological link between specific systemic conditions and delirium. The classic model of such a link is anticholinergic drug toxicity, which has been presumed to cause delirium as a direct consequence of hypoactivity of cholinergic systems. Some recent work has demonstrated increased GABAergic transmission, putatively because of increased concentrations of endogenous benzodiazepine-like substances, in patients with delirium and fulminant liver failure.

Differential Diagnosis Much attention has been given to differentiating delirium from dementia. Usually that distinction can be easily made by noting temporal factors (course of onset and progression of the disturbance) and by recognizing that level of consciousness and attention are affected prominently and early in delirium. Dementia by definition does not involve an alteration of consciousness, although attentional dysfunction develops as the syndrome progresses in severity. However, delirium is often superimposed on a pre-existing dementia. If the history is unknown and mental status examination results are lacking in a patient with severe dementia, it can be difficult to tell if there is a new delirium, or if the delirium has resolved and the patient is back to baseline (which may be a new baseline reflecting deterioration from a previous level of function). In such cases it is prudent to assume that the patient has delirium and to proceed with a careful clinical evaluation.

Although thought process disorganization, perceptual disturbances, or mood symptoms may lead the uninitiated to diagnose idiopathic psychiatric illness, the constellation of altered level of consciousness, prominent attentional and other cognitive deficits, and temporal course usually makes the differentiation of delirium from mood, psychotic, and anxiety disorders straightforward. The previous psychiatric history can be helpful, but the clinician must use care in interpreting it because patients with chronic psychiatric illness are also at risk for developing delirium due to medications, drug abuse, or other conditions. Rarely, patients with other Axis I illnesses (particularly the schizophrenias and bipolar disorders) may develop flagrantly disorganized, incoherent states with obvious attentional impairment and the examiner may be unable to test their other cognitive functions. (When found in the course of bipolar disorder, this state has been incorrectly called manic delirium.) Such states cannot be reliably distinguished phenomenologically from delirium due to the more usual medical causes, and they warrant the same thorough search for contributing etiologies accorded other deliria.

Course and Prognosis By most definitions, although not by DSM-IV criteria, delirium is a transient condition. For most patients the syndrome resolves within days to a few weeks. However, in sicker populations the mortality associated with delirium is high in the short term (acute hospitalization) and increases with several months of follow-up. It is not clear if increased mortality is independently associated with delirium or if it can be accounted for by known medical pathology. In some patients an apparently new dementia becomes evident on resolution of the delirium; the dementia may not have been present or may have been present but unrecognized prior to the delirium.

Treatment The primary treatment of delirium is to identify and ameliorate any causal or contributing medical conditions. As part of that effort, the dosages of all sedatives and other CNS-active medications should be minimized as much as possible. (The exception is sedative-hypnotic or alcohol withdrawal delirium, in which treatment of the underlying problem requires the administration of a cross-tolerant agent such as a benzodiazepine.) Delirious patients may need extra supportive physical care; maintenance of basic functions such as food and fluid intake is crucial to rapid recovery. Keeping the patient in an environment that is quiet and free of unnecessary stimulation may help reduce agitation. Frequent cues to orientation may also be helpful. Supportive contacts with the patient, family, and sometimes staff members are necessary to reassure the patient that the new, often frightening behavioral state reflects physical illness and that the patient is not going crazy. Attention may need to be paid to the patient's legal capacity to participate in informed clinical care decisions.

The patient with a quiet, hypoactive delirium needs no specific pharmacotherapy. However, many delirious patients show persistent or intermittent psychomotor agitation that may interfere with nursing care or necessary tests and procedures. Control of the agitation is essential to prevent inadvertent self-damage and allow appropriate evaluation and treatment. Physical restraints may be used transiently when necessary. If sedation is desired, the drug of choice is a high-potency antipsychotic agent in relatively low dosages (e.g., haloperidol 0.5 to 1 mg orally or parenterally, up to several mg a day). Low-potency agents, benzodiazepines, and other sedatives (antihistamines, barbiturates) should generally be avoided because they are likely to worsen the delirious state. At times of severe, life-threatening agitation (e.g., if a patient in the intensive care unit is removing the endotracheal tube, arterial lines, and so forth), sedation at nearly any cost becomes necessary, and combinations of antipsychotic agents, benzodiazepines, and opioids have been used, as have neuromuscular-blocking agents, such as pancuronium (Pavulon), use of which depends on the availability of adequate ventilatory support).

There have been case reports of improvement in or remission of delirious states due to intractable medical illnesses with ECT. Although ECT may rarely be advised by a consultant with expertise in the procedure, routine consideration of ECT for delirium is not advised.

Dementia Interest in the study and care of patients with dementia has increased, coincident with the proportional increase of the elderly in the population. Although dementing disorders are defined by their multiple cognitive deficits, patients can present with the full array of psychiatric symptoms. And although dementia is most often associated with progressive processes, it does not by itself denote a deteriorating course. Thus, the clinician must seek any curable or treatable causes of dementia whenever it is recognized clinically, before irreversible CNS changes supervene.

Definition Dementia is a diminution in cognition in the setting of a stable level of consciousness. Dementia denotes a decrement of two or more intellectual functions, in contrast to focal or specific impairments such as amnestic disorder or aphasia. The persistent and stable nature of the impairment distinguishes dementia from the altered consciousness and fluctuating deficits of delirium. Dementia must also be distinguished from long-standing mental subnormality, as the former represents an acquired loss of or decline in prior intellectual and functional capacities.

History

Dementia has long been understood as describing an acquired cognitive and behavioral decline associated with brain disease. Jean Étienne Dominique Esquirol, in his classic, early nineteenth-century nosological work, *Mental Maladies: A Treatise on Insanity*, provided perhaps the first modern definition of dementia: “A cerebral affection usually chronic . . . and characterized by a weakening of the sensibility, understanding, and will.” In his study of over 300 patients, Esquirol described the noncognitive symptoms of dementia, reporting hallucinations, delusions, aggressive behavior, and motor abnormalities in many of the patients. Interestingly, however,

he included among the causes of dementia not only aging, head trauma, syphilis, and alcohol abuse, but also conditions such as “menstrual disorders, . . . onanism, . . . disappointed affections, . . . and political shocks.” Later investigators described neuropathological correlations for the dementia syndromes, firmly establishing the relation between brain disease and dementia. Contemporary interest has focused again on an etiological basis for the observed pathological and pathophysiological abnormalities and on risk factors, preventive measures, and specific treatments for dementia.

Comparative Nosology In DSM-III and DSM-III-R, dementia was listed as both a syndrome and a disorder. The development of specific criteria for the symptom constellation was a major departure from all previous nosologies. It proved to be a major conceptual advance for clinical practice and research. The dementia syndrome was one of the possible presentations of psychoactive substance-induced organic mental conditions and of organic mental conditions associated with Axis III physical disorders. Dementia was also listed as a group of specific disorders, including primary degenerative dementia of the Alzheimer's type, multi-infarct dementia, dementia associated with alcoholism, and dementia not otherwise specified. A severity scale of mild, moderate, or severe was provided. DSM-IV eliminates the distinction between dementia as a syndrome and dementia as a disorder. Instead, it delineates those dementing disorders that are related to specific systemic medical or cerebral conditions (e.g., dementia of the Alzheimer's type and vascular dementia). DSM-IV criteria emphasize the defining features of dementia, namely the multiple deficits that represent a decline from a previously attained level of functioning, and incorporate specific information for distinguishing the etiological subcategories from each other, relying on course of the disease, the presence or absence of focal neurological signs and symptoms, laboratory evidence of neurological damage, a history of significant substance abuse, or other evidence of a contributing medical condition. Dementia of the Alzheimer's type is a diagnosis of exclusion, requiring that other potentially etiological CNS or systemic medical conditions be ruled out.

Beyond DSM-IV, there are alternative, conceptually overlapping systems for diagnosing dementia. ICD-10, in contrast to DSM-IV, maintains the approach adopted in DSM-III and DSM-III-R, with a general syndromic definition, which is then applied to specific disorders; for example, dementia in Alzheimer's disease or dementia in Huntington's disease. ICD-10 defines *dementia* as a syndrome in which:

> there is a disturbance of multiple higher cortical functions, including memory, thinking, orientation, comprehension, calculation, learning capacity, language, and judgement. Consciousness is not clouded. Impairments of cognitive function are commonly accompanied, and occasionally preceded, by deterioration in emotional control, social behaviour, or motivation . . . In assessing the presence or absence of a dementia, special care should be taken to avoid false-positive identification: motivational or emotional factors, particularly depression, in addition to motor slowness and general physical frailty, rather than loss of intellectual capacity, may account for failure to perform.

ICD-10 also states:

> Dementia produces an appreciable decline in intellectual functioning, and usually some interference with personal activities of daily living, such as washing, dressing, eating, personal hygiene, excretory and toilet activities. How such a decline manifests itself will depend largely on the social and cultural setting in which the patient lives. Changes in role performance, such as lowered ability to keep or find a job, should not be used as criteria of dementia because of the large cross-cultural differences that exist in what is appropriate, and because there may be frequent, externally imposed changes in the availability of work within a particular culture.

This latter statement differs fundamentally from DSM-IV. It underscores an unresolved controversy in the clinical and scientific literature where, in the absence of diagnostic tests for specific disease entities, clinicians and researchers look for sensitive indicators of onset and disease impact. Although ICD-10 explicitly eschews a functional performance criterion, its diagnostic guidelines for dementia then state: “The primary requirement for diagnosis is evidence of a decline in both memory and thinking which is sufficient to impair personal activities of daily living. The impairment of memory typically affects the registration, storage, and retrieval of new information, but previously learned and familiar material may also be lost, particularly in the later stages. Dementia is more than dysmnesia: there is also impairment of thinking and of reasoning capacity, and a reduction in the flow of ideas. The processing of incoming information is impaired, in that the individual finds it increasingly difficult to attend to more than one stimulus at a time, such as taking part in a conversation with several persons, and to shift the focus of attention from one topic to another. If dementia is the sole diagnosis, evidence of clear consciousness is required.” Thus the central component outlined in ICD-10 is “a decline . . . sufficient to impair personal activities of daily living.” Many investigators view this level of decrement as overly severe or too far progressed, potentially precluding use of newly available therapeutic agents until the degenerative process has advanced unnecessarily. Also, these distinctive approaches to diagnostic criteria underscore the potential for substantial variation between the results of studies employing one set versus the other. In the absence of a ‘gold standard' test to externally validate one approach or the other, clinicians and investigators comparing research results must maintain a high degree of caution.

ICD-10 includes four dementia categories: (1) dementia in Alzheimer's disease; (2) vascular dementia; (3) dementia in diseases classified elsewhere in the ICD (e.g., dementia in Pick's disease, Huntington's disease, Parkinson's disease, Creutzfeldt-Jakob disease); and (4) unspecified dementia.

Another set of research criteria for the diagnosis of dementia of the Alzheimer's type, established by the National Institute of Neurological Communicative Diseases and Stroke (NINCDS) and the Alzheimer's Disease and Related Disorders Association (ADRDA), now the Alzheimer's Association, has become known as the NINCDS-ADRDA criteria. Several studies have shown that a diagnosis of probable dementia of the Alzheimer's type according to NINCDS-ADRDA criteria selects patients similar to those diagnosed using DSM-III criteria. Depending on the case series, both criteria sets have been capable of identifying cases of Alzheimer's disease confirmed postmortem with a 70 to 90 percent specificity. The DSM-IV criteria share many features for the diagnosis of probable dementia of the Alzheimer's type but go beyond them to more clearly define important behavioral subtypes, akin to ICD-10, that may help guide symptomatic treatment interventions.

Recent critics regard the DSM-IV specifying phrase “with behavioral disturbance” as inadequate. Some advocate the enumeration of discrete subtypes of noncognitive neuropsychiatric syndromes to further classify the behavioral and psychological signs and symptoms found in patients with neurodegenerative dementing disorders. Whether such an approach will prove useful will depend upon defining more completely: (1) the presentation (i.e., form) of the clinical signs and symptoms that require treatment; (2) whether specific noncognitive neuropsychiatric syndromes exist as a central feature (although neither necessary nor sufficient diagnostically) of Alzheimer's disease or other diseases that cause dementia; (3) the prognostic significance of such symptoms, signs, or syndromes; (4) their pathobiological and causal substrates; (5) psychological, social, and environmental factors that affect their expression; and (6) their response(s) to specific therapeutic interventions.

Epidemiology The prevalence of dementia rises exponentially with age. The estimated prevalence of moderate to severe dementia in a population aged 65 years or older is consistently reported at approximately 5 percent. Within that age group the exponential curve is pronounced so that the prevalence in the subgroup aged 65 to 69 years is 1.5 to 2 percent; in the subgroup aged 75 to 79 years it is 5.5 to 6.5 percent; and in the subgroup aged 85 to 89 years it is 20 to 22 percent. Dementia of the Alzheimer's type is the most common dementing disorder in clinical and neuropathological prevalence studies reported from North America, Scandinavia, and Europe. Prevalence studies from Russia and Japan show vascular dementia to be more common in those countries. It remains unclear whether those apparent clinical differences reflect true etiological distinctions or inconsistent uses of diagnostic criteria. Dementia of the Alzheimer's type becomes more common with increasing age; among persons older than 75 years, the risk is six times greater than the risk for vascular dementia. There is a suggestion of higher rates of dementia of the Alzheimer's type in females and higher rates of vascular dementia in males. In geriatric psychiatric patient samples, dementia of the Alzheimer's type is a much more common etiology (50 to 70 percent) than vascular dementia (15 to 25 percent).

Studies of the incidence of dementia have been plagued by widely differing methodology and results. Again, there is an exponential increase in incidence with age, although some reports have noted a leveling off starting around age 75 years.

Etiology Table 10-27 lists common causes of dementia. Alzheimer's disease, the most common type of degenerative dementia, was discussed in an earlier section. Huntington's disease and Parkinson's disease were also discussed earlier in the chapter as paradigmatic examples of subcortical degenerative processes, with clinical and neuropathological descriptions separating them from cortical dementias. There may be clinical and neuropathological overlap between Alzheimer's disease and Parkinson's disease, especially among older patients. The significance of this finding remains unknown.

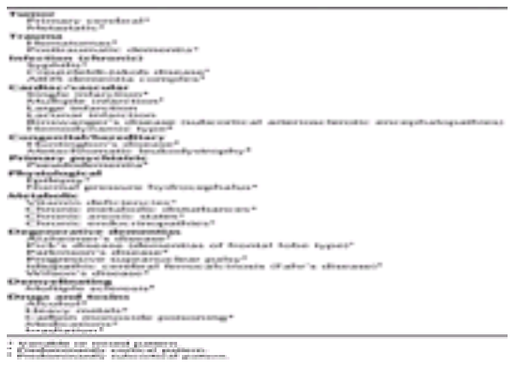


Table 10-27 Causes of Dementia

Frontal Lobe Degeneration In recent years several authors have sought to distinguish dementias of the frontal lobe from other disorders. The uncertain status of dementias of the frontal lobe as distinct clinical and neuropathological entities has not yet warranted their formal inclusion in DSM-IV or ICD-10. They are described as cortical dementias that are found in as many as 10 to 20 percent of cases in some neuropathological series. Age at onset is apparently between 50 and 60 years for the majority, but the reported range is broad—20 to 80 years. The early clinical features of frontal lobe dementias are typified by damage to the frontal lobes and include prominent changes in personality and behavior. The personality changes include disinhibition, social misconduct, and lack of insight; these changes progress to apathy, mutism, and repetitive behaviors. A variant of the Kluver-Bucy syndrome, a condition originally described in monkeys that had undergone surgical ablation of the temporal lobes, is also described in the early stages of frontal lobe dementias and is characterized by combinations of disrupted eating behavior, hyperorality, mood disturbances, and sensory agnosias. Language, praxis, and gnosis are relatively spared early in the disease course, in contrast to dementia of the Alzheimer's type. However, dementias of the frontal lobe are described as progressive conditions that may in some cases involve memory as well as other cognitive functions. To date no studies have attempted to prospectively discriminate dementia of frontal lobe origin from dementia of the Alzheimer's type, with subsequent neuropathological confirmation to determine clinical diagnostic accuracy.

Neuropsychological testing in patients suspected of having dementia of frontal lobe origin may demonstrate disproportionate impairment in tasks related to frontal lobe function, such as deficiency in abstract thinking, attentional shifting, or set formation. Structural neuroimaging, such as CT or MRI, may reveal prominent atrophy of the frontal lobe, especially early in the disease process. Functional neuroimaging may prove more reliable for distinguishing dementia of frontal lobe origin from dementia of the Alzheimer's type. Regional cerebral blood flow studies using radioactively labeled xenon and SPECT studies have demonstrated disproportionate decreases in blood flow, radio tracer uptake, and glucose metabolism in the frontal lobes in patients with suspected or autopsy-confirmed frontal lobe dementia.

At present, the definitive diagnosis of any degenerative dementia rests on postmortem neuropathological examination. Only one type of frontal lobe dementia, Pick's disease, is associated with distinctive histopathological abnormalities that allow for certain diagnosis. Swollen neurons known as Pick cells and intraneuronal inclusions known as Pick bodies define the disorder neuropathologically (Fig. 10-12). Demyelination and gliosis of the frontal lobe white matter may also be found. Other frontal lobe dementias have been referred to as dementia of the frontal lobe type or frontal lobe degeneration of non-Alzheimer's type. They have been distinguished from Alzheimer's disease by their marked gross morphological involvement of frontal and anterior temporal lobes, with relative sparing of the postcentral and temporoparietal areas mostly affected in Alzheimer's disease, and by the absence of amyloid plaques and neurofibrillary tangles microscopically. The lack of positive neuropathological inclusion criteria leaves many of these clinical conditions as disease entities of uncertain status, defined histopathologically by the absence of specific features. Whenever the hallmark findings of Alzheimer's disease are present, that diagnosis has been applied, irrespective of prior clinical findings. Thus, there are no data available to determine how many clinically diagnosed cases of frontal lobe dementia have been recast as Alzheimer's disease after death.

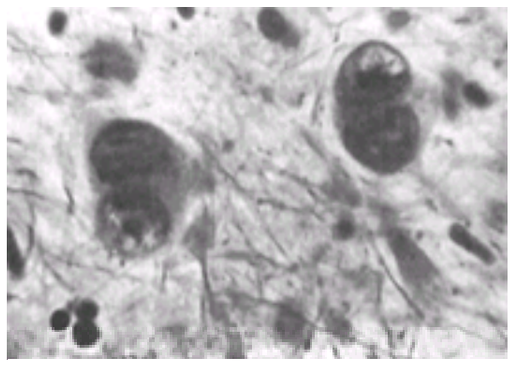

FIGURE 10-12 Intraneuronal inclusions in Pick's disease. Silver stain. (Reprinted with permission from Rowland LP, editor: *Merritt's Textbook of Neurology*, ed 9. Williams & Wilkins, Baltimore, 1995.)

Of the potentially multiple forms of dementia associated with progressive frontal lobe dysfunction, only one type can be distinguished from Alzheimer's disease neuropathologically; the others show no defining postmortem signs. They may also be difficult to distinguish clinically in life. In the early stages of disease, the predominance of behavioral and personality disturbance, the presence of primitive reflexes, and neuropsychological and neuroimaging evidence of disproportionate frontal lobe involvement can help with a more confident premortem diagnosis of frontal lobe dementia. Some authors have assumed that there are many variants of dementia of frontal lobe origin that cannot be distinguished from each other clinically; at present, only Pick's disease has definitive neuropathological features.

Subcortical Degeneration Huntington's disease and Parkinson's disease were discussed earlier as examples of degenerative disorders with a subcortical pattern of deficits. *Progressive supranuclear palsy*, first described in 1964, is a degenerative disease involving the brainstem, cerebellum, and basal ganglia. The presenting history is usually notable for a gait disturbance, particularly spontaneous toppling. The clinical examination is notable for supranuclear paralysis of extraocular movements, particularly in the vertical plane. Dysarthria and dystonic rigidity of the neck and trunk are also common. Onset is usually after age 50 years, with progressive muscular rigidity. Neuropathology is notable for cell loss and gliosis of various nuclei in the brainstem, basal ganglia, and cerebellum, with striking preservation of the cortex. Progressive supranuclear palsy and Huntington's disease were the two disorders to which the label “subcortical dementia” was originally applied. In progressive supranuclear palsy a marked slowing of cognitive processes, apathy, and lack of initiative have been described, associated with relative sparing of language, memory, and praxis. *Fahr's disease* involves idiopathic calcification of the basal ganglia. A subcortical dementia with a parkinsonian syndrome has been described. (Mild basal ganglia calcification is frequently observed incidentally on neuroimaging studies. The clinical significance of that finding is unknown.) Basal ganglia calcification can also be seen in patients with disorders of calcium metabolism, with the expected patterns of subcortical dementia and movement disorder.

Vascular Etiologies Cerebrovascular diseases together comprise the second most common cause of dementia. This category of dementia was referred to in the past as arteriosclerotic dementia, reflecting the belief that vascular insufficiency was responsible for the cognitive degeneration. That has now been supplanted by the belief that tissue damage or infarction underlies the vascular dementias. Cerebral infarction can be the result of a number of processes, of which thromboembolism from a large vessel plaque or cardiothrombus is the most common (Fig. 10-13). Anoxia due to cardiac arrest, hypotension, anemia, or sleep apnea can also produce ischemia and infarction. Cerebral hemorrhage related to hypertension or an arteriovenous malformation accounts for approximately 15 percent of cerebrovascular disease (Fig. 10-14).

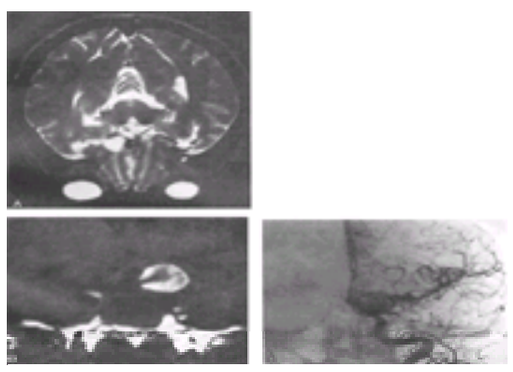

FIGURE 10-14 Giant aneurysm. **A**, T2-weighted axial MRI scan shows a large, hyperintense mass in the left suprasellar region with medial displacement of the distal left internal carotid artery. **B**, T1-weighted coronal MRI scan demonstrates the heterogeneous parasellar mass; the areas of increased signal intensity indicate thrombus. A small curvilinear focus of flow void is seen medially most consistent with small residual patent vascular lumen. These findings are suggestive of partially thrombosed giant aneurysm. **C**, Anteroposterior view of arterial phase of left common carotid arteriogram illustrates a giant aneurysm of the left internal carotid artery. (Reprinted with permission from Rowland LP, editor: *Merritt's Textbook of Neurology*, ed 9. Williams & Wilkins, Baltimore, 1995.)

The clinical characteristics of a vascular dementia depend on the area of infarction. As such, there is a wide variability in the possible presenting features of a vascular dementia. Single infarctions may result in the discrete loss of one particular function (e.g., language) without dementia per se. However, some strategically located infarctions can affect more than one domain of cognitive function and mimic the clinical picture of a global dementia. An example is the angular gyrus syndrome that can occur with large posterior lesions in the dominant hemisphere. It has been characterized as manifesting with alexia with agraphia, aphasia, constructional disturbances, and Gerstmann syndrome (acalculia, agraphia, right-left disorientation, and finger agnosia). Although the findings are similar to those of dementia of the Alzheimer's type, angular gyrus syndrome can be distinguished by its abrupt onset, the presence of focal neurological, EEG, and imaging abnormalities, and preservation of memory and ideomotor praxis.

Vascular dementia is more commonly associated with multiple infarctions. The infarctions may take the form of numerous large infarctions accompanied by widespread cognitive and motor deficits. Tiny, deep infarctions, *lacunes*, result from disease of the small arteries that usually involves subcortical structures, such as the basal ganglia, thalamus, and internal capsule. The neurological and cognitive deficits may resolve quickly after each of the small strokes; however, the deficits may accumulate, leading to a persisting functional and intellectual decline. In the past a stepwise pattern of deterioration was described for that type of vascular dementia, but it was dropped from the DSM-IV criteria, as no specific pattern of deterioration has been reliably demonstrated for vascular dementias. Similarly, the description of patchy deficits has been deleted, in light of the marked variability in presentation of vascular dementia, depending on the type of vasculature and the site and extent of infarction.

Binswanger's Disease Also called subcortical arteriosclerotic encephalopathy, this is characterized by microinfarctions of the white matter with sparing of the cortex. It was originally believed to be a rare form of dementia that could be diagnosed only at autopsy. With the advent of sophisticated neuroimaging techniques such as CT and MRI and the common observation of white matter hyperintensities, there is renewed interest in the disease. Binswanger's disease produces a subcortical pattern of dementia, as the neuropathology is restricted to white matter. However, the mere presence of white matter hyperintensities on MRI is not adequate for diagnosis, as those areas may represent small infarctions, focal demyelination, or simply dilated perivascular spaces. Some studies have found no postmortem pathological correlate to white matter hyperintensities detected on MRI in vivo. Recently, criteria have been proposed for the diagnosis of Binswanger's disease that include clinical and neuropsychological confirmation of dementia, the presence of vascular risk factors, evidence of focal cerebrovascular disease, evidence of subcortical dysfunction, and bilateral white matter abnormalities greater than 2 mm in size on CT or T2-weighted MRI scans. Vascular dementia of the hemodynamic type is a classification that has been used to refer to cognitive impairments that arise secondary to hypotensive episodes, such as those due to cardiac dysrhythmias or hypotension. They may overlap phenomenologically with other conditions that result from chronic hypoxia.

