Section IX: Energy Sources, Storage and Transmission

Preface for Third Edition

Introduction

The purpose of Power Electronics Handbook is to provide a reference that is both concise and useful for engineering students and practicing professionals. It is designed to cover a wide range of topics that make up the field of power electronics in a well-organized and highly informative manner. The Handbook is a careful blend of both traditional topics and new advancements. Special emphasis is placed on practical applications; thus, this Handbook is not a theoretical one, but an enlightening presentation of the usefulness of the rapidly growing field of power electronics. The presentation is tutorial in nature in order to enhance the value of the book to the reader and foster a clear understanding of the material.

The contributors to this Handbook span the globe, with fifty-four authors from twelve different countries, some of whom are the leading authorities in their areas of expertise. All were chosen because of their intimate knowledge of their subjects, and their contributions make this a comprehensive state-of-the-art guide to the expanding field of power electronics and its applications covering the following:

- the characteristics of modern power semiconductor devices, which are used as switches to perform the power conversions from ac-dc, dc-dc, dc-ac, and ac-ac;
- both the fundamental principles and in-depth study of the operation, analysis, and design of various power converters; and
- examples of recent applications of power electronics

Power Electronics Backgrounds

The first electronics revolution began in 1948 with the invention of the silicon transistor at Bell Telephone Laboratories by Bardeen, Bratain, and Schockley. Most of today's advanced electronic technologies are traceable to that invention, and modern microelectronics has evolved over the years from these silicon semiconductors. The second electronics revolution began with the development of a commercial thyristor by the General Electric Company in 1958. That was the beginning of a new era of power electronics. Since then, many different types of power semiconductor devices and conversion techniques have been introduced.

The demand for energy, particularly in electrical forms, is ever-increasing in order to improve the standard of living. Power electronics helps with the efficient use of electricity, thereby reducing power consumption. Semiconductor devices are used as switches for power conversion or processing, as are solid state electronics for efficient control of the amount of power and energy flow. Higher efficiency and lower losses are sought for devices used in a range of applications, from microwave ovens to high-voltage dc transmission. New devices and power electronic systems are now evolving for even more effective control of power and energy.

Power electronics has already found an important place in modern technology and has revolutionized control of power and energy. As the voltage and current ratings and switching characteristics of power semiconductor devices keep improving, the range of applications continue to expand in areas, such as lamp controls, power supplies to motion control, factory automation, transportation, energy storage, multimegawatt industrial drives, and electric power transmission and distribution. The greater efficiency and tighter control features of power electronics are becoming attractive for applications in motion control by replacing the earlier electromechanical and electronic systems. Applications in power transmission and renewable energy include high-voltage dc (VHDC) converter stations, flexible ac transmission system (FACTS), static var compensators, and energy storage. In power distribution, these include dc-to-ac conversion, dynamic filters, frequency conversion, and custom power system.

Almost all new electrical or electromechanical equipments, from household air conditioners and computer power supplies to industrial motor controls, contain power electronic circuits and/or systems. In order to keep up, working engineers involved in control and conversion of power and energy into applications ranging from several hundred voltages at a fraction of an ampere for display devices to about 10,000 V at high-voltage dc transmission should have a working knowledge of power electronics.

Organization

The Handbook starts with an introductory chapter and moves on to cover topics on power semiconductor devices, power converters, applications, and peripheral issues. The book is organized into nine areas, the first of which includes chapters on operation and characterizations of the following power semiconductor devices: power diode, thyristor, gate turn-off thyristor (GTO), power bipolar transistor (BJT), power MOS-FET, insulated gate bipolar transistor, MOS-controlled thyristor (MCT), and static induction devices. The next topic area includes chapters covering various types of power converters, the principles of operation, and the methods for the analysis and design of power converters. This also includes gate drive circuits and control methods for power converters. The next two chapters cover applications in power supplies, electronic ballasts, HVDC transmission, VAR compensation, pulse power, and capacitor charging.

The following two chapters focus on the operation, theory, and control methods of motor drives and automotive systems. We then move on to two chapters on power quality issues and active filters, and two chapters on computer simulation, packaging and smart power systems. The final chapter is on energy sources, storage, and transmission.

Changes in the Third Edition

The five new contributions are added in keeping with the new development and applications.

- Solid State Pulsed Power Electronics
- Novel AI-Based Soft Computing Applications In Motor Drives
- Energy Sources
- Energy Storage
- Electric Power Transmission

The following eleven chapters are revised, and the contributions are reorganized under nine chapters.

- Introduction to Power Electronics
- Static Induction Devices
- Multilevel Converters
- AC-AC Converters
- Power Electronics in Capacitor Charging Applications
- Solar Power Conversion
- Fuel-Cell Power Electronics for Distributed Generation
- Flexible AC Transmission
- Control Methods for Power Converters

- Fuzzy Logic in Electric Drives
- EMI Effects of Power Converters

Locating Your Topic

A table of contents is presented at the front of the book, and each chapter begins with its own table of contents. The reader should look over these tables of contents to become familiar with the structure, organization, and content of the book.

Audience

The Handbook is designed to provide both students and practicing engineers with answers to questions involving the wide spectrum of power electronics. The book can be used as a textbook for graduate students in electrical or systems engineering, or as a reference book for senior undergraduate students and for engineers who are interested and involved in operation, project management, design, and analysis of power electronic equipment and motor drives.

Introduction

Philip T. Krein, Ph.D.

Department of Electrical and Computer Engineering, University of Illinois, Urbana, Illinois, USA

1.1 Power Electronics Defined[1]

It has been said that people do not use electricity, but rather they use communication, light, mechanical work, entertainment, and all the tangible benefits of energy and electronics. In this sense, electrical engineering as a discipline is much involved in energy conversion and information. In the general world of electronics engineering, the circuits engineers design and use are intended to convert information. This is true of both analog and digital circuit design. In radio-frequency applications, energy and information are on more equal footing, but the main function of any circuit is information transfer.

What about the conversion and control of electrical energy itself? Energy is a critical need in every human endeavor. The capabilities and flexibility of modern electronics must be brought to bear to meet the challenges of reliable, efficient energy. It is essential to consider how electronic circuits and systems can be applied to the challenges of energy conversion and management. This is the framework of *power electronics*, a discipline defined in terms of *electrical energy conversion, applications*, and *electronic devices*. More specifically,

> **DEFINITION**   *Power electronics* involves the study of electronic circuits intended to control the flow of electrical energy. These circuits handle power flow at levels much higher than the individual device ratings.

Rectifiers are probably the most familiar examples of circuits that meet this definition. Inverters (a general term for dc–ac converters) and dc–dc converters for power supplies are also common applications. As shown in Fig. 1.1, power electronics represents a median point at which the topics of energy systems, electronics, and control converge and combine [1]. Any useful circuit design for an energy application must address issues of both devices and control, as well as of the energy itself. Among the unique aspects of power electronics are its emphasis on large semiconductor devices, the application of magnetic devices for energy storage, special control methods that must be applied to nonlinear systems, and its fundamental place as a central component of today's energy systems and alternative resources. In any study of electrical engineering, power electronics must be placed on a level with digital, analog, and radio-frequency electronics to reflect the distinctive design methods and unique challenges.

Applications of power electronics are expanding exponentially. It is not possible to build practical computers, cell

FIGURE 1.2   General system for electric power conversion. (From [2], © 1998, Oxford University Press, Inc.; used by permission.)

phones, personal data devices, cars, airplanes, industrial processes, and a host of other everyday products without power electronics. Alternative energy systems such as wind generators, solar power, fuel cells, and others require power electronics to function. Technology advances such as electric and hybrid vehicles, laptop computers, microwave ovens, flat-panel displays, LED lighting, and hundreds of other innovations were not possible until advances in power electronics enabled their implementation. Although no one can predict the future, it is certain that power electronics will be at the heart of fundamental energy innovations.

The history of power electronics [2–5] has been closely allied with advances in electronic devices that provide the capability to handle high power levels. Since about 1990, devices have become so capable that a transition from a "device-driven" field to an "applications-driven" field continues. This transition has been based on two factors: (1) advanced semiconductors with suitable power ratings exist for almost every application of wide interest, and (2) the general push toward miniaturization is bringing advanced power electronics into a growing variety of products. Although the devices continue to improve, their development now tends to follow innovative applications.

1.2   Key Characteristics

All power electronic circuits manage the flow of electrical energy between an electrical source and a load. The parts in a circuit must direct electrical flows, not impede them. A general power conversion system is shown in Fig. 1.2. The function of the power converter in the middle is to control the energy flow between a source and a load. For our purposes, the power converter will be implemented with a power electronic circuit. Because a power converter appears between a source and a load, any energy used within the converter is lost to the overall system. A crucial point emerges: to build a power converter, we should consider only lossless components. A realistic converter design must approach 100% efficiency.
A power converter connected between a source and a load also affects system reliability. If the energy source is perfectly reliable (it is available all the time), then a failure in the converter affects the user (the load) just as if the energy source had failed. An unreliable power converter creates an unreliable system. To put this in perspective, consider that a typical American household loses electric power only a few minutes a year. Energy is available 99.999% of the time. A converter must be better than this to prevent system degradation. An ideal converter implementation will not suffer any failures over its application lifetime. Extreme high reliability can be a more difficult objective than high efficiency.

1.2.1   The Efficiency Objective – The Switch

A circuit element as simple as a light switch reminds us that the extreme requirements in power electronics are not especially novel. Ideally, when a switch is on, it has zero voltage drop and will carry any current imposed on it. When a switch is off, it blocks the flow of current regardless of the voltage across it. The *device power*, the product of the switch voltage and current, is identically zero at all times. A switch therefore controls energy flow with no loss. In addition, reliability is also high. Household light switches perform over decades of use and perhaps 100,000 operations. Unfortunately, a mechanical light switch does not meet all practical needs. A switch in a power supply may function 100,000 times each second. Even the best mechanical switch will not last beyond a few million cycles. Semiconductor switches (without this limitation) are the devices of choice in power converters.

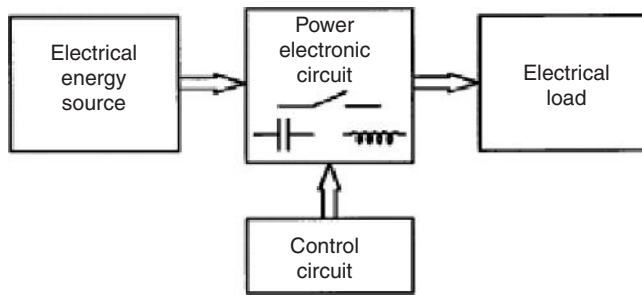
A circuit built from ideal switches will be lossless. As a result, switches are the main components of power converters, and many people equate power electronics with the study of switching power converters. Magnetic transformers and lossless storage elements such as capacitors and inductors are also valid components for use in power converters. The complete


FIGURE 1.3 A basic power electronic system. (From [2], © 1998, Oxford University Press, Inc.; used by permission.)

concept, shown in Fig. 1.3, illustrates a *power electronic system*. Such a system consists of an electrical energy source, an electrical load, a *power electronic circuit*, and a control function.

The power electronic circuit contains switches, lossless energy storage elements, and magnetic transformers. The controls take information from the source, the load, and the designer, and then determine how the switches operate to achieve the desired conversion. The controls are built up with low-power analog and digital electronics.

Switching devices are selected based on their *power handling* rating – the product of their voltage and current ratings – rather than on power dissipation ratings. This is in contrast to other applications of electronics, in which power dissipation ratings dominate. For instance, a typical stereo receiver performs a conversion from ac line input to audio output. Most audio amplifiers do not use the techniques of power electronics, and the semiconductor devices do not act as switches. A commercial 100-W amplifier is usually designed with transistors big enough to dissipate the full 100 W. The semiconductor devices are used primarily to reconstruct the audio information rather than to manipulate the energy flows. The sacrifice in energy is large – a home theater amplifier often functions at less than 10% energy efficiency. In contrast, emerging *switching amplifiers* do use the techniques of power electronics. They provide dramatic efficiency improvements. A home theater system implemented with switching amplifiers can exceed 90% energy efficiency in a smaller, cooler package. The amplifiers can even be packed inside the loudspeakers.

Switches can reach extreme power levels, far beyond what might be expected for a given size. Consider the following examples.

EXAMPLE 1.1 The NTP30N20 is a metal oxide semiconductor field effect transistor (MOSFET) with a drain current rating of 30 A, a maximum drain source breakdown voltage of 200 V, and a rated power dissipation of up to 200 W under ideal conditions. Without a heat sink, however, the device can handle less than 2.5 W of dissipation. For power electronics purposes, the power handling rating is $30\,\text{A} \times 200\,\text{V} = 6\,\text{kW}$. Several manufacturers have developed controllers for domestic refrigerators, air

conditioners, and high-end machine tools based on this and similar devices. The second part of the definition of power electronics in Section 1.1 points out that the circuits handle power at levels much higher than that of the ratings of individual devices. Here a device is used to handle 6000 W – compared with its individual rating of no more than 200 W. The ratio 30:1 is high, but not unusual in power electronics contexts. In contrast, the same ratio in a conventional audio amplifier is close to unity.

EXAMPLE 1.2 The IRGPS60B120KD is an insulated gate bipolar transistor (IGBT) – a relative of the bipolar transistor that has been developed specifically for power electronics – rated for 1200 V and 120 A. Its power handling rating is 144 kW which is sufficient to control an electric or hybrid car.

1.2.2 The Reliability Objective – Simplicity and Integration

High-power applications lead to interesting issues. In an inverter, the semiconductors often manipulate 30 times their power dissipation capability or more, which implies that only about 3% of the power being controlled is lost. A small design error, unexpected thermal problem, or minor change in layout could alter this somewhat. For instance, if the loss turns out to be 4% rather than 3%, the device stresses are 33% higher, and quick failure is likely to occur. The first issue for reliability in power electronic circuits is that of managing device voltage, current, and power dissipation levels to keep them well within rating limits. This is challenging when power-handling levels are high.

The second issue for reliability is simplicity. It is well established in electronics design that the more parts there are in a system, the more likely it is to fail. Power electronic circuits tend to have few parts, especially in the main energy flow paths. Necessary operations must be carried out through shrewd use of these parts. Often, this means that sophisticated control strategies are applied to seemingly simple conversion circuits.