Wilson's disease (*hepatolenticular degeneration*) is an inherited disorder involving abnormal metabolism of copper. Copper accumulates in both the liver and the CNS, particularly in the striatum, caudate, and putamen. Onset usually occurs during childhood or adolescence, although it may be delayed until middle age. Personality change and behavioral disturbance are the most common neuropsychiatric manifestations (and frequently the presenting symptoms of the disease), but cognitive impairment may also be present. The latter takes the form of a subcortical dementia, with psychomotor slowing and loss of initiative, in the presence of relatively spared language functions, memory, and praxis. Motor symptoms are prominent in a parkinsonian pattern and include rigidity, tremor, and, at times, athetosis. The diagnosis is confirmed by assay of serum copper levels and urinary copper excretion. Treatment with chelating agents—dimercaprol (BAL); in the past and penicillamine (Cuprimine) more recently—can retard the progression of the disease and in some instances can result in improvement in clinical features. Neuropsychiatric symptoms are treated symptomatically.

Other Causes Primary psychiatric disorders can present with cognitive impairment. The term “pseudodementia” has been used to describe cognitive deficits that can be seen in the presence of idiopathic psychiatric illness, especially major depressive disorder. The deficits are usually subcortical in nature, involving attention, speed of mental processing, memory retrieval, and verbal fluency and elaboration. Patients may register new material but have difficulty with spontaneous recall that typically improves when they are presented with recognition cues. Pseudodementia was originally thought to be simply another expression of the depressed patient's lack of energy and unwillingness to attend to tasks. More recently, it has become clear that the deficits of pseudodementia represent fundamental cognitive deficits related to the same brain dysfunction that is responsible for the depressive symptoms. *Pseudodementia syndrome of depression* is one current term that is synonymous with *pseudodementia* and may more accurately reflect the nature of the pathobiological process. Recent studies have indicated that it may have a poorer prognosis, especially in the elderly, and several investigators have described a persistent mild anomia in the same patient population.

Schizophrenia was viewed at first as a disorder in which cognitive impairment was a prominent feature (dementia precox). Negative symptoms such as paucity of speech, poverty of ideas, blunting of affect, and functional deterioration contributed to that perception. Contemporary studies have demonstrated consistent cognitive deficits in certain subgroups of schizophrenia patients, primarily involving neuropsychological tasks thought to be sensitive to frontal lobe function. However, it is unclear whether those deficits are acquired over the course of the illness or represent cognitive skills that have never developed, consistent with the neurodevelopmental hypothesis of schizophrenia.

Normal pressure hydrocephalus is an idiopathic disorder caused by partial obstruction to the flow of CSF into the subarachnoid space. Onset typically occurs after age 60 years. The pathophysiology is thought to be related to disruption of neural function, either through stretching of periventricular fibers or through disruption of the pressure differential between the ventricular and subdural spaces, compromising neuronal function by altering cerebral blood flow. The classic clinical triad of dementia, incontinence, and gait disturbance is not present uniformly in all patients with normal pressure hydrocephalus, especially early in the course, although it

nearly always emerges if the condition goes unrecognized or untreated. The diagnosis is based on clinical findings, neuroimaging evidence of ventricular dilation in the absence of sulcal widening (Fig. 10-15), and normal CSF pressure measurements on lumbar puncture. The dementia can be of a subcortical or cortical pattern and may at times be reversed with CSF shunt surgery. Specific indicators of a positive outcome remain to be established, although identification of the etiology and a short disease course favor improvement in the dementia. Rarely, case reports have documented marked improvements up to 4 years after the onset of progressive dementia.

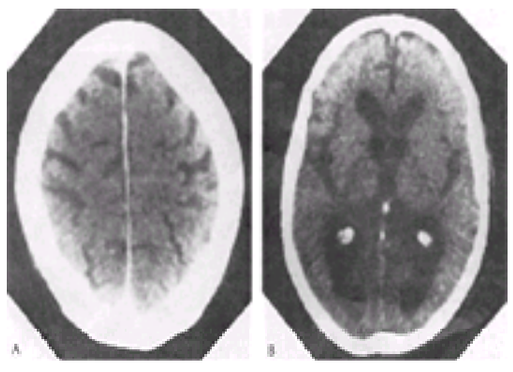

FIGURE 10-15 Brain CT scans. Marked ventricular dilatation (**A**) and widening of cortical sulci (**B**) indicative of hydrocephalus ex vacuo in a 64-year-old woman with dementia. (Reprinted with permission from Rowland LP, editor: *Merritt's Textbook of Neurology*, ed 9. Williams & Wilkins, 1995.)

Irradiation-induced dementia is an iatrogenic concomitant of cranial radiation treatment that has been reported with greater frequency as the posttreatment survival time for patients with intracranial tumors has lengthened. Although transient cognitive deficits can be observed coincident with treatment or soon after treatment, a progressive irreversible dementia can begin 6 to 24 months after the termination of treatment. White matter is particularly sensitive to the deleterious effects of irradiation, and the dementia is predominantly subcortical in nature, reflecting the preferential white matter degeneration. The pathophysiology has been hypothesized to involve arteriolar leakage and localized edema.

DIAGNOSIS AND CLINICAL FEATURES

DSM-IV has eliminated the general syndrome of dementia that was included in DSM-III-R. The dementia diagnoses in DSM-IV are dementia of the Alzheimer's type (Table 10-28), vascular dementia (Table 10-29), dementia due to other general medical conditions (Table 10-30), substance-induced persisting dementia (Table 10-31), dementia due to multiple etiologies (Table 10-32), and dementia not otherwise specified (Table 10-33). The ICD-10 diagnostic criteria for dementia are presented in Table 10-34, Table 10-35, Table 10-36, and Table 10-37.

Table 10-28 DSM-IV Diagnostic Criteria for Dementia of the Alzheimer's Type

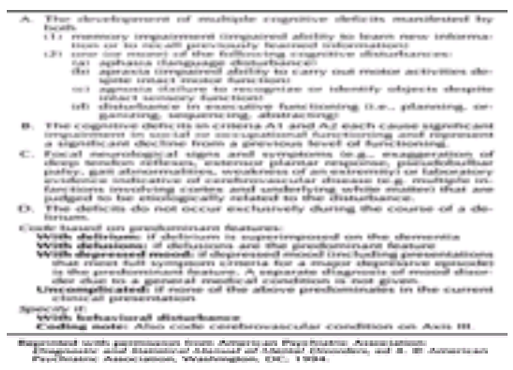

Table 10-29 DSM-IV Diagnostic Criteria for Vascular Dementia

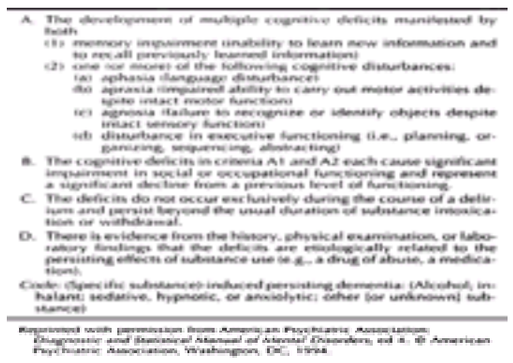
Table 10-30 DSM-IV Diagnostic Criteria for Dementia Due to Other General Medical Conditions



A. The development of multiple cognitive deficits manifested by both
(1) memory impairment (inability to learn new information and to recall previously learned information)
(2) one (or more) of the following cognitive disturbances:
(a) aphasia (language disturbance)
(b) apraxia (impaired ability to carry out motor activities despite intact motor function)
(c) agnosia (failure to recognize or identify objects despite intact sensory function)
(d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
C. The deficits do not occur exclusively during the course of a delirium and persist beyond the usual duration of substance intoxication or withdrawal.
D. There is evidence from the history, physical examination, or laboratory findings that the deficits are etiologically related to the persisting effects of substance use (e.g., a drug of abuse, a medication).
Code: (Specific substance)-induced persisting dementia: (Alcohol); inhalant; sedative, hypnotic, or anxiolytic; other (or unknown) substance)

Table 10-31 DSM-IV Diagnostic Criteria for Substance-Induced Persisting Dementia

A. The development of multiple cognitive deficits manifested by both
(1) memory impairment (inability to learn new information and to recall previously learned information)
(2) one (or more) of the following cognitive disturbances:
(a) aphasia (language disturbance)
(b) apraxia (impaired ability to carry out motor activities despite intact motor function)
(c) agnosia (failure to recognize or identify objects despite intact sensory function)
(d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
C. There is evidence from the history, physical examination, or laboratory findings that the disturbance has more than one etiology (e.g., head trauma plus chronic alcohol use, dementia of the Alzheimer's type with the subsequent development of vascular dementia).
D. The deficits do not occur exclusively during the course of delirium.
Coding note: Use multiple codes based on specific dementias and specific etiologies, e.g., dementia of the Alzheimer's type, with late onset uncomplicated; vascular dementia, uncomplicated.

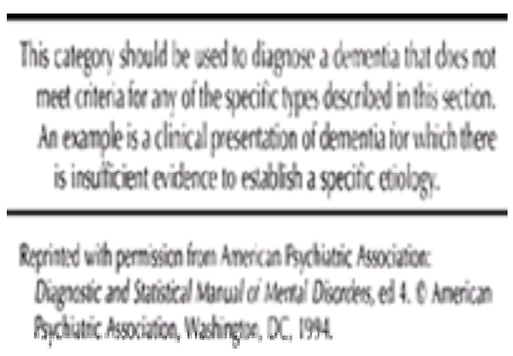
Table 10-32 DSM-IV Diagnostic Criteria for Dementia Due to Multiple Etiologies



This category should be used to diagnose a dementia that does not meet criteria for any of the specific types described in this section. An example is a clinical presentation of dementia for which there is insufficient evidence to establish a specific etiology.

Table 10-33 DSM-IV Diagnostic Criteria for Dementia Not Otherwise Specified

Table 10-34 ICD-10 Diagnostic Criteria for Dementia

Table 10-35 ICD-10 Diagnostic Criteria for Dementia in Alzheimer's Disease

Table 10-36 ICD-10 Diagnostic Criteria for Vascular Dementia

Table 10-37 ICD-10 Diagnostic Criteria for Dementia in Other Diseases Classified Elsewhere

Dementia of the Alzheimer's Type The DSM-IV diagnostic criteria for dementia of the Alzheimer's type emphasize the presence of memory impairment and the associated presence of at least one other symptom of cognitive decline (aphasia, apraxia, agnosia, or abnormal executive functioning). The diagnostic criteria also require a continuing and gradual decline in functioning, impairment in social or occupational functioning, and the exclusion of other causes of dementia. DSM-IV suggests that the age of onset be characterized as early (at age 65 or below) or late (after age 65) and that a predominant behavioral symptom be coded with the diagnosis, if appropriate.

Vascular Dementia The general symptoms of vascular dementia are the same as those for dementia of the Alzheimer's type, but the diagnosis of vascular dementia requires the presence of either clinical or laboratory evidence supportive of a vascular cause of the dementia.

Dementia Due to Other General Medical Conditions DSM-IV lists six specific causes of dementia that can be coded directly: HIV disease, head trauma, Parkinson's disease, Huntington's disease, Pick's disease, and Creutzfeldt-Jakob disease. A seventh category allows the clinician to specify other nonpsychiatric medical conditions associated with dementia.

Substance-Induced Persisting Dementia The primary reason that this DSM-IV category is listed both with the dementias and with the substance-related disorders is to facilitate the clinician's thinking regarding differential diagnosis. The specific substances that DSM-IV cross-references are alcohol; inhalant; sedative, hypnotic, or anxiolytic; and other or unknown substances.

Clinical Diagnosis and Evaluation The first step in the diagnosis of dementia is to establish that the cognitive deficits have occurred in a patient with a stable level of consciousness, without fluctuation or waxing and waning. It must also be demonstrated that the patient has multiple deficits rather than a focal disturbance such as that seen in amnestic disorder or primary progressive aphasia (the insidious onset of a slowly progressive language disturbance with relatively preserved memory, reasoning, judgment, and comportment). Once the basic criteria for the diagnosis of dementia have been met, the task is to determine which etiology is responsible by using the standard means of history, clinical examination, and laboratory evaluation.

A 61-year-old high-school science department head, who was an experienced and enthusiastic camper and hiker, became extremely fearful while on a trek in the mountains. Gradually, over the next few months he lost interest in his usual hobbies. Formerly a voracious reader, he stopped reading. He had difficulty doing computations and made gross errors in home financial management. On several occasions he became lost while driving in areas that were formerly familiar to him. He began to write notes to himself so that he would not forget to do errands. Very abruptly, and in uncharacteristic fashion, he decided to retire from work, without discussing his plans with his wife. Intellectual deterioration gradually progressed. He spent most of the day piling miscellaneous objects in one place and then transporting them to another spot in the house. He became stubborn and querulous. Eventually he required assistance to shave and dress.

When examined 6 years after the first symptoms had developed, the patient was alert and cooperative. He was disoriented with respect to place and time. He could not recall the names of four or five objects after a 5-minute interval of distraction. He could not remember the names of his college and graduate school or the subject in which he had majored. He could describe his job by title only. In 1978 he thought that John Kennedy was president of the United States. He did not know Joseph Stalin's nationality. His speech was fluent and well articulated, but he had considerable difficulty finding words and used many long and essentially meaningless phrases. He called a cup a vase, and identified the rims of glasses as “the holders.” He did simple calculations poorly. He could not copy a cube or draw a house. His interpretation of proverbs was concrete, and he had no insight into the nature of his disturbance.

An elementary neurological examination revealed nothing abnormal, and routine laboratory tests were also negative. A CT scan, however, showed marked cortical atrophy. (Reprinted with permission from *DSM-IV Casebook*.)

For dementia of the Alzheimer's type, a family history of the dementia is probably the most important risk factor after advanced age. A family history of Down syndrome or of hematological malignancies, such as leukemia, myelolymphoma, or Hodgkin's disease, is also associated with an increased risk for Alzheimer's disease. There is some evidence for a familial predisposition to vascular dementia, but it has not been demonstrated as clearly as for dementia of the Alzheimer's type. The family history is of greatest significance in the heredity dementias, such as Huntington's disease, which is transmitted via a single autosomal dominant gene with nearly 100 percent penetrance. A history of a parent or grandparent with a movement disorder and dementia should alert the clinician to that diagnostic possibility. Huntington's disease does not skip generations, although family members may have died from other causes prior to the emergence of definable symptoms. A familial pattern has been established for Wilson's disease, with a presumptive autosomal recessive gene responsible for abnormal copper metabolism. Metachromatic leukodystrophy similarly is inherited in a recessive pattern with incomplete penetrance.

Degenerative dementias as a group do not have well-established risk factors other than old age and familial patterns. For dementia of the Alzheimer's type, other risk factors identified tentatively in recent years include female sex, a past history of head trauma, and lower education. Vascular dementias are highly associated with the risk factors for cerebrovascular disease. Those factors include hypertension (especially with systolic pressures greater than 160 mmHg), cardiac disease, transient ischemic attacks, diabetes mellitus, carotid bruits, and sickle cell disease. Obesity, a sedentary lifestyle, tobacco use, alcohol consumption, and elevated serum cholesterol and lipid levels are less well established as risk factors for cerebrovascular disease.

A history of severe head trauma or multiple traumas over a period of time (such as in boxers) should raise the suspicion of dementia related to brain trauma. Although severe head trauma earlier in life increases the risk of dementia of the Alzheimer's type, its mechanism of action is unknown. A history of an untreated or partially treated sexually transmitted disease should raise the suspicion for neurosyphilis. The presence of risk factors for HIV infection, namely homosexuality, multiple sexual partners, and intravenous drug use, similarly increase the risk for dementia due to HIV disease. Patients with chronic medical illnesses, especially if poorly controlled, such as epilepsy, renal failure, or hepatic cirrhosis, are also at greater risk for developing dementias. A history of occupational exposure to heavy metals or other toxins should be obtained as part of any evaluation for dementia.

Pathology and Laboratory Examination A general physical examination is a routine component of the workup for dementia. It may reveal evidence of systemic disease causing brain dysfunction, such as an enlarged liver and hepatic encephalopathy, or it may demonstrate systemic disease related to particular CNS processes. The detection of Kaposi's sarcoma, for example, should alert the clinician to the probable presence of AIDS and the associated possibility of AIDS dementia complex. Focal neurological findings, such as asymmetrical hyperreflexia or weakness, are seen more often in vascular than in degenerative diseases. Frontal release signs and primitive reflexes, while suggesting pathology in the frontal lobe, are present in many disorders and often point to a greater extent of

progression.

Laboratory evaluation can assist in definitive identification of the etiological agent. The range of possible etiologies of dementia mandates selective use of laboratory tests. The evaluation should follow informed clinical suspicion, based on the history and physical and mental status examination results. Table 10-4 lists a number of laboratory tests useful in evaluating specific diseases presenting as dementia.

Differential Diagnosis The first step in the diagnosis of dementia is to exclude delirium. Delirium can mimic every possible psychiatric disorder and symptom. It is most common in the same populations in which dementia is most common, namely the elderly and the brain-injured. It can be distinguished from dementia by its cardinal feature, disturbance of consciousness. Level of consciousness or arousal must be determined to be stable before a diagnosis of dementia can be made with confidence. Dementia must also be distinguished from focal or specific cognitive impairments, such as those seen in aphasic or amnestic patients. Mood disorders can present with cognitive symptoms, particularly in the dementia of depression or pseudodementia. A history of a mood disorder or a current disturbance in neurovegetative function should alert the clinician to the possibility of a major depressive disorder.

Course and Prognosis The course and prognosis of a dementia syndrome vary with its cause. Dementia does not in itself imply a progressive deterioration, although many of the pathobiological processes underlying dementia are degenerative, and there is no known means of altering the progressive clinical deterioration. The rate of progression may vary within families or from individual to individual. Occasionally, progression can be halted or slowed in the vascular dementias if contributing risk factors for further vascular events can be reduced. Some dementias, such as those related to endocrine or metabolic processes or drug intoxications, may resolve entirely with the treatment or with removal of the basic disorder. However, a long-standing cerebral insult often leads to chronic clinical deficits that persist even when the insult has been removed. Dementias related to tumor and infection usually follow a similar pattern.

Age at onset is an important feature of any illness. Alzheimer's disease is the most common cause of dementia in the United States. Onset usually occurs after age 60 years and the prevalence increases exponentially with each successive decade, although cases have been reported in patients as young as 30 years. Familial forms of dementia of the Alzheimer's type appear to have an earlier age at onset. Cerebrovascular disease, the second most common cause of dementia, is associated with an earlier age at onset overall. Dementia secondary to other medical conditions usually arises only after the disease has progressed for some time. This observation is true of the dementias associated with infectious, physiological, metabolic, and toxic processes. The age at onset of Huntington's disease is usually between 30 and 50 years, but onset may occur earlier or later.

The dementias can be distinguished to some extent by their course, especially earlier in the disease process. Degenerative dementias are insidious in onset and gradually progressive. Despite the clinical rule of a steadily progressive course in dementia of the Alzheimer's type, some individuals may reach a plateau for several years in the overall functional impairment before progression resumes and continues on to death. Vascular dementias may follow a stepwise pattern, in which new deficits appear abruptly and associated with new vascular events, but the vascular dementias also often have an insidious onset and a slow but steadily progressive course. Dementias related to infection are usually acute, although syphilis and cryptococcal meningitis can have an indolent course. Metabolic dementias may begin rapidly or slowly, depending on the underlying systemic disease; correction of the basic deficiency or disturbance may result in improvement, although the cognitive deficits often persist. Drug- or toxin-related dementias may improve once the insult has been discontinued, although radiation-induced dementia is an exception: It first manifests many months after radiation exposure has ceased, and a progressive course ensues.

Treatment The first step in the treatment of dementia is verification of the diagnosis. Accurate diagnosis is imperative, for the progression may be halted or even reversed if appropriate therapy is provided. Preventive measures are important, particularly in vascular dementia. Such measures might include changes in diet, exercise, and control of diabetes and hypertension. Pharmacological agents might include antihypertensive, anticoagulant, or antiplatelet agents. Blood pressure control should aim for the higher end of the normal range, as that has been demonstrated to improve cognitive function in patients with vascular dementia. Blood pressure below the normal range has been demonstrated to result in further impairment of cognitive function in the patient with dementia. The choice of antihypertensive agent can be significant in that beta-blocking agents have been associated with exaggeration of cognitive impairment. Angiotensin-converting enzyme (ACE) inhibitors and diuretics have not been linked to the exaggeration of cognitive impairment and are thought to lower blood pressure without affecting cerebral blood flow (cerebral blood flow is presumed to correlate with cognitive function). Surgical removal of carotid plaques may prevent subsequent vascular events in carefully selected patients.

For the degenerative dementias, no direct therapies have been demonstrated conclusively to reverse or retard the fundamental pathophysiological processes. The search for such an agent has been exhaustive and fraught with frustration. Such studies are constructed on a growing foundation of knowledge regarding brain neurochemistry and the derangements found in dementia. Numerous neurotransmitters, including acetylcholine, dopamine, norepinephrine, GABA, and serotonin, and several neuropeptides, including somatostatin and substance P, are decreased in dementia. Alzheimer's disease has been studied the most extensively, but similar decreases in neurotransmitters have been found in Huntington's disease, alcohol–induced persisting dementia, vascular dementia, Parkinson's disease, and (rarely) in normal aging. Multiple neuropharmacological strategies have been devised in the hope of replenishing the deficient neurotransmitters. Replacement therapy for acetylcholine has been the most common and widely publicized strategy. Efforts at replenishment have included the use of acetylcholine precursors (e.g., example, choline [Anthropan] and lecithin [Phoschol]), cholinergic agonists (e.g., pilocarpine [Salagen] and arecoline), and cholinesterase inhibitors. Treatment with physostigmine (Antilirium, Eserine), a short-acting cholinesterase inhibitor, has consistently resulted in small but statistically significant improvements in memory in patients with dementia of the Alzheimer's type and in healthy control subjects during brief-duration infusion studies. New, longer-acting forms now are being investigated. Tacrine (Cognex), became the focus of public debate after a 1986 study reported alleged marked improvements in 16 patients with dementia of the Alzheimer's type. That study, however, was criticized for substantial methodological limitations and was not replicated in several subsequent attempts. Two multicenter studies of varying design were published in late 1992. One study, with an enriched population, aimed to maximize detection of beneficial effect, but found only marginal improvement and no overall evidence of clinically meaningful change. The second reported statistically significant but still modest improvements in cognition. The Food and Drug Administration (FDA) eventually approved the use of tacrine as a therapeutic agent for dementia of the Alzheimer's type. Clinicians must be aware of both its limited demonstrated benefit and its hepatotoxic potential.

Recently the FDA approved the cholinesterase inhibitor, donepezil (Aricept), for symptomatic treatment of mild to moderate cognitive deficits in patients with presumed Alzheimer's disease. Therapeutic effects have been modest. Dosages of 5 to 10 mg daily were given in experimental trials; common adverse effects have included nausea, diarrhea, and vomiting. Insomnia, muscle cramps, and anorexia have occurred occasionally, but unlike tacrine, so far there has been no reported hepatotoxicity. In summary, it has become clear that there are therapies available that may improve the function of patients with dementia of the Alzheimer's type without incurring severe toxicity. Thus it now seems reasonable to declare “When in doubt, treat!” This reflects a fundamental shift in the care of these individuals, moving beyond long-held nihilism to a more optimistic view of clinical intervention. It is the first step in a treatment revolution that will reach full force during the next 10 to 15 years.

Other experimental approaches to treating cognitive impairment or disease progression include a plant extract of *Ginkgo biloba*, estrogens, vitamin E, and prednisone (Deltasone, Orasone). Many researchers have concluded that the notion of a single or selective neurotransmitter defect for any specific dementing illness is simplistic and that future research efforts should be directed toward neuronal protection and regeneration. Selegiline (Eldepryl), a monoamine oxidase (MAO) type B (MAOB) inhibitor, has apparently slowed the progression of Parkinson's disease, presumably by limiting endogenous generation of destructive oxidative products. Similar antioxidant treatments are being used experimentally with other dementias, including Huntington's disease and vascular dementia. Naloxone (Narcan), an opiate antagonist, is thought to have possible application in vascular dementia based on animal studies in which it was demonstrated to decrease the sequelae of cerebral ischemia. Nerve growth factor is being studied as a means of promoting neural regeneration or sprouting.

The absence of curative therapies does not preclude efforts to ameliorate disturbing clinical problems. Symptomatic measures are the rule for behavioral management of most dementia syndromes. Programs that emphasize a high degree of regularity and consistency in daily schedule and environment can mitigate the risk of development of catastrophic reactions or explosive outbursts. All pharmacological agents that are used for the idiopathic psychiatric disorders can be used in patients with dementia, although usually at dosages one half to two thirds lower. Antidepressant medications and ECT are safe and effective for significant depressive symptoms. The use of antipsychotic should be restricted to patients with defined psychotic symptoms because patients with dementia are more susceptible to the parkinsonian adverse effects inherent in these agents. Clinicians and researchers are now cautiously using newer atypical antipsychotic drugs, seeking to avoid these adverse effects. Benzodiazepines may be used briefly and judiciously for emergency sedation but otherwise should be avoided because they can produce delirium and tend to further compromise residual cognitive capacities. Lithium (Eskalith), centrally active b-adrenergic blockers, carbamazepine (Tegretol), and valproate (Depakene) have been used empirically in the treatment of affective lability and aggressive outbursts. Empirical management therapies should be used in conjunction with environmental modifications. Individual psychotherapy may have benefit for patients in the early stages of dementia, especially to assist them in coping with their losses. The positive effects of a therapeutic relationship can still be felt at later stages when patients have more severe cognitive deficits. Family education and support are vital components of any treatment approach, as all members benefit from extensive knowledge about course and prognosis, as well as needing

assistance when assuming new roles in their relationships with the patient.

Amnestic Disorders The inclusion of amnestic disorders in the psychiatric nosology reflects the classification's roots as a manual for state hospital or asylum patients. The number of individuals given amnestic diagnoses due to nutritional deficiency, often related to chronic alcohol dependence, has declined. In contrast, traumatic causes have increased dramatically during recent decades.

Definition The essential feature of amnestic disorders is the acquired impaired ability to learn and recall new information, coupled variably with the inability to recall previously learned knowledge or past events. The impairment must be sufficiently severe to compromise personal, social, or occupational functioning. The diagnosis is not made if the memory impairment exists in the context of reduced ability to maintain and shift attention, as encountered in delirium, or in association with significant functional problems due to the compromise of multiple intellectual abilities, as seen in dementia. Amnestic disorders are secondary syndromes caused by systemic medical or primary cerebral diseases, substance use disorders, or medication adverse effects, as evidenced by findings from clinical history, physical examination, or laboratory examination.