The third issue for reliability is integration. One way to avoid the reliability–complexity tradeoff is to integrate multiple components and functions on a single substrate. A microprocessor, for example, might contain millions of gates. All interconnections and signals flow within a single chip, and the reliability is near that of a single part. An important parallel trend in power electronic devices involves the integrated module [6]. Manufacturers seek ways to package multiple switching devices, with their interconnections and protection components, together as a unit. Control circuits for converters are also integrated as much as possible to keep the reliability high. The package itself is a factor in reliability, and one that is a subject of active research. Many semiconductor packages include small bonding wires

that can be susceptible to thermal or vibration damage. The small geometries also tend to enhance electromagnetic interference among the internal circuit components.

1.3 Trends in Power Supplies

Two distinct trends drive electronic power supplies, one of the major classes of power electronic circuits. At the high end, microprocessors, memory chips, and other advanced digital circuits require increasing power levels and increasing performance at very low voltage. It is a challenge to deliver 100 A or more efficiently at voltages that can be less than 1 V. These types of power supplies are expected to deliver precise voltages, even though the load can change by an order of magnitude in nanoseconds.

At the other end is the explosive growth of portable devices with rechargeable batteries. The power supplies for these devices and for other consumer products must be cheap and efficient. Losses in low-cost power supplies are a problem today; often, low-end power supplies and battery chargers draw energy even when their load is off. It is increasingly important to use the best possible power electronics design techniques for these supplies to save energy while minimizing costs. Efficiency standards such as the EnergyStar program place increasingly stringent requirements on a wide range of low-end power supplies.

In the past, bulky "linear" power supplies were designed with transformers and rectifiers from the ac line frequency to provide dc voltages for electronic circuits. In the late 1960s, use of dc sources in aerospace applications led to the development of power electronic dc–dc conversion circuits for power supplies. In a well-designed power electronics arrangement today, called a *switch-mode power supply*, an ac source from a wall outlet is rectified without direct transformation. The resulting high dc voltage is converted through a dc–dc converter to the 1, 3, 5, and 12 V, or other levels required. A personal computer commonly requires multiple 3.3- and 5-V supplies, 12-V supplies, additional levels, and a separate converter for 1-V delivery to the microprocessor. This does not include supplies for the video display or peripheral devices. Only a switch-mode supply can support such complex requirements with acceptable costs.

Switch-mode supplies often take advantage of MOSFET semiconductor technology. Trends toward high reliability, low cost, and miniaturization have reached the point where a 5-V power supply sold today might last more than 1,000,000 h (more than a century), provide 100 W of output in a package with volume less than 15 cm^3, and sell for a price less than US$ 0.10/W. This type of supply brings an interesting dilemma: the ac line cord to plug it in takes up more space than the power supply itself. Innovative concepts such as integrating a power supply within a connection cable will be used in the future.

Device technology for power supplies is also being driven by expanding needs in the automotive and telecommunications industries as well as in markets for portable equipment. The automotive industry is making a transition to higher voltages to handle increasing electric power needs. Power conversion for this industry must be cost effective, yet rugged enough to survive the high vibration and wide temperature range to which a passenger car is exposed. Global communication is possible only when sophisticated equipment can be used almost anywhere. This brings with it a special challenge, because electrical supplies are neither reliable nor consistent throughout much of the world. Although voltage swings in the domestic ac supply in North America are often ±5% around a nominal value, in many developing nations the swing can be ±25% – when power is available. Power converters for communications equipment must tolerate these swings and must also be able to make use of a wide range of possible backup sources. Given the enormous size of worldwide markets for mobile devices and consumer electronics, there is a clear need for flexible-source equipment. Designers are challenged to obtain maximum performance from small batteries and to create equipment with minimal energy requirements.

1.4 Conversion Examples

1.4.1 Single-Switch Circuits

Electrical energy sources take the form of dc voltage sources at various values, sinusoidal ac sources, polyphase sources, among others. A power electronic circuit might be asked to transfer energy between two different dc voltage levels, between an ac source and a dc load, or between sources at different frequencies. It might be used to adjust an output voltage or power level, drive a nonlinear load, or control a load current. In this section, a few basic converter arrangements are introduced, and energy conservation provides a tool for analysis.

EXAMPLE 1.3 Consider the circuit shown in Fig. 1.4. It contains an ac source, a switch, and a resistive load. It is a simple but complete power electronic system.
FIGURE 1.4 A simple power electronic system. (From [2], © 1998, Oxford University Press, Inc.; used by permission.)
FIGURE 1.5 Input and output waveforms for Example 1.4.

Let us assign a (somewhat arbitrary) control scheme to the switch. What if the switch is turned on whenever $V_{ac} > 0$, and turned off otherwise? The input and output voltage waveforms are shown in Fig. 1.5. The input has a time average of 0, and root-mean-square (RMS) value equal to $V_{peak}/\sqrt{2}$, where V_{peak} is the maximum value of V_{ac}. The output has a nonzero average value given by

$$\langle v_{out}(t)\rangle = \frac{1}{2\pi}\left(\int_{-\pi/2}^{\pi/2} V_{peak}\cos\theta\, d\theta + \int_{\pi/2}^{3\pi/2} 0\, d\theta\right)$$

$$= \frac{V_{peak}}{\pi} = 0.3183\, V_{peak} \qquad (1.1)$$

and an RMS value equal to $V_{peak}/2$. Since the output has nonzero dc voltage content, the circuit can be used as an ac–dc converter. To make it more useful, a low-pass filter would be added between the output and the load to smooth out the ac portion. This filter needs to be lossless, and will be constructed from only inductors and capacitors.

The circuit in Example 1.3 acts as a half-wave rectifier with a resistive load. With the hypothesized switch action, a diode can substitute for the ideal switch. The example confirms that a simple switching circuit can perform power conversion functions. But note that a diode is not, in general, the same as an ideal switch. A diode places restrictions on the current direction, whereas a true switch would not. An ideal switch allows control over whether it is on or off, whereas a diode's operation is constrained by circuit variables.

Consider a second half-wave circuit, now with a series *L–R* load, shown in Fig. 1.6.

EXAMPLE 1.4 A series diode *L–R* circuit has ac voltage source input. This circuit operates much differently than the half-wave rectifier with resistive load. A diode will be on if forward-biased, and off if reverse-biased. In this circuit, when the diode is off, the current will be zero.
FIGURE 1.6 Half-wave rectifier with *L–R* load for Example 1.5.

Whenever the diode is on, the circuit is the ac source with *L–R* load. Let the ac voltage be $V_0 \cos(\omega t)$. From Kirchhoff's Voltage Law (KVL),

$$V_0\cos(\omega t) = L\frac{di}{dt} + Ri.$$

Let us assume that the diode is initially off (this assumption is arbitrary, and we will check it as the example is solved). If the diode is off, the diode current is $i = 0$, and the voltage across the diode will be v_{ac}. The diode will become forward-biased when v_{ac} becomes positive. The diode will turn on when the input voltage makes a zero-crossing in the positive direction. This allows us to establish initial conditions for the circuit: $i(t_0) = 0$, $t_0 = -\pi/(2\omega)$. The differential equation can be solved in a conventional way to give

$$i(t) = V_0\left[\frac{\omega L}{R^2 + \omega^2 L^2}\exp\left(\frac{-t}{\tau} - \frac{\pi}{2\omega\tau}\right)\right.$$
$$+ \frac{R}{R^2 + \omega^2 L^2}\cos(\omega t)$$
$$\left. + \frac{\omega L}{R^2 + \omega^2 L^2}\sin(\omega t)\right] \qquad (1.2)$$
FIGURE 1.7   Input and output waveforms for Example 1.5.

where τ is the time constant L/R. What about when the diode is turned off? The first guess might be that the diode turns off when the voltage becomes negative, which is not correct. From the solution, we can note that the current is not zero when the voltage first becomes negative. If the switch attempts to turn off, it must instantly drop the inductor current to zero. The derivative of current in the inductor, di/dt, would become negative infinite. The inductor voltage $L(di/dt)$ similarly becomes negative infinite, and the devices are destroyed. What really happens is that the falling current allows the inductor to maintain forward bias on the diode. The diode will turn off only when the *current* reaches zero. A diode has definite properties that determine the circuit action, and both the voltage and current are relevant. Figure 1.7 shows the input and output waveforms for a time constant τ equal to about one-third of the ac waveform period.

1.4.2 The Method of Energy Balance

Any circuit must satisfy conservation of energy. In a lossless power electronic circuit, energy is delivered from source to load, possibly through an intermediate storage step. The energy flow must balance over time such that the energy drawn from the source matches that delivered to the load. The converter in Fig. 1.8 serves as an example of how the method of energy balance can be used to analyze circuit operation.

> **EXAMPLE 1.5**   The switches in the circuit of Fig. 1.8 are controlled cyclically to operate in alternation: when the left switch is on, the right switch is off, and so on. What does the circuit do if each switch operates half the time? The inductor and capacitor have large values.
>
> When the left switch is on, the source voltage V_{in} appears across the inductor. When the right switch is on,
FIGURE 1.8   Energy transfer switching circuit for Example 1.5. (From [2], © 1998, Oxford University Press, Inc.; used by permission.)

the output voltage V_{out} appears across the inductor. If this circuit is to be viewed as a useful converter, the inductor should receive energy from the source and then deliver it to the load without loss. Over time, this means that energy does not build up in the inductor, but instead flows through on average. The power into the inductor, therefore, must equal the power out, at least over a cycle. Therefore, the *average* power in must equal the *average* power out of the inductor. Let us denote the inductor current as i. The input is a constant voltage source. Because L is large, this constant voltage source will not be able to change the inductor current quickly, and we can assume that the inductor current is also constant. The average power into L over the cycle period T is

$$P_{in} = \frac{1}{T} \int_0^{T/2} V_{in}\, i\, dt = \frac{V_{in} i}{2}. \tag{1.3}$$

For the average power out of L, we must be careful about current directions. The current *out* of the inductor will have a

value $-i$. The average output power is

$$P_{\text{out}} = \frac{1}{T} \int_{T/2}^{T} -iV_{\text{out}}\,\mathrm{d}t = -\frac{V_{\text{out}}i}{2} \qquad (1.4)$$

For this circuit to be viewed useful as a converter, the net energy should flow from the source to the load over time. The power conservation relationship $P_{\text{in}} = P_{\text{out}}$ requires that $V_{\text{out}} = -V_{\text{in}}$.

The method of energy balance shows that, when operated as described in the example, the circuit shown in Fig. 1.8 serves as a polarity reverser. The output voltage magnitude is the same as that of the input, but the output polarity is negative with respect to the reference node. The circuit is often used to generate a negative supply for analog circuits from a single positive input level. Other output voltage magnitudes can be achieved at the output if the switches alternate at unequal times.

If the inductor in the polarity reversal circuit is moved instead to the input, a step-up function is obtained. Consider the circuit shown in Fig. 1.9 in the following example.

> **EXAMPLE 1.6** The switches shown in Fig. 1.9 are controlled cyclically in alternation. The left switch is on for two-thirds of each cycle, and the right switch for the remaining one-third of each cycle. Determine the relationship between V_{in} and V_{out}. The inductor's energy should not build up when the circuit is operating normally as a converter. A power balance calculation can be used to relate the input and output voltages. Again, let i be the inductor current. When the left switch is on, power is injected into the inductor. Its average value is
>
> $$P_{\text{in}} = \frac{1}{T} \int_{0}^{2T/3} V_{\text{in}}i\,\mathrm{d}t = \frac{2V_{\text{in}}i}{3}. \qquad (1.5)$$
>
> Power leaves the inductor when the right switch is on. Care must be taken with respect to polarities, and the current should be set negative to represent output power.
FIGURE 1.9 Switching converter Example 1.6. (From [2], © 1998, Oxford University Press, Inc.; used by permission.)

The result is

$$P_{\text{out}} = \frac{1}{T} \int_{2T/3}^{T} -(V_{\text{in}} - V_{\text{out}})i\,\mathrm{d}t$$

$$= -\frac{V_{\text{in}}i}{3} + \frac{V_{\text{out}}i}{3}. \qquad (1.6)$$

When the input and output power are equated,

$$\frac{2V_{\text{in}}i}{3} = -\frac{V_{\text{out}}i}{3} + \frac{V_{\text{out}}i}{3}, \quad \text{and} \quad 3V_{\text{in}} = V_{\text{out}} \qquad (1.7)$$

and the output voltage is found to be triple the input. Many seasoned engineers find the dc–dc step-up function shown in Fig. 1.9 to be surprising. Yet, it is just one example of such action. Others (including flyback circuits related to Fig. 1.8) are used in systems ranging from controlled power supplies to spark ignitions for automobiles.

The circuits in the preceding examples have few components, provide useful conversion functions, and are efficient. If the switching devices are ideal, each circuit is lossless. Over the history of power electronics, development has tended to flow around the discovery of such circuits: a circuit with a particular conversion function is discovered, analyzed, and applied. As the circuit moves from laboratory testing to a complete commercial product, control and protection functions are added. The power portion of the circuit remains close to the original idea. The natural question arises as to whether a systematic approach to conversion is possible: can we start with a desired function and design an appropriate converter, rather than starting from the converter and working backwards toward the application? What underlying principles can be applied to design and analysis? In this chapter, a few of the key concepts are introduced. Note that, although many of the circuits look deceptively simple, all circuits are nonlinear systems with unusual behavior.

1.5 Tools for Analysis and Design

1.5.1 The Switch Matrix

The most readily apparent difference between a power electronic circuit and other types of electronic circuits is the switch action. In contrast to a digital circuit, the switches do not indicate a logic level. Control is effected by determining the times at which switches should operate. Whether there is just one switch or a large group, there is a complexity limit: if a converter has m inputs and n outputs, even the densest possible collection of switches would have a single switch between each input and output lines. The $m \times n$ switches in the circuit can be arranged
FIGURE 1.10   The general switch matrix.

according to their connections. The pattern suggests a matrix, as shown in Fig. 1.10.