History and Comparative Nosology Although amnestic disorder has been long described, its specific recognition has been relatively recent. It was most clearly elaborated by Sergei Korsakoff and was included among the alcoholic psychoses in DSM-I and DSM-II, as well as in earlier editions. In DSM-I it was classified under chronic brain syndrome associated with intoxication. Understanding that *psychosis* was the term used to denote more severe disturbances of mental status, the authors of DSM-I stated: “The latter [severe alcohol-related brain damage] may manifest itself by the type of chronic delirium formerly diagnosed as Korsakoff's psychosis.” Specific discussion of the amnestic syndromes was absent. Like DSM-I, DSM-II provided little clinical description of amnestic disorders, although a slightly longer definition was presented in the text.

DSM-III and DSM-III-R, in contrast, provided an in-depth discussion and more specific diagnostic criteria. However, both volumes failed to underscore the essential quality of amnestic disorder as characterized by a specific cognitive deficit in the realm of memory, while dementia syndromes were reflective of multiple failures, including memory and other impaired intellectual abilities. DSM-III and DSM-III-R required “demonstrable evidence of impairment in both short- and long-term memory,” whereas the key feature of the disorder is an inability to learn and later recall new information. In addition, neither DSM-III nor DSM-III-R provided for the separation of transient from persistent amnesia. ICD-10 maintains the approach of DSM-III.

Epidemiology Data are not available for estimating the point or lifetime prevalence, incidence, or lifetime risk of persistent amnestic disorder. One recent study indicated that transient global amnesia may have an incidence of 5.2 cases per 100,000 population per year. There are no specific data available on age at onset or culture- or sex-related aspects beyond those relating to the genesis of primary etiological disease processes. For example, transient global amnesia typically occurs after age 50 years.

Etiology Amnestic disorder often occurs as the result of pathological processes that cause damage to specific diencephalic and middle temporal lobe structures (e.g., mammillary bodies, the hippocampus). The pathology is commonly bilateral, but deficits may arise from unilateral lesions. Pathogenic processes include closed-head trauma and penetrating missile wounds, focal tumors, surgical intervention, encephalitis due to infection from herpes simplex virus, infarction of the territory of the posterior cerebral artery, and hypoxia. A common cause of amnestic disorder is the chronic use of alcohol and associated thiamine deficiency.

Transient amnestic disorder, when encountered as a transient global amnesia, is typically associated with cerebrovascular disease and pathology in the vertebrobasilar system. Transient amnesia may also arise from episodic physiological or metabolic disorders, such as acute intoxications or seizures.

DIAGNOSIS AND CLINICAL FEATURES

Diagnosis The differentiation between amnestic syndrome and amnestic disorder made in DSM-III-R has been eliminated in DSM-IV. For the diagnosis of amnestic disorder, DSM-IV requires the “development of memory impairment as manifested by impairment in the ability to learn new information or the inability to recall previously learned information,” and the “memory disturbance causes significant impairment in social or occupational functioning.” A diagnosis of amnestic disorder due to a general medical condition (Table 10-38) is made when there is evidence of a causatively relevant specific medical condition (including physical trauma). DSM-IV further categorizes the diagnosis as being transient or chronic. A diagnosis of substance-induced persisting amnestic disorder is made when there is evidence that the symptoms are causatively related to the use of a substance (Table 10-39). DSM-IV refers the clinician to specific diagnoses within substance-related disorders: alcohol-induced persisting amnestic disorder; sedative, hypnotic, or anxiolytic-induced persisting amnestic disorder; and other (or unknown) substance-induced persisting amnestic disorder. DSM-IV also provides for the diagnosis of amnestic disorder not otherwise specified (Table 10-40). The ICD-10 diagnostic criteria for organic amnesia syndrome not induced by alcohol and other psychoactive substances are listed in Table 10-41.

A. The development of memory impairment as manifested by impairment in the ability to learn new information or the inability to recall previously learned information.
B. The memory disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning.
C. The memory disturbance does not occur exclusively during the course of a delirium or a dementia.
D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition (including physical trauma).

Specify if:
Transient: if memory impairment lasts for 1 month or less.
Chronic: if memory impairment lasts for more than 1 month.

Coding note: Include the name of the general medical condition on Axis I, e.g., amnestic disorder due to head trauma; also code the general medical condition on Axis III.

Table 10-38 DSM-IV Diagnostic Criteria for Amnestic Disorder Due to a General Medical Condition

A. The development of memory impairment as manifested by impairment in the ability to learn new information or the inability to recall previously learned information.
B. The memory disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning.
C. The memory disturbance does not occur exclusively during the course of a delirium or a dementia and persists beyond the usual duration of substance intoxication or withdrawal.
D. There is evidence from the history, physical examination, or laboratory findings that the memory disturbance is etiologically related to the persisting effects of substance use (e.g., a drug of abuse, a medication).

Code: (Specific substance)-induced persisting amnestic disorder: (Alcohol; sedative, hypnotic, or anxiolytic; other [or unknown] substance)

Table 10-39 DSM-IV Diagnostic Criteria for Substance-Induced Persisting Amnestic Disorder

This category should be used to diagnose an amnestic disorder that does not meet criteria for any of the specific types described in this section.

An example is a clinical presentation of amnesia for which there is insufficient evidence to establish a specific etiology (i.e., dissociative, substance induced, or due to a general medical condition).

Table 10-40 DSM-IV Amnestic Disorder Not Otherwise Specified

A. There is memory impairment, manifest in both
   1. A defect of recent memory (impaired learning of new material) to a degree sufficient to interfere with daily living
   2. A reduced ability to recall past experiences
B. There is no
   1. Defect in immediate recall (as tested, for example, by the digit span)
   2. Clouding of consciousness and disturbance of attention. Delirium, not induced by alcohol and other psychoactive substances
   3. Global intellectual decline (dementia)
C. There is objective evidence from physical and neurological examination, laboratory tests and/or history of an insult to, or a disease of the brain (especially, involving bilaterally the diencephalic and medial temporal structures but other than alcohol encephalopathy) that can reasonably be presumed to be responsible for the clinical manifestations

Comments: Associated features, including confabulations, emotional changes (apathy, lack of initiative), and lack of insight are useful additional pointers to the diagnosis but are not invariably present.

Table 10-41 ICD-10 Diagnostic Criteria for Organic Amnesic Syndrome, Not Induced by Alcohol and Other Psychoactive Substances

Clinical Features The inability to learn and recall new information, the cardinal feature of the disorder, is most apparent on spontaneous, unstructured recall tasks but is also evident on tasks that provide recall cues or recognition paradigms where the stimulus is presented again, often among mnemonically equivalent distractor items. Depending on lesion localization, deficits may be predominantly related to verbal or visual stimuli. (Studies have demonstrated repeatedly that individuals with amnestic disorder may learn how to perform novel procedures that are not mediated verbally, such as motor tasks, even though they later fail to recall having had those learning experiences.)

Problems remembering previously learned materials are present variably among amnestic patients. For example, a patient who suffered traumatic brain damage and who continues to exhibit deficits in new learning may remember events up to a time shortly before the injury. In some cases the interval of preinjury recall impairment may diminish as the patient recovers (shrinking retrograde amnesia), where inaccessible memories from several years before the injury are gradually produced and the extent of the amnesia diminishes in the context of clinical improvement. Recall deficits due to other causes may involve memory for knowledge and events gained over many years' duration.

For some forms of amnestic disorder, events from the remote past may be better remembered than more recent events. However, such a gradient of recall is not present uniformly among individuals with amnestic disorders. Typically, the ability to immediately repeat a sequential string of information (e.g., a digit span) is not impaired in amnestic disorder; when such impairment is evident, it suggests the presence of attentional dysfunction that may be indicative of delirium. Amnestic disorders may be transient, lasting for several hours to a few days, as in transient global amnesia, or persistent, lasting at least 1 month. In the context of a newly developed but unresolved memory impairment, the term *provisional* should be added to a diagnosis of transient amnesia.

Transient global amnesia is a form of transient amnestic disorder associated with episodes that are characterized by a dense, transitory inability to learn new information (i.e., to form sustained memories), with a variable (ultimately shrinking on recovery) inability to recall events that occurred during the duration of the disturbance. The episode is followed by restoration to a completely intact cognitive state. There are no data to suggest that the memory impairment is associated with disturbed or abnormal behavior beyond the mild confusion or perplexity that may be manifest during the episode.

Depending on the cause of the disorder, the onset of amnesia may be sudden or gradual. Head trauma, vascular events, or specific types of neurotoxic exposure (e.g., carbon monoxide poisoning) may lead to acute mental status changes. Prolonged substance abuse, chronic neurotoxic exposure, or sustained nutritional deficiency exemplify conditions that may lead to an insidious memory decline, eventually causing a clinically definable cognitive impairment.

Amnestic disorder may develop as a result of alcohol dependence, associated with dietary and vitamin deficiency. Alternatively, it may be the primary clinical deficit arising from traumatic head injury and may present as the major feature of a postconcussional state. When memory dysfunction exceeds other features of a postconcussional syndrome, it is preferable to diagnose the condition as amnestic disorder due to head trauma.

Although persons with amnestic disorders may manifest other features of the primary systemic or cerebral disease that cause the development of the memory impairment, disordered mental status may be the sole presenting feature. Thus, a clinician may misconstrue the history of a blandly confabulating person unless other corroborating persons are available. When amnestic disorder is the result of alcohol dependence and vitamin deficiency, other neurological complications of alcohol ingestion and malnutrition such as peripheral neuropathy and cerebellar ataxia, may be observed.

A 46-year-old house painter is admitted to the hospital with a history of 30 years of heavy drinking. He has had two previous admissions for detoxification, but his family states that he has not had a drink in several weeks, and he shows no signs of alcohol withdrawal. He looks malnourished, however, and on examination is found to be ataxic and to have a bilateral sixth cranial nerve palsy. He appears confused and mistakes one of his physicians for a dead uncle.

Within a week the patient walks normally, and there is no longer any sign of a palsy. He seems less confused and can now find his way to the bathroom without direction. He remembers the names and birthdays of his siblings, but has difficulty naming the past five United States presidents. More strikingly, he has great difficulty in retaining information for longer than a few minutes. He can repeat a list of numbers immediately after he has heard them, but a few minutes later does not recall being asked to perform the task. Shown three objects (keys, comb, ring), he cannot recall them 3 minutes later. He does not seem worried about this. Asked if he can recall the name of his doctor, he replies, “Certainly,” and proceeds to call the doctor “Dr. Masters” (not his name), whom, he claims, he first met during the Korean War. He tells a long untrue story about how he and “Dr. Masters” served as fellow soldiers.

The patient is calm, alert, and friendly. Because of his intact immediate memory and spotty but sometimes adequate remote memory, one can be with him for a short period and not realize he has a severe memory impairment. Although treated with high doses of thiamine, the short-term memory deficit persists and appears to be irreversible. (Reprinted with permission from *DSM-IV Casebook*.)

Pathology and Laboratory Examination Laboratory findings diagnostic of the disorder may be obtained using quantitative neuropsychological testing. Standardized tests also are available to assess recall of well-known historical events or public figures, to characterize the nature of an individual's inability to remember previously learned information. Performance on such tests varies among individuals with amnestic disorder. Subtle deficits in other cognitive functions may be noted in individuals with amnestic disorder. However, memory deficits constitute the predominant feature of the mental status examination and account largely for any functional deficits. No specific or diagnostic features are detectable on imaging studies such as MRI or CT. However, damage of middle-temporal lobe structures is common and may be reflected in enlargement of third ventricle or temporal horns or in structural atrophy detected on MRI.

Differential Diagnosis The central feature of amnestic disorder is the inability to learn and recall new information, in the context of variable difficulties recalling

previously learned factual knowledge. Less efficient memory is a component of normatively defined age-related cognitive decline but is neither functionally impairing nor below the statistically normal range when assessed with quantitative procedures. Patients with amnesia uniformly show significant abnormalities on cognitive or neuropsychological tests. Disordered memory is also a feature of delirium and dementia. When memory dysfunction occurs in the context of impaired consciousness, with reduced ability to focus, sustain, or shift attention, delirium predominates. The coexistence of memory impairment and multiple cognitive deficits (e.g., aphasia, apraxis, agnosis, and disturbance in executive functioning) warrants the diagnosis of dementia. Confabulation is a mental status finding encountered in patients with dementia as well as amnesia.

Amnestic disorder may emerge from an evolving clinical picture that includes confusion and disorientation, occasionally with attentional problems that suggest delirium. For example, classically described Korsakoff's syndrome has been associated most often with the delirium of Wernicke's encephalopathy. The latter typically clears quickly with appropriate treatment. Confabulation may be noted during the early stages of the disease process and is often indicated by the recitation of imaginary events to fill gaps in memory, but that sign tends to disappear with time. Profound amnesia typically is associated with disorientation to place and time but rarely to person. Disorientation to self may be encountered in patients with severe dementing disturbances characterized by multiple cognitive deficits but is atypical of pure amnestic disorder. Many patients with severe amnestic disorder lack insight into their deficits, and they explicitly deny its presence despite evidence to the contrary. The lack of insight may contribute to accusations or agitation in rare instances. More commonly, apathy, lack of initiative, emotional blandness, or other changes suggestive of altered personality function may be encountered. Individuals may be superficially friendly or agreeable, but they frequently have a shallow or diminished range of affective expression. Patients with transient global amnesia most often appear bewildered or befuddled. Although they have been described participating in complex activity or conversations in the course of an episode, that is a much less common presentation.

Occasionally, patients may demonstrate intact abilities to learn new information associated with profound memory loss for a circumscribed period of time. That pattern occurs in the setting of a discrete (time-limited) process that temporarily interferes with the patient's ability to establish new memories. Such processes include acute intoxication, transient delirium or encephalopathy (e.g., a seizure), or some other transient disruption of cerebral functioning (e.g., a transient ischemic attack). Such transient amnestic episodes must be defined clinically in the context of the primary disease processes; failure to establish a primary systemic or cerebral etiology suggests a psychogenic origin when that symptom pattern is encountered.

Dissociative amnesia typically does not involve deficits in learning and recalling new information; rather, patients present with a circumscribed inability to recall previously learned information while they continue to function normally in the present.

Psychiatric consultation is requested by an emergency room physician on an 18-year-old male who has been brought into the hospital by the police. The youth appears exhausted and shows evidence of prolonged exposure to the sun. He identifies the current date incorrectly, giving it as September 27 instead of October 1. It is difficult to get him to focus on specific questions, but with encouragement he supplies a number of facts. He recalls sailing with friends, apparently about September 25, on a weekend cruise off the Florida coast, when bad weather was encountered. He is unable to recall any subsequent events and does not know what became of his companions. He has to be reminded several times that he is in a hospital, as he expresses uncertainty as to his whereabouts. Each time he is told, he seems surprised.

There is no evidence of head injury or dehydration. Electrolytes and cranial nerve examination are unremarkable. Because of the patient's apparent exhaustion, he is permitted to sleep for 6 hours. Upon awakening, he is much more attentive, but is still unable to recall events after September 25, including how he came to the hospital. There is no longer any doubt in his mind that he is in the hospital, however, and he is able to recall the contents of the previous interview and the fact that he had fallen asleep. He is able to remember that he was a student at a southern college, maintained a B average, had a small group of close friends, and has a good relationship with his family. He denies any previous psychiatric history and says he has never abused drugs or alcohol.

Because of the patient's apparently sound physical condition, a sodium amytal interview is performed. During this interview he relates that neither he nor his companions were particularly experienced sailors capable of coping with the ferocity of the storm they encountered. Although he had taken the precaution of securing himself to the boat with a life jacket and tie line, his companions had failed to do this and had been washed overboard in the heavy seas. He completely lost control of the boat and felt he was saved only by virtue of good luck and his lifeline. He had been able to consume a small supply of food that was stowed away in the cabin over a 3-day period. He never saw either of his sailing companions again. He was picked up on October 1 by a Coast Guard cutter and brought to shore, and subsequently the police had brought him to the hospital. (Reprinted with permission from *DSM-V Casebook*.)

Patients with resolved transient amnesia (e.g., transient global amnesia) may have a superficially similar history retrospectively. They manifest failure of recall for matters or events that occurred during the discrete episode in question. Thorough clinical investigations of patients with amnestic disorder typically reveal a primary cerebral or systemic medical condition that is etiologically related to the genesis of the mental status abnormality. During an episode, patients with transient amnesia generally have a confused or bewildered demeanor and exhibit marked difficulty with new learning tasks. Episodes of psychogenic amnesia end abruptly, typically associated with an expressed awareness of having no memories for the time period of the amnestic or fugue state. In contrast, the retrograde memory defect of transient global amnesia gradually shortens as the patient recovers; when recovery is complete, the memory gap spans only the period of the episode.

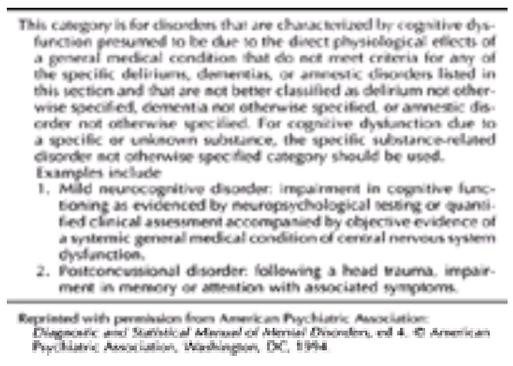
Course Although the mode of onset is typically abrupt, data suggest that individuals with alcohol-induced amnestic disorder may develop deficits insidiously over many years as a result of repeated toxic and nutritional insults before the emergence of a final, dramatically impairing episode of illness apparently related to thiamine deficiency. Transient amnesia due to a cerebrovascular etiology may be recurrent, with episodes lasting from several hours to several days. Amnestic disorders due to head trauma, for example, may last variable amounts of time, with the greatest deficit apparent immediately after injury and improvement occurring during the ensuing 2 years (further improvement beyond 24 months has been noted, but less commonly). Full recovery may occur, although severe injuries are typically characterized by residual deficits. Disorders due to destruction of middle-temporal lobe structures, such as infarction, encephalitis, surgical ablation, or malnutrition in the context of alcohol dependence, may cause densely persisting impairments.

Treatment Whenever a primary systemic or cerebral disorder is causally tied to the amnestic syndrome, initial treatment (with thiamine, antiviral medication, aspirin) must be directed toward the underlying pathological process. Presently there are no known, definitively effective treatments for amnestic disorder that are specifically aimed at reversing apparent memory deficits. A variety of pharmacotherapeutic trials have been to no avail. Recently, centers for cognitive rehabilitation have been established whose rehabilitation-oriented therapeutic milieu is intended to promote recovery from brain injury, especially from traumatic causes. Despite the high cost of extended care at these sites, which provide both long-term institutional and daytime services, no data have been developed to define therapeutic effectiveness for the heterogeneous groups of patients who participate in such tasks as memory retraining. Persons with amnestic disturbances worthy of diagnosis experience major impediments in their social and vocational functioning. They may require supervised living situations to ensure appropriate feeding and care.

Other Cognitive Disorders Disorders such as dementia and amnesia are specific categorical designations that are intended to define disease states. However, intellectual functioning can also be viewed from a dimensional perspective, ranging from optimal to grossly deficient. Dementia represents an abnormal decline from a previous level of attainment; mental retardation reflects the failure to develop adequate intellectual function.

Within this broad framework multiple domains of intellect are recognized that involve a wide variety of brain-related cognitive processes. The determination of normal and abnormal usually is made by comparing a person's performance on a variety of neuropsychological tests with predetermined normative standards. Ideally, the clinician would like lifelong (i.e., premorbid) serial cognitive testing to aid with diagnosis; occasionally, school, military, or vocational records provide an acceptable alternative. Usually one must compare a patient's results against published norms. Those norms may vary in quality, and the clinician should be aware whenever possible of factors such as the education, sex distribution, socioeconomic status, and age distribution of normative samples.

Cognitive Disorder Not Otherwise Specified DSM-IV includes a new diagnostic category, *cognitive disorder not otherwise specified,* to deal with patients whose clinical presentation does not conform to a diagnosis of delirium, dementia, or amnesia. The designation is useful for patients with mild deficits in cognitive functioning that result from conditions such as head trauma, chronic alcohol dependence, or HIV infection. In the recovering alcoholic, for example, or the patient with a significant but resolving posttraumatic amnesia, intellectual abnormalities may be detectable objectively and noted subjectively, although they may be only minimally impairing functionally. Those deficits may disappear over time or remain as subtle residua. HIV infection may cause a mild decline in cognition; current research has demonstrated such decrements repeatedly. Of note, the performance of many patients has remained within the normal range even as the test scores have decreased significantly. The diagnostic criteria for cognitive disorder not otherwise specified appear in Table 10-42.



This category is for disorders that are characterized by cognitive dysfunction presumed to be due to the direct physiological effects of a general medical condition that do not meet criteria for any of the specific deliriums, dementias, or amnestic disorders listed in this section and that are not better classified as delirium not otherwise specified, dementia not otherwise specified, or amnestic disorder not otherwise specified. For cognitive dysfunction due to a specific or unknown substance, the specific substance-related disorder not otherwise specified category should be used.

Examples include

1. Mild neurocognitive disorder: impairment in cognitive functioning as evidenced by neuropsychological testing or quantified clinical assessment accompanied by objective evidence of a systemic general medical condition of central nervous system dysfunction.
2. Postconcussional disorder: following a head trauma, impairment in memory or attention with associated symptoms.

Table 10-42 DSM-IV Diagnostic Criteria for Cognitive Disorder Not Otherwise Specified

Mild Neurocognitive Disorder To define those conditions with greater specificity, the World Health Organization developed the ICD-10 diagnostic category of mild cognitive disorder (Table 10-43). A similar DSM-IV construct (mild neurocognitive disorder) is included in an appendix as an example of cognitive disorder not otherwise specified. Table 10-44 lists the DSM-IV research criteria for mild neurocognitive disorder. To date, the interface between amnestic disorders or dementing disorders and mild neurocognitive disorder has not been defined reliably or validly.

Table 10-43 ICD-10 Diagnostic Criteria for Other Mental Disorders Due to Brain Damage and Dysfunction and Due to Physical Disease

A. The presence of two (or more) of the following impairments in cognitive functioning, lasting most of the time for a period of at least 2 weeks (as reported by the individual or a reliable informant):
   (1) memory impairment as identified by a reduced ability to learn or recall information
   (2) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
   (3) disturbance in attention or speed of information processing
   (4) impairment in perceptual-motor abilities
   (5) impairment in language (e.g., comprehension, word finding)
B. There is objective evidence from physical examination or laboratory findings (including neuroimaging techniques) of a neurological or general medical condition that is judged to be etiologically related to the cognitive disturbance.
C. There is evidence from neuropsychological testing or quantified cognitive assessment of an abnormality or decline in performance.
D. The cognitive deficits cause marked distress or impairment in social, occupational, or other important areas of functioning and represent a decline from a previous level of functioning.
E. The cognitive disturbance does not meet criteria for a delirium, a dementia, or an amnestic disorder and is not better accounted for by another mental disorder (e.g., a substance-related disorder, major depressive disorder).

Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 10-44 DSM-IV Research Criteria for Mild Neurocognitive Disorder

In addition to conditions such as HIV infection, head trauma, or alcohol dependence, mild cognitive decline with neuropsychological performance below the level of age-matched peers may be encountered as an early sign of a progressive degenerative disease. The use of cognitive disorder not otherwise specified as a diagnosis can serve to describe provisionally a patient who the physician suspects will develop a more malignant dementia of the Alzheimer's type and in whom a definitive diagnosis is premature owing to the relative mildness of the symptoms and an associated lack of clarity regarding clinical course. The label of not otherwise specified demands maximum clinical scrutiny and vigilance when employed in this fashion.

Other Cognitive Conditions Clinical investigators and geriatric psychiatrists have recently joined cognitive psychologists in studying aging-related cognitive decline involving such functions as spontaneous verbal memory, cognitive flexibility and abstracting ability, visuospatial processing, divided attention, speed of mental processing, and naming. Aging-related decrements in those functions do not relate to any specific or defined neuropathology, although they may reflect underlying neurobiological deterioration. Of note, objective documentation of individual decline in test performance may be impossible. Although experimental comparisons of groups of healthy older subjects with comparably educated younger groups show consistent changes with aging, there are no data to suggest that the overall decline is a harbinger of disease.

Many persons with normal (i.e., normatively defined) aging-related intellectual decrements seek clinical evaluation for forgetfulness, especially out of fear that they may be developing Alzheimer's disease. Their complaints often include inability to recall names or words spontaneously, absent-mindedness, the need to use reminder lists, or subtle problems with concentration. Careful interviewing typically reveals mild anxiety about minor intellectual problems, the use of effective compensatory mental strategies, and intact personal and social functioning, with little evidence of definable interference from perceived cognitive inadequacies in their daily lives. The absence of significant functional decline, together with performance within the normative (i.e., based on similarly aged samples) range on neuropsychological testing, in the context of an unrevealing general medical evaluation points to aging-associated cognitive alterations.

Because of ample data on the phenomenon and clinicians' need to provide concerned patients with an understandable terminology to define their perceived difficulties, DSM-IV groups age-related cognitive decline among those conditions not attributable to a mental disorder that are a focus of attention or treatment. A variety of other common problems are included in that class, among them borderline intellectual functioning, academic problems, adult antisocial behavior, and marital problems.

Figure 10-16 presents schematically in a dimensional perspective the relations between increasing age and cognitive performance, depicting changes in the normative range, mild cognitive impairment, and dementia. The aging-related decline in normative performance underscores the difficulty of establishing an absolute standard of cognitive deficit that is indicative of impairment due to a categorical disease process. The figure also suggests that there will always be patients detected in the range of mild impairment. As long as there are few (or no) pathobiologically exact laboratory tests to determine with certainty specific cognitive impairment disorders, thoughtful clinical judgment will remain a central part of the diagnostic process.