Power electronic circuits fall into two broad classes:

1. **Direct switch matrix circuits.**   In these circuits, energy storage elements are connected to the matrix only at the input and output terminals. The storage elements effectively become part of the source or the load. A rectifier with an external low-pass filter is an example of a direct switch matrix circuit. In the literature, ac–ac versions of these circuits are sometimes called *matrix converters.*
2. **Indirect switch matrix circuits,** also termed embedded converters.   These circuits, like the polarity-reverser example, have energy storage elements connected *within* the matrix structure. Indirect switch matrix circuits are most commonly analyzed as a cascade connection of direct switch matrix circuits with storage in between.

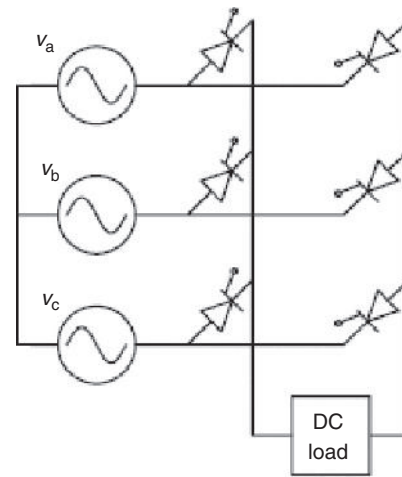
The switch matrices in realistic applications are small. A 2 × 2 switch matrix, for example, covers all possible cases with a single-port input source and a two-terminal load. The matrix is commonly drawn as the *H-bridge* shown in Fig. 1.11. A more complicated example is the three-phase bridge rectifier shown in Fig. 1.12. There are three possible inputs, and the two terminals of the dc circuit provide outputs, which gives a 3 × 2
FIGURE 1.11   H-bridge configuration of a 2 × 2 switch matrix.


FIGURE 1.12   Three-phase bridge rectifier circuit, a 3 × 2 switch matrix.

switch matrix. In a computer power supply with five separate dc loads, the switch matrix could be 2 × 10. Very few practical converters have more than 24 switches, and most designs use fewer than 12.

A switch matrix provides a way to organize devices for a given application. It also helps us focus on three major task areas, which must be addressed individually and effectively in order to produce a useful power electronic system.

- The "**Hardware**" Task – Build a switch matrix. This involves the selection of appropriate semiconductor switches and the auxiliary elements that drive and protect them.
- The "**Software**" Task – Operate the matrix to achieve the desired conversion. All operational decisions are implemented by adjusting switch timing.
- The "**Interface**" Task – Add energy storage elements to provide the filters or intermediate storage necessary to meet the application requirements. Lossless filters with simple structures are required.

In a rectifier or other converter, we must choose the electronic parts, how to operate them, and how best to filter the output to satisfy the needs of the load.

1.5.2 Implications of Kirchhoff's Voltage and Current Laws

A major challenge of switch circuits is their capacity to "violate" circuit laws. First, consider the simple circuits shown in Fig. 1.13. We might try the circuit shown in Fig. 1.13a for ac–dc conversion, but there is a problem. According to Kirchhoff's Voltage Law (KVL), the "sum of voltage drops around a closed loop is zero." However, with the switch closed, the sum of voltages around the loop is not zero. In reality, this is not a valid result. Instead, a very large current will flow
FIGURE 1.13 Hypothetical power converters: (a) possible ac–dc converter (b) possible dc–dc converter. (From [2], © 1998, Oxford University Press Inc.; used by permission.)

and cause a large $I \cdot R$ drop in the wires. KVL *will* be satisfied by the wire voltage drop, but a fire or, better yet, fuse action, might result. There is, however, nothing that would prevent an operator from trying to close the switch. KVL, then, implies a crucial restriction: a switch matrix must not attempt to interconnect unequal voltage sources directly. Notice that a wire, or dead short, can be thought of as a voltage source with $V = 0$, so KVL is a generalization of avoiding shorts across an individual voltage source.

A similar constraint holds for Kirchhoff's Current Law (KCL) that states that "currents into a node must sum to zero." When current sources are present in a converter, we must avoid any attempts to violate KCL. In Fig. 1.13b, if the current sources are different and if the switch is opened, the sum of the currents into the node will not be zero. In a real circuit, high voltages will build up and cause an arc to create another current path. This situation has real potential for damage, and a fuse will not help. As a result, KCL implies the restriction that a switch matrix must not attempt to interconnect unequal current sources directly. An open circuit can be thought of as a current source with $I = 0$, so KCL applies to the problem of opening an individual current source.

In contrast to conventional circuits, in which KVL and KCL are automatically satisfied, switches do not "know" KVL or KCL. If a designer forgets to check, and accidentally shorts two voltages or breaks a current source connection, some problem or damage will result. KVL and KCL place necessary constraints on the operation of a switch matrix. In the case of voltage sources, switches must not act to create short-circuit paths among unlike sources. In the case of KCL, switches must act to provide a path for currents. These constraints drastically reduce the number of valid switch-operating conditions in a switch matrix, thereby leading to manageable operating design problems.

When energy storage is included, there are interesting implications of the circuit law restrictions. Figure 1.14 shows two "circuit law problems." In Fig. 1.14a, the voltage source will cause the inductor current to ramp up indefinitely, since $V = L \, di/dt$. We might consider this to be a "KVL problem"
FIGURE 1.14 Short-term KVL and KCL problems in energy storage circuits: (a) an inductor cannot sustain dc voltage indefinitely; (b) a capacitor cannot sustain dc current indefinitely.

because the long-term effect is similar to shorting the source. In Fig. 1.14b, the current source will cause the capacitor voltage to ramp toward infinity. This causes a "KCL problem"; eventually, an arc will be formed to create an additional current path, just as if the current source had been opened. Of course, these connections are not problematic if they are only temporary. However, it should be evident that an inductor will not support dc voltage, and a capacitor will not support dc current. On average, over an extended time interval, the voltage across an inductor must be zero, and the current into a capacitor must be zero.

1.5.3 Resolving the Hardware Problem – Semiconductor Devices

A switch is either on or off. When on, an ideal switch will carry any current in any direction. When off, it will never carry current, no matter what voltage is applied. It is entirely lossless and changes from its on-state to its off-state instantaneously. A *real switch* can only approximate an ideal switch. The following are the aspects of real switches that differ from the ideal:

- limits on the amount and direction of on-state current;
- a nonzero on-state voltage drop (such as a diode forward voltage);

- some levels of leakage current when the device is supposed to be off;
- limitations on the voltage that can be applied when off;
- operating speed. The duration of transition between the on-states and off-states is important.

The degree to which the properties of an ideal switch must be met by a real switch depends on the application. For example, a diode can easily be used to conduct dc current; the fact that it conducts only in one direction is often an advantage, not a weakness.

Many different types of semiconductors have been applied in power electronics. In general, these fall into three groups:

1. Diodes, which are used in rectifiers, dc–dc converters, and in supporting roles.
2. Transistors, which in general are suitable for control of single-polarity circuits. Several types of transistors are applied to power converters. The IGBT type is unique to power electronics and has good characteristics for applications such as inverters.
3. Thyristors, which are multijunction semiconductor devices with latching behavior. In general, thyristors can be switched with short pulses and then maintain their state until current is removed. They act only as switches. The characteristics are especially well suited

to high-power controllable rectifiers, they have been applied to all power-conversion applications.

Some of the features of the most common power semiconductors are listed in Table 1.1. The table shows a wide variety of speeds and rating levels. As a rule, faster speeds apply to lower ratings. For each device type, cost tends to increase both for faster devices and for devices with higher power-handling capacity.
Conducting direction and blocking behavior are fundamentally tied to the device type, and these basic characteristics constrain the choice of device for a given conversion function. Consider again a diode. It carries current in only one direction and always blocks current in the other direction. Ideally, the diode exhibits no forward voltage drop or off-state leakage current. Although an ideal diode lacks the many features of an ideal switch, it is an important switching device. Other real devices operate with polarity limits on current and voltage and have corresponding ideal counterparts. It is convenient to define a special type of switch to represent this behavior: the *restricted switch*.

DEFINITION   A *restricted switch* is an ideal switch with the addition of restrictions on the direction of current flow and voltage polarity. The *ideal diode* is one example of a restricted switch.

TABLE 1.1   Examples of semiconductor devices used in power electronics

Device type	Characteristics of power devices
Diode	Current ratings from under 1 A to more than 5000 A. Voltage ratings from 10 V to 10 kV or more. The fastest power devices switch in less than 10 ns, whereas the slowest require 100 μs or more. The function of a diode applies in rectifiers and dc–dc circuits.
BJT	(Bipolar junction transistor) Conducts collector current (in one direction) when sufficient base current is applied. The function applies to dc–dc circuits. Power BJTs have mostly been supplanted by FETs and IGBTs.
FET	(Field effect transistor) Conducts drain current when sufficient gate voltage is applied. Power FETs (nearly always enhancement-mode MOSFETs) have a parallel connected reverse diode by virtue of their construction. Ratings from about 0.5 A to about 150 A and 20 V up to 1200 V. Switching times are fast, from 20 ns or less up to 200 ns. The function applies to dc–dc conversion, where the FET is in wide use, and to inverters.
IGBT	(Insulated gate bipolar transistor) A special type of transistor that has the function of a BJT with its base driven by an FET. Faster than a BJT of similar ratings, and easy to use. Ratings from 10 A to more than 600 A, with voltages of 600 to 2500 V. The IGBT is popular in inverters from about 1 to 200 kW or more. It is found almost exclusively in power electronics applications.
SCR	(Silicon-controlled rectifier) A thyristor that conducts like a diode after a gate pulse is applied. Turns off only when current becomes zero. Prevents current flow until a pulse appears. Ratings from 10 A up to more than 5000 A, and from 200 V up to 6 kV. Switching requires 1 to 200 μs. Widely used for controlled rectifiers. The SCR is found almost exclusively in power electronics applications, and is the most common member of the thyristor family.
GTO	(Gate turn-off thyristor) An SCR that can be turned off by sending a negative pulse to its gate terminal. Can substitute for transistors in applications above 200 kW or more. The ratings approach those of SCRs, and the speeds are similar as well.
TRIAC	A semiconductor constructed to resemble two SCRs connected in reverse parallel. Ratings from 2 to 50 A and 200 to 800 V. Used in lamp dimmers, home appliances, and hand tools. Not as rugged as many other device types, but very convenient for many ac applications.
IGCT	(Integrated gate commutated thyristor) A combination device that includes a high-power thyristor and external electronics to control it. This device is a member of a larger family of combination devices, in which multiple semiconductor chips packaged together perform a single power function. The IGCT provides a high-performance GTO function for power levels above 1 MW or more.

TABLE 1.2 The types of restricted switches

Action	Device	Quadrants	Restricted switch symbol	Device symbol
Carries current in one direction, blocks in the other (forward-conducting reverse-blocking)	Diode			
Carries or blocks current in one direction (forward-conducting forward-blocking)	BJT			
Carries in one direction or blocks in both directions (forward-conducting bidirectional-blocking)	GTO			
Carries in both directions, but blocks only in one direction (bidirectional-carrying forward-blocking)	FET			
Fully bidirectional	Ideal switch			

The diode always permits current flow in one direction, while blocking flow in the other direction. It therefore represents a *forward-conducting reverse-blocking* restricted switch and operates in one quadrant on a graph of device current versus. voltage. This function is automatic – the two diode terminals provide all the necessary information for switch action. Other restricted switches require a third *gate* terminal to determine their state. Consider the polarity possibilities given in Table 1.2. Additional functions such as bidirectional-conducting reverse-blocking can be obtained by reverse connection of one of the five types in the table.

The quadrant operation shown in the table indicates polarities. For example, the current in a diode will be positive when on, and the voltage will be negative when off. This means diode operation is restricted to the single quadrant comprising the upper vertical (current) axis and the left horizontal (voltage) axis. Other combinations appear in the table. Symbols for restricted switches can be built up by interpreting the diode's triangle as the current-carrying direction and the bar as the blocking direction. Five types of symbols can be drawn as shown in Table 1.2. These symbols are used infrequently, but are useful for showing the polarity behavior of switching devices. A circuit drawn with restricted switches represents an idealized power converter.

Restricted switch concepts guide the selection of devices. For example, consider an inverter intended to deliver ac load current from a dc voltage source. A switch matrix built to perform this function must be able to manipulate ac current and dc voltage. Regardless of the physical arrangement of the matrix, we would expect bidirectional-conducting forward-blocking switches to be useful for this conversion. This is a correct result: modern inverters operating from dc voltage sources are built with FETs or with IGBTs packaged with reverse-parallel diodes. As new power devices are introduced to the market, it is straightforward to determine what types of converters will use them.

1.5.4 Resolving the Software Problem – Switching Functions

The physical $m \times n$ switch matrix can be associated with a mathematical $m \times n$ *switch state matrix*. Each element of this matrix, called a *switching function*, shows whether the corresponding physical device is on or off.

> **DEFINITION** A *switching function*, $q(t)$, has a value of 1 when the corresponding physical switch is on and 0 when it is off. Switching functions are discrete-valued functions of time, and control of switching devices can be represented with them.

Figure 1.15 shows a typical switching function. It is periodic, with period T, representing the most likely repetitive switch action in a power converter. For convenience, it is drawn on a relative time scale that begins at 0 and draws out the square wave period by period. The actual timing is arbitrary, so the
FIGURE 1.15 A generic switching function with period T, duty ratio D, and time reference t_0.

center of the first pulse is defined as a specified time t_0 in the figure. In many converters, the switching function is generated as an actual control voltage signal that might drive the gate of either a MOSFET or some other semiconductor switching device.

The timing of switch action is the only alternative for control of a power converter. Because switch action can be represented with a discrete-valued switching function, timing can be represented within the switching function framework. On the basis of Fig. 1.15, a generic switching function can be characterized completely with three parameters:

1. The *duty ratio*, D, is the fraction of time during which the switch is on. For control purposes, the on-time interval or pulse width can be adjusted to achieve a desired result. We can term this adjustment process *pulse-width modulation* (PWM), perhaps the most important process for implementing control in power converters.
2. The frequency $f_{\text{switch}} = 1/T$ (with radian frequency $\omega = 2\pi f_{\text{switch}}$) is most often constant, although not in all applications. For control purposes, frequency can be adjusted. This strategy is sometimes used in low-power dc–dc converters to manage wide load ranges. In other converters, frequency control is unusual because the operating frequency is often dictated by the application.
3. The time delay t_0 or phase $\varphi_0 = \omega t_0$. Rectifiers often use *phase control* to provide a range of adjustment. Phase-shifted bridge circuits are common for high-power dc–dc conversion. A few specialized ac–ac converter applications use phase modulation.