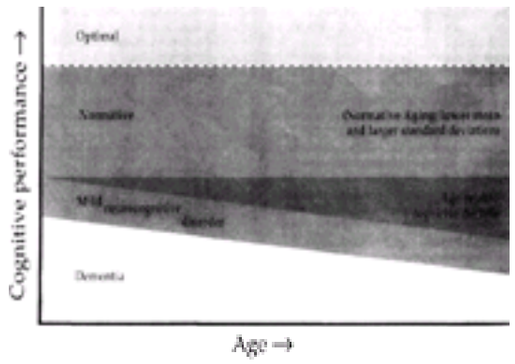

FIGURE 10-16 Aging-associated changes in ranges of cognitive performance.

Mental Disorders Due to a General Medical Condition DSM-IV has taken a different approach to categorizing the mental disorders due to a general medical condition than did DSM-III-R. In DSM-III-R the disorders were classified under the broader category of organic mental disorders. In DSM-IV each mental disorder due to a general medical condition is classified within the category that most resembles its symptoms (Table 10-45). For example, the diagnosis psychotic disorder due to a general medical condition is found in the DSM-IV section on schizophrenia and other psychotic disorders. The symptom-based organization of DSM-IV is meant to facilitate clinical decision making regarding the differential diagnosis of symptoms. For example, the clinician who is evaluating a patient with depression can refer to the DSM-IV section on mood disorders and find mood disorder due to a general medical condition as one of the diagnoses. That diagnosis should help to clarify the importance of considering the possibility of a mental disorder due to a general medical condition for almost all psychiatric presentations.

DSM-IV Category	Mental Disorders due to a General Medical Condition
Delirium, dementia, amnestic, and other cognitive disorders	Delirium due to a general medical condition Dementia due to other general medical conditions Amnestic disorder due to a general medical condition
Schizophrenia and other psychotic disorders	Psychotic disorder due to a general medical condition
Mood disorders	Mood disorder due to a general medical condition
Anxiety disorders	Anxiety disorder due to a general medical condition
Sexual disorders	Sexual dysfunction due to a general medical condition
Sleep disorders	Sleep disorder due to a general medical condition
Mental disorders due to a general medical condition not elsewhere classified	Catatonic disorder due to a general medical condition Personality change due to a general medical condition Mental disorder not otherwise specified due to a general medical condition

Table 10-45 Mental Disorders Due to a General Medical Condition

Mood Disorder Due to a General Medical Condition Secondary mood syndromes are characterized by a prominent mood alteration that is thought to be the direct physiological effect of a specific medical illness or agent. These disorders are often difficult to define and have not been extensively researched; therefore, only limited information can be provided.

Definition The key feature is prominent, persistent, distressing, or functionally impairing depressed mood (anhedonia) or elevated, expansive, or irritable mood, judged to be caused by either an Axis III condition or by substance intoxication or withdrawal. Cognitive impairment is not the predominant clinical feature; otherwise, the mood disturbance would be viewed as part of delirium, dementia, or other cognitive deficit disorder. The diagnostician is asked to specify if the mood syndrome is manic, depressed, or mixed, and if criteria for a fully symptomatic major depressive or manic syndromic are fulfilled.

History and Comparative Nosology Mood disturbances secondary to medical conditions have long been described, but attention was rarely paid to the presence or absence of coexisting intellectual deficits. DSM-III introduced the term and the formal concept of organic affective syndrome, which required both mood alteration and two associated symptoms (as found in primary affective illnesses) to be present and thought due to specific medical etiologies. DSM-III-R eliminated the requirement for associated symptoms. DSM-IV marks the first explicit diagnostic criteria to denote whether or not the disturbance meets full major depressive or manic syndromic criteria. There has been much disagreement in the literature about primary depressive disorders and whether minor depressive disorders exist and how best to define them. Similar arguments might apply to lesser depressive syndromes of secondary origin. Terminology aside, there has been little research in the area of secondary mood disorders; what data exist are hampered by differing (or absent) operationalization of what constitutes sufficient evidence for defining causality.

Epidemiology There are no clear data on which to base statements of incidence or prevalence of secondary mood disorders in any clinical or community population. It is clear that depressive symptoms and a wide array of systemic and primary cerebral conditions coexist to a far higher degree than can be explained by chance. Unfortunately, establishing a causal relation between depressive symptoms and a specific medical entity is difficult; therefore, the percentage of those coexisting symptoms that can be called secondary remains unknown. Further, many reported studies did not assess a range of syndromic criteria (i.e., major versus minor depression), and many simply quantified depressive symptoms by using rating scales without determining if the symptoms attained a threshold level of clinical significance. One noteworthy point is that depression in the medically ill appears to be equally prevalent by sex, or possibly slightly higher in men than in women. This disparity, when compared with the preponderance of females with primary depressive disorders, is often cited as an indicator of the importance of viewing secondary mood disturbances separately.

Rates of mood disorder in the medically ill have been carefully described in several neurological diseases. For example, at least one research group has documented high rates of criteria-defined major and minor depressive syndromes in patients shortly after cerebrovascular accidents. Correlation of stroke lesion location and size with presence (and possibly with type) of depressive syndrome suggests the role of direct disruption of brain physiology as a causal mechanism. Also, the presence or severity of depression does not correlate highly with physical impairment due to hemiparesis, for example, and may be higher than rates found in patients with similar levels of overall disability due to nonneurological conditions, suggesting that depression in neurological patients is not simply a psychological reaction to illness and disability. Similarly, less extensive descriptions of increased rates of depressive symptoms and syndromes have been reported for populations with Parkinson's disease, Huntington's disease, HIV infection (with presumed direct CNS involvement), and multiple sclerosis.

Determination of the secondary or symptomatic nature of these mood syndromes is problematic and is further complicated by the fact that at least some of the patients with these neurological illnesses had substantial cognitive impairment. Although DSM-IV attempts to address these issues directly, uncertainties remain. For example, if a patient with Huntington's disease has dementia and a depressive syndrome, the clinician might choose the diagnosis of dementia due to Huntington's disease with depressed mood. However, early in the disease process a syndromically depressed Huntington's patient with few cognitive impairments would warrant a diagnosis of mood disorder due to Huntington's disease with major depressive episode. As the intellectual impairment progresses, does the clinician abandon one diagnosis for another or add a second Axis I diagnosis of dementia? Such borderline situations are expected to generate uncertainty, which can be ameliorated by careful documentation of one's clinical reasoning.

Secondary mania appears to be much less prevalent in most neurological illnesses, with the exceptions of multiple sclerosis and possibly Huntington's disease. Case reports abound of putative secondary mania due to a variety of other causes, but the prevalence is not known. Finally, patients with secondary mood syndromes may have increased rates of prior mood disorders and higher rates of family history of mood disorder. Therefore, secondary syndromes may reflect an interaction between a precipitating agent or illness and the patient's diathesis toward mood pathology.

Etiology The list of potential causes for both depressive and manic syndromes is long. Table 10-46 lists some of the causes most commonly considered.

Table 10-46 Causes of Secondary Mood Disorders

Diagnosis and Clinical Features The depressive or manic symptoms found in secondary mood disorders are phenomenologically similar to those found in primary (idiopathic) mood disorders (see Table 14.6-17). It is not known if certain symptoms occur more commonly in the secondary disorders; presumably the prevalence may vary depending on the specific etiology of the secondary disorder. For example, anxiety has been described as prominent in major depressive syndromes seen in patients with Parkinson's disease; however, no studies have compared depressed patients with Parkinson's disease with similarly aged patients experiencing idiopathic major depressive disorder.

Associated clinical phenomena may include other manifestations of the cause of the secondary mood disorder, such as soft neurological signs or contributing cognitive impairment; indeed, those findings are used to support the assessment of the mood symptoms as secondary in origin. There are no specific tests to confirm the diagnosis of a secondary mood disorder. In addition, little is known about how neurobiological abnormalities seen in idiopathic mood disorders differ from secondary syndromes. Moreover, despite recent interest in secondary mood disorders, there is still little definitive understanding of the neuroanatomical substrate of those disorders. Physical (including neurological) examination and specific laboratory tests or procedures may be crucial to establishing the presence of the primary disease state.

Differential Diagnosis There are two broad domains of differential diagnosis to consider when establishing the presence of a secondary mood disorder. The first is phenomenological: Does the patient have clinically significant manic or depressive symptoms in the absence of evidence of a predominant cognitive deficit? That assessment requires attention to symptoms and function in the history and mental status examination. As part of the process, the clinician is also establishing whether there is a clearly defined mood syndrome sufficient to warrant an empirical treatment trial with antidepressant medications.

The second domain is etiological: Does the patient have an Axis III condition or a state of substance intoxication or withdrawal that is causing the mood disturbance? Establishing the presence of the relevant condition depends on standard psychiatric and medical-neurological assessments; establishing the causal relation to the mood disorder may be difficult.

Course and Prognosis Although the literature on the course of clearly defined secondary mood disorders is scant, substantial work has demonstrated that all depressive conditions that are comorbid with general medical illnesses or substance-related disorders have poorer prognoses than those that have no demonstrated associations, whether measured by means of symptomatic expression, functional disability, or mortality. It is therefore likely that secondary depressive illness is most often a chronic disease that is sometimes characterized by periods of remission followed by recurrences and sometimes by continuous illness. The prognosis varies, depending on the etiological disease state; depression secondary to a readily treatable disease (e.g., hypothyroidism) has a better outcome than depression associated with a terminal, essentially untreatable condition (e.g., metastatic pancreatic carcinoma). Little is known about the relation of specific depressive syndromes to outcome even within a specific etiological group. For example, there have been attempts to distinguish outcome in poststroke patients based on the presence of minor or major depressive syndromes; this work has had little replication by other investigator groups and the results may not generalize to depression secondary to other conditions. There is even less information available on the course of secondary mania, although many case reports suggest it is chronic and refractory to treatment.

Treatment Treatment response has received limited study. Standard antidepressant medications (e.g., tricyclic antidepressants, MAO inhibitors, selective serotonin reuptake inhibitors (SSRIs), and ECT are effective in many depressed patients with medical and neurological illnesses or substance use disorders. However, the utility of studies of antidepressant drugs has been limited by the scant clinical definition of study patients in many publications; a designation of secondary mood disorder, with depressive features, provides little information on specific target symptoms and their response. The efficacy of newer somatic agents (e.g., SSRIs, bupropion [Wellbutrin]) and of newer psychotherapeutic approaches has received little systematic study. A comparison of response to specific treatment modalities in syndromically similar primary and secondary mood disorders has not been done. However, the comorbid pathology found in secondary syndromes may limit treatment trials, either because of contraindications or because of increased susceptibility to adverse effects.

Given the severely limited data, the clinician treating a patient with a secondary mood disorder must rely on the following general guidelines. The underlying causes should be treated as effectively as possible. Persisting manic or major depressive syndromes are likely to require somatic therapies; standard treatment approaches as used for the corresponding primary mood disorder should be employed, although the risk of toxic effects may require more gradual dosage increases. At a minimum, psychotherapy should focus on psychoeducational issues (in particular, the concept of a secondary behavioral disturbance may be new or difficult for many patients and families) and support. More specific intrapsychic, interpersonal, and family issues are addressed as indicated. Approaches to subsyndromal secondary mood disorders are even less well established, but clinically significant disturbances warrant empirical trials of the same treatments used in fully syndromic patients.

Psychotic Disorder Due to a General Medical Condition *Psychosis* has been a term of inconsistent definition, used in recent years to refer exclusively to symptoms of a striking nature, such as hallucinations and delusions, but in the past to severe affective syndrome (e.g., psychotic versus neurotic depression); to cognitive symptoms, such as confusion, disorientation, or altered memory (such as Korsakoff's psychosis); or as a means of describing the severity of any psychiatric symptom (“of psychotic proportions”). DSM-III-R in its appended glossary defined psychosis as “gross impairment in reality testing and the creation of a new reality.” Hallucinations, delusions, bizarre behavior, and incoherent speech were considered direct evidence of psychosis. Psychotic symptoms have been recognized as nonspecific, as they can be seen in any of the major psychiatric illnesses, such as dementia, schizophrenia, or bipolar I disorder, as well as in many systemic medical or cerebral disorders.

Definition In order to establish the diagnosis of psychotic disorder due to a general medical condition the clinician first must exclude syndromes in which psychotic symptoms may be present in association with cognitive impairment (e.g., delirium and dementia of the Alzheimer's type) but not the defining feature, and the clinician must determine with confidence the causal link. In turn, secondary psychotic disorders must be excluded before a diagnosis of a primary (idiopathic) psychotic disorder is entertained.

History Psychotic symptoms, including delusions, hallucinations, incoherent speech or formal thought disorder, and bizarre behavior, have been recognized for centuries. In medical prehistory they were perceived in a theological light as evidence of demonic possession or punishment for a moral failing. In the eighteenth century, at the threshold of the modern brain disease model, psychosis was sometimes attributed to a bodily dysfunction, either systemic or related specifically to the CNS. However, tension has persisted among clinicians since the 1800s as to whether psychotic symptoms are the manifestations of a dysfunctional brain or are volitional or psychological reactions to life circumstances. Reports of secondary psychosis have abounded for centuries and have contributed to an understanding of those behaviors as specific symptoms of brain disease. Many descriptions, however, have had limited use because of vagaries in the definition of psychosis and the lack of any uniform means for establishing a correlation between psychotic symptoms and the associated systemic or cerebral medical condition under study.

Recently, three types of investigations have emerged for the study of secondary syndromes, including secondary psychosis. One type of study compares psychopathological symptoms in patient groups with and without known primary medical conditions. This comparison has been done strictly on a retrospective basis for secondary psychosis, with only one available prospective study of secondary delusional disorders. Another type of investigation has examined patient groups with known CNS disease, such as cerebrovascular disorder or Huntington's disease, with a careful description of any associated psychopathology. The third investigative track has selected patients with known psychopathology, such as hallucinations in schizophrenia, and sought evidence to correlate symptoms with CNS dysfunction using a variety of measures (e.g., neuroimaging of the temporal lobe). The secondary psychotic disorders are a window through which insights into the

neurobiological basis for psychotic processes may be obtained.

Comparative Nosology Secondary psychotic syndromes were categorized in DSM-II as psychoses associated with organic brain syndromes. The syndromes included in that category were the dementias, deliria, and psychoses associated with other cerebral and systemic conditions. Entry into the category depended on cognitive symptoms, such as disturbances of orientation, memory, judgment, and lability of affect. The term “psychosis” continued to be used for the sake of historic continuity, with the acknowledgment that “many patients for whom these diagnoses are clinically justified are not in fact psychotic.” DSM-III improved on the nosology by establishing the general rubric of organic brain syndromes, with six specific syndromes, including organic hallucinosis and organic delusional syndrome. In DSM-IV, psychotic disorder due to a general medical condition (with its available subtypes) has been moved out of the organic group to the phenomenological cluster to which it is related. This shift underscores the need for differential diagnosis, the clinical importance of defining etiology whenever possible, and the idea that primary psychopathology is idiopathic—that is, without known cause.

Epidemiology The incidence and prevalence of secondary psychotic disorders in the general population are unknown. The prevalence of psychotic symptoms is increased in selected clinical populations, such as nursing home residents with dementia of the Alzheimer's type, but it is unclear how to extrapolate these findings to other patient groups.

Etiology Virtually any cerebral or systemic disease that affects brain function can produce psychotic symptoms. Table 10-27 lists examples within each of the broad categories of diseases that can produce dementia; each of those diseases is also capable of producing psychotic symptoms, both in the presence and in the absence of cognitive impairment. Degenerative disorders, such as Alzheimer's disease or Huntington's disease, may present initially with new-onset psychosis, with minimal evidence of cognitive impairment at the earliest stages.

Diagnosis and Clinical Features To establish the diagnosis of a secondary psychotic syndrome (see Table 13.3-13). The clinician first determines that the patient is not delirious, as evidenced by a stable level of consciousness. A careful mental status assessment is conducted to exclude significant cognitive impairments, such as those encountered in dementia or amnestic disorder. The next step is to search for systemic or cerebral diseases that might be causally related to the psychosis. Psychotic symptomatology per se is not helpful in distinguishing a secondary from a primary (idiopathic) cause.

Comparative studies have not demonstrated any distinguishing phenomenological features in secondary psychosis or any difference in frequency or severity of the psychosis when compared to idiopathic psychosis. Olfactory and auditory hallucinations, although claimed anecdotally to suggest a secondary or symptomatic etiology, have proved unreliable. Some studies have suggested that exclusively positive psychotic symptoms, in the absence of negative symptoms and personality change, reflect a secondary cause; this suggestion has not been tested prospectively. Age at onset is a factor that should alert clinicians to the possible emergence of a secondary psychotic disorder, reflecting both the age-related increased prevalence of diseases affecting brain function and the natural history of primary psychotic syndromes, with their markedly diminished incidence after ages 40 to 45 years.

All patients who present with the new onset of psychotic symptoms should undergo a thorough clinical evaluation emphasizing personal medical history, family medical history, and medical review of systems. A systematic physical and neurological examination should be performed. (The examiner should bear in mind, however, that nonlocalizing, soft neurological signs and a variety of dyskinesias can be present in idiopathic schizophrenia, even in the drug-naïve patient.) A neuroimaging evaluation with MRI for any new-onset psychosis, irrespective of patient age, is recommended. The detection of a systemic or cerebral abnormality does not automatically lead to the determination of secondary psychosis; establishing a secondary status requires thoughtful clinical reasoning.

Differential Diagnosis The differential diagnosis involves first establishing that the symptoms and signs encountered are in fact psychotic, according to the more specific modern definition. Confabulation may be mistaken for delusions. *Confabulation* is the spontaneous or prompted production of inconsistent and fabricated statements, often in response to questions or environmental stimuli. Although memory impairment is present in those who confabulate, the more salient cognitive deficit involves an inability to suppress or self-analyze the automatic fabrications and responses. Confabulation differs from delusions in that the fabricated beliefs are quite transient and varying. A behavioral response to the confabulated belief is usually absent. The presence of confabulation is also suggestive of brain disease, often involving the anterior temporal lobe (memory impairment) and the frontal lobes (loss of self-analysis). Perceptual disturbances that result in illusions or other misinterpretations of environmental stimuli must be distinguished from hallucinations, which are experienced as true perceptual experiences but without an actual stimulus.

Agnosias, or deficit syndromes, such as *prosopagnosia, topographic agnosia,* or *phonagnosia* (inability to recognize familiar faces, places, or sounds, respectively), can occur in the context of intact peripheral perception and can be mistaken for delusional beliefs as well as hallucinations. It is important to distinguish these deficit syndromes and to recognize that they point to parietal lobe dysfunctions that are not associated with other psychotic symptoms.

The phenomenology or type of psychotic symptom does not help distinguish idiopathic from secondary etiologies. However, once the suspicion of a secondary etiology has arisen, the specific psychotic presentation may suggest a particular brain region or direction for further investigation. Table 10-47 lists a number of specific psychotic symptoms that have been consistently associated with disease in particular brain regions. *First-rank symptoms,* originally described by Kurt Schneider as pathognomonic symptoms of schizophrenia, are now accepted as nonspecific psychotic symptoms occurring in all psychotic disorders. Although nonspecific for diagnosis, they have been associated with abnormalities in the left temporal lobe. Complex delusions have been associated with lesions in subcortical regions. Simple persecutory ideas are more common than complex or systematized delusions in patients with significant cognitive deficits. Patients apparently require a variety of intact intellectual abilities (and presumably underlying brain substrate) in order to produce psychotic symptoms of greater complexity. *Anton's syndrome* refers to denial of blindness, classically described in patients with acquired cortical blindness arising from bilateral occipital cortex damage. More recently, it has been described in patients with peripheral optic neuropathy, suggesting that the syndrome may be a variant of the other denial-of-deficit syndromes, such as anosognosia. *Misidentification syndromes* have been described primarily in idiopathic psychotic disorders, although recent studies have pointed to nondominant parietal and frontal lesions as the basis for many. One recent neuropsychological theory proposes that the right hemisphere plays a role in the appreciation of the individuality or uniqueness of people, places, and objects and that lesions in the right hemisphere can result in delusions of misidentification.

Symptoms	Site	Laterality
First-rank symptoms Thoughts spoken aloud Voices commenting Third-person voices arguing Made actions Made feelings Thought withdrawal Thought diffusion Delusional perception	Temporal lobe	Dominant hemisphere
Complex delusions	Subcortical or limbic	
Anton syndrome	Occipital lobe, optic tract	Bilateral
Anosognosia	Parietal lobe	Nondominant hemisphere
Misidentification syndromes Capgras syndrome Reduplicative paramnesia Fregoli syndrome Intermetamorphosis syndrome	Parietal, temporal, frontal lobes	Nondominant hemisphere, bilateral

Table 10-47 Psychotic Symptoms Associated With Abnormality of Specific Brain Regions

Course and Prognosis The course and prognosis of secondary psychotic syndromes depend on their etiology. Vivid psychotic symptoms arising from head trauma may improve dramatically during recovery. Delusions associated with degenerative diseases may diminish as the disease worsens, for the capacity to generate those more complex cognitions is gradually lost. Some secondary psychotic disorders improve with treatment of the underlying disorder, such as the interictal psychosis of epilepsy, which often improves with the pharmacological or surgical control of seizures. Psychotic disorders secondary to infectious disease may not improve, despite eradication of the infectious organism, because of irreversible tissue damage sustained during the acute infection.

Treatment The principles of treatment for a secondary psychotic disorder are similar to those for any secondary neuropsychiatric disorder, namely, rapid identification of the etiological agent and treatment of the underlying cause. Antipsychotics medications afford empirical symptomatic treatment for the psychotic symptoms, although secondary psychotic disorders often prove more refractory than idiopathic disorders to such treatment. Patients with primary systemic or cerebral diseases frequently are more vulnerable to the untoward adverse effects of antipsychotic drugs. To date, there has been insufficient use of serotonin-dopamine antagonists,

such as clozapine (Clozaril), to judge their utility with these conditions.

Anxiety Disorder Due to a General Medical Condition Secondary anxiety syndromes are characterized by prominent anxiety symptoms that are thought to be the direct physiological effect of a specific physical illness or agent. Those disorders have received even less careful scrutiny than secondary mood disorders; therefore, the qualifications made in the section above apply equally or more so to the following discussion.

Definition The key feature of anxiety disorder due to a general medical condition is the presence of prominent anxiety symptoms, which may include generalized anxiety, panic attacks, obsessions, compulsions, or phobias and which are judged to be caused by either an Axis III condition or by substance intoxication or withdrawal. In addition, the anxiety symptoms are not thought to be better explained by another mental disorder (e.g., the anxiety that can be seen in delirium or adjustment disorder with anxious mood). The diagnostician is asked to specify if the anxiety syndrome includes generalized anxiety, panic attacks, obsessive-compulsive symptoms, or phobias.

History and Comparative Nosology For centuries clinicians have described anxiety symptoms as prominent features in a variety of conditions; for most of the twentieth century many of those descriptions focused on patients with endocrinopathies, neurological illnesses, mitral valve prolapse, and substance-related states. The formal concept of any organic mental disorder other than cognitive disorders was introduced by DSM-III; however, organic anxiety disorder was not presented as a distinct entity until DSM-III-R. DSM-III-R limited the diagnosis to either generalized anxiety or panic attacks; DSM-IV broadens the possible related phenomena to include obsessions and compulsions.

Secondary anxiety syndromes have received little study. There are numerous descriptions of anxiety symptoms associated with medical illness or substance-related states, but the operationalization of “secondariness” is generally absent. Further, most studies have included patients with generalized anxiety or panic symptoms; reports of secondary obsessive-compulsive phenomena are few.

Epidemiology The prevalence of anxiety symptoms is high in general medical patients and in patients with many of the specific medical illnesses that are putative potential causes for secondary anxiety syndromes. However, the incidence and prevalence of secondary anxiety disorders, obtained from well-operationalized criteria for syndromic and etiological diagnosis, are not known. Similarly, rates of prior anxiety disturbances or of a family history for anxiety disorders are not known.

Etiology The list of potential causes for anxiety syndromes is long, with nearly complete overlap with the potential causes for mood syndromes. Causes most commonly described in anxiety syndromes include substance-related states (intoxication with caffeine, cocaine, amphetamines, and other sympathomimetic agents; withdrawal from nicotine, sedative-hypnotics, and alcohol), endocrinopathies (especially pheochromocytoma, hyperthyroidism, hypercortisolemic states, and hyperparathyroidism), metabolic derangements (e.g., hypoxemia, hypercalcemia, and hypoglycemia), and neurological disorders (including vascular, trauma, and degenerative). Many of these conditions are either inherently transient or easily remediable. Whether that reflects the pathophysiology of secondary anxiety or is an artifact of reporting (e.g., anxiety with subacute onset and complete resolution after removal of a pheochromocytoma is more likely to be reported as an example of anxiety due to a medical illness than is chronic anxiety in the context of chronic obstructive pulmonary disease) is not known. Much attention has been paid to the association of panic attacks and mitral valve prolapse. The nature of that association is unknown, and therefore the diagnosis of panic attacks secondary to mitral valve prolapse currently is premature. Interestingly, several recent reports have sought to tie obsessive-compulsive symptoms to the development of pathology in the basal ganglia.

Diagnosis and Clinical Features The symptoms of secondary anxiety disorders are by definition phenomenologically similar to those found in the corresponding primary anxiety disorder (e.g., panic attacks and obsessions) (see Table 15.6-17). It is not known if certain symptoms are seen more commonly in the secondary variety; presumably the rate of co-occurrence may vary, depending on the specific etiology of the secondary disorder. As with all secondary syndromes, associated clinical phenomena may include other manifestations of the cause of the secondary anxiety disorder, such as soft neurological signs or subtle cognitive impairment (which may have been used to support the assessment of the anxiety symptoms as being secondary in origin).

There are no specific tests to confirm the diagnosis of secondary anxiety disorder, and little is known about how neurobiological abnormalities seen in primary anxiety disorders differ in secondary syndromes. Physical (including neurological) examination and specific laboratory tests or procedures may be necessary to establish the presence of the etiological disease state.

Differential Diagnosis As for other secondary disorders, two broad domains of differential diagnosis must be considered to establish the presence of a secondary anxiety disorder. The first is phenomenological: does the patient have clinically significant anxiety, panic attacks, obsessions, or compulsions, along with an absence of evidence for another primary or secondary psychiatric syndrome? The second is etiological: does the patient have an Axis III condition, or a state of substance intoxication or withdrawal, that is causing the phenomenology? As always, establishing the causal relationship may be difficult.

Course and Prognosis Little information is available on the course of secondary anxiety disorders. The outcome presumably depends on the specific etiology; thus, anxiety due to hyperthyroidism may well remit with treatment of the hyperthyroid state whereas anxiety due to cardiomyopathy with a low-output state may run a more chronic course.

Treatment Well-designed treatment studies of carefully described patients with secondary anxiety disorders are lacking. Aside from treating the underlying causes, clinicians have found benzodiazepines to be helpful in decreasing anxiety symptoms; supportive psychotherapy (including psychoeducational issues focusing on the diagnosis and prognosis) may also be useful. The efficacy of other, more specific therapies in secondary syndromes (e.g., antidepressant medications for panic attacks, SSRIs for obsessive-compulsive symptoms, behavior therapy for simple phobias) is unknown.

Sleep Disorder Due to a General Medical Condition Sleep disorders can result from a diversity of causes, among them stressful life circumstances, crossing time zones, pulmonary or laryngeal structural abnormalities, systemic diseases (e.g., renal failure), or primary cerebral pathology. However, many sleep disorders, such as narcolepsy, sleep terrors, and enuresis, are idiopathic and occur without known systemic or central abnormalities. The epidemiology of secondary sleep disorders has not been studied systematically.

Definition and Diagnosis Sleep disorders can manifest in four ways: by an excess of sleep (*hypersomnia*), by a deficiency of sleep (*insomnia*), by abnormal behavior or activity during sleep (*parasomnia*), and by a disturbance in the timing of sleep (*circadian rhythm sleep disorders*). Primary sleep disorders occur unrelated to any other medical or psychiatric illness. The DSM-IV nosology is deliberately simple and nondetailed. The patient is assigned to broad categories based on presenting symptoms and the etiological consideration of primary versus secondary disorder (see Table 21-17). The *International Classification of Sleep Disorder* is a more comprehensive and detailed nosology that requires the usage of polysomnography for many of the diagnoses (see Table 21-3).

Etiology and Differential Diagnosis Table 10-48 lists a number of conditions in which a disturbance of sleep has been frequently and characteristically described, allowing conditions to be designated as causes of secondary sleep disorder. *Parkinsonism,* related to either idiopathic Parkinson's disease, medications, or head trauma, frequently results in a secondary sleep disorder. As many as 75 percent of patients with Parkinson's disease complain of sleep disturbance, usually frequent awakenings during sleep. The difficulty maintaining sleep can have a number of causes. Sleep is fragmented owing to the brain degeneration that disrupts the neurophysiological and neurochemical pathways of sleep. In addition, the symptoms of Parkinson's disease can disrupt sleep. Although tremor is diminished during sleep, muscular rigidity is increased and can prevent the patient from turning or finding a comfortable position, resulting in arousal and awakening. Medications used to treat Parkinson's disease can disrupt sleep. Levodopa preparations frequently cause disruptive dreams and nightmares and may also increase nocturnal myoclonus, repetitive, brief leg jerks that awaken the patient and fragment sleep. Levodopa can be stimulating and may prevent the initiation of sleep if taken close to bedtime. Dementia due to degenerative disease can impinge on sleep in a manner similar to parkinsonism, with the degeneration of pathways vital for normal sleep. *Sundowning*, the emergence of severely disruptive behavior, such as agitation and paranoia, at night, associated with the inability to maintain sleep, is a major management issue in the home care of patients with dementia. The pathophysiology is unknown at present, although some have speculated that sundowning is a nocturnal delirium secondary to degeneration of the suprachiasmatic nucleus. Alternatively, sundowning is viewed as a disruption of circadian rhythms, rapid eye movement (REM) parasomnias, or simply postawakening confusion during which the patient with dementia is unable to distinguish between dreams and current reality. Dementia of the Alzheimer's type is accompanied by an exaggeration of the sleep changes associated with normal aging, with a decrease in total sleep time as well as in slow wave and REM sleep. The sleep disturbances worsen as the disease progresses.

Condition	Sleep Symptoms
Parkinsonism	Frequent awakenings, disturbance of circadian rhythms
Dementia	Sundowning, frequent awakenings
Epilepsy	Difficulty initiating sleep, frequent awakenings, parasomnias
Cerebrovascular disease	Difficulty initiating sleep, frequent awakenings
Huntington's disease	Frequent awakening
Kleine-Levin syndrome	Hypersomnia
Uremia	Restless legs, nocturnal myoclonus

Table 10-48 Medical Conditions Commonly Associated With a Secondary Sleep Disorder

Epilepsy can be a true sleep disorder. Most seizure disorders are activated by sleep or arousal from sleep. Both local and generalized epilepsy can occur during sleep, resulting in difficulties maintaining sleep. Seizures may manifest as parasomnias, such as night terrors, sleepwalking, or head banging, although most parasomnias are not related to epilepsy.

Cerebrovascular disorders can impinge on the initiation and maintenance of sleep. No specific lesions have been consistently correlated with a particular sleep disturbance, although brainstem lesions in general are apt to disrupt sleep architecture.

In *Huntington's disease* patients experience frequent awakenings and decreased total sleep time, a pattern common to many subcortical dementia syndromes. With the progression of the disease the movement disorder may manifest during sleep, further disrupting sleep.

Chronic renal failure, anemia, and diabetes mellitus can cause nocturnal myoclonus and the *restless legs syndrome*. The latter is characterized by the experience of deep pains in the lower calf, prompting the patient to keep the legs in constant motion and impinging severely on the ability to initiate sleep.

Kleine-Levin syndrome is a rare disorder characterized by hypersomnia, compulsive eating, sexual disinhibition, personality change, and psychosis. There is a 3 to 1 male-to-female predominance, with onset of symptoms typically occurring in adolescence. Hypersomnia is marked and is the most consistent feature. Compulsive eating and sexual disinhibition, such as public masturbation or propositioning of strangers, complete the syndrome. Incomplete or atypical variants are more common than the full syndrome. Irritability is frequent, and hallucinations or affective symptoms may be present. Symptoms last hours to weeks and are cyclical, with a full return to baseline on many occasions. Symptoms recur in a varying frequency of 1 to several months. The syndrome can be preceded by flulike symptoms or head trauma, although the precise etiology and pathophysiology are unknown. Presumably, there is hypothalamic system dysfunction with the manifest disturbances in sleep, eating, and sexual behavior. In most patients the episodes decrease in frequency and eventually disappear entirely.

Treatment The diagnosis of a secondary sleep disorder hinges on the identification of an active disease process known to exert the observed effect on sleep. Treatment first addresses the underlying neurological or medical disease. Symptomatic treatments focus on behavior modifications, such as improvement of sleep hygiene. Pharmacological options may also be used, such as benzodiazepines for restless legs syndrome or nocturnal myoclonus, stimulants for hypersomnia, and tricyclic antidepressant medications for manipulation of REM sleep.

Sexual Dysfunction Due to a General Medical Condition Specific syndromes characterized by sexual dysfunction thought to be physiologically caused by a general medical condition are female or male hypoactive sexual desire disorder, male erectile disorder, dyspareunia, and other male or female sexual dysfunction.

History and Comparative Nosology Numerous medical conditions, medications, and drugs of abuse can affect sexual desire and performance. However, despite the attention psychiatry has paid to presumed psychologically mediated sexual dysfunction, the role of physiological diseases was downplayed in earlier psychiatric diagnostic systems. DSM-III listed only functional sexual dysfunctions. DSM-III-R allowed sexual dysfunctions to be classified as psychogenic only or as due to both biogenic and psychogenic causes, but required purely biogenic syndromes to be coded on Axis III. The inclusion of secondary sexual disorders as Axis I diagnoses in DSM-IV is consistent with that edition's inclusive approach to behavioral syndromes.

Epidemiology Although surveys have repeatedly demonstrated a high prevalence of sexual dysfunctions in the general population, valid data on secondary dysfunctions are lacking. Similarly, certain medications may be associated with specific rates of sexual symptoms, but the percentage of patients with truly secondary syndromes is not known.

Etiology Potential causes of sexual dysfunctions are listed in Table 10-49. The type of sexual dysfunction is affected by the etiology, but specificity is rare; that is, a given etiology may manifest as one (or more than one) of several syndromes. General categories include medications and drugs of abuse, local disease processes that affect the primary or secondary sexual organs, and systemic illnesses that affect sexual organs via neurological, vascular, or endocrinological routes.

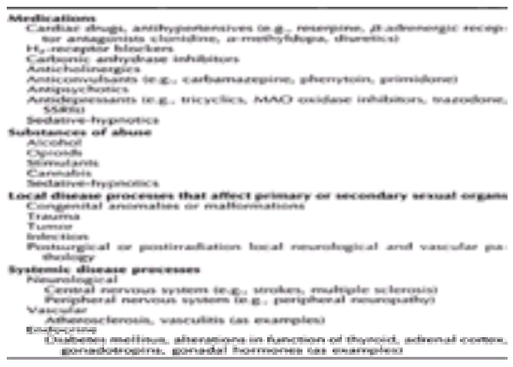

Table 10-49 Causes of Secondary Sexual Dysfunctions

Diagnosis and Clinical Features The clinical features of the sexual dysfunction resemble those of the various primary dysfunctions (see Table 19.1a-17. There may be additional findings due to the underlying disease process. For example, in male erectile disorder due to diabetic autonomic neuropathy, the patient may have symptoms of bowel and bladder autonomic dysfunction as well as evidence of diabetes mellitus itself.

Differential Diagnosis Phenomenology determines the syndromic diagnosis (e.g., erectile dysfunction versus orgasmic disorder). Medical history, physical examination, and relevant laboratory testing are required to demonstrate the presence of physical conditions that are potentially etiological for the sexual dysfunction. However, presence alone does not establish an etiological link. Clinical judgment is necessary and is based on temporal association, assessment of potentially contributory psychosocial factors (or more gross psychopathology), and other factors; the determination of secondary status is often difficult. One exception to that difficulty is male erectile dysfunction. Patients with secondary erectile dysfunction are unable to sustain erections under any circumstances whereas those with primary (i.e., psychogenic) disorders may give a history of variable erectile ability, depending on environment, partner, or other circumstances. If in doubt, a nocturnal penile tumescence study may be helpful because only males with secondary erectile dysfunction will fail to demonstrate tumescence during sleep.

Course and Prognosis The course and prognosis of secondary sexual dysfunctions vary widely, depending on the etiology. Drug-induced syndromes generally remit with discontinuation (or dosage reduction) of the offending agent. Endocrine-based dysfunctions also generally improve with restoration of normal physiology. By

contrast, dysfunctions due to neurological disease may run protracted, even progressive, courses.

Treatment The treatment approach varies widely, depending on the etiology. When reversal of the underlying cause is not possible, supportive and behaviorally oriented psychotherapy with the patient (and perhaps the partner) may minimize distress and increase sexual satisfaction (e.g., example, by developing sexual interactions that are not limited by the specific dysfunction). Support groups for people with specific types of dysfunction are available. Other symptom-based treatments may be used in certain conditions; for example, sildenfanil (Viagra) administration or surgical implantation of a penile prosthesis may be used in the treatment of male erectile dysfunction.

Mental Disorders Due to a General Medical Condition Not Elsewhere Classified DSM-IV has three additional diagnostic categories for clinical presentations of mental disorders due to a general medical condition that do not meet the diagnostic criteria for specific diagnoses. The first of the diagnoses is catatonic disorder due to a general medical condition (Table 10-50). The second diagnosis is personality change due to a general medical condition. The third diagnosis is mental disorder not otherwise specified due to a general medical condition (Table 10-51).

A. The presence of catatonia as manifested by motoric immobility, excessive motor activity that is apparently purposeless and not influenced by external stimuli, extreme negativism or mutism, peculiarities of voluntary movement, or echolalia or echopraxia.
B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.
C. The disturbance is not better accounted for by another mental disorder (e.g., a manic episode).
D. The disturbance does not occur exclusively during the course of a delirium.

Coding note: Include the name of the general medical condition on Axis I, e.g., catatonic disorder due to hepatic encephalopathy; also code the general medical condition on Axis III.

Table 10-50 DSM-IV Diagnostic Criteria for Catatonic Disorder Due to a General Medical Condition

This residual category should be used for situations in which it has been established that the disturbance is caused by the direct physiological effects of a general medical condition, but the criteria are not met for a specific mental disorder due to a general medical condition (e.g., dissociative symptoms due to a complex partial seizure).

Coding note: Include the name of the general medical condition on Axis I, e.g., mental disorder not otherwise specified due to HIV disease; also code the general medical condition on Axis III.

Table 10-51 DSM-IV Mental Disorder Not Otherwise Specified Due to a General Medical Condition

Personality Change Due to a General Medical Condition Personality refers to the constellation of enduring traits and behavioral style that essentially defines the person. Personality develops through adolescence and achieves a degree of stability in early adulthood. Both biological disposition as well as environmental factors influence the development of personality. In adults, behavioral style can be described in terms of interests, activities, pleasures, social relations, predominant mood and temperament, standards, usual outlook on life, range of coping mechanisms, and so forth. There is a robust theoretical and clinical literature delineating specific traits, such as self-consciousness, impulsivity, gregariousness, excitement-seeking, openness, and so forth, along dimensions or continua. Standardized measures are available to determine where along the spectrum for each trait a particular patient lies. This provides a personality profile that can be considered relative to standardized norms. The process is quite similar to the dimensional perspective used to assess intelligence and the determination of an I.Q.

The past concept of organic personality syndrome focused on identifying a generic category of particular traits and behaviors associated with brain injury or dysfunction. This conceptual approach has been maintained in DSM-IV, although it sought to base its classification of personality changes solely upon consistently reported behavioral alterations. Suggestions to classify disorders upon anatomical localization (such as frontal lobe syndrome) were rejected. To date there has been little theoretical work attempting to integrate the dimensional perspectives used in the description of normal personality with the categorical approach used in the study of CNS disease and related personality disturbances.

Definition Personality change means that the person's fundamental means of interacting and behaving have been altered; that is, traits that had been regular and consistent over a lifetime have changed. Personality change must be distinguished from the transient disturbances of behavior that frequently occur in reaction to environmental circumstances. When a true personality change occurs in adulthood, the clinician should always suspect brain injury or insult.

History The impact of brain insults on personality has long been recognized. John M. Harlow's description of personality change in Phineas Gage, who sustained a penetrating head injury, remains the classic description:

> He is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires, at times pertinaciously obstinate, yet capricious and vacillating, devising many plans of future operation, which are no sooner arranged than they are abandoned in turn for others appearing more feasible. A child in his intellectual capacity and manifestations, he has the animal passions of a strong man. . . . In this regard his mind was radically changed, so decidedly that his friends and acquaintances said he was “no longer Gage.”

The frequency of association between brain injury and personality change prompted a search for a generic personality disorder applicable to all brain injury, as well as brain–locale-specific or disease-specific personality disorders. An example of the former is the organic personality disorder found in the earlier versions of DSM. Organic personality disorder was defined as a persistent disturbance of personality due to a specific organic factor involving affective instability, recurrent aggression or rage, impaired social judgment, apathy and indifference, or suspiciousness or paranoid ideation. The interictal personality disorder of temporal lobe epilepsy, characterized by hyperreligiosity, overinclusive speech and behavior, and sexual deviance, was originally presented as a disease-specific personality disorder that was thought to be of high validity. Subsequent studies did not find these traits specific for temporal lobe epilepsy or any other epilepsy. Attempts at defining locale-specific personality disorder have been hampered by difficulties in finding naturalistic human lesions that are indeed localized: Strokes, head trauma, and degenerative diseases, for example, rarely are confined to neat anatomical lobar boundaries.

Nonetheless, the most fruitful approach to delineating personality change disorders has come from the study of frontal lobe injury, where consistent and well-defined traits and behaviors have been associated with particular areas of brain injury. At least two distinct but overlapping secondary personality changes have been identified after injury to the orbitofrontal and frontal convexity areas. Frontal lobe dysfunction may play a key role in all personality and behavioral disturbances because there are vast networks of neural connections between specific areas of the frontal lobe and various limbic and subcortical structures. A similarly complex neuropsychological system suggests that the frontal lobe (more specifically, the prefrontal cortex) modulates many of the basic cognitive, linguistic, attentional, and perceptual processes that originate in other brain areas. Injury to the frontal lobes results in dysfunction in how basic cognitive functions, such as language or memory, are expressed.

Comparative Nosology DSM-I included a category of acute and chronic brain syndromes, defined as disorders due to a diffuse impairment of brain tissue function

from any cause. DSM-II provided basic symptoms for a generic organic brain syndrome, such as impairments in orientation, memory, calculation, learning, and judgment, and lability and shallowness of affect. Although there was no specific category for secondary personality change, it would have been included in the nonpsychotic organic brain syndromes. DSM-III eliminated the unitary organic mental syndrome and allowed for a variety of organic syndromes in which an organic factor was judged etiologically related. Organic personality syndrome nonetheless required at least one of four specific characteristics, including lability, impulsivity, apathy, or suspiciousness; DSM-III-R added recurrent aggression to the list of criteria.

The limitations of the nosology are clear. Personality encompasses a broad range of traits and behaviors not limited to those specified in the organic personality disorder category. The disturbance of personality is identified not from the presence of any particular behavior or trait, but rather as a change from premorbid personality. DSM-IV has dropped the category of organic personality disorder and replaced it with personality change due to a general medical condition. The specific phenomenological criteria were dropped in favor of a general persistent personality disturbance that represents a change from the individual's previous characteristic personality pattern. Subtypes based on the particular phenomenology evident include labile type, disinhibited type, aggressive type, paranoid type, apathetic type, other type, combined type, and unspecified type.

Epidemiology The epidemiological difficulties in ascertaining cases of secondary personality changes are clear: No one particular behavior or trait is diagnostic; rather, a change in a patient's personality structure must be documented. Such documentation often requires recourse to an external informant because patients with personality change are frequently unreliable self-informants. The overinclusive range of personality traits enumerated in previous editions of DSM allowed researchers to pick and choose traits; in addition, the means of measuring them were not consistent from study to study. As a result, reliable incidence and prevalence figures for secondary personality change are not available. Specific personality trait changes for particular brain diseases—for example, passive and self-centered behaviors in dementia of the Alzheimer's type—have been reported; the studies reporting those results, however, have not been replicated, and it remains uncertain how the findings should be applied to other disorders.

Etiology The range of etiologies of secondary personality change is vast and diverse and may involve any of the basic pathological processes described in the previous section. Diseases that preferentially affect the frontal lobes or subcortical structures are more likely to manifest with prominent personality change. Head trauma is a common cause. Strokes involving the anterior communicating or middle cerebral arteries selectively damage frontal lobe structures, often resulting in personality change. The anterior communicating artery is also a common site for aneurysms, which can result in secondary personality change. Frontal lobe tumors, such as meningiomas and gliomas, can grow to considerable size before coming to medical attention, as they may be neurologically silent (i.e., without focal signs). Degenerative disorders affecting the frontal lobes can present with personality change long before cognitive symptoms are evident. Among progressive dementia syndromes, especially those with a subcortical pattern of degeneration, such as AIDS dementia complex, Huntington's disease, or progressive supranuclear palsy, significant personality disturbance manifests often. Multiple sclerosis can impinge on the personality, reflecting subcortical white matter degeneration. Exposures to toxins with a predilection for white matter, such as irradiation, may also produce significant personality change disproportionate to the cognitive or motor impairment.

Diagnosis and Clinical Features The DSM-IV diagnostic criteria for personality change due to a general medical condition are listed in Table 10-52. The diagnosis of a secondary personality change rests entirely on the history. A clear and detailed description of the patient's premorbid personality must be obtained. This history usually is collected from an external informant who knew the patient at baseline as well as currently. The first task in evaluating the history is to determine whether a change in personality has indeed occurred or whether the current disruptive behaviors represent long-standing traits that have been exacerbated by a change in circumstance. In addition, delirium must be ruled out.

A. A persistent personality disturbance that represents a change from the individual's previous characteristic personality pattern. (In children, the disturbance involves a marked deviation from normal development or a significant change in the child's usual behavior patterns lasting at least 1 year.)
B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.
C. The disturbance is not better accounted for by another mental disorder (including other mental disorders due to a general medical condition).
D. The disturbance does not occur exclusively during the course of a delirium and does not meet criteria for a dementia.
E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify type:
Labile type: if the predominant feature is affective lability
Disinhibited type: if the predominant feature is poor impulse control as evidenced by sexual indiscretions, etc.
Aggressive type: if the predominant feature is aggressive behavior
Apathetic type: if the predominant feature is marked apathy and indifference
Paranoid type: if the predominant feature is suspiciousness or paranoid ideation
Other type: if the predominant feature is not one of the above, e.g., personality change associated with a seizure disorder
Combined type: if more than one feature predominates in the clinical picture
Unspecified type

Coding note: Include the name of the general medical condition on Axis I, e.g., personality change due to temporal lobe epilepsy; also code the general medical condition on Axis III.

Table 10-52 DSM-IV Diagnostic Criteria for Personality Change Due to a General Medical Condition

Once a diagnosis of a personality change has been established, the search for an etiological agent begins. An insidious and progressive course is suggestive of a degenerative process or a neoplasm. An abrupt onset of personality change is more suggestive of a vascular event or trauma. Risk factors for HIV infection should raise the suspicion of HIV or neurosyphilis infection. A complete history of toxic exposures, including alcohol and recreational drug use, environmental or occupational toxin exposures, and medications, should be obtained. The search for a causative agent can be aided by the presence of other evidence of brain dysfunction, such as motor abnormalities and cognitive impairment.

The particular form of a personality change may be helpful in determining the locus of injury or brain dysfunction, although much research remains to be done. The prefrontal cortex is often implicated in secondary personality change disorders. Two frontal lobe personality syndromes have been described, correlating with injury to the orbitofrontal and dorsolateral frontal cortical regions. Table 10-53 outlines the behavioral and personality changes associated with each. The anatomical designations for those syndromes may be misleading because frontal regions form rich neuronal networks with subcortical and limbic structures. Subcortical dementia also is characterized by significant personality deteriorations, such as apathy, aspontaneity, and slowing. Patients with multiple sclerosis sometimes present with a euphoric personality, which probably reflects a disruption of the orbitofrontal subcortical network.

Orbitofrontal	Frontopolar
Disinhibition	Apathy
Inappropriate jocularity	Indifference
Affective lability	Psychomotor slowing
Impulsivity	Inaction

Table 10-53 Frontal Lobe Personality Change Syndromes

Global degenerative processes, such as dementia of the Alzheimer's type, involve significant personality change that has been less well characterized. In general, there is a coarsening of the personality with loss of subtlety and finesse. An exacerbation of premorbid traits is possible, with a suspicious patient becoming paranoid or a flamboyant patient becoming histrionic. Agitation or aggression is a common concomitant of brain disease. When they occur in a patient with a premorbid history of violence and a short temper, it may be difficult to determine if a secondary personality change has occurred, even when CNS dysfunction is evident.

Laboratory evaluation for secondary personality change is the same as for other secondary disorders. The most important element is informed clinical suspicion

regarding specific disease processes.

Differential Diagnosis Secondary personality change must be differentiated from adjustment disorders occurring, for example, in response to environmental stressors or major medical disorders. Apathetic and amotivational symptoms in patients with dorsolateral frontal lesions may be mistaken for major depressive disorder. The former can be distinguished by a lack of pervasive dysphoria, intact neurovegetative function, and the absence of self-disparagement and hopelessness. Euphoria and disinhibition with the orbitofrontal syndrome may be ascribed to mania. The orbitofrontal syndrome, however, does not display heightened motor activity, excessive energy, and disrupted sleep; neither does it follow the cyclical course of bipolar I disorder but rather produces a persistent and consistent clinical picture.

Course and Prognosis The course of and prognosis of secondary personality syndromes depend on the course of the etiological systemic or cerebral disorder. Personality change secondary to mass lesions or hydrocephalus can improve dramatically with surgery, chemotherapy, or radiation therapy. However, each of these treatments may result in a different personality change syndrome. Personality change secondary to head trauma may improve slowly and gradually over the course of months or years, although residual disturbances may remain. Personality change due to degenerative processes can be most disruptive early in the disease process when the patient retains a measure of volition and control of motor capacities. Ironically, management of such patients may ease as the disease progresses, when the personality evolves into greater apathy, unresponsiveness, and akinesia. Personality change associated with epilepsy can improve dramatically with seizure control by pharmacotherapy or surgery.

Treatment Treatment for secondary personality syndromes is first directed toward correcting the underlying etiology. Symptomatic treatments as a group have been marginally effective at best. Lithium carbonate, carbamazepine, and valproic acid have been used for the control of affective lability and impulsivity. Aggression or explosiveness may be treated with lithium, anticonvulsant medications, or a combination of lithium and an anticonvulsant agent. Centrally active b-adrenergic receptor antagonists, such as propranolol (Inderal), have some efficacy as well. Antipsychotic medications are no more effective in the dampening of aggression than the previously mentioned agents, induce greater discomfort, and introduce the risk of tardive dyskinesia. Apathy and inertia have occasionally improved with psychostimulant agents. Because cognition and verbal skills may be preserved in patients with secondary personality changes, they may be candidates for psychotherapy. Families should be involved in the therapy process, with a focus on education and understanding the origins of the patient's inappropriate behaviors and coarsening. Issues such as competency, disability, and advocacy are frequently of clinical concern in those patients in light of the unpredictable and pervasive behavior change.