With just three parameters to vary, there are relatively few possible ways to control any power electronic circuit. dc–dc converters and inverters usually rely on duty ratio adjustment (PWM) to alter their behavior. Phase control is common in controlled rectifier applications.

Switching functions are powerful tools for the general representation of converter action [7]. The most widely used control approaches derive from averages of switching functions [2, 8]. Their utility comes from their application in writing circuit equations. For example, in the boost converter shown in

Fig. 1.9, the loop and node equations change depending on which switch is acting at a given moment. The two possible circuit configurations each have distinct equations. Switching functions allow them to be combined. By assigning switching functions $q_1(t)$ and $q_2(t)$ to the left- and right-switching devices, respectively, we obtain

$$q_1\left(V_{\text{in}} - L\frac{di_L}{dt} = 0\right),$$

$$q_1\left(C\frac{dv_C}{dt} + \frac{v_C}{R} = 0\right), \text{ left switch on} \qquad (1.8)$$

$$q_2\left(V_{\text{in}} - L\frac{di_L}{dt} = v_C\right),$$

$$q_2\left(C\frac{dv_C}{dt} + \frac{v_C}{R} = i_L\right), \text{ right switch on} \qquad (1.9)$$

Because the switches alternate, and the switching functions must be 0 or 1, these sets of equations can be combined to give

$$V_{\text{in}} - L\frac{di_L}{dt} = q_2 v_C, \quad C\frac{dv_C}{dt} + \frac{v_C}{R} = q_2 i_L \qquad (1.10)$$

The combined expressions are simpler and easier to analyze than the original equations.

For control purposes, the average of equations such as (1.10) often proceeds with the replacement of switching functions q with duty ratios d. The discrete time action of a switching function thus will be represented by an average duty ratio parameter. Switching functions, the advantages gained by averaging, and control approaches such as PWM are discussed at length in several chapters in this handbook.

1.5.5 Resolving the Interface Problem – Lossless Filter Design

Lossless filters for power electronic applications are sometimes called smoothing filters [9]. In applications in which dc outputs are of interest, such filters are commonly implemented as simple low-pass LC structures. The analysis is facilitated because in most cases the residual output waveform, termed ripple, has a predictable shape. Filter design for rectifiers or dc–dc converters is a question of choosing storage elements large enough to keep ripple low, but not so large that the whole circuit becomes unwieldy or expensive.

Filter design is more challenging when ac outputs are desired. In some cases, this is again an issue of low-pass filter design. However, in many applications, low-pass filters are not adequate to meet low noise requirements. In these situations, active filters can be used. In power electronics, the term active filter refers to lossless switching converters that actively inject or remove energy moment-by-moment to compensate for distortion. The circuits (discussed in Chapter 41 – Active Filters

in this handbook) are not related to the linear active filter op-amp circuits used in analog signal processing. In ac applications, there is a continuing opportunity for innovation in filter design.

1.6 Sample Applications

Although power electronics is becoming universal for electronic systems, a few emerging applications have generated wide interest. Some are discussed briefly here to introduce the breadth of activity in the field.

A hybrid electric vehicle typically has two major power electronic systems and dozens or even hundreds of smaller systems [10]. The two large units are the inverter system, which controls the electric drive motor, and a rectifier system, which manages battery charging. Smaller systems include motor controllers in electric power steering units, lighting electronics for high-intensity headlamps, controllers for the wide range of small motors that actuate everything from windshield wipers to DVD players, and power supplies for the host of microcontrollers embedded in a modern car. As plug-in hybrid and electric cars continue to develop, the efficiency and sophistication of battery chargers and drive motor controllers will increase.

In a hybrid car, a typical inverter rating is about 50 kW. Fully electric automobiles have inverter ratings to about 200 kW. Hybrid and electric drive power levels increase from there to include multimegawatt inverters that power high-speed trains.

At the other power extreme, designers have been working on small power electronic systems that extract energy from various ambient sources for local purposes [11]. These energy harvesting applications will be an emerging growth area. An example application is a corrosion sensor, built into a highway bridge, that gathers energy from vibration. The vibration energy is converted and stored, then used for intermittent communication with a central monitoring computer. Typical power levels can be less than 0.001 W.

Solar, wind, and other alternative energy resources are tightly linked to power electronics. A typical solar panel produces about 30-V dc, with tolerances from 20 to 40 V or more. This randomly changing dc source must be converted to clean, tightly regulated ac voltage that synchronizes to the electricity grid and delivers energy. Solar inverter efficiency, reliability, and cost are major factors in successful energy innovation. A dual application, meaning that energy flows in the opposite direction but that many other characteristics are shared, is that of solid-state lighting [12]. In that case, flexible control of a dc current must be provided from an ac grid source.

For wind energy, a typical large-scale wind turbine can produce 2 MW of high-frequency ac power. The frequency and voltage vary rapidly according to wind speed. This power must be converted to fixed frequency and voltage for grid interconnection.

1.7 Summary

Power electronics is the study of electronic circuits for the control and conversion of electrical energy. The technology is a critical part of our energy infrastructure and is central for a wide range of uses of electricity. For power electronics design, we consider only those circuits and devices that, in principle, introduce no loss and achieve near-perfect reliability. The two key characteristics of high efficiency and high reliability are implemented with switching circuits, supplemented with energy storage. Switching circuits can be organized as switch matrices. This facilitates their analysis and design.

In a power electronic system, the three primary challenges are the hardware problem of implementing a switch matrix, the software problem of deciding how to operate that matrix, and the interface problem of removing unwanted distortion and providing the user with the desired clean power source. The hardware is implemented with a few special types of power semiconductors. These include several types of transistors, especially MOSFETs and IGBTs, and several types of thyristors, especially SCRs and GTOs. The software problem can be represented in terms of switching functions. The frequency, duty ratio, and phase of switching functions are available for operational purposes. The interface problem is addressed by means of lossless filter circuits. Most often, these are lossless LC passive filters to smooth out ripple or reduce harmonics. Active filter circuits also have been applied to make dynamic corrections in power conversion waveforms.

Improvements in devices and advances in control concepts have led to steady improvements in power electronic circuits and systems. This is driving tremendous expansion of applications. Personal computers, for example, would be unwieldy and inefficient without power electronic dc supplies. Mobile devices and laptop computers would be impractical. High-efficiency lighting, motor controls, and a wide range of industrial controls depend on power electronics. Strong growth is occurring in automotive applications, in lighting, in dc power supplies for portable devices, in high-end converters for advanced microprocessors, and in alternative and renewable energy. During the next generation, we will reach a time when almost all electrical energy is processed through power electronics somewhere in the path from generation to end use.

2.1 Diode as a Switch

Among all the static switching devices used in power electronics (PE), the power diode is perhaps the simplest. Its circuit symbol is shown in Fig. 2.1. It is a two terminal device, and terminal A is known as the anode whereas terminal K is known as the cathode. If terminal A experiences a higher potential compared to terminal K, the device is said to be forward biased and a current called forward current (I_F) will flow through the device in the direction as shown. This causes a small voltage drop across the device (<1 V), which in ideal condition is usually ignored. On the contrary, when a diode is reverse biased, it does not conduct and a practical diode do experience a small current flowing in the reverse direction called the leakage current. Both the forward voltage drop and the leakage current are ignored in an ideal diode. Usually in PE applications a diode is considered to be an ideal static switch.

The characteristics of a practical diode show a departure from the ideals of zero forward and infinite reverse impedance, as shown in Fig. 2.2a. In the forward direction, a potential barrier associated with the distribution of charges in the vicinity of the junction, together with other effects, leads to a voltage drop. This, in the case of silicon, is in the range of 1 V for currents in the normal range. In reverse, within the normal operating range of voltage, a very small current flows which is largely independent of the voltage. For practical purposes, the static characteristics is often represented by Fig. 2.2b.

In the figure, the forward characteristic is expressed as a threshold voltage V_o and a linear incremental or slope resistance, r. The reverse characteristic remains the same over the range of possible leakage currents irrespective of voltage within the normal working range.

2.2 Properties of PN Junction

From the forward and reverse biased condition characteristics, one can notice that when the diode is forward biased, current rises rapidly as the voltage is increased. Current in the reverse biased region is significantly small until the breakdown voltage of the diode is reached. Once the applied voltage is over this limit, the current will increase rapidly to a very high value limited only by an external resistance.

DC diode parameters. The most important parameters are the followings:

- *Forward voltage, V_F* is the voltage drop of a diode across A and K at a defined current level when it is forward biased.
- *Breakdown voltage, V_B* is the voltage drop across the diode at a defined current level when it is beyond reverse biased level. This is popularly known as avalanche.
- *Reverse current I_R* is the current at a particular voltage, which is below the breakdown voltage.
FIGURE 2.1   Power diode: (a) symbol; (b) and (c) types of packaging.
FIGURE 2.2a   Typical static characteristic of a power diode (forward and reverse have different scale).
FIGURE 2.2b   Practical representation of the static characteristic of a power diode.

AC diode parameters. The commonly used parameters are the followings:

- *Forward recovery time, t_{FR}* is the time required for the diode voltage to drop to a particular value after the forward current starts to flow.
- *Reverse recovery time t_{rr}* is the time interval between the application of reverse voltage and the reverse current dropped to a particular value as shown in Fig. 2.3. Parameter t_a is the interval between the zero crossing of the diode current to when it becomes I_{RR}. On the other hand, t_b is the time interval from the maximum reverse recovery current to approximately 0.25 of I_{RR}. The ratio of the two parameters t_a and t_b is known as the softness factor (SF). Diodes with abrupt recovery characteristics are used for high frequency switching.

In practice, a design engineer frequently needs to calculate the reverse recovery time. This is in order to evaluate the possibility of high frequency switching. As a thumb rule, the lower t_{RR} the faster the diode can be switched.

$$t_{rr} = t_a + t_b \qquad (2.1)$$

If t_b is negligible compared to t_a which is a very common case, then the following expression is valid:

$$t_{RR} = \sqrt{\frac{2Q_{RR}}{(di/dt)}}$$

(a) Soft recovery   (b) Abrupt recovery
FIGURE 2.3   Diode reverse recovery with various softness factors.

from which the reverse recovery current

$$I_{RR} = \sqrt{\frac{di}{dt} 2Q_{RR}}$$

where Q_{RR} is the storage charge and can be calculated from the area enclosed by the path of the recovery current.

EXAMPLE 2.1   The manufacturer of a selected diode gives the rate of fall of the diode current $di/dt = 20$ A/μs, and its reverse recovery time $t_{rr} = 5$ μs. What value of peak reverse current do you expect?

SOLUTION.   The peak reverse current is given as:

$$I_{RR} = \sqrt{\frac{di}{dt} 2Q_{RR}}$$

The storage charge Q_{RR} is calculated as:

$$Q_{RR} = \frac{1}{2}\frac{di}{dt}t_{rr}^2 = 1/2 \times 20 \text{ A/μs} \times (5 \times 10^{-6})^2 = 50 \text{ μC}$$

Hence,

$$I_{RR} = \sqrt{20\frac{\text{A}}{\text{μs}} \times 2 \times 50 \text{ μC}} = 44.72 \text{ A}$$

- **Diode capacitance**, C_D is the net diode capacitance including the junction (C_J) plus package capacitance (C_P).

In high-frequency pulse switching, a parameter known as transient thermal resistance is of vital importance since it indicates the instantaneous junction temperature as a function of time under constant input power.

2.3 Common Diode Types

Depending on their applications, diodes can be segregated into the following major divisions:

Small signal diode: They are perhaps the most widely used semiconductor devices used in wide variety of applications. In general purpose applications, they are used as a switch in rectifiers, limiters, capacitors, and in wave-shaping. Some common diode parameters a designer needs to know are the forward voltage, reverse breakdown voltage, reverse leakage current, and the recovery time.

Silicon rectifier diode: These are the diodes, which have high forward current carrying capability, typically up to several hundred amperes. They usually have a forward resistance of only a fraction of an ohm while their reverse resistance is in the mega-ohm range. Their primary application is in power conversion, like in power supplies, UPS, rectifiers/inverters, etc.

In case of current exceeding the rated value, their case temperature will rise. For stud-mounted diodes, their thermal resistance is between 0.1 and 1°C/W.

Zener diode: Its primary applications are in the voltage reference or regulation. However, its ability to maintain a certain voltage depends on its temperature coefficient and the impedance. The voltage reference or regulation applications of zener diodes are based on their avalanche properties. In the reverse biased mode, at a certain voltage the resistance of these devices may suddenly drop. This occurs at the zener voltage V_X, a parameter the designer knows beforehand.

Figure 2.4 shows a circuit using a zener diode to control a reference voltage of a linear power supply. Under normal operating condition, the transistor will transmit power to the load (output) circuit. The output power level will depend on the transistor base current. A very high base current will impose a large voltage across the zener and it may attain zener voltage V_X, when it will crush and limit the power supply to the load.
FIGURE 2.4   Voltage regulator with a zener diode for reference.

Photo diode: When a semiconductor junction is exposed to light, photons generate hole–electron pairs. When these charges diffuse across the junction, they produce photocurrent. Hence this device acts as a source of current, which increases with the intensity of light.

Light emitting diode (**LED**): Power diodes used in PE circuits are high power versions of the commonly used devices employed in analog and digital circuits. They are manufactured in wide varieties and ranges. The current rating can be from a few amperes to several hundreds while the voltage rating varies from tens of volts to several thousand volts.

2.4 Typical Diode Ratings

2.4.1 Voltage Ratings

For power diodes, a given datasheet has two voltage ratings. One is the repetitive peak inverse voltage (V_{RRM}), the other is the non-repetitive peak inverse voltage. The non-repetitive voltage (V_{RM}) is the diodes capability to block a reverse voltage that may occur occasionally due to a overvoltage surge.

Repetitive voltage on the other hand is applied on the diode in a sustained manner. To understand this, let us look at the circuit in Fig. 2.5.