SUGGESTED CROSS-REFERENCES

A discussion of psychiatric clinical manifestations of specific neurological and systemic disorders appears in Chapter 2 on neuropsychiatry and behavioral neurology. Neuropsychological and intellectual assessment of adults is presented in Section 7.3, assessment of children in Section 7.5, and medical assessment and laboratory testing in Section 7.6. Discussions of substance-related disorders appear in Chapter 11, schizophrenia in Chapter 12, psychotic disorders in Chapter 13, anxiety disorders in Chapter 15, factitious disorders in Chapter 17, dissociative disorders (including dissociative amnesia) in Chapter 18, sexual dysfunctions in Section 19.1a on normal human sexuality and sexual dysfunctions, sleep disorders in Chapter 21, and personality disorders in Chapter 24. Primary care psychiatry is presented in Section 28.1, and the psychiatric aspects of HIV infection and AIDS in Section 2.8. Physiological aspects of normal aging (including age-related cognitive decline) is discussed in Section 51.2c and dementia of the Alzheimer's type and other dementing disorders of late life are discussed in Section 51.3e.

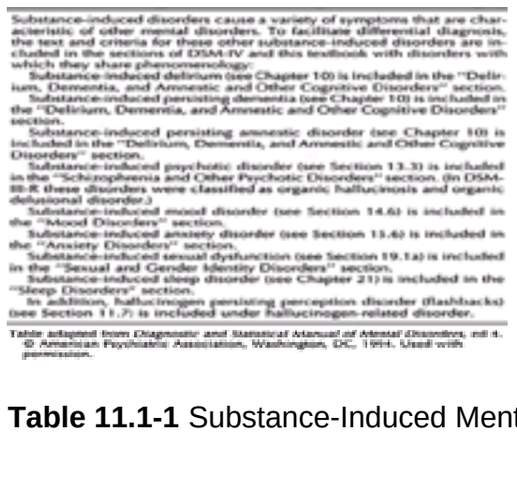
CHAPTER 11. SUBSTANCE-RELATED DISORDERS

11.1 INTRODUCTION AND OVERVIEW

JEROME H. JAFFE, M.D.

Whether a society views substance use primarily as a moral or a legal problem, when it creates difficulties for the user or ceases to be entirely volitional it becomes the concern of all the helping professions, including psychiatry. This chapter on substance-related disorders is made up of separate sections organized around the syndromes engendered by the use of each of the major groups of pharmacological agents that are commonly misused (abused). This section deals with issues that are common across categories of drugs—the nomenclature and diagnostic schemes of the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and the 10th revision of *International Classification of Diseases and Related Health Problems* (ICD-10), the history of substance use and dependence, epidemiology, and the etiological factors and treatment principles that appear to be common to these syndromes.

General Organization of DSM-IV and ICD-10 DSM-IV includes two broad categories of substance-related disorders: substance use disorders (substance dependence and substance abuse), and a diverse grouping of substance-induced disorders (such as intoxication, withdrawal, psychotic disorder, and mood disorders). Thus, in DSM-IV the topic of substance-related disorders goes beyond substance dependence and abuse and closely related problems to include a wide variety of adverse reactions not only to substances of abuse, but also to medications and toxins. The medications associated with substance-induced disorders range from anesthetics to over-the-counter medications and include such diverse drug categories as anticholinergics, antidepressants, anticonvulsants, antimicrobial drugs, antihypertensive agents, corticosteroids, antiparkinson agents, chemotherapeutic agents, nonsteroidal anti-inflammatory drugs, and disulfiram (Antabuse). In addition, several categories of substance-induced disorders can be associated with a wide range of nonmedicinal toxic materials, ranging from heavy metals and industrial solvents to insecticides and household cleaning agents. DSM-IV groups the diagnostic criteria for substance dependence, abuse, intoxication, hallucinogen persisting perception disorder, and withdrawal syndromes in a section titled “Substance-Related Disorders,” whereas the other substance-related disorders (e.g., substance-induced mood disorders and substance-induced delusional disorders) are described in the sections covering the disorders that they most closely resemble phenomenologically (Table 11.1-1).



Substance-induced disorders cause a variety of symptoms that are characteristic of other mental disorders. To facilitate differential diagnosis, the text and criteria for these other substance-induced disorders are included in the sections of DSM-IV and this textbook with disorders with which they share phenomenology:

Substance-induced delirium (see Chapter 10) is included in the "Delirium, Dementia, and Amnestic and Other Cognitive Disorders" section.

Substance-induced persisting dementia (see Chapter 10) is included in the "Delirium, Dementia, and Amnestic and Other Cognitive Disorders" section.

Substance-induced persisting amnestic disorder (see Chapter 10) is included in the "Delirium, Dementia, and Amnestic and Other Cognitive Disorders" section.

Substance-induced psychotic disorder (see Section 13.3) is included in the "Schizophrenia and Other Psychotic Disorders" section. (In DSM-III-R these disorders were classified as organic hallucinosis and organic delusional disorder.)

Substance-induced mood disorder (see Section 14.6) is included in the "Mood Disorders" section.

Substance-induced anxiety disorder (see Section 13.4) is included in the "Anxiety Disorders" section.

Substance-induced sexual dysfunction (see Section 19.1a) is included in the "Sexual and Gender Identity Disorders" section.

Substance-induced sleep disorder (see Chapter 21) is included in the "Sleep Disorders" section.

In addition, hallucinogen persisting perception disorder (flashbacks) (see Section 11.3) is included under hallucinogen-related disorder.

Table adapted from *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994. Used with permission.

Table 11.1-1 Substance-Induced Mental Disorders Included Elsewhere in the Textbook

The DSM-IV section dealing with substance dependence and substance abuse presents descriptions of the clinical phenomena associated with the use of 11 designated classes of pharmacological agents: alcohol, amphetamines or similarly acting agents; caffeine; cannabis; cocaine; hallucinogens; inhalants; nicotine; opioids; phencyclidine (PCP) or similar agents; and sedatives, hypnotics, and anxiolytics. A residual twelfth category includes a variety of agents, such as anabolic steroids and nitrous oxide, that are not in the 11 designated classes.

ICD-10 considers the disorders due to psychoactive substance use within the confines of an alphanumeric system that allows only nine categories of pharmacological agents, with one residual category to cover both multiple drug use and use of psychoactive substances not included in the nine designated categories. DSM-IV and ICD-10 categorize substances comparably, with the following exceptions. Caffeine and PCP are considered distinct categories in DSM-IV; whereas in ICD-10, problems related to caffeine are included in the category of other stimulants such as amphetamine, and phencyclidine must be included with hallucinogens or in the residual category. Also, ICD-10 has a special category for abuse of non–dependence-producing substances (Table 11.1-2). Specifically mentioned are antidepressants, analgesics, antacids, vitamins, and steroids or hormones.

A wide variety of medicaments and folk remedies may be involved, but the particularly important groups are psychotropic drugs that do not produce dependence, such as antidepressants, laxatives, and analgesics that may be purchased without medical prescription, such as aspirin and paracetamol. Although the medicines may have been originally prescribed or recommended in the first instance, prolonged, unnecessary, and often excessive dosage develops, which is facilitated by the availability of the substances without medical prescription.

Persistent and unjustified use of these substances is usually associated with undue energy expense, often involves unnecessary contacts with medical professionals or supporting staff, and is sometimes marked by the harmful physical effects of the substances. Attempts to discourage or forbid the use of the substance are often met with resistance, for laxatives and analgesics this may be in spite of warnings about or even the development of physical harm such as renal dysfunction or ophthalmic disturbance. Although it is usually clear that the patient has a strong motivation to take the substance, no dependence or withdrawal symptoms develop as in the case of the psychoactive substances specified in mental and behavioral disorders due to psychoactive substance use.

Identify the type of substance involved:

Antidepressants
(such as tricyclic and tetracyclic antidepressants and monoamine oxidase inhibitors)

Laxatives

Analgesics
(such as aspirin, paracetamol, phenacetin, not specified as psychoactive substance use)

Antacids

Vitamins

Steroids or hormones

Specific herbal or folk remedies

Other substances that do not produce dependence
(such as glycerol)

Unspecified

Table 11.1-2 ICD-10 Diagnostic Criteria for Abuse of Non-Dependence-Producing Substances

DEFINITIONS AND DIAGNOSIS

Substance Dependence The revised third edition of DSM (DSM-III-R), DSM-IV, and ICD-10 formulations for substance abuse and dependence closely follow the concepts and terminology developed in 1980 by an International Working Group sponsored by the World Health Organization (WHO) and the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) of the United States, which defined substance dependence as follows:

> A syndrome manifested by a behavioral pattern in which the use of a given psychoactive drug, or class of drugs, is given a much higher priority than other behaviors that once had higher value. The term “syndrome” is taken to mean no more than a clustering of phenomena so that not all the components need always be present or not always present with the same intensity. . . . The dependence syndrome is not absolute, but is a quantitative phenomenon that exists in different degrees. The intensity of the syndrome is measured by the behaviors that are elicited in relation to using the drug and by the other

behaviors that are secondary to drug use. . . . No sharp cut-off point can be identified for distinguishing drug dependence from non-dependent but recurrent drug use. At the extreme, the dependence syndrome is associated with “compulsive drug-using behavior.”

That central notion is continued in DSM-IV, which states:

> The essential feature of dependence is a cluster of cognitive, behavioral, and physiological symptoms indicating that the individual continues substance use despite significant substance-related problems.

The central notion in ICD-10 is virtually the same:

> a cluster of behavioural, cognitive, and physiological phenomena that develop after repeated substance use and typically include a strong desire to take the drug, difficulties in controlling its use, persisting in its use despite harmful consequences, a higher priority given to drug use than to other activities and obligations, increased tolerance, and sometimes a physical withdrawal state.

The DSM-IV and ICD-10 criteria for substance dependence are presented in Table 11.1-3 and Table 11.1-4. DSM-IV uses seven criteria to describe a generic concept of dependence that applies across 11 classes of pharmacological agents. ICD-10 requires that three of six criteria be met and also applies across classes of drugs.

Table 11.1-3 DSM-IV Diagnostic Criteria for Substance Dependence

Table 11.1-4 ICD-10 Diagnostic Criteria for Mental and Behavioral Disorders Due to Psychoactive Substance Use

DSM-IV and ICD-10 use a polythetic syndrome definition, in which no one specific criterion is required so long as three or more are present. However, DSM-IV asks the clinician to specify whether physiological dependence (evidence of criterion 1, tolerance, or criterion 2, withdrawal) is present or absent. Evidence indicates that physiological dependence is associated with a more severe form of the disorder.

In addition to requiring the clustering of three criteria in a 12-month period, DSM-IV includes a few other qualifications. It states specifically that the diagnosis of dependence can be applied to every class of substances except caffeine. That point is admittedly controversial, and some researchers believe, on the basis of the same DSM-IV generic criteria, that caffeine produces a distinct form of dependence, although it is relatively benign for most persons.

Some persons use several categories of drugs and are clearly drug dependent, according to the generic criteria, but it may not be possible to ascertain whether they are dependent on any one specific class of drugs. When at least three groups of substances are involved, DSM-IV calls the condition polysubstance dependence (Table 11.1-5). DSM-IV also makes provision for classifying substance-related disorders that cannot be classified in any of the previous categories (e.g., nitrous oxide, anticholinergics, anabolic-androgenic steroids) or for an initial diagnosis of dependence or abuse when the specific substance is not known. A similar residual category is included in ICD-10, but steroids are given a distinct code. The DSM-IV diagnostic criteria for other (or unknown) substance-related disorders are listed in Table 11.1-6.

Table 11.1-6 DSM-IV Diagnostic Criteria for Other (or Unknown) Substance-Related Disorders

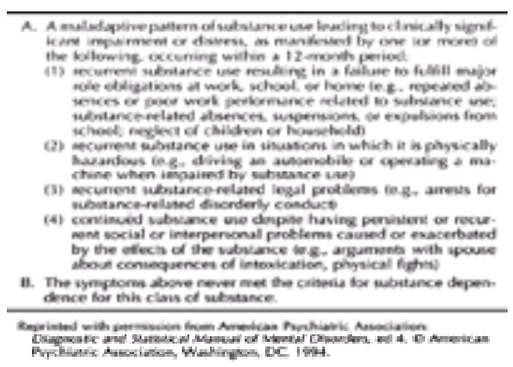
Patterns of Remission and Course Specifiers DSM-IV and ICD-10 deal with remission by providing distinct modifying terms that can be appended to a diagnosis of substance dependence. DSM-IV terms are more varied than those of ICD-10 (Table 11.1-7). The DSM-IV course specifiers require a period of at least 1 month, after a period of active dependence, during which no criteria of dependence are present. If a patient has not met any criteria for dependence for at least 1 month but for less than 12 months, the course specifier to use is early full remission. If the period during which no criteria of dependence are met exceeds 12 months, the specifier of sustained full remission can be used. If the full criteria for dependence or abuse have not been met for less than a year, but one or more criteria have been present, early partial remission may be used. If the period exceeds 12 months, sustained partial remission may be used. Two additional remission specifiers should be used when appropriate: “on agonist therapy (includes partial agonists)” and “in a controlled environment.” Several factors, such as duration of remission and duration of period of dependence, must be considered in deciding that a person has fully recovered and no longer warrants a diagnosis of dependence. The modifiers that describe the course of dependence in ICD-10 are similar, but specific criteria for selecting them are not provided (Table 11.1-4).

Table 11.1-7 DSM-IV Course Modifiers for Substance Dependence

Substance Abuse DSM-IV defines the essential features of substance abuse as follows:

> A maladaptive pattern of substance use manifested by recurrent and significant adverse consequences related to the repeated use of substances. . . . These problems must occur recurrently during the same 12-month period. . . . [T]he criteria for Substance Abuse do not include tolerance, withdrawal, or a pattern of compulsive use and instead include only the harmful consequences of repeated use. A diagnosis of Substance Abuse is preempted by the diagnosis of Substance Dependence if the individual's pattern of substance use has ever met the criteria for Dependence for that class of substances.

The DSM-IV criteria for substance abuse are shown in Table 11.1-8.



A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:
(1) recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
(2) recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
(3) recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct)
(4) continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)
B. The symptoms above never met the criteria for substance dependence for this class of substance.

Table 11.1-8 DSM-IV Diagnostic Criteria for Substance Abuse

A major difference exists between DSM-IV and ICD-10 with regard to the diagnosis of substance abuse. ICD-10 does not use the term “abuse.” Instead, it includes a category of *harmful use*, which substantially differs from the DSM-IV concept of “abuse.” The concept of “harmful use” is limited to mental and physical health (e.g., hepatitis and overdose, or episodes of depressive disorder resulting from heavy alcohol use). The concept specifically excludes social impairment, stating: “The fact that a pattern of use of a particular substance is disapproved of... or may have led to socially negative consequences such as arrest or marital arguments is not in itself evidence of harmful use.” Four diagnostic criteria must be met to make the ICD-10 diagnosis of harmful use.

Substance Withdrawal *Substance withdrawal*, as used in DSM-IV, is a diagnostic term rather than a technical term. Thus minor symptoms that technically are due to cessation of substance use (e.g., the coffee drinker's early morning precoffee lethargy or minor headache) would not by themselves fulfill the criteria for substance withdrawal, unless they are accompanied by a maladaptive behavior change and cause some clinically significant distress or impairment in social, occupational, or other important area of functioning. DSM-IV does not recognize withdrawal from caffeine, cannabis, or PCP, although some observers believe that specific signs and symptoms can be observed when those agents are abruptly discontinued after a period of heavy use. ICD-10 does describe a cannabinoid withdrawal state.

Withdrawal is commonly, but not invariably, associated with substance dependence. The signs and symptoms of withdrawal vary with the specific class of drug. In general, the severity of withdrawal is related to the amount of substance used and the duration and patterns of use. Withdrawal is seen not only when substance use is stopped but also when reduced use of a substance or a change in metabolism results in lower tissue levels. The DSM-IV generic criteria for substance withdrawal are shown in Table 11.1-9; the ICD-10 general criteria are shown in Table 11.1-4. Specific diagnostic criteria for withdrawal from each category of drugs, to be used when the general criteria have been met, are also provided.

A. The development of a substance-specific syndrome due to the cessation of (or reduction in) substance use that has been heavy and prolonged.
B. The substance-specific syndrome causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
C. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Table 11.1-9 DSM-IV Diagnostic Criteria for Substance Withdrawal

Substance Intoxication Substance intoxication is defined more narrowly in DSM-IV than it might be in a pharmacology text. A variety of substances may produce unwanted physiological or psychological effects that could be construed as substance intoxication effects (e.g., excessive sleepiness following use of an antihistamine), but unless the symptoms are associated with maladaptive behavior, the effects would not constitute substance-induced intoxication as defined in DSM-IV. Furthermore, whether a behavioral effect is maladaptive depends on the social and environmental context in which it occurs. If alcohol makes a person unusually sociable, a bit garrulous, and a little uncoordinated at a family celebration this is probably not maladaptive drinking behavior, the same behavior at a formal business meeting probably is. Similarly, ICD-10 specifies that intoxication must produce disturbances in the level of consciousness, cognition, perception, affect, or behavior that are of clinical importance. However, it requests clinicians to further specify which of several common complications of intoxication (e.g., trauma, delirium, convulsions) are also present. The DSM-IV general criteria for substance intoxication are shown in Table 11.1-10. In addition, ICD-10 provides specific sets of diagnostic criteria for each of the drug categories and for multiple drugs, to be used once the generic criteria for intoxication have been met. Also shown are the additional specifiers for complications of intoxication (Table 11.1-4).

A. The development of a reversible substance-specific syndrome due to recent ingestion of (or exposure to) a substance. **Note:** Different substances may produce similar or identical syndromes.
B. Clinically significant maladaptive behavioral or psychological changes that are due to the effect of the substance on the central nervous system (e.g., belligerence, mood lability, cognitive impairment, impaired judgment, impaired social or occupational functioning) and develop during or shortly after use of the substance.
C. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Table 11.1-10 DSM-IV Diagnostic Criteria for Substance Intoxication

Substance-Induced Disorders In addition to dependence, abuse, intoxication, and withdrawal, the use of certain psychoactive drugs can induce syndromes that used to be called organic mental disorders. To avoid implying that other psychiatric disorders do not have an organic basis, DSM-IV designates these syndromes substance-induced disorders and recognizes the following categories: substance intoxication, substance withdrawal, substance-induced withdrawal delirium, substance-induced intoxication delirium, substance-induced persisting dementia, substance-induced persisting amnestic disorder, substance-induced mood disorder, substance-induced anxiety disorder, substance-induced psychotic disorder, substance-induced sexual dysfunction, and substance-induced sleep disorder.

In recording a diagnosis of a substance-related disorder, the clinician should indicate the specific agent causing the disorder, if known, rather than the broad drug category; that is, substance-induced intoxication, pentobarbital (Nembutal) rather than substance-induced intoxication, sedative-hypnotics. However, the diagnostic code should be selected from the list of classes of substances provided in sets of criteria for the substance-induced disorder being recorded. For each of the substance-induced disorders (other than intoxication and withdrawal), the clinician is asked to specify whether the onset was during intoxication or during withdrawal. Thus, a specific substance-induced disorder would have a three-part name delineating (1) the specific substance, (2) the context (whether the disorder occurred during intoxication or during withdrawal or occurs or persists beyond those stages), and (3) the phenomenological presentation (e.g., diazepam [Valium]-induced anxiety disorder with onset during withdrawal).

Table 11.1-11 shows the various disorders induced by the major categories of substances recognized by DSM-IV and indicates which disorders are seen during intoxication and during withdrawal. Although they are not included specifically in the table, anabolic-adrenergic steroids can also induce psychotic mood, anxiety, and sleep and sexual disorders, and their withdrawal can also be associated with mood and sleep disorders. ICD-10 has a distinctly different approach to recording these drug-related disorders. With the first and second digits after the letter committed to designating the drug category, additional psychiatric syndromes are indicated by the use of the third and fourth digits. For example, persistent mood disorder associated with hallucinogens is designated F16.72. For the diagnosis to be made, the mood disorder would need to meet the criteria listed for mood (affective) disorders.

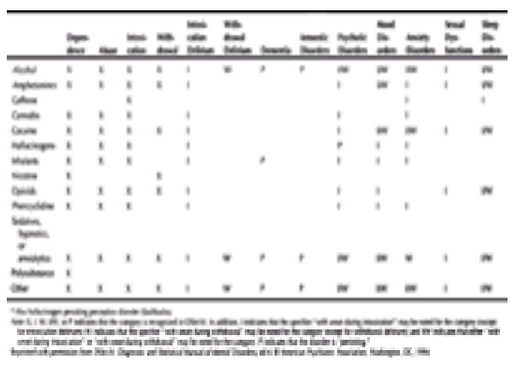

Table 11.1-11 DSM-IV Diagnoses Associated With Class of Substances

Evolving Terminology The terminology used to describe the substance-related disorders has been repeatedly revised as concepts about the nature of drug-using behavior have evolved. In the 1980 third edition of the DSM (DSM-III) drug use disorders were divided into two major categories, drug abuse and drug dependence, and specific criteria for diagnosis were given. In DSM-III-R, adopted in 1987, the two categories were retained, but the diagnostic criteria were modified. Further revisions were made for DSM-IV, which adopted the terms “substance abuse” and “substance dependence,” probably to eliminate the use of the more cumbersome term “alcohol and drug dependence including tobacco.” For similar reasons, ICD-10 adopted the term “psychoactive substance dependence.”

In much of the world literature on drug dependence, the term “dependence” is used to convey two distinct ideas: (1) a behavioral syndrome and (2) physical or physiological dependence. *Physiological dependence* can be defined as an alteration in neural systems that is manifested by tolerance and the appearance of withdrawal phenomena when a chronically administered drug is discontinued or displaced from its receptor. Because the dual use of the word causes confusion, the

1980 ADAMHA-WHO working group recommended restricting use of the term “dependence” to describe the behavioral syndrome and substituting the term “neuroadaptation” for physical dependence. Such a substitution would have emphasized several points. First, the continued use of many drugs, including tricyclic antidepressants and b-adrenergic receptor antagonists, causes neuroadaptive changes followed by withdrawal phenomena, but not by drug-seeking behavior, on their discontinuation. Second, neuroadaptive changes begin with the first dose of an opioid or sedative drug, and therefore, such changes in and of themselves are not a sufficient cause (or definition) of drug dependence as a behavioral syndrome.

Why Use “Addiction”? The words “addict” and “addiction” often have pejorative connotations; they are also frequently trivialized and used to refer to ordinary activities, such as exercising and solving crossword puzzles. However, the term “addiction” continues to have the core connotation of decreased control, and some chapters in this book have retained such terms as “opioid addict” because they are less awkward to use than terms such as “severely opioid-dependent person” when referring to persons who are dependent on drugs to a severe degree. Here the word “dependent,” unmodified, is used to mean behaviorally dependent. The term “physiological dependence” or “physical dependence” is used to refer to the physiological changes that result in withdrawal symptoms when drugs are discontinued.

COMPARATIVE NOSOLOGY

DSM-IV and ICD-10 The generic concept of dependence is virtually identical in DSM-IV and ICD-10. By requiring the clinician to specify whether tolerance and withdrawal are present, DSM-IV appears to recognize a special significance for tolerance and physiological dependence. Some data indicate that among alcoholics the presence of physical dependence and, to a lesser degree, tolerance is associated with a more severe variety of the syndrome. In practice, however, requiring evidence of these criteria would not substantially reduce the number of cases meeting the criteria for dependence in most drug categories, with the exception of hallucinogens, a class of drugs for which DSM-IV does not list physiological dependence as a criterion. There is generally a high level of agreement between DSM-IV and ICD-10 for making a diagnosis of dependence, although the descriptions of the criteria for determining the presence and severity of the syndrome differ. They both require that three elements of the syndrome have been present in a 12-month period. The DSM-IV categorization of drug classes differs somewhat from the one used by ICD-10, which, constrained by a new alphanumeric system, uses only nine drug categories by including caffeine with amphetamine-like stimulants and PCP with other psychoactive agents.

The word “abuse” is also commonly used in ways that differ significantly from the definitions developed for use in DSM-IV. In popular and legislative contexts *drug abuse* means any use of an illicit substance or any nonprescribed use of a drug intended as a medicine, as well as the harmful or excessive use of legally available substances, such as alcohol and tobacco.

Despite the reliability of DSM-IV and ICD-10 criteria for dependence in many European and Anglo-American cultures, several criteria (e.g., narrowing of drinking repertoire, time spent obtaining the drug, and even tolerance for the drug) have posed difficulties in other cultures, especially when dealing with alcohol. Tolerance is often understood when applied to drugs, but not to alcohol; in some cultures, holding one's liquor is a sign of manhood. Clinicians are more likely to make a diagnosis of drug dependence than alcohol dependence even when behavioral signs are comparable. In several cultures, little or no distinction is recognized between use, abuse, and harmful use of illicit drugs.

Other Perspectives The criteria for diagnosis in DSM-IV and ICD-10 were developed from what is essentially a biopsychosocial model of substance dependence. In such a model multiple factors—genetic, psychological, sociological, and pharmacological—contribute to the observed clinical syndromes. Such apparent unanimity about drug dependence should not obscure the existence of dissenting perspectives, which take several forms. In one the biopsychosocial model is accused of giving too much weight to biological factors and too little recognition to the notion of human will and responsibility, of medicalizing deviant behavior for the benefit of treatment professionals, and of creating universal exculpation for all those who fail to live up to reasonable societal expectations. But some professionals have implicitly criticized the same biopsychosocial model for not giving sufficient weight to the ideas that substance dependence is a specific primary disease (i.e., not a symptom of other psychiatric difficulties), that those who develop the disease have no control over their intake of certain substances, and that denial of the presence of a problem is a major characteristic of the disease.

Concepts about substance dependence can be arrayed along several dimensions that are not entirely independent or orthogonal: broad versus narrow, disease versus learned behavior, and social versus medical. The narrow concept of substance dependence accepts as disorders those maladaptive behaviors associated primarily, if not exclusively, with the ingestion of substances generally accepted as pharmacological agents. Compulsive eating, gambling, running, hair pulling, and repetitive excessive sexual activities are not included among the dependence disorders, although those problems may share certain features that resemble a decreased ability to choose and are sometimes ameliorated by participation in support groups founded on principles similar to those of Alcoholics Anonymous (AA). A broad approach would create a superclass of disorders that would include a number of such behaviors not involving pharmacological agents.