EXAMPLE 2.2 Two equal source voltages of 220 V peak and phase shifted from each other by 180° are supplying a common load as shown. (a) Show the load voltage; (b) describe when diode D1 will experience V_{RRM}; and (c) determine the V_{RRM} magnitude considering a safety factor of 1.5.

SOLUTION. (a) The input voltage, load voltage, and the voltage across D1 when it is not conducting (V_{RRM}) are shown in Fig. 2.5b.

(b) Diode D1 will experience V_{RRM} when it is not conducting. This happens when the applied voltage V1 across it is in the negative region (from 70 to 80 ms as shown in the figure) and consequently the diode is reverse biased. The actual ideal voltage across it is the peak value of the two input voltages i.e. $220 \times 2 = 440$ V. This is because when D1 is not conducting, D2 conducts. Hence in addition V_{an}, V_{bn} is also applied across it since D2 is practically shorted.

(c) The $V_{RRM} = 440$ V is the value in ideal situation. In practice, higher voltages may occur due to stray circuit inductances and/or transients due to the reverse

recovery of the diode. They are hard to estimate. Hence, a design engineer would always use a safety factor to cater to these overvoltages. Hence, one should use a diode with a $220 \times 2 \times 1.5 = 660$ V rating.

2.4.2 Current Ratings

Power diodes are usually mounted on a heat sink. This effectively dissipates the heat arising due to continuous conduction. Hence, current ratings are estimated based on temperature rise considerations. The datasheet of a diode normally specifies three different current ratings. They are (1) the average current, (2) the rms current, and (3) the peak current. A design engineer must ensure that each of these values is not exceeded. To do that, the actual current (average, rms, and peak) in the circuit must be evaluated either by calculation, simulation, or measurement. These values must be checked against the ones given in the datasheet for that selected diode. The calculated values must be less than or equal to the datasheet values. The following example shows this technique.

EXAMPLE 2.3 The current waveform passing through a diode switch in a switch mode power supply application is shown in Fig. 2.6. Find the average, rms, and the peak current.

SOLUTION. The current pulse duration is shown to be 0.2 ms within a period of 1 ms and with a peak amplitude of 50 A. Hence the required currents are:

$$I_{average} = 50 \times \frac{0.2}{1} = 10 \text{ A}$$

$$I_{rms} = \sqrt{50^2 \times \frac{0.2}{1}} = 22.36 \text{ A}$$

$$I_{peak} = 50 \text{ A}$$

Sometimes, a surge current rating and its permissible duration is also given in a datasheet. For protection of diodes and other semiconductor devices, a fast acting fuse is required. These fuses are selected based on their I^2t rating which is normally specified in a datasheet for a selected diode.

FIGURE 2.5a The circuit.

FIGURE 2.5b The waveforms.
FIGURE 2.6 The current waveform.

2.5 Snubber Circuits for Diode

Snubber circuits are essential for diodes used in switching circuits. It can save a diode from overvoltage spikes, which may arise during the reverse recovery process. A very common snubber circuit for a power diode consists of a capacitor and a resistor connected in parallel with the diode as shown in Fig. 2.7.

When the reverse recovery current decreases, the capacitor by virtue of its property will try to hold the voltage across it, which, approximately, is the voltage across the diode. The resistor on the other hand will help to dissipate some of the energy stored in the inductor, which forms the I_{RR} loop. The dv/dt across a diode can be calculated as:

$$\frac{dv}{dt} = \frac{0.632 \times V_S}{\tau} = \frac{0.632 \times V_S}{R_S \times C_S} \quad (2.2)$$

where V_S is the voltage applied across the diode.

Usually the dv/dt rating of a diode is given in the manufacturers datasheet. Knowing dv/dt and the R_S, one can choose the value of the snubber capacitor C_S. The R_S can be calculated from the diode reverse recovery current:

$$R_S = \frac{V_S}{I_{RR}} \quad (2.3)$$

The designed dv/dt value must always be equal or lower than the dv/dt value found from the datasheet.
FIGURE 2.7 A typical snubber circuit.

2.6 Series and Parallel Connection of Power Diodes

For specific applications, when the voltage or current rating of a chosen diode is not enough to meet the designed rating, diodes can be connected in series or parallel. Connecting them in series will give the structure a high voltage rating that may be necessary for high-voltage applications. However, one must ensure that the diodes are properly matched especially in terms of their reverse recovery properties. Otherwise, during reverse recovery there may be a large voltage imbalances between the
FIGURE 2.8 Series connected diodes with necessary protection.

series connected diodes. Additionally, due to the differences in the reverse recovery times, some diodes may recover from the phenomenon earlier than the other causing them to bear the full reverse voltage. All these problems can effectively be overcome by connecting a bank of a capacitor and a resistor in parallel with each diode as shown in Fig. 2.8.

If a selected diode cannot match the required current rating, one may connect several diodes in parallel. In order to ensure equal current sharing, the designer must choose diodes with the same forward voltage drop properties. It is also important to ensure that the diodes are mounted on similar heat sinks and are cooled (if necessary) equally. This will affect the temperatures of the individual diodes, which in turn may change the forward characteristics of diode.

Tutorial 2.1   Reverse Recovery and Overvoltages

Figure 2.9 shows a simple switch mode power supply. The switch (1-2) is closed at $t = 0$ s. When the switch is open, a freewheeling current $I_F = 20$ A flows through the load (RL), freewheeling diode (DF), and the large load circuit inductance (LL). The diode reverse recovery current is 20 A and it then decays to zero at the rate of 10 A/μs. The load is rated at 10 Ω and the forward on-state voltage drop is neglected.

  (a) Draw the current waveform during the reverse recovery (I_{RR}) and find its time (t_{rr}).

  (b) Calculate the maximum voltage across the diode during this process (I_{RR}).

SOLUTION. (a) A typical current waveform during reverse recovery process is shown in Fig. 2.10 for an ideal diode.

When the switch is closed, the steady-state current is, $I_{SS} = 200\,\text{V}/10\,\Omega = 20$ A, since under steady-state condition, the inductor is shorted. When the switch is open, the reverse recovery current flows in the right-hand side
FIGURE 2.9 A simple switch mode power supply with freewheeling diode.
FIGURE 2.10 Current through the freewheeling diode during reverse recovery.

loop consisting of the LL, RL, and DF. The load inductance, LL is assumed to be shorted. Hence, when the switch is closed, the loop equation is:

$$V = L\frac{di_S}{dt}$$

from which

$$\frac{di_S}{dt} = \frac{V}{L} = \frac{200}{10} = 20\,\text{A}/\mu\text{s}$$

At the moment the switch is open, the same current keeps flowing in the right-hand side loop. Hence,

$$\frac{di_d}{dt} = -\frac{di_S}{dt} = -20\,\text{A}/\mu\text{s}$$

from time zero to time t_1 the current will decay at a rate of 20 A/s and will be zero at $t_1 = 20/20 = 1\,\mu\text{s}$. The reverse recovery current starts at this point and, according to the given condition, becomes 20 A at t_2. From this point on, the rate of change remains unchanged at 20 A/μs. Period $t_2 - t_1$ is found as:

$$t_2 - t_1 = \frac{20\,\text{A}}{20\,\text{A}/\mu\text{s}} = 1\,\mu\text{s}$$

From t_2 to t_3, the current decays to zero at the rate of 20 A/μs. The required time:

$$t_3 - t_2 = \frac{20\,\text{A}}{10\,\text{A}/\mu\text{s}} = 2\,\mu\text{s}$$

Hence the actual *reverse recovery time*: $t_{rr} = t_3 - t_1 = (1 + 1 + 2) - 1 = 3\,\mu\text{s}$.

(b) The diode experiences the maximum voltage just when the switch is open. This is because both the source voltage 200 V and the newly formed voltage due to the change in current through the inductor L. The voltage across the diode:

$$V_D = -V + L\frac{di_S}{dt} = -200 + (10 \times 10^{-6})(-20 \times 10^6) = -400\,\text{V}$$

Tutorial 2.2   Ideal Diode Operation, Mathematical Analysis, and PSPICE Simulation

This tutorial illustrates the operation of a diode circuit. Most of the PE applications operate at a relative high voltage, and in such cases, the voltage drop across the power diode usually is small. It is quite often justifiable to use the ideal diode model. An ideal diode has a zero conduction drop when it is forward biased and has zero current when it is reverse biased. The explanation and the analysis presented below is based on the ideal diode model.

Circuit Operation   A circuit with a single diode and an RL load is shown in Fig. 2.11. The source V_S is an alternating sinusoidal source. If $V_S = \text{E}\sin(\omega t)$, then V_S is positive when $0 < \omega t < \pi$, and V_S is negative when $\pi < \omega t < 2\pi$. When V_S starts becoming positive, the diode starts conducting and the positive source keeps the diode in conduction till ωt reaches π radians. At that instant, defined by $\omega t = \pi$ radians, the current through the circuit is not zero and there is some energy stored in the inductor. The voltage across an inductor is positive when the current through it is increasing and becomes negative when the current through it tends to fall. When the
FIGURE 2.11   Circuit diagram.
FIGURE 2.12   Current increasing, $0 < \omega t < \pi/2$.
FIGURE 2.13   Current decreasing, $\pi/2 < \omega t < \pi$.

voltage across the inductor is negative, it is in such a direction as to forward bias the diode. The polarity of voltage across the inductor is as shown in Fig. 2.12 or 2.13.

When V_S changes from a positive to a negative value, there is current through the load at the instant $\omega t = \pi$ radians and the diode continues to conduct till the energy stored in the inductor becomes zero. After that the current tends to flow in the reverse direction and the diode blocks conduction. The entire applied voltage now appears across the diode.

Mathematical Analysis   An expression for the current through the diode can be obtained as shown in the equations. It is assumed that the current flows for $0 < \omega t < \beta$, where $\beta > \pi$, when the diode conducts, the driving function for the differential equation is the sinusoidal function defining the source voltage. During the period defined by $\beta < \omega t < 2\pi$, the diode blocks current and acts as an open switch. For this period, there is no equation defining the behavior of the circuit. For $0 < \omega t < \beta$, Eq. (2.4) applies.

$$L\frac{di}{dt} + R \times i = E \times \sin(\theta), \; where \; -0 \leq \theta \leq \beta \quad (2.4)$$

$$L\frac{di}{dt} + R \times i = 0 \quad (2.5)$$

$$\omega L\frac{di}{d\theta} + R \times i = 0 \quad (2.6)$$

$$i(\theta) = A \times e^{-R\theta/\omega L} \quad (2.7)$$

Given a linear differential equation, the solution is found out in two parts. The homogeneous equation is defined by Eq. (2.5). It is preferable to express the equation in terms of the angle θ instead of "t." Since $\theta = \omega t$, we get that $d\theta = \omega \cdot dt$. Then Eq. (2.5) gets converted to Eq. (2.6). Equation (2.7) is the solution to this homogeneous equation and is called the complementary integral.

The value of constant A in the complimentary solution is to be evaluated later. The particular solution is the steady-state response and Eq. (2.8) expresses the particular solution. The steady-state response is the current that would flow in steady state in a circuit that contains only the source, resistor, and inductor shown in the circuit, the only element missing being the diode. This response can be obtained using the differential equation or the Laplace transform or the ac sinusoidal circuit analysis. The total solution is the sum of both the complimentary and the particular solution and it is shown in Eq. (2.9). The value of A is obtained using the initial condition. Since the diode starts conducting at $\omega t = 0$ and the current starts building up from zero, $i(0) = 0$. The value of A is expressed by Eq. (2.10).

Once the value of A is known, the expression for current is known. After evaluating A, current can be evaluated at different values of ωt, starting from $\omega t = \pi$. As ωt increases, the current would keep decreasing. For some values of ωt, say β, the current would be zero. If $\omega t > \beta$, the current would evaluate to a negative value. Since the diode blocks current in the reverse direction, the diode stops conducting when ωt reaches. Then an expression for the average output voltage can be obtained. Since the average voltage across the inductor has to be zero, the average voltage across the resistor and average voltage at the cathode of the diode are the same. This average value can be obtained as shown in Eq. (2.11).

$$i(\theta) = \left(\frac{E}{Z}\right)\sin(\omega t - \alpha) \quad (2.8)$$

where

$$\alpha = a\tan\left(\frac{\omega l}{R}\right) \; and \; Z^2 = R^2 + \omega l^2$$

$$i(\theta) = A \times e^{(-R\theta/\omega L)} + \frac{E}{Z}\sin(\theta - \alpha) \quad (2.9)$$

$$A = \left(\frac{E}{Z}\right)\sin(\alpha) \quad (2.10)$$

Hence, the average output voltage:

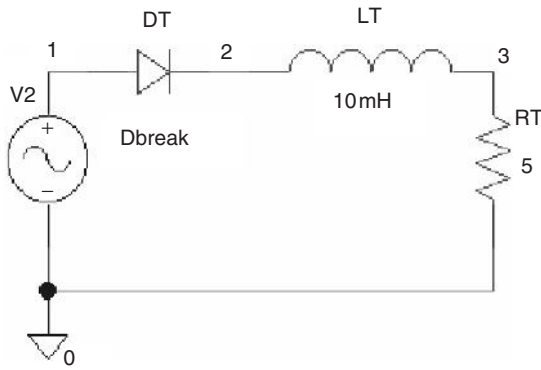
$$V_{OAVG} = \frac{E}{2\pi}\int_0^\beta \sin\theta \cdot d\theta = \frac{E}{2\pi} \times [1 - \cos(\beta)] \quad (2.11)$$


FIGURE 2.14   PSPICE model to study an R–L diode circuit.

PSPICE Simulation   For simulation using PSPICE, the circuit used is shown in Fig. 2.14. Here the nodes are numbered. The ac source is connected between the nodes 1 and 0. The diode is connected between the nodes 1 and 2 and the inductor links the nodes 2 and 3. The resistor is connected from the node 3 to the reference node, that is, node 0. The circuit diagram is shown in Fig. 2.14.

The PSPICE program in textform is presented below.

```

```

The diode is described using the MODEL statement. The TRAN statement simulates the transient operation for a period of 100 ms at an interval of 10 ms. The OPTIONS statement sets limits for tolerances. The output can be viewed on the screen because of the PROBE statement. A snapshot of various voltages/currents is shown in Fig. 2.15.

From Fig. 2.15, it is evident that the current lags the source voltage. This is a typical phenomenon in any inductive circuit and is associated with the energy storage property of the inductor. This property of the inductor causes the current to change slowly, governed by the time constant $\tau = \tan^{-1}(\omega l/R)$. Analytically, this is calculated by the expression in Eq. (2.8).

2.7 Typical Applications of Diodes

A. In rectification

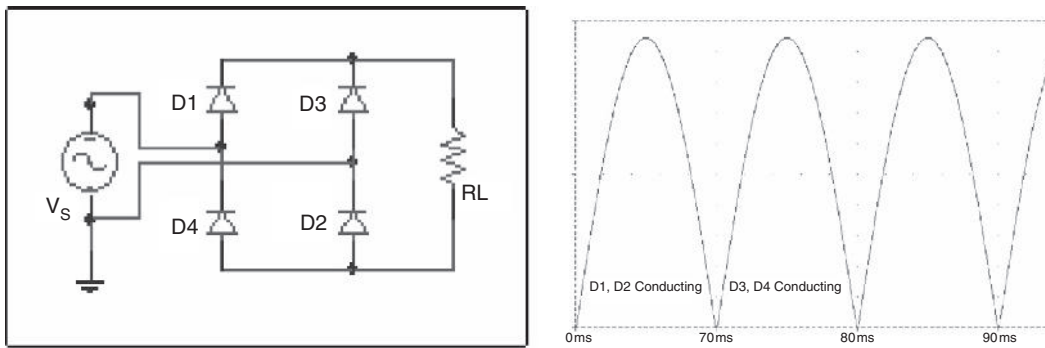
Four diodes can be used to fully rectify an ac signal as shown in Fig. 2.16. Apart from other rectifier circuits, this topology does not require an input transformer. However, they are used for isolation and protection. The direction of the current is decided by two diodes conducting at any given time. The direction of the current through the load is always the same. This rectifier topology is known as the full bridge rectifier.
FIGURE 2.15   Voltage/current waveforms at various points in the circuit.


FIGURE 2.16 Full bridge rectifier and its output dc voltage.

The average rectifier output voltage:

$$V_{dc} = \frac{2V_m}{\pi}, \text{ where } V_m \text{ is the peak input voltage}$$

The rms rectifier output voltage:

$$V_{rms} = \frac{V_m}{\sqrt{2}}$$

This rectifier is twice as efficient as compared to a single phase one.

B. For voltage clamping

Figure 2.17 shows a voltage clamper. The negative pulse of the sinusoidal input voltage charges the capacitor to its maximum value in the direction shown. After charging, the capacitor cannot discharge, since it is open circuited by the diode. Hence the output voltage:

$$V_o = V_c + V_i = V_m(1 + \sin(\omega t))$$

The output voltage is clamped between zero and $2V_m$.

C. As voltage multiplier

Connecting diode in a predetermined manner, an ac signal can be doubled, tripled, and even quadrupled. This is shown in Fig. 2.18. As evident, the circuit will yield a dc voltage equal to $2V_m$. The capacitors are alternately charged to the maximum value of the input voltage.
FIGURE 2.18 Voltage doubler and quadrupler circuit.
FIGURE 2.17 Voltage clamping with diode.

2.8 Standard Datasheet for Diode Selection

In order for a designer to select a diode switch for specific applications, the following tables and standard test results can be used. A power diode is primarily chosen based on forward current (I_F) and the peak inverse (V_{RRM}) voltage. For example, the designer chooses the diode type V30 from the table in Fig. 2.19 because it closely matches their calculated values of I_F and V_{RRM} without going over. However, if for some reason only the V_{RRM} matches but the calculated value of I_F comes higher, one should go for diode H14, and so on. Similar concept is used for V_{RRM}.

FIGURE 2.20 Details of diode characteristics for diode *V30* selected from Fig. 2.19.

In addition to the above mentioned diode parameters, one should also calculate parameters like the peak forward voltage, reverse recovery time, case and junction temperatures, etc. and check them against the datasheet values. Some of these datasheet values are provided in Fig. 2.20 for the selected diode V30. Figures 2.21–2.23 give the standard experimental relationships between voltages, currents, power, and case temperatures for our selected V30 diode. These characteristics help a designer to understand the safe operating area for the diode, and to make a decision whether or not to use a snubber or a heat sink. If one is particularly interested in the actual reverse recovery time measurement, the circuit given in Fig. 2.24 can be constructed and experimented upon.

Power Bipolar Transistors

Marcelo Godoy Simoes, Ph.D.

Engineering Division, Colorado School of Mines, Golden, Colorado, USA

3.1 Introduction

The first transistor was discovered in 1948 by a team of physicists at the Bell Telephone Laboratories and soon became a semiconductor device of major importance. Before the transistor, amplification was achieved only with vacuum tubes. Even though there are now integrated circuits with millions of transistors, the flow and control of all the electrical energy still require single transistors. Therefore, power semiconductors switches constitute the heart of modern power electronics. Such devices should have larger voltage and current ratings, instant turn-on and turn-off characteristics, very low voltage drop when fully on, zero leakage current in blocking condition, ruggedness to switch highly inductive loads which are measured in terms of safe operating area (SOA) and reverse-biased second breakdown (ES/b), high temperature and radiation withstand capabilities, and high reliability. The right combination of such features restrict the devices suitability to certain applications. Figure 3.1 depicts voltage and current ranges, in terms of frequency, where the most common power semiconductors devices can operate.

The plot gives actually an overall picture where power semiconductors are typically applied in industries: high voltage and current ratings permit applications in large motor drives, induction heating, renewable energy inverters, high voltage DC (HVDC) converters, static VAR compensators, and active filters, while low voltage and high-frequency applications concern switching mode power supplies, resonant converters, and motion control systems, low frequency with high current and voltage devices are restricted to cycloconverter-fed and multimegawatt drives.

Power-npn or -pnp bipolar transistors are used to be the traditional component for driving several of those industrial applications. However, insulated gate bipolar transistor (IGBT) and metal oxide field effect transistor (MOSFET) technology have progressed so that they are now viable replacements for the bipolar types. Bipolar-npn or -pnp transistors still have performance areas in which they may be still used, for example they have lower saturation voltages over the operating temperature range, but they are considerably slower, exhibiting long turn-on and turn-off times. When a bipolar transistor is used in a totem-pole circuit the most difficult design aspects to overcome are the based drive circuitry. Although bipolar transistors have lower input capacitance than that of MOSFETs and IGBTs, they are current driven. Thus, the drive circuitry must generate high and prolonged input currents.

The high input impedance of the IGBT is an advantage over the bipolar counterpart. However, the input capacitance is also high. As a result, the drive circuitry must rapidly charge and discharge the input capacitor of the IGBT during the transition time. The IGBTs low saturation voltage performance is analogous to bipolar power-transistor performance, even over the operating-temperature range. The IGBT requires a −5 to 10 V gate–emitter voltage transition to ensure reliable output switching.

The MOSFET gate and IGBT are similar in many areas of operation. For instance, both devices have high input impedance, are voltage-driven, and use less silicon than the bipolar power transistor to achieve the same drive performance. Additionally, the MOSFET gate has high input capacitance, which places the same requirements on the gate-drive circuitry as the IGBT employed at that stage. The IGBTs
FIGURE 3.1 Power semiconductor operating regions; (a) voltage vs frequency and (b) current vs frequency.

outperform MOSFETs when it comes to conduction loss vs supply-voltage rating. The saturation voltage of MOSFETs is considerably higher and less stable over temperature than that of IGBTs. For such reasons, during the 1980s, the insulated gate bipolar transistor took the place of bipolar junction transistors (BJTs) in several applications. Although the IGBT is a cross between the bipolar and MOSFET transistor, with the output switching and conduction characteristics of a bipolar transistor, but voltage-controlled like a MOSFET, early IGBT versions were prone to latch up, which was largely eliminated. Another characteristic with some IGBT types is the negative temperature coefficient, which can lead to thermal runaway and making the paralleling of devices hard to effectively achieve. Currently, this problem is being addressed in the latest generations of IGBTs.

It is very clear that a categorization based on voltage and switching frequency are two key parameters for determining whether a MOSFET or IGBT is the better device in an application. However, there are still difficulties in selecting a component for use in the crossover region, which includes voltages of 250–1000 V and frequencies of 20–100 kHz. At voltages below 500 V, the BJT has been entirely replaced by MOSFET in power applications and has been also displaced in higher voltages, where new designs use IGBTs. Most of regular industrial needs are in the range of 1–2 kV blocking voltages, 200–500 A conduction currents, and switching speed of 10–100 ns. Although on the last few years, new high voltage projects displaced BJTs towards IGBT, and it is expected to see a decline in the number of new power system designs that incorporate BJTs, there are still some applications for BJTs; in addition the huge built-up history of equipments installed in industries make the BJT yet a lively device.

3.2 Basic Structure and Operation

The bipolar junction transistor (BJT) consists of a three-region structure of n-type and p-type semiconductor materials, it
FIGURE 3.2 Structure of a planar bipolar junction transistor.

can be constructed as npn as well as pnp. Figure 3.2 shows the physical structure of a planar npn BJT. The operation is closely related to that of a junction diode where in normal conditions the pn junction between the base and collector is forward-biased ($V_{BE} > 0$) causing electrons to be injected from the emitter into the base. Since the base region is thin, the electrons travel across arriving at the reverse-biased base–collector junction ($V_{BC} < 0$) where there is an electric field (depletion region). Upon arrival at this junction the electrons are pulled across the depletion region and draw into the collector. These electrons flow through the collector region and out the collector contact. Because electrons are negative carriers, their motion constitutes positive current flowing into the external collector terminal. Even though the forward-biased base–emitter junction injects holes from base to emitter they do not contribute to the collector current but result in a net current flow component into the base from the external base terminal. Therefore, the emitter current is composed of those two components: electrons destined to be injected across the base–emitter junction, and holes injected from the base into the emitter. The emitter current is exponentially related to the base–emitter voltage by the equation:

$$i_E = i_{E0}(e^{V_{BE}/\eta V_T} - 1) \tag{3.1}$$

where i_E is the saturation current of the base–emitter junction which is a function of the doping levels, temperature, and the area of the base–emitter junction, V_T is the thermal voltage Kt/q, and η is the emission coefficient. The electron current arriving at the collector junction can be expressed as a fraction α of the total current crossing the base–emitter junction

$$i_C = \alpha i_E \qquad (3.2)$$

Since the transistor is a three terminals device, i_E is equal to $i_C + i_B$, hence the base current can be expressed as the remaining fraction

$$i_B = (1 - \alpha)i_E \qquad (3.3)$$

The collector and base currents are thus related by the ratio

$$\frac{i_C}{i_B} = \frac{\alpha}{1 - \alpha} = \beta \qquad (3.4)$$

The values of α and β for a given transistor depend primarily on the doping densities in the base, collector, and emitter regions, as well as on the device geometry. Recombination and temperature also affect the values for both parameters. A power transistor requires a large blocking voltage in the off state and a high current capability in the on state, and a vertically oriented four layers structures as shown in Fig. 3.3 is preferable because it maximizes the cross-sectional area through which the current flows, enhancing the on-state resistance and power dissipation in the device. There is an intermediate collector region with moderate doping, the emitter region is controlled so as to have an homogenous electrical field.

Optimization of doping and base thickness are required to achieve high breakdown voltage and amplification capabilities.
FIGURE 3.3   Power transistor vertical structure.

Power transistors have their emitters and bases interleaved to reduce parasitic ohmic resistance in the base current path and also improving the device for second breakdown failure. The transistor is usually designed to maximize the emitter periphery per unit area of silicon, in order to achieve the highest current gain at a specific current level. In order to ensure those transistors have the greatest possible safety margin, they are designed to be able to dissipate substantial power and, thus, have low thermal resistance. It is for this reason, among others, that the chip area must be large and that the emitter periphery per unit area is sometimes not optimized. Most transistor manufacturers use aluminum metalization, since it has many attractive advantages, among these are ease of application by vapor deposition and ease of definition by photolithography. A major problem with aluminum is that only a thin layer can be applied by normal vapor deposition techniques. Thus, when high currents are applied along the emitter fingers, a voltage drop occurs along them, and the injection efficiency on the portions of the periphery that are furthest from the emitter contact is reduced. This limits the amount of current each finger can conduct. If copper metalization is substituted for aluminum, then it is possible to lower the resistance from the emitter contact to the operating regions of the transistors (the emitter periphery).

From a circuit point of view, the Eqs. (3.1)–(3.4) are used to relate the variables of the BJT input port (formed by base (B) and emitter (E)) to the output port (collector (C) and emitter (E)). The circuit symbols are shown in Fig. 3.4. Most of the power electronics applications use npn transistor because electrons move faster than holes, and therefore, npn transistors have considerable faster commutation times.
FIGURE 3.4   Circuit symbols: (a) npn transistor and (b) pnp transistor.

3.3 Static Characteristics

Device static ratings determine the maximum allowable limits of current, voltage, and power dissipation. The absolute voltage limit mechanism is concerned to the avalanche such that thermal runaway does not occur. Forward current ratings are specified at which the junction temperature does not exceed a rated value, so leads and contacts are not evaporated. Power dissipated in a semiconductor device produces
FIGURE 3.5   Family of current–voltage characteristic curves: (a) base–emitter input port and (b) collector–emitter output port.

a temperature rise and are related to the thermal resistance. A family of voltage–current characteristic curves is shown in Fig. 3.5. Figure 3.5a shows the base current i_B plotted as a function of the base–emitter voltage V_{BE} and Fig. 3.5b depicts the collector current i_C as a function of the collector–emitter voltage V_{CE} with i_B as the controlling variable.

Figure 3.5 shows several curves distinguished each other by the value of the base current. The active region is defined where flat, horizontal portions of voltage–current curves show "constant" i_C current, because the collector current does not change significantly with V_{CE} for a given i_B. Those portions are used only for small signal transistor operating as linear amplifiers. Switching power electronics systems on the other hand require transistors to operate in either the saturation region where V_{CE} is small or in the cut off region where the current is zero and the voltage is uphold by the device. A small base current drives the flow of a much larger current between collector and emitter, such gain called beta (Eq. (3.4)) depends upon temperature, V_{CE} and i_C. Figure 3.6 shows current gain increase with increased collector voltage; gain falls off at both high and low current levels.
FIGURE 3.6   Current gain depends on temperature, V_{CE} and i_C.
FIGURE 3.7   Darlington connected BJTs.