At the disease end of the disease-versus-behavioral syndrome dimension is a belief that dependence is not a learned behavior that can be modified or ameliorated with relearning but is a primary disorder caused by an interaction between a substance and a person with some genetic vulnerability and that only total abstinence can arrest the progression of the disease. The medical-versus-social dimension typically describes a range of views on how best to respond to problems with substances, rather than differences about the essential nature of the problems. The medical model stresses issues of assessment—treatment, planning, and record keeping—and sometimes treatment that can be rendered only by those with professional training (not necessarily physicians). The social model emphasizes the importance of social supports and integrating the person with a problem into a network of recovering persons who can offer continuing support. The assessment and recording of progress and outcome as generally practiced by credentialed professionals is minimized.

HISTORY

The most commonly abused drugs have been in use for hundreds, if not thousands, of years. For example, opium has been used for medicinal purposes for at least 3500 years, references to cannabis (marijuana) as medicinal can be found in ancient Chinese herbals, and wine is mentioned frequently in the Bible. The indigenous people of the Western Hemisphere were smoking tobacco and chewing coca leaves generations before the arrival of the Spaniards. Some of the problems caused by alcohol and other drugs, such as drunkenness, are described in the Bible and in the writings of the ancient Greeks and Romans. As new and more concentrated forms of drugs were discovered or invented or new routes of administering them were developed, new problems related to their use emerged. For instance, when cheap gin was introduced into England in the eighteenth century, the alcohol-related problems that emerged were considered more serious than those associated with beer and wine. Although opium smoking was a major problem in Asia in the eighteenth and nineteenth centuries, new problems were seen after morphine, the most active opium alkaloid, was isolated in 1806. Morphine was subject to misuse by injection from the late nineteenth century on, and intravenous morphine and heroin use began to spread in the early part of the twentieth century. Tobacco use and its associated problems did not become widespread until the nineteenth century, when new methods of curing the leaves produced a mild smoking tobacco and cigarettes were introduced, which made common the practice of inhaling tobacco smoke deeply into the lungs. By the early twentieth century, cigarette smoking was a popular practice.

Medicalizing Excessive Drug Use In 1810 Benjamin Rush, who is often credited as the first American physician to suggest that excessive use of alcohol was a disease rather than exclusively a moral defect, proposed the establishment of a sober house; in 1835 Samuel Woodward, a pioneer in the establishment of asylums for the insane, advocated similar asylums for inebriates. Contemporaneous with those early moves to involve medicine in dealing with excessive alcohol use was the emergence of the temperance movement and the Washingtonians—groups of reformed drunkards concerned with helping others to adopt and maintain sobriety. In the process the Washingtonians developed many of the principles of self-help that were rediscovered by AA almost a century later. When the ideas of voluntarism and self-help as exemplified by Washingtonian societies failed to eliminate the problem of drunkenness, physicians began to debate more seriously the idea of coerced treatment in inebriate asylums supported by public funds. In 1870 advocates of the approach established the American Association for the Cure of Inebriates (AACI), dedicated to setting up hospitals for such persons, conducting research, and teaching medical students and physicians how to treat inebriety. At first those physicians who believed in a more spiritual, voluntary approach to the problem (neo-Washingtonians) were part of the AACI, but gradually the more somatically oriented factions, which advocated medically supervised asylums (and compulsory treatment when needed), gained ascendancy. Furthermore, the focus of concern was no longer limited to those who abused alcohol. Thomas Crothers, the secretary of AACI, saw inebriate asylums as places to treat all those who used any variety of intoxicant or narcotic to excess. However, very few publicly supported inebriate asylums ever opened.

Early Attitudes The closing years of the nineteenth century saw growing concern about the excessive and inappropriate use of drugs, including alcohol and tobacco as well as opiates and cocaine. First isolated from the coca leaf in 1860, cocaine came into widespread use in 1885 when pharmaceutical companies began selling it in the United States and Europe. In 1884 Sigmund Freud had published a review of the potential therapeutic uses of cocaine. Some medical authorities in the United States shared his enthusiasm, and cocaine was recommended by the Hay Fever Association as a remedy for that malady. Within a few years, however, it was recognized that cocaine had the capacity to induce toxic psychosis as well as gain control over behavior. It was also recognized that long-term opiate use had dependence-inducing effects. Nevertheless, in the United States, until the beginning of the twentieth century, both the opium alkaloids and cocaine were still found in

patent medicines that were sold over the counter for a wide variety of indications, and their labeling often did not reveal their contents.

Although achieving long-term cure of morphinism was reported to be exceedingly difficult, until the turn of the twentieth century neither the public nor the medical profession saw the habitual user of opium or morphine as invariably suffering from a moral deficit. Those who had developed the morphine habit represented the entire socioeconomic spectrum, with women outnumbering men by about two to one. Various political and literary figures were known to use opiates but to lead otherwise productive and exemplary lives. However, cocaine use and the morphine habit were also common among gamblers, petty thieves, prostitutes, and other disreputable members of society. Persons with emotional problems and those who had formerly used alcohol to excess were probably also overrepresented among opium users, since it was not unusual at the time for physicians to prescribe opiates to control emotional problems and alcoholism.

The problem of using the same institution for treatment of drug users who had antisocial tendencies and those who led more conventional lives was as vexing to early advocates of medical treatment as it is to present-day practitioners. Many proponents of inebriate asylums did not want to take responsibility for persons who had frequent or serious encounters with the police because it was thought that such persons would make it impossible to create an atmosphere conducive to recovery. Partly to cope with the problem, even some of the proponents of a disease model of inebriety maintained the distinction between “inebriety the disease” and “intemperance the vice.”

Early Control Efforts: Evolution of the Criminal Model By the late 1890s the public and the medical community were no longer indifferent to drug use and habituation. In 1893 the Anti-Saloon League was founded, reinvigorating a temperance movement that advocated the total prohibition of alcohol. Medical texts in England, Europe, and the United States contained descriptions of morphinism, theories of its causation, and recommendations for withdrawal and postwithdrawal treatment. Some texts also described problems of cocainism. Medical authorities in the United States cautioned against overly liberal prescribing of cocaine and opiates by physicians and expressed great concern about the presence of those drugs in unlabeled proprietary over-the-counter medicines. State laws were passed aimed at controlling the sale of opiates and cocaine, especially in patent medicines. In 1900 the cocaine in Coca-Cola was replaced by caffeine.

Partly to support the efforts of the Chinese government to control opium use in China, representatives of the United States government led the movement to negotiate an international treaty to control traffic in opium, cocaine, and related drugs. The first such treaty was signed in The Hague in 1912. Negotiators from the United States were also interested in the international control of cannabis but could not get other nations to view the substance as sufficiently problematic to warrant it. (Such control was achieved in 1925 at the Second Geneva Convention.) The Hague Convention required the signatories to pass domestic legislation controlling opiates and cocaine. The Harrison Act of 1914, the first federal legislation to regulate opiates and cocaine, was designed to restrict access to opiates and cocaine to doctors, dentists, pharmacists, and legitimate importers and manufacturers and brought the United States into compliance with the convention.

State regulations concerning the sale of opiates and cocaine, the introduction of aspirin and the barbiturates, and the Pure Food and Drug Act of 1906, which required labeling of patent medicines, were already having an impact on the use of opiates in medicine when the Harrison Act was passed in 1914. Although many medical and political leaders in the United States believed that much of the problem of drug dependence resulted from careless prescribing by physicians, the Harrison Act was not originally intended to interfere with the legitimate practice of medicine or to cause special hardship for those already dependent on opiates. For several years after the Harrison Act was passed, a few cities operated clinics that prescribed morphine to persons with established morphine habits. Most of those dependent on opiates before the Harrison Act became abstinent within a few years after it was passed, although generally not as a result of treatment at the clinics.

Fluctuating Attitudes Major changes had taken place in American attitudes and practices by the 1920s. The Eighteenth Amendment to the U.S. Constitution, which prohibited the sale of alcohol, became law in 1920 and radically changed drinking behavior in the United States. Within a year after alcohol prohibition was enacted, 14 states also passed cigarette prohibition laws. Even less popular than alcohol prohibition, those laws were all repealed by 1927, and by the mid-1920s Americans were smoking 80 billion cigarettes a year. However, cocaine use, so prevalent at the turn of the century, was no longer widespread.

Disillusioned by the reluctance of morphine addicts at clinics to detoxify and by repeated relapses among those who did, doctors began to recommend (not for the first time) compulsory treatment with confinement until cure. As the new laws curtailed legitimate supplies of opiates, an illicit traffic developed to provide them to morphine addicts who could not or would not use the clinics. Increasingly, the drug sold was heroin, which had been introduced for medical use in 1898 but was quickly found by drug users to have effects quite similar to those of morphine. Many who patronized the illicit traffickers and used the clinics had histories of delinquency and criminal activity, and eventually that subgroup came to predominate. Reformers, moralists, and the popular press found in the opiate habit, and in the reputation of those who continued to use morphine, proof of the evils inherent in those drugs.

Negative publicity, lurid stories, medical disillusionment, and pressure from law enforcement agents combined to label the morphine clinics as medical folly and brought about their closing, the last in 1923. At the same time a series of United States Supreme Court decisions implied that prescribing even small amounts of opiates or cocaine to an addict for treatment of addiction was not proper medical practice and was thus an illegal sale of narcotic drugs. Several physicians were imprisoned, and numerous others were tried, reprimanded, or otherwise harassed. By the early 1920s persons addicted to opiates were not welcome in doctor's offices, and they were often refused treatment at hospitals. *Dope addict* and *dope fiend* had become common terms, and the average layperson, as well as some otherwise well-informed members of the medical profession, appeared to believe that the opiate molecule was inherently evil. In the late 1930s cannabis acquired a similar reputation, and in 1937 the United States Congress passed legislation prescribing criminal penalties for its use, sale, or possession. Alcohol prohibition had been repealed in 1933.

New Drug Problems The first of the barbiturate sedatives, barbital, was introduced into clinical medicine in 1903, followed over the next 30 years by scores of congeners that differed primarily in their duration of action. Within a few years after the introduction of each new compound, the first case reports of abuse, dependence, and withdrawal appeared in the medical journals, a pattern that was repeated with the nonbarbiturate sedatives, such as glutethimide (Doriden), ethchlorvynol (Placidyl), and meprobamate (Miltown) in the 1950s.

Amphetamine, first synthesized in 1887, was put into clinical use in 1932 as a drug to shrink mucous membranes. By 1935 its central stimulant effects had been recognized and found useful for treating narcolepsy, and dozens of other suggested uses soon followed. Reports that amphetamine was being used as a euphoriant began to appear in the late 1930s, but the full significance of its abuse potential was not appreciated until the post-World War II epidemic of intravenous methamphetamine addiction in Japan. That epidemic, precipitated by the sale of surplus methamphetamine tablets intended for combat troops, involved millions of people. Other amphetamine-like drugs, which have also been subject to abuse, were introduced during the 1950s and early 1960s.

The psychological effects of mescaline were already known and written about at the end of the 19th century. However, public concern about hallucinogens did not reach a high level until the 1960s, when the use of a newly discovered and exceedingly potent compound, lysergic acid diethylamide (LSD), evolved from experimentation by a few college students to more widespread use by even younger people. Phencyclidine, a general anesthetic developed in the 1950s, also became a drug of abuse in the 1970s.

Despite repeated reports of abuse and dependence associated with barbiturates, barbiturate-like sedatives, and amphetamines and related stimulants, and in spite of concerns about experimentation with LSD and related hallucinogens, there were no federal criminal sanctions related to these drugs until 1964, when authority for their control was assigned to the Food and Drug Administration (FDA). In contrast, in the 1950s, concern about heroin addiction had led to ever harsher criminal penalties for its sale or possession. Although law enforcement efforts aimed at controlling heroin use were increased, both the number of new heroin addicts and the crime rates continued to rise throughout the late 1960s. At about that time there was also a sharp increase in the nonmedical use of other substances, such as cannabis and LSD, and a major epidemic of amphetamine abuse and dependence. In addition to amphetamines diverted from medical channels, supplies came from clandestine laboratories. Drug use, especially cannabis, became linked to antiestablishment attitudes, politics, and lifestyles.

Evolving Treatment Approaches Treatment for substance-related problems underwent several dramatic changes during the twentieth century. The large specialized asylums that were advocated in the nineteenth century never materialized. Toward the end of the nineteenth century physicians were primarily concerned about how to manage withdrawal syndromes and whether or not longer compulsory treatment was needed. With the advent of prohibition, the impetus to develop treatments for alcoholism declined sharply. Interest in treating opioid-dependent patients also declined as physicians became discouraged by their tendency to relapse after being detoxified and as opioid use and dependence came to be seen more as criminal behaviors than as medical disorders. A few private sanitoriums continued to provide treatment for opioid dependence. By 1930, as drug-addicted prisoners began to fill the penitentiaries, the federal government saw the need to establish two hospitals, at Lexington, Kentucky, and Fort Worth, Texas, to provide treatment for that population and also to conduct research on the problem of opiate addiction. Treatment of barbiturate and amphetamine dependence took place largely in the mainstream of medical practice and in state hospitals, but there was no consensus on what constituted effective posthospital care.

In the mid-1930s two recovering alcoholics rediscovered the principles of the Washingtonians, added some new principles, and initiated the self-help movement now known as AA. By the 1950s, this movement had begun to inspire analogous self-help efforts among other types of substance abusers.

The situation changed again in the early 1960s. With new outbreaks of heroin use by young people and increasing crime, the federal government and individual states attempted to respond to the problem. California initiated a civil commitment program for addicts under the administrative control of the Department of Corrections; New York City reopened Riverside Hospital to treat juvenile heroin addicts. The first follow-up studies of patients treated at the federal hospital at Lexington revealed exceedingly high rates of relapse after treatment. Both the medical community and the general public demanded new ideas and solutions, including a reconsideration of providing addicts with legitimate opioids through medical channels.

From 1958 to 1967 several major new approaches to treating opioid dependence were developed. Synanon, the prototype therapeutic community, was started in California in 1958 and was soon replicated in New York with the establishment of Daytop Village and Phoenix House. Vincent Dole and Marie Nyswander showed that maintaining selected long-term heroin addicts on large daily doses of methadone (Dolophine) was effective in reducing crime and heroin use. Several research groups demonstrated that heroin addicts would voluntarily try treatment with narcotic antagonists. In the mid-1960s, New York State and the federal government legislated civil commitment programs modeled after the program in California, with an initial period of prolonged institutional care as a key element. Although many treatment programs initiated in the early 1960s continued to focus on the treatment of opioid dependence, others, especially the therapeutic communities, viewed all nonmedical drug use as stemming from similar defects in character structure and offered a generic approach to treating drug dependence.

Alcohol and Nicotine In the 1950s clinicians at Wilmar State Hospital in Minnesota developed a treatment program for alcoholism built on a synthesis of the medical model and the experiences of recovering alcohol abusers using the 12-step principles of AA. That treatment approach was refined and expanded at the Johnson Institute and Hazelden Foundation, also in Minnesota. The modified programs, widely adopted by others, are often referred to as 28-day programs, 12-step programs, or the Minnesota model. In the early 1970s the effort to recognize alcoholism as a disease gained momentum, and the decision of medical insurance carriers to provide coverage for detoxification and inpatient treatment fueled an unprecedented growth of private-sector facilities offering treatment for alcoholism. Almost without exception, they were residential programs using the Minnesota model. The decriminalization of public intoxication spurred a parallel increase in alcohol treatment programs supported by the public sector.

The Surgeon General's Report of 1964 linked cigarette smoking to lung cancer and concluded that tobacco smoking was a form of dependence, although not an addiction. By the 1970s, tobacco dependence was more widely accepted as a valid clinical entity, and various treatments for it were developed. By the late 1980s, as smoking was becoming socially unacceptable, many buildings were declared smoke free, smoking was banned on most airplane flights and in many hospitals, and pharmaceutical companies began to market new products for delivering nicotine (e.g., nicotine chewing gum and transdermal patches) as aids for smoking cessation. By the late 1990s the tobacco companies were negotiating settlements in multiple civil law suits by states and by individuals who had been injured by their tobacco use, and Congress had unsuccessfully debated major tax increases on tobacco and regulation by the FDA.

Two-Tiered System When the cocaine epidemic of the early 1980s struck the middle class, much of the large, private-sector system for treating alcoholism evolved into chemical dependency units offering similar treatments to persons with alcohol problems and those with other varieties of substance dependence. By 1990 it was estimated that more than 8000 recognized programs existed that deal with alcoholism and other substance dependence. The treatment methods used varied widely in terms of settings, costs, philosophical underpinnings, and populations served. New categories of substance-abuse professionals had emerged, and psychiatrists who once had considered the problems to be a low-status area successfully lobbied for the creation of a recognized subspecialty in addiction psychiatry. Treatment capacity was described as a two-tiered system with private and public sectors, in which the private sector served 40 percent of the population but received 60 percent of the total expenditures for treatment. One response to the escalating cost of substance abuse services among those with private medical insurance was the rise of a managed care industry created to control costs on behalf of employers who pay for health insurance, generally by severely limiting the length of stay in hospital settings. Managed care, by refusing to recognize (and pay for) the medical necessity of inpatient treatment for most cases of substance dependence, largely dismantled the rest of the “28-day” inpatient alcohol and drug treatment programs that had serviced patients with insurance. By the mid-1990s managed care principles were routine in the public sector as well, and little remained of the two-tiered system.

Legislation and National Strategies In 1969 Congress recognized the need to give greater attention to the problem of alcoholism and established the National Institute on Alcohol Abuse and Alcoholism (NIAAA) in the National Institute of Mental Health (NIMH). In 1970 legislation was passed, reorganizing the jumble of drug regulatory statutes that had evolved since the passage of the Harrison Act, increasing the resources for controlling the availability of illicit drugs, and assigning the task of enforcement to a new agency, the Drug Enforcement Agency (DEA), which incorporated elements of the FDA and the Bureau of Narcotic and Dangerous Drugs. All drugs subject to special controls were included in one of several categories of the Controlled Substances Act.

In 1971 when United States troops in Vietnam were reported to be using heroin heavily, the Special Action Office for Drug Abuse Prevention (SAODAP) was established in the Executive Office of the President to coordinate government activities and policies relating to drug abuse and to develop and publish an overall national drug strategy. The creation of that office and the associated legislation marked a turning point in United States policy. The notion that opioid dependence was an incurable disorder, which justified the harshest of penalties in the name of prevention, was superseded by a policy that recognized that a substantial proportion of opioid addicts (as well as those with other varieties of drug dependence) could eventually reenter the mainstream of society. New commitments were made to basic research, epidemiology, development of new treatment methods, and evaluation of existing treatment approaches. Methadone maintenance was moved, by executive fiat, from the legal limbo of experimental status to a category that recognized its legitimacy. Regulations intended to prevent inappropriate prescribing of opioids were developed. Federal support for the expansion of community treatment programs was also greatly increased. By 1973 about 200,000 substance users, most of them opioid users, were in treatment in community programs. Those programs were repeatedly and intensively evaluated over the subsequent decade. The legislation that established SAODAP also provided the legislative framework for the National Institute on Drug Abuse (NIDA) in the Department of Health, Education and Welfare (HEW). When it was established in 1974 NIDA became the lead agency for implementing federal policy on treatment, research, and prevention.

By the early 1980s treatment for opioid dependence was generally accepted to have demonstrable impact. However, for most patients in treatment programs, the primary drugs of abuse were no longer opioids but more typically, cannabis, stimulants, or sedatives. During the early and mid-1970s some groups had argued for the decriminalization or legalization of cannabis. The arguments lost much of their force when it was found that in 1979 almost 10 percent of high school students were using cannabis on a daily basis. In response to what they perceived as tolerance toward cannabis use, a number of parents' organizations were formed that were committed to making all drug use unacceptable. Those groups forced NIDA to review and remove from all its publications any statements that could be interpreted as tolerating drug use. This decreased tolerance for drug use grew in parallel with a more general conservative shift in public attitudes. For example, in the 1970s the public and the courts had rejected the use of urine testing as a means of detecting drug use in an effort to interrupt the heroin epidemic; but starting in 1986, federal employees were required by presidential order to undergo such tests. Similar drug testing was encouraged in private industry, giving rise to new industries for detecting the presence of drugs, interpreting test results, and placing drug users in treatment.

By the 1970s it was obvious that the major drug abuse problems in the United States in terms of social and economic impact and health costs were alcoholism and tobacco dependence. Although the Surgeon General's Report of 1964 linking cigarettes to cancer had not produced any dramatic decrease in smoking, the rate of increase in cigarette consumption among men had begun to level out. In 1988 the *Surgeon General's report on the Health Consequences of Smoking* officially defined tobacco dependence as analogous to other varieties of drug dependence. In 1994 the FDA held hearings on the appropriateness of regulating the nicotine in tobacco as an addictive drug. Shortly thereafter, with backing from the president, the FDA assumed authority to regulate advertising of tobacco products; the White House lobbied Congress to pass legislation that would limit advertising and raise federal taxes on tobacco.

In the early 1980s rising demand for the treatment of cocaine dependence, the sudden cocaine-induced deaths of several prominent athletes, and concern about the spread of the human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS) among intravenous drug users led to the Anti-Drug Abuse Act of 1986, which authorized the government to spend nearly $4 billion to intensify efforts against drugs and drug abuse. Although most of that money was allocated to law enforcement activities, federal resources for the treatment of drug dependence and research were also substantially increased. Recognizing the need to do more to prevent drug dependence and provide more treatment, the federal government created a series of offices that by 1992 evolved into the Substance Abuse and Mental Health Services Administration (SAMHSA), with several constituent centers, including the Center for Substance Abuse Treatment (CSAT) and the Center for Substance Abuse Prevention (CSAP). The 1988 Anti-Drug Abuse Act and the 1989 Emergency Supplemental Appropriation created the Office of National Drug Control Policy (ONDCP) in the White House. While still devoting more than two thirds of federal resources available for drug problems to controlling drug supply, this legislation also increased funding for treatment and prevention.

Critics of the emphasis on supply-control gained public attention when they were supported by several prominent conservative writers and economists and garnered the financial support of several well-endowed foundations. While the more thoughtful of these critics have stopped calling for outright legalization of drugs, they have

called for greater emphasis on reducing the harm related to drug use by medically prescribing heroin and other psychoactive drugs and more support for needle-exchange programs. Despite some evidence suggesting that availability of sterile needles can reduce HIV transmission, the federal government continues to ban the use of federal money for such programs.

EPIDEMIOLOGY

A number of distinct methods have been developed to gauge the extent and medical consequences of substance use, abuse, and dependence in the United States. The major recurring surveillance instrument are the National Household Survey on Drug Abuse (Household Survey), the Drug Abuse Warning Network (DAWN), Arrestee Drug Abuse Monitoring System (ADAM—formerly known as the Drug Use Forecasting [DUF] program), and the Monitoring the Future Study (better known as the High School Survey). In addition, data on street availability and purity of illicit drugs, drug seizures, and arrests for drug offenses are collected nationally from the DEA and the Federal Bureau of Investigation (FBI) and locally from municipal police departments. Each of these data sources has strengths and limitations. For example, the Household Survey annually interviews a representative sample of individuals age 12 and older living in households, college dormitories, homeless shelters, and rooming houses. It oversamples minority populations and certain large urban areas, and focuses in detail on drug-using behaviors. It does not interview military personnel or individuals who are living on the street or in institutions (jails or hospitals). It does not attempt to determine whether respondents need treatment or meet formal criteria for drug dependence. In addition, some respondents may be reluctant to admit to certain types of drug use.

The ADAM system interviews, and obtains anonymous urine specimens from, a sample of arrestees in moderate-size cities in the United States. By design, persons charged with sale or possession of drugs cannot make up more than 25 percent of the sample. Although it does not depend on self-reports to measure use, the ADAM results cannot be easily extrapolated to a national population, and the information that can be derived from a single urine test is limited.

In 1989 the DAWN system, which obtains data on drug-related episodes from medical examiners and hospital emergency rooms, was modified so that the reporting emergency rooms constitute a representative sample of such facilities in the continental United States. The DAWN data provide useful information on trends in the morbidity associated with various illicit drugs; but these data need to be interpreted with caution because the DAWN system reports only episodes in which a drug is part of the presenting clinical picture. For example, a rising number of emergency room episodes associated with heroin could mean that more heroin users with AIDS-related problems are seeking primary medical care, rather than that more individuals are using heroin. Similarly, reports by medical examiners of more violent deaths associated with cocaine may signal an escalation of competition among drug dealers, rather than more people using cocaine. The analytical methods do not reveal the nature of the linkage between drug use and the presenting problem, which drugs (if any) played a causal role in the episode, or whether the user was a novice or a chronic user.

The High School Survey has obtained information each year since 1975 from forms returned anonymously by high school seniors. It now includes former seniors now in college and students in the eighth and tenth grades. Although the survey depends on self-report, the trend information it provides is exceedingly useful.

In addition to the recurring data-gathering efforts, important epidemiological information is available from two national studies that systematically interviewed representative samples of the population and used DSM-III or DSM-III-R criteria to develop estimates of current and lifetime prevalence of psychiatric disorders, including substance abuse and substance dependence. These studies are the NIMH Epidemiological Catchment Area (ECA) Study, conducted in the early 1980s, and the National Comorbidity Survey (NCS), conducted between 1990 and 1992. The ECA interviews in five areas of the United States included individuals in institutions (mental hospitals, jails, nursing homes, etc.) and used DSM-III criteria to develop estimates of prevalence. The NCS interviews of a nationally representative sample of noninstitutionalized people used DSM-III-R criteria. Although the ECA was conducted before the cocaine epidemic of the 1980s crested and criteria for diagnosis used were altered somewhat in DSM-III-R, it nevertheless remains a landmark study of the extent of drug abuse and dependence and co-occurring psychiatric disorders.