High voltage BJTs typically have low current gain, and hence Darlington connected devices, as indicated in Fig. 3.7 are commonly used. Considering gains β_1 and β_2 for each one of those transistors, the Darlington connection will have an increased gain of $\beta_1 + \beta_2 + \beta_1\beta_2$, diode D_1 speedsup the turn-off process, by allowing the base driver to remove the stored charge on the transistor bases.

Vertical structure power transistors have an additional region of operation called quasi-saturation, indicated in the characteristics curve of Fig. 3.8. Such feature is a consequence of the lightly doped collector drift region where the collector–base junction supports a low reverse bias. If the transistor enters in the hard-saturation region the on-state power dissipation is minimized, but has to be traded off with the fact that in quasi-saturation the stored charges are smaller. At high collector currents beta gain decreases with increased temperature and with quasi-saturation operation such negative feedback allows careful device paralleling. Two mechanisms on microelectronic level determine the fall off in beta, namely
FIGURE 3.8 Voltage–current characteristics for a vertical power transistor.

FIGURE 3.9 Forward-bias safe operating area (FBSOA).

FIGURE 3.10 Reverse-bias safe operating area (RBSOA).

conductivity modulation and emitter crowding. One can note that there is a region called primary breakdown due to conventional avalanche of the C–B junction and the attendant large flow of current. The BV_{SUS} is the limit for primary breakdown, it is the maximum collector–emitter voltage that can be sustained across the transistor when it is carrying high collector current. The BV_{SUS} is lower than BV_{CEO} or BV_{CBO} which measure the transistor's voltage standoff capability when the base current is zero or negative. The bipolar transistor have another potential failure mode called second breakdown, which shows as a precipitous drop in the collector–emitter voltage at large currents. Because the power dissipation is not uniformly spread over the device but it is rather concentrated on regions make the local gradient of temperature can rise very quickly. Such thermal runaway brings hot spots which can eventually melt and recrystallize the silicon resulting in the device destruction. The key to avoid second breakdown is to (1) keep power dissipation under control, (2) use a controlled rate of change of base current during turn-off, (3) use of protective snubbers circuitry, and (4) positioning the switching trajectory within the safe operating area (SOA) boundaries.

In order to describe the maximum values of current and voltage, to which the BJT should be subjected two diagrams, are used: the forward-bias safe operating area (FBSOA) given in Fig. 3.9 and the reverse-bias safe operating area (RBSOA) shown in Fig. 3.10. In the FBSOA the current I_{CM} is the maximum current of the device, there is a boundary defining the maximum thermal dissipation and a margin defining the second breakdown limitation. Those regions are expanded for switching mode operation. Inductive load generates a higher peak energy at turn-off than its resistive counterpart. It is then possible to have a secondary breakdown failure if RBSOA is exceeded. A reverse base current helps cut off characteristics expanding RBSOA. The RBSOA curve shows that for voltages below V_{CEO} the safe area is independent of reverse bias voltage V_{EB} and is only limited by the device collector current, whereas above V_{CEO} the collector current must be
under control depending upon the applied reverse-bias voltage, in addition temperature effects derates the SOA. Ability for the transistor to switch high currents reliably is thus determined by its peak power handling capabilities. This ability is dependent upon the transistor's current and thermal density throughout the active region. In order to optimize the SOA capability, the current density and thermal density must be low. In general, it is the hot spots occurring at the weakest area of the transistor that will cause a device to fail due to second breakdown phenomena. Although a wide base width will limit the current density across the base region, good heat sinking directly under the collector will enable the transistor to withstand high peak power. When the power and heat are spread over a large silicon area, all of these destructive tendencies are held to a minimum, and the transistor will have the highest SOA capability.

When the transistor is on, one can ignore the base current losses and calculate the power dissipation on the on state (conduction losses) by Eq. (3.5). Hard saturation minimizes

collector–emitter voltage, decreasing on-state losses.

$$P_{ON} = I_C V_{CE(sat)} \qquad (3.5)$$

3.4 Dynamic Switching Characteristics

Switching characteristics are important to define the device velocity in changing from conduction (on) to blocking (off) states. Such transition velocity is of paramount importance also because most of the losses are due to high-frequency switching. Figure 3.11 shows typical waveforms for a resistive load. Index "r" refers to the rising time (from 10 to 90% of maximum value), for example t_{ri} is the current rise time which depends upon the base current. The falling time is indexed by "f"; the parameter t_{fi} is the current falling time, i.e. when the transistor is blocking such time corresponds to crossing from the saturation to the cut off state. In order to improve t_{fi} the base current for blocking must be negative and the device must be kept in quasi-saturation to minimize the stored charges. The delay time is denoted by t_d, corresponding to the time to discharge the capacitance of base–emitter junction, which can be reduced with a larger current base with high slope. Storage time (t_s) is a very important parameter for BJT transistor, it is the required time to neutralize the carriers stored in the collector and base. Storage time and switching losses are key points to deal extensively with bipolar power transistors. Switching losses occur at both turn-on and turn-off and for high frequency operation the rising and falling times for voltage and current transitions play important role as indicated by Fig. 3.12.

A typical inductive load transition is indicated in Fig. 3.13. The figure indicates a turn-off transition. Current and voltage are interchanged at turn-on and an approximation based upon on straight line switching intervals (resistive load) gives the

FIGURE 3.12   Inductive load switching characteristics.

switching losses by Eq. (3.6).

$$P_s = \frac{V_S I_M}{2} \tau f_s \qquad (3.6)$$

where τ is the period of the switching interval, and V_S and I_M are the maximum voltage and current levels as shown in Fig. 3.10.

Most advantageous operation is achieved when fast transitions are optimized. Such requirement minimizes switching losses. Therefore, a good bipolar drive circuit highly influences the transistor performance. A base drive circuit should provide a high forward base drive current (I_{B1}) as indicated in Fig. 3.14 to ensure the power semiconductor turn-on quickly. Base drive current should keep the BJT fully saturated to minimize forward conduction losses, but a level I_{B2} would maintain the transistor in quasi-saturation avoiding excess of charges

FIGURE 3.11   Resistive load dynamic response.
FIGURE 3.13 Turn-off voltage and current switching transition: (a) inductive load and (b) resistive load.
FIGURE 3.14 Recommended base current for BJT driving.

in base. Controllable slope and reverse current I_{BR} sweeps out stored charges in the transistor base, speeding up the device turn-off.

3.5 Transistor Base Drive Applications

A plethora of circuits have been suggested to successfully command transistors for operating in power electronics switching systems. Such base drive circuits try to satisfy the following requirements: supply the right collector current, adapt the base current to the collector current, and extract a reverse current from base to speed up the device blocking. A good base driver reduces the commutation times and total losses, increasing efficiency and operating frequency. Depending upon the grounding requirements between the control and the power circuits, the base drive might be isolated or non-isolated types. Fig. 3.15 shows a non-isolated circuit. When T_1 is switched on T_2 is driven and diode D_1 is forward-biased providing a reverse-bias keeping T_3 off. The base current I_B is positive and saturates the power transistor T_P. When T_1 is switched off, T_3 switches on due to the negative path provided by R_3, and $-V_{CC}$, providing a negative current for switching off the power transistor T_P.

When a negative power supply is not provided for the base drive, a simple circuit like Fig. 3.16 can be used in low power applications (step per motors, small dc–dc converters, relays, pulsed circuits). When the input signal is high, T_1 switches on and a positive current goes to T_P keeping the capacitor charged with the zener voltage, when the input signal goes low
FIGURE 3.15 Non-isolated base driver.
FIGURE 3.16 Base command without negative power supply.
FIGURE 3.17 Antisaturation diodes (Baker's clamp) improve power transistor storage time.

FIGURE 3.18 Isolated base drive circuit.

T_2 provides a path for the discharge of the capacitor, imposing a pulsed negative current from the base–emitter junction of T_P.

A combination of large reverse base drive and antisaturation techniques may be used to reduce storage time to almost zero. A circuit called Baker's clamp may be employed as illustrated in Fig. 3.17. When the transistor is on, its base is two diode drops below the input. Assuming that diodes D_2 and D_3 have a forward-bias voltage of about 0.7 V, then the base will be 1.4 V below the input terminal. Due to diode D_1 the collector is one diode drop, or 0.7 V below the input. Therefore, the collector will always be more positive than the base by 0.7 V, staying out of saturation, and because collector voltage increases, the gain β also increases a little bit. Diode D_4 provides a negative path for the reverse base current. The input base current can be supplied by a driver circuit similar to the one discussed in Fig. 3.15.

Several situations require ground isolation, off-line operation, floating transistor topology, in addition safety needs may call for an isolated base drive circuit. Numerous circuits have been demonstrated in switching power supplies isolated topologies, usually integrating base drive requirements with their power transformers. Isolated base drive circuits may provide either constant current or proportional current excitation. A very popular base drive circuit for floating switching transistor is shown in Fig. 3.18. When a positive voltage is impressed on the secondary winding (V_S) of T_{R1} a positive current flows into the base of the power transistor T_P which switches on (resistor R_1 limits the base current). The capacitor C_1 is charged by (V_S–V_{D1}–V_{BE}) and T_1 is kept blocked because the diode D_1 reverse biases T_1 base–emitter. When V_S is zipped off, the capacitor voltage V_C brings the emitter of T_1 to a negative potential with respect to its base. Therefore, T_1 is excited so as to switch on and start pulling a reverse current from T_P base. Another very effective circuit is shown in Fig. 3.19 with a
FIGURE 3.19 Transformer coupled base drive with tertiary winding transformer.

minimum number of components. The base transformer has a tertiary winding which uses the energy stored in the transformer to generate the reverse base current during the turn-off command. Other configurations are also possible by adding to the isolated circuits the Baker clamp diodes, or zener diodes with paralleled capacitors.

Sophisticated isolated base drive circuits can be used to provide proportional base drive currents where it is possible to control the value of β, keeping it constant for all collector currents leading to shorter storage time. Figure 3.20 shows one of the possible ways to realize a proportional base drive circuit. When transistor T_1 turns on, the transformer T_{R1} is in negative saturation and the power transistor T_P is off. During the time that T_1 is on, a current flows through winding N_1, limited by resistor R_1, storing energy in the transformer,
FIGURE 3.20 Proportional base drive circuit.

holding it into saturation. When the transistor T_1 turns off, the energy stored in N_1 is transferred to winding N_4, pulling the core from negative to positive saturation. The windings N_2 and N_4 will withstand as a current source, the transistor T_P will stay on and the gain β will be imposed by the turns ratio given by Eq. (3.7).

$$\beta = \frac{N_4}{N_2} \tag{3.7}$$

In order to use the proportional drive given in Fig. 3.20 careful design of the transformer must be done, so as to have flux balanced which will keep core under saturation. The transistor gain must be somewhat higher than the value imposed by the transformer turns ratio, which requires cautious device matching.

The most critical portion of the switching cycle occurs during transistor turn-off, since normally reverse base current is made very large in order to minimize storage time, such conditions may avalanche the base–emitter junction leading to destruction. There are two options to prevent this from happening: turning off the transistor at low values of collector–emitter voltage (which is not practical in most of the applications) or reducing collector current with rising collector voltage, implemented by *RC* protective networks called snubbers. Therefore, an *RC* snubber network can be used to divert the collector current during the turn-off improving the RBSOA in addition the snubber circuit dissipates a fair amount of switching power relieving the transistor. Figure 3.21 shows a turn-off snubber network; when the power transistor is off, the capacitor C is charged through diode D_1. Such collector current flows temporarily into the capacitor as the collector-voltage rises; as the power transistor turns on,
FIGURE 3.21 Turn-off snubber network.

the capacitor discharges through the resistor R back into the transistor.

It is not possible to fully develop all the aspects regarding simulation of BJT circuits. Before giving an example some comments are necessary regarding modeling and simulation of BJT circuits. There are a variety of commercial circuit simulation programs available on the market, extending from a set of functional elements (passive components, voltage controlled current sources, semiconductors) which can be used to model devices, to other programs with the possibility of

implementation of algorithm relationships. Those streams are called subcircuit (building auxiliary circuits around a SPICE primitive) and mathematical (deriving models from internal device physics) methods. Simulators can solve circuit equations exactly, given models for the non-linear transistors, and predict the analog behavior of the node voltages and currents in continuous time. They are costly in computer time and such programs have not been written to usually serve the needs of designing power electronic circuits, rather for designing low-power and low-voltage electronic circuits. Therefore, one has to decide which approach should be taken for incorporating BJT power transistor modeling, and a trade-off between accuracy and simplicity must be considered. If precise transistor modeling are required subcircuit oriented programs should be used. On the other hand, when simulation of complex power electronic system structures, or novel power electronic topologies are devised, the switch modeling should be rather simple, by taking in consideration fundamental switching operations, and a mathematical oriented simulation program should be used.

3.6 SPICE Simulation of Bipolar Junction Transistors

SPICE is a general-purpose circuit program that can be applied to simulate electronic and electrical circuits and predict the circuit behavior. SPICE was originally developed at the Electronics Research Laboratory of the University of California, Berkeley (1975), the name stands for: Simulation Program for Integrated Circuits Emphasis. A circuit must be specified in terms of element names, element values, nodes, variable parameters, and sources. SPICE can do several types of circuit analyses:

- Non-linear dc analysis, calculating the dc transference.
- Non-linear transient analysis: calculates signals as a function of time.
- Linear ac analysis: computes a bode plot of output as a function of frequency.
- Noise analysis.
- Sensitivity analysis.
- Distortion analysis.
- Fourier analysis.
- Monte-Carlo analysis.

In addition, PSpice has analog and digital libraries of standard components such as operational amplifiers, digital gates, flip-flops. This makes it a useful tool for a wide range of analog and digital applications. An input file, called source file, consists of three parts: (1) data statements, with description of the components and the interconnections, (2) control statements, which tells SPICE what type of analysis to perform on the circuit, and (3) output statements, with specifications of what

outputs are to be printed or plotted. Two other statements are required: the title statement and the end statement. The title statement is the first line and can contain any information, while the end statement is always .END. This statement must be a line be itself, followed by a carriage return. In addition, there are also comment statements, which must begin with an asterisk (*) and are ignored by SPICE. There are several model equations for BJTs.