The ECA study found that 16.7 percent of the U.S. population ages 18 and older met the DSM-III criteria for a lifetime diagnosis of either abuse or dependence on some substance, with 13.8 percent meeting the criteria for an alcohol-related disorder, and 6.2 percent meeting the criteria for abuse or dependence of a drug other than alcohol or tobacco. The NCS found a 26.6 percent lifetime prevalence of substance abuse and dependence, substantially higher than the 16.7 percent found in the ECA. Some of this is probably due to questions in the NCS about prescription drugs that were posed when a patient reported symptoms of dependence, and on differences in criteria (DSM-III versus DSM-III-R). However, there may also have been real increases in prevalence. For illegal drugs and the nonmedical use of prescription drugs, the lifetime rate for dependence in the NCS was 7.9 percent, a figure much closer to the 6.2 percent found for such drugs in the ECA study. The NCS found a 12-month prevalence estimate for any addictive disorder (including dependence and abuse) of 8.2 percent; 4.5 percent alcohol dependence, and 1.8 percent drug dependence. Except for tobacco, men are far more likely than women to use drugs and alcohol and are correspondingly more likely to develop dependence. For example, lifetime and 12-month prevalence rates of alcohol dependence are 20.1 percent and 6.6 ercent for men, but only 8.2 percent and 2.2 percent for women.

Among the major achievements of the NCS analyses were the findings on the proportions of people who had used drugs at any time in their lives (*lifetime users*) who became dependent (overall and for each drug category); the demographic factors that predicted use, dependence, and persistence of dependence; and the prevalence and significance of multiple psychiatric diagnoses. Dependence cannot develop if a drug is never used; thus, presenting data on the prevalence of dependence in the population as whole, including those who never used, can obscure the likelihood of dependence developing among those who do use a particular drug. In the NCS, prevalence of lifetime dependence on the broad range of illicit and nonprescribed medications was 14.7 percent, with male users only slightly more likely (16.4 percent) than female users (12.6 percent) to develop dependence. In a similar analysis of the 12-month prevalence of dependence on these drugs, the rate for the population as a whole was 1.8 percent. However, the 12-month prevalence was 3.5 percent for those who had used any of these drugs at any time in their lives; 10.3 percent for those who had used them in the past 12 months, and 23.8 percent among those who had a lifetime history of dependence. The likelihood of being drug dependent within the past 12 months, given a lifetime history of dependence, was similar for men (24.9 percent) and women (22.2 percent). Lower educational and lower income levels predicted a lifetime history of dependence (odds ratios greater than 2), but race, ethnicity, or living in an urban environment did not. There were also differences in the likelihood that users of a particular drug would become dependent on it. For example, for heroin, the lifetime opioid dependence rate was 23 percent; for tobacco, 32 percent; for cocaine, 16.7 percent; for alcohol, 15.4 percent but only 4.9 percent for psychedelics. Men who used alcohol were more likely to become dependent (21.4 percent) than women (9.2 percent), possibly because they drink more than women but genetics may also play a role.

Table 11.1-12 shows data from the 1996 Household Survey on percentage of respondents who reported using various drugs. The data are shown for four age groups. Persons aged 18 to 25 years reported the highest level of use of illicit drugs during the 30 days preceding the interview; those ages 26 to 34 had the next highest rate and reported a higher lifetime experience with cocaine. Illicit drug use during the 30 days preceding the interview is far more prevalent among young adults (ages 18 to 34, and particularly those 18 to 25 years old) than among those above age 35 or below age 18. Also, whereas recent use is more common in large metropolitan areas than in rural areas, regional, racial, and ethnic differences vary with the age group considered. With the exception of tobacco dependence, all forms of substance abuse or dependence are more common among men than among women. However, recent data indicate that when adjustment is made for differences in rates of use and experimentation with illicit drugs, women are about as likely as men to become dependent. Current illicit drug use (past 30 days) was more common among male (8.1 percent) than female (4.2 percent) respondents, and among the unemployed. Among other demographic subgroups, it was slightly more common among blacks and in the western states.

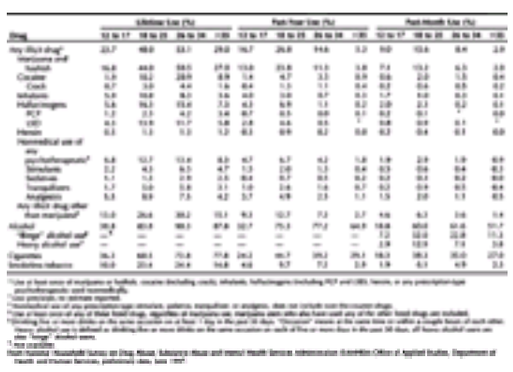

Table 11.1-12 Use of Illicit Drugs, Alcohol, and Tobacco in the U.S. Population by Age Groups

The High School Survey found that self-reported use of cannabis and illicit drugs in general (mostly cannabis) in the past 30 days declined sharply from the high levels (38 to 40 percent) reported in 1977 through 1979 to much lower levels (16 percent) in 1991. The decline in cocaine use began in 1987. However, 30-day prevalence rates for cannabis increased from 1992 through 1997. Cocaine and crack cocaine 30-day prevalence rates also increased slightly from a low of 1.3 percent in 1993 to 2.3 percent in 1997. Other substance use increased also, but levels were still below the peaks observed a decade earlier. In 1997 the annual prevalence rate among high school seniors for use of any illicit drug was 42.4 percent, and for an illicit drug other than cannabis, it was 20.7 percent.

The ADAM system obtains data from a population in which illicit drug use is high and thus provides trend data not readily available from other sources. In general, current drug use among arrestees is several times higher than that among those sampled by national surveys, even though urine tests detect drug use for only a few days, whereas surveys typically ask about drug use over the preceding 30 days. For example, in 1988, the peak of the cocaine epidemic, more than 60 percent of arrestees tested positive for cocaine (80 percent among male arrestees in Manhattan). More-recent data (1995) show a decline in cocaine use and low levels of heroin use.

Epidemics Several major overlapping drug abuse epidemics have occurred over the past 30 years, affecting somewhat different populations. Cannabis use, which had been endemic among certain minority groups and jazz musicians, began to increase in the 1960s, especially among young people, and then spread to other segments of the population. At its peak, in 1978 to 1979, 10 percent of high school seniors were using marijuana on a daily basis. Daily use declined to 5 percent by 1984, to 2 percent by 1991, and then reversed direction and again rose. Similar changes in use rates were reflected in the Household Survey.

An epidemic of heroin use also began in the early 1960s, and incidence peaked between 1969 and 1971. The population of active heroin users reached its highest levels in the early 1970s, but periodic upsurges have occurred as supplies became more available, law enforcement activity waxed and waned, and relapse rates increased among former users. In 1977 the United States government estimated that there were 500,000 opioid abusers and dependent users, and more recently, it revised the estimate to 320,000 occasional users and 810,000 chronic users. In general, the heroin-using population is an aging one, with a high and still growing prevalence of HIV in some areas. The 1996 Household Survey estimated that about 2.3 million people had tried heroin at least once and that 245 thousand had used it in the past year. However, it is believed that a large percentage of heroin users are outside the population interviewed by the survey.

The cocaine epidemic began in the 1970s and reached its peak around 1985, when it was estimated that 5.8 million people in the United States (2.9 percent of the population) had used cocaine in the month prior to survey. The epidemic seems to have passed its peak in most segments of society, with current (past 30 days) use rates in 1996 at about 1.5 to 2 percent among those 18 to 34 (0.8 percent for ages 17 and older). Cocaine use among the heaviest users (weekly or almost weekly) did not decline significantly, but rates decreased among arrestees in 1995.

In the early 1990s, fueled by abundant supplies of cheap illicit methamphetamine produced in many small laboratories, methamphetamine use began to increase in a number of cities in western, southwestern and northwestern parts of the United States. By 1996, gauged by drug tests on arrestees, that epidemic had passed its peak in those areas.

ETIOLOGY

The model of drug dependence from which the DSM-IV and ICD-10 criteria were derived conceptualizes dependence as a result of a process in which multiple interacting factors influence drug-using behavior and the loss of flexibility with respect to decisions about using a given drug. Although the actions of a given drug are critical in the process, it is not assumed that all persons who become dependent on the same drug experience its effects in the same way or are motivated by the same set of factors. Furthermore, it is postulated that different factors may be more or less important at different stages of the process. Thus, drug availability, social acceptability, and peer pressures may be the major determinants of initial experimentation with a drug, but other factors such as personality and individual biology probably are more important in how the effects of a given drug are perceived. Still other factors, including the particular actions of the drug, may be primary determinants of whether drug use will progress to drug dependence, whereas still others may be important influences on the likelihood that drug use will lead to adverse effects or the likelihood of successful recovery from dependence.

Figure 11.1-1 illustrates how various factors might interact in the development of drug dependence. The central element is the drug-using behavior itself. The decision to use a drug is influenced by immediate social and psychological situations, as well as by the person's more remote history. Use of the drug initiates a sequence of consequences that can be rewarding or aversive, and which, through a process of learning, can result in a greater or lesser likelihood that the drug-using behavior will be repeated. For some drugs, use also initiates the biological processes associated with tolerance, physical dependence, and (not shown in the figure) sensitization. In turn, tolerance can reduce some of the adverse effects of the drug, permitting or requiring the use of larger doses, which then can accelerate or intensify the development of physical dependence. Above a certain threshold, physical dependence is generally a distinct recurrent motive for further drug use. Sensitization of motivational systems may increase the salience of drug-related stimuli.

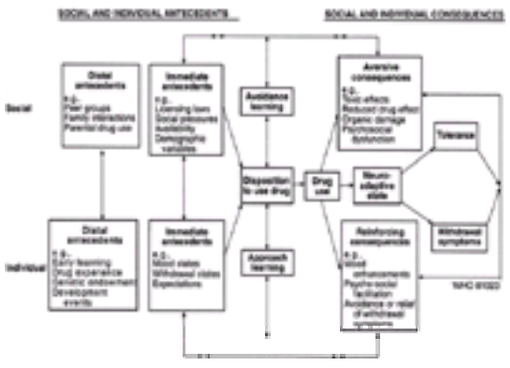

FIGURE 11.1-1 WHO schematic model of drug use and dependence. (Reprinted with permission from Edwards G, Arif A, Hodgson R: Nomenclature and classification of drug- and alcohol-related problems. A WHO memorandum. Bull WHO *99:*225, 1981.)

For simplicity Figure 11.1-1 shows drug use alone as initiating that chain of consequences, but the choices a person makes over and over again are more complex. The decision is whether to use one drug or another or to engage in some behavior that does not involve drug use. Each of those decisions can initiate positive and negative consequences. Changes in the availability, costs, and consequences of alternative behaviors can also influence what appears to be compulsive use of a pharmacological agent. For example, patients in a methadone maintenance program who were using cocaine despite negative consequences (no take-home methadone) reduced their cocaine use when vouchers for goods and services were awarded for clean (negative for cocaine) urine specimens.

Social and Environmental Factors Cultural factors, social attitudes, peer behaviors, laws, and drug cost and availability all influence initial experimentation with substances, including alcohol and tobacco. These factors also influence initial use of more socially disapproved drugs such as cocaine and opioids, but personality factors assume a more important role. Social and environmental factors also influence continued use, although individual vulnerability and psychopathology are probably more important determinants of the development of dependence. In general, the use of the less socially disapproved substances (alcohol, tobacco, and cannabis) precedes the use of opioids and cocaine, and those antecedent substances are sometimes referred to as gateway drugs.

Substantial evidence indicates that consumption of alcohol and tobacco in a population can be altered by changes in their price and availability. When alcohol availability is increased by increasing the number of sales outlets or extending sale hours, consumption tends to rise. When the cost of either alcohol or tobacco is increased in relation to disposable income (e.g., by increased taxes), consumption falls. These factors even influence the behavior of dependent persons, although perhaps not to the same degree as for those who are not dependent. Availability can be altered independently of cost, and alterations can be limited to selected populations (e.g., prohibiting sale of alcohol and tobacco to those under a specific age).

Social, cultural, and economic factors do not always operate synergistically but may sometimes influence consumption in opposite directions. For example, in the late

1980s increased public awareness of how alcohol use adversely affects health resulted in a decline in its consumption. That decline occurred even though alcohol was more freely available, its cost relative to income remained constant or actually decreased, and social pressures against women drinking (unless pregnant) also decreased.

Illicit Drugs Social and cultural factors, including beliefs about the effects of a drug, frequently exert more influence on drug-use patterns than the laws that supposedly reflect such factors. For example, cannabis use increased among high school students from the early 1970s to 1979 and then fell steadily over the next decade, although use and possession were illegal throughout the entire 18-year period, and nothing indicates that it became more expensive or less available during the 1980s. An upward trend in use was noted from 1993 to 1997, although it never reached the peak levels of 1979. Some experts believe the decline in use seen during the 1980s was linked to changing perceptions about the toxic effects of cannabis on health. The rise beginning in the 1990s was correlated with a decline in the perception of the risk of harm from regular use. Similarly, cocaine use increased in the late 1970s, despite high prices for the drug and high risk of criminal penalties; but following several well-publicized deaths from cocaine in the mid-1980s, its use declined among high school seniors and in the general population, even as the price of the drug declined.

Social and cultural factors profoundly influence the availability of illicit drugs, which in turn influences which groups in a society are most likely to become users. Currently, illicit opioids and cocaine are more available in the inner cities of large urban areas than in other parts of the country. Such availability not only influences initial and continued use but also affects relapse rates among those who seek treatment but must live in high-availability areas. When a significant number of users of illicit drugs live in one area, a subculture evolves that supports experimentation and continued use. Many of the areas in which illicit drugs are readily available are also characterized by a high crime rate, high unemployment, and demoralized school systems—all of which serve to reduce the sense of hope and sense of self-esteem associated with resistance to use and good prognosis once dependence develops. Social and educational factors also affect the likelihood for successful recovery from drug dependence; those who find satisfying alternatives are more likely to abstain from drug use.

VIETNAM The experience of United States service personnel who used heroin in Vietnam provided a unique natural experiment in which the influences of availability, vulnerability, and social norms could be observed. From 1970 to 1972 high-grade heroin at very low cost was readily available to young persons separated from their families and usual social norms. Among Army enlisted personnel, about half of those who tried heroin became dependent (at least they developed withdrawal symptoms when they attempted to stop using heroin). Of those who used heroin at least five times, 73 percent became dependent. The background factors that predicted heroin use in the general civilian population—early deviant behavior, such as fighting, drunkenness, arrest, and school expulsion—also predicted drug use in Vietnam, but they were not the best predictors of relapse after the soldiers returned to the United States. Relapse was related to being white, being older, and having parents who had criminal histories or were alcoholic.

Availability and Health Professionals The important role of availability is also illustrated by the repeated observation that physicians, dentists, and nurses have far higher rates of dependence on DEA-controlled substances, such as opioids, stimulants, and sedatives, than other professionals of comparable educational achievement (e.g., accountants or lawyers) who do not have such easy access to the drugs. Compared with controls, physicians appear to be four to five times as likely to take sedatives and minor tranquilizers without supervision by a professional other than themselves. Yet even in that situation other factors play a role. Physicians who had unhappy childhoods are more likely to self-prescribe than those who are healthier psychologically.

Drugs as Reinforcers The belief that persons take drugs because of the subjective effects the drugs produce can be traced to antiquity. Different drugs produce distinctive subjective states, and extensive laboratory evidence shows that persons with experience can distinguish one drug class from another and can even rank different classes and doses on the basis of how much they like the effects. Yet the hold that drugs can eventually exert on a user's behavior is not entirely a function of its initial likeable or euphorigenic actions. For example, the effects of cocaine are typically described as powerfully euphorigenic, producing increased self-esteem, alertness, energy, and well-being; the effects of nicotine are more subtle, producing some mixture of alerting and relaxing; and the subjective effects of alcohol are more likely to be described as relaxing, are more variable, and appear to be more dependent on personality. Despite those differences, dependence (or addiction) can occur with each, and they appear to have shared or overlapping neural substrates for their reinforcing properties.

Almost all of the drugs that are used for their subjective effects and are associated with the development of dependence induce some degree of tolerance. In some cases the tolerance to the toxic and aversive effects is more pronounced than the tolerance to the reinforcing and mood-elevating effects. For example, most opioid users quickly develop tolerance to opioid-induced nausea and vomiting. This may allow users to increase the dose and thus experience greater euphoric effects. Conversely, those who continue to experience aversive drug effects (such as severe flushing with alcohol) may be less likely to persist in using the drug and are at lower risk for developing dependence. Tolerant opioid users do not continue to self-administer opioids solely to prevent the highly aversive withdrawal phenomena. Interviews with heroin users have indicated that despite some tolerance to many of the drug's effects, they continue to experience a brief euphoric effect immediately after an intravenous injection. Among nonalcoholic sons of alcoholic fathers, intrinsic tolerance may be a marker of biological vulnerability to developing alcohol dependence. Sons of alcoholic fathers who were more tolerant to a test dose of alcohol were far more likely to have developed alcohol dependence at 8-year follow-up than those who were less tolerant.

With a few notable exceptions, animals in experimental situations will self-administer most of the drugs that humans tend to use and abuse. Included among the drugs are μ and d opioid agonists, cocaine, amphetamine and amphetamine-like agents, alcohol, barbiturates, many benzodiazepines, a number of volatile gases and vapors (e.g., nitrous oxide and ether), and PCP. Nicotine is also self-administered, although under more specialized conditions; cannabinoid self-administration has been difficult to demonstrate; and LSD-like drugs are not generally found to be reinforcing.

Biological Substrates Knowledge about the neurobiology of drug reinforcement and the mechanisms underlying tolerance and dependence has increased substantially. For opioids (and probably for other drugs as well) the neural systems involved in drug reinforcement and self-administration are distinct from those responsible for some of the other actions (e.g., opioid-induced analgesia) as well as from those that mediate the more visible signs of the withdrawal syndrome characteristic for that drug class. The pathways critical for the reinforcing actions of a number of dependence-producing drugs, such as opioids, amphetamine, cocaine, and to some degree nicotine and alcohol, have their origins in dopaminergic neurons with cell bodies in the ventral tegmental area and projections to the nucleus accumbens and the related structures that make up the “extended amygdala.” This comprises several neural structures receiving input from the limbic cortex, hippocampus, lateral amygdala and midbrain, and projecting axons to the ventral pallidum, the medial ventral tegmental area and the lateral hypothalamus. The medial part of the nucleus accumbens is a particularly important site; dopamine release here is critical for the reinforcing effects of cocaine and amphetamines. It is also important for the reinforcing effects of opioids, but there are opioid receptors on neurons in the nucleus accumbens, and opioids can exert reinforcing effects at that site even when the dopaminergic terminals are destroyed. Evidence suggests that such drugs as nicotine, cannabinoids, and alcohol also activate dopaminergic pathways linked to the nucleus accumbens. Some researchers have proposed that all positive reinforcement, including the reinforcement associated with food reward and sex, critically depends on this dopaminergic circuit.

Dopamine release from mesolimbic dopaminergic neurons may play more than one role in the genesis of drug seeking and drug dependence. Dopamine release has been postulated to facilitate learning which events and behaviors lead to important consequences for the organism and to alert the organism to pay greater attention to such events. In this way, drug-induced dopamine release leads to a greater salience of drug-using opportunities and is linked to wanting and craving.

However, the diverse categories of drugs that activate the mesolimbic dopaminergic system do so by distinct mechanisms, and most have actions on many other neural systems. Reinforcing mechanisms are briefly described in the chapters devoted to specific drugs; however, only a few examples are given. The ventral tegmental area dopaminergic neurons have both nicotinic and g-aminobutyric acid (GABA) receptors. These neurons normally are inhibited by GABAergic activity. The GABAergic neurons acting on the ventral tegmental area express μ- and d-opioid receptors. When these receptors are activated by μ opioids, GABAergic transmission is inhibited and the dopaminergic ventral tegmental area neurons become more active and release dopamine in the nucleus accumbens. However, opioids can also act directly on neurons in the nucleus accumbens, independent of dopamine action.

As a reinforcing drug, cocaine acts primarily at the nerve endings of the serotonergic, dopaminergic, and noradrenergic neurons. When transmitters are released from these neuron into the synapse, they are transported back into the nerve endings by transporter proteins. By occupying these transporter sites, cocaine prevents the reuptake of the transmitters, thus increasing their concentration in the synapse. Cocaine's binding to the dopamine transporter is primarily responsible for its reinforcing effects, but the actions on other neurotransmitters also influence its subjective effects. Amphetamine too, increases dopamine levels at the synapse and binds to the dopamine transporter to some degree. But amphetamine actions at the transporter are not as important as its major action, which is to displace dopamine and norepinephrine from their storage sites in the neuron and thereby lead to their release.

Alcohol is no longer believed to act like a general anesthetic, altering neuronal membranes. Instead, at clinically relevant concentrations its actions may be exerted more selectively on specific receptors and neurotransmitter systems. At clinically relevant concentrations these actions include enhancing the inhibitory action of GABAergic neurotransmitters (by increasing the sensitivity of the GABA receptor) and reducing the excitatory actions of glutamatergic neurotransmitters (by altering

the response of the *N*-methyl D-aspartate [NMDA] receptors). By its blocking actions at the NMDA receptor, ethanol can indirectly alter the release of other neurotransmitters (e.g., serotonin, dopamine, norepinephrine, glutamate, aspartate, and GABA). Low doses of alcohol increase dopamine levels in the nucleus accumbens and elevate brain serotonin concentration. Various regions of the brain differ in their sensitivity to these actions of ethanol. The endogenous opioid system may be involved in some aspects of the mood-elevating effects of alcohol, since the opioid antagonist naloxone reduces alcohol self-administration in animals and the antagonist naltrexone reduces relapse rates in treated alcoholics.

Mesolimbic dopaminergic neurons have multiple nicotinic cholinergic receptors on their cell bodies and terminals in the nucleus accumbens. When activated, these receptors increase dopamine release. Interestingly, regular exposure to tobacco smoke containing nicotine may be more reinforcing than nicotine itself because other chemical entities in tobacco inhibit brain monoamine oxidase type A (MAO_A) and MAO_B, which are involved in the regulation of intraneuronal stores of dopamine. This inhibition increases the amount of dopamine available for release when the dopaminergic neurons are activated.

Drugs can also be reinforcers by terminating aversive states; some of these actions involve dopaminergic systems, but others do not. Some researchers argue that compulsive drug use can be explained on the basis of the positive reinforcing effects of drugs without any need to invoke alleviation of withdrawal distress or any obvious source of antecedent pain or dysphoria. Furthermore, they argue, craving is primarily associated not with cues that evoke withdrawal but with those that evoke memories of positive reinforcement (euphoria). However, evidence now indicates that even when there are no obvious and dramatic withdrawal symptoms (e.g., cocaine, nicotine), adaptive changes in the reward system result in a relative dopaminergic deficiency state (measurable as decreased dopamine levels in the nucleus accumbens) when drug use is stopped or its action ceases. This deficiency state is experienced as dysphoria or anhedonia. Quite often the same drug-using behavior that terminates this dysphoria moves the system to a hyperdopaminergic state associated with euphoria. In short, the behaviors associated with chronic drug use are typically driven by both the avoidance of dysphoria (negative reinforcement) and the pursuit of euphoria (positive reinforcement).

The sensitivity of neural systems to reinforcing drugs such as cocaine and opioids is enhanced by corticosteroids. In animal models, a variety of stresses acting through release of corticotropin-releasing factor (CRF) and the hypothalamic pituitary-adrenal axis can sensitize neural systems and trigger reinitiation of drug taking. There is ample clinical evidence that such stresses can act similarly in drug-dependent individuals immediately following withdrawal and for long periods thereafter. In addition, some drugs may sensitize neural systems to the reinforcing effects of the drug.

Learning and Conditioning Drug use, whether occasional or compulsive, can be viewed as behavior maintained by its consequences. Any event that strengthens an antecedent behavior pattern can be considered a reinforcer of that behavior. In that sense certain drugs reinforce drug-taking behavior. Drugs can also reinforce antecedent behaviors by terminating some noxious or aversive state, such as pain, anxiety, or depression. In some social situations the use of the drug, quite apart from its pharmacological effects, can be reinforcing if it results in special status or the approval of friends. Social reinforcement can maintain drug use until the effects of primary reinforcement or reinforcement by alleviation of withdrawal symptoms come into play. Each use of the drug evokes rapid positive reinforcement, either as a result of the *rush* (the drug-induced euphoria), alleviation of disturbed affects, alleviation of withdrawal symptoms, or any combination of these effects. In addition, some drugs may sensitize neural systems to the reinforcing effects of the drug. With short-acting substances, such as heroin, cocaine, nicotine, and alcohol, such reinforcement occurs several times a day, day in and day out, creating powerfully reinforced habit patterns. Eventually, the paraphernalia (needles, bottles, cigarette packs) and behaviors associated with substance use can become secondary reinforcers as well as cues signaling availability of the substance, and in their presence, craving or a desire to experience the effects increases. With socially acceptable substances, such as tobacco, use becomes so woven into the matrix of daily functioning that some users are reminded of the substances when performing ordinary tasks. Stresses can also act as cues that induce drug taking, particularly in the postwithdrawal period.

Classical Conditioning In addition to the operant reinforcement of drug-using and drug-seeking behaviors, other learning mechanisms probably play a role in dependence and relapse. Opioid and alcohol withdrawal phenomena can be conditioned (in the Pavlovian or classic sense) to environmental or interoceptive stimuli. Such conditioning has been demonstrated in both laboratory animals and abstinent and methadone-dependent human volunteers. For a long time following withdrawal (from opioids, nicotine, or alcohol), the addict exposed to environmental stimuli previously linked with substance use or withdrawal may experience conditioned withdrawal, conditioned craving, or both. The increased feelings of craving are not necessarily accompanied by symptoms of withdrawal. The most intense craving is elicited by conditions associated with the availability or use of the substance, such as watching someone else use heroin or light a cigarette or being offered some drug by a friend. Some workers now believe that the cues that induce memories of drug-induced euphoria are more important for stimulating craving and in predisposing to relapse than either protracted or conditioned withdrawal. Those learning and conditioning phenomena can be superimposed on any preexisting psychopathology, but preexisting difficulties are not required for the development of powerfully reinforced substance-seeking behavior.