SPICE has built-in models for the semiconductor devices, and the user need to specify only the pertinent model parameter values. The model for the BJT is based on the integral-charge model of Gummel and Poon. However, if the Gummel–Poon parameters are not specified, the model reduces to piecewise-linear Ebers-Moll model as depicted in Fig. 3.22. In either case, charge-storage effects, ohmic resistances, and a current-dependent output conductance may be included. The forward gain characteristics is defined by the parameters I_S and B_F, the reverse characteristics by I_S and B_R. Three ohmic resistances R_B, R_C, and R_E are also included. The two diodes are modeled by voltage sources, exponential equations of Shockley can be transformed into logarithmic ones. A set of device model parameters is defined on a separate .MODEL card and assigned a unique model name. The device element cards in SPICE then reference the model name. This scheme lessens the need to specify all of the model parameters on each device element card. Parameter values are defined by appending the parameter name, as given below for each model type, followed by an equal sign and the parameter value. Model parameters that are not given a value are assigned the default values given below for each model type. As an example, the

Figure 3.23 shows a BJT buck chopper. The dc input voltage is 12 V, the load resistance R is 5 Ω, the filter inductance L is 145.84 μH, and the filter capacitance C is 200 μF. The chopping frequency is 25 kHz and the duty cycle of the chopper is 42% as indicated by the control voltage statement (V_G). The listing below plots the instantaneous load current (I_O), the input current (I_S), the diode voltage (V_D), the output voltage (V_C), and calculate the Fourier coefficients of the input current (I_S). It is suggested for the careful reader to have more details and enhancements on using SPICE for simulations on specialized literature and references.

3.7 BJT Applications

Bipolar junction power transistors are applied to a variety of power electronic functions, switching mode power supplies, dc motor inverters, PWM inverters just to name a few. To conclude the present chapter, three applications are next illustrated.

A flyback converter is exemplified in Fig. 3.24. The switching transistor is required to withstand the peak collector voltage at turn-off and peak collector currents at turn-on. In order to limit the collector voltage to a safe value, the duty cycle must be kept relatively low, normally below 50%, i.e. 6. < 0.5. In practice, the duty cycle is taken around 0.4, which limits the peak collector. A second design factor which the transistor must meet is the working collector current at turn-on, dependent on the primary transformer-choke peak current, the primary-to-secondary turns ratio, and the output load current. When the transistor turns on the primary current builds up in the primary winding, storing energy, as the transistor turns off, the diode at the secondary winding is forward biasing, releasing such stored energy into the output capacitor and load. Such transformer operating as a coupled inductor is actually defined as a transformer-choke. The design of the transformer-choke of the flyback converter must be done carefully to avoid saturation because the operation is unidirectional on the *B–H* characteristic curve.

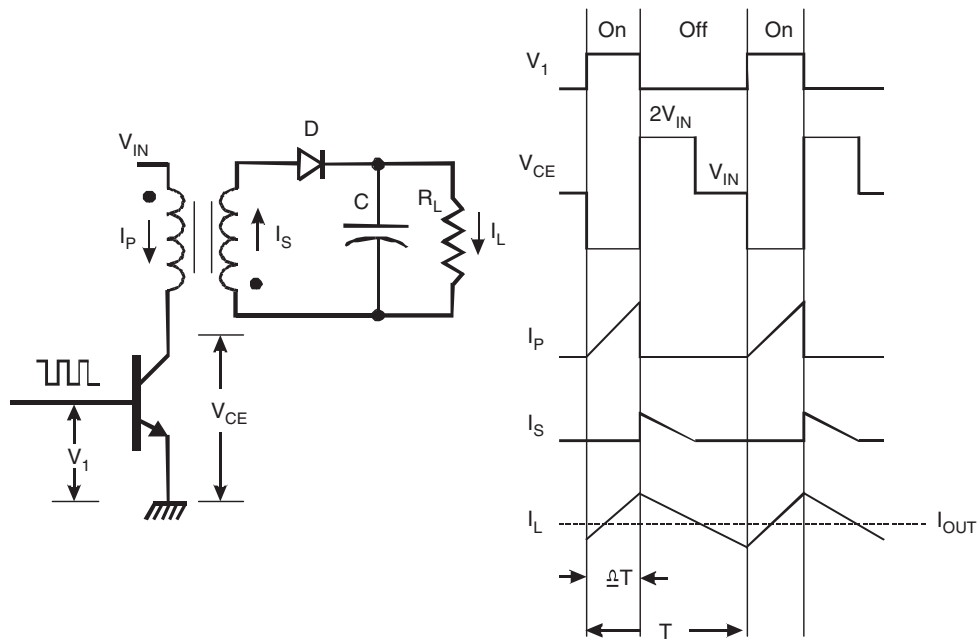
Therefore, a core with a relatively large volume and air gap must be used. An advantage of the flyback circuit is the simplicity by which a multiple output switching power supply may


FIGURE 3.24   Flyback converter.
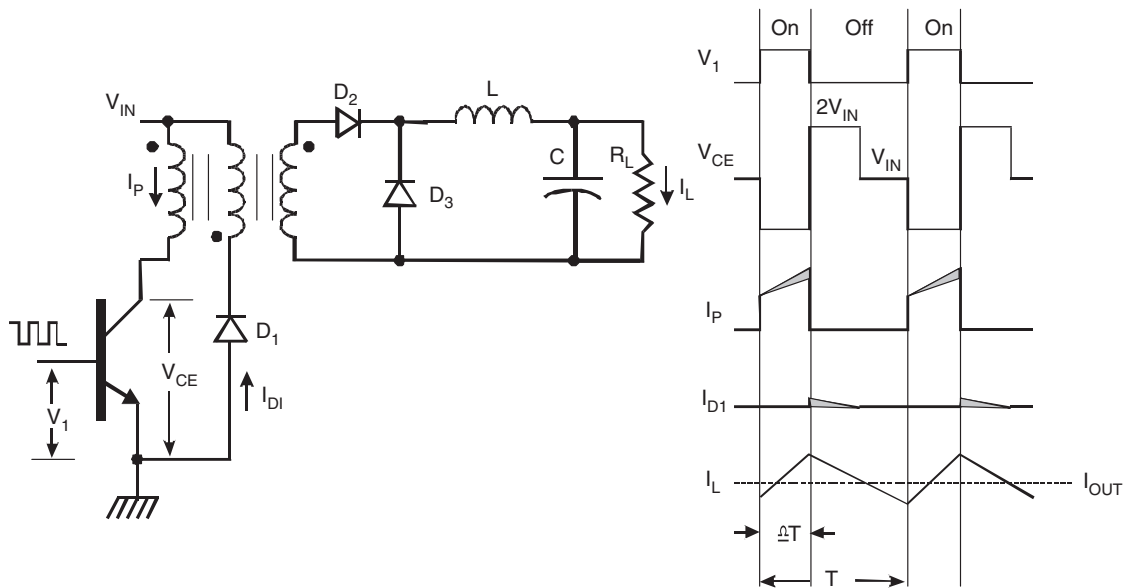

FIGURE 3.25   Isolated forward converter.

be realized. This is because the isolation element acts as a common choke to all outputs, thus only a diode and a capacitor are needed for an extra output voltage.

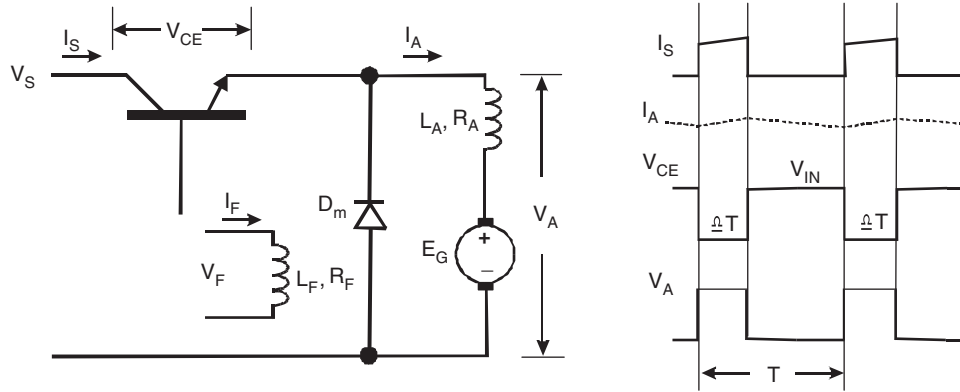
Figure 3.25 shows the basic forward converter and its associated waveforms. The isolation element in the forward converter is a pure transformer which should not store energy, and therefore, a second inductive element L is required at the output for proper and efficient energy transfer. Notice that the primary and secondary windings of the transformer have the same polarity, i.e. the dots are at the same winding ends. When the transistor turns on, current builds up in the primary winding. Because of the same polarity of the transformer secondary winding, such energy is forward transferred to the output and also stored in inductor L through diode D_2 which is forward-biased. When the transistor turns off, the transformer winding voltage reverses, back-biasing diode D_2


FIGURE 3.26   Chopper-fed dc drive.

and the flywheel diode D_3 is forward-biased, conducting current in the output loop and delivering energy to the load through inductor *L*. The tertiary winding and diode D, provide transformer demagnetization by returning the transformer magnetic energy into the output dc bus. It should be noted that the duty cycle of the switch must be kept below 50%, so that when the transformer voltage is clamped through the tertiary winding, the integral of the volt-seconds between the input voltage and the clamping level balances to zero. Duty cycles above 50%, i.e. 6 > 0.5, will upset the volt-seconds balance, driving the transformer into saturation, which in turn produces high collector current spikes that may destroy the switching transistor. Although the clamping action of the tertiary winding and the diode limit the transistor peak collector voltage to twice the dc input, care must be taken during construction to couple the tertiary winding tightly to the primary (bifilar wound) to eliminate voltage spikes caused by leakage inductance.

Chopper drives are connected between a fixed-voltage dc source and a dc motor to vary the armature voltage. In addition to armature voltage control, a dc chopper can provide regenerative braking of the motors and can return energy back to the supply. This energy-saving feature is attractive to transportation systems as mass rapid transit (MRT), chopper drives are also used in battery electric vehicles. A dc motor can be operated in one of the four quadrants by controlling the armature or field voltages (or currents). It is often required to reverse the armature or field terminals in order to operate the motor in the desired quadrant. Figure 3.26 shows a circuit arrangement of a chopper-fed dc separately excited motor. This is a one-quadrant drive, the waveforms for the armature voltage, load current, and input current are also shown. By varying the duty cycle, the power flow to the motor (and speed) can be controlled.

The Power MOSFET

Issa Batarseh, Ph.D.

School of Electrical Engineering and Computer Science, University of Central Florida, 4000 Central Florida Blvd., Orlando, Florida, USA

4.1 Introduction

In this chapter, an overview of power MOSFET (metal oxide semiconductor field effect transistor) semiconductor switching devices will be given. The detailed discussion of the physical structure, fabrication, and physical behavior of the device and packaging is beyond the scope of this chapter. The emphasis here will be given on the terminal i–v switching characteristics of the available device, turn-on, and turn-off switching characteristics, PSPICE modeling and its current, voltage, and switching limits. Even though, most of today's available semiconductor power devices are made of silicon or germanium materials, other materials such as gallium arsenide, diamond, and silicon carbide are currently being tested.

One of the main contributions that led to the growth of the power electronics field has been the unprecedented advancement in the semiconductor technology, especially with respect to switching speed and power handling capabilities. The area of power electronics started by the introduction of the silicon controlled rectifier (SCR) in 1958. Since then, the field has grown in parallel with the growth of the power semiconductor device technology. In fact, the history of power electronics is very much connected to the development of switching devices and it emerged as a separate discipline when high power bipolar junction transistors (BJTs) and MOSFETs devices where introduced in the 1960s and 1970s. Since then, the introduction of new devices has been accompanied with dramatic improvement in power rating and switching

performance. Because of their functional importance, drive complexity, fragility, cost, power electronic design engineer must be equipped with the thorough understanding of the device operation, limitation, drawbacks, and related reliability and efficiency issues.

In the 1980s, the development of power semiconductor devices took an important turn when new process technology was developed that allowed the integration of MOS and BJT technologies on the same chip. Thus far, two devices using this new technology have been introduced: integrated gate bipolar transistor (IGBT) and MOS controlled thyristor (MCT). Many of the IC processing methods and equipment have been adopted for the development of power devices. However, unlike microelectronic IC's which process information, power devices IC's process power, hence, their packaging and processing techniques are quite different. Power semiconductor devices represent the "heart" of modern power electronics, with two major desirable characteristics of power semiconductor devices that guided their development are: the *switching speed* and *power handling capabilities.*

The improvement of semiconductor processing technology along with manufacturing and packaging techniques has allowed power semiconductor development for high voltage and high current ratings and fast turn-*on* and turn-*off* characteristics. Today, switching devices are manufactured with amazing power handling capabilities and switching speeds as will be shown later. The availability of different devices with different switching speed, power handling capabilities, size, cost, ... etc. make it possible to cover many power

electronics applications. As a result, trade-offs are made when it comes to selecting power devices.

4.2 Switching in Power Electronic Circuits

As stated earlier, the heart of any power electronic circuit is the semiconductor-switching network. The question arises here is do we have to use switches to perform electrical power conversion from the source to the load? The answer of course is no, there are many circuits which can perform energy conversion without switches such as linear regulators and power amplifiers. However, the need for using semiconductor devices to perform conversion functions is very much related to the converter efficiency. In power electronic circuits, the semiconductor devices are generally operated as switches, i.e. either in the *on*-state or the *off*-state. This is unlike the case in power amplifiers and linear regulators where semiconductor devices operate in the linear mode. As a result, very large amount of energy is lost within the power circuit before the processed energy reaches the output. The need to use semiconductor switching devices in power electronic circuits is their ability to control and manipulate very large amounts of power from the input to the output with a relatively very low power dissipation in the switching device. Hence, resulting in a very high efficient power electronic system.

Efficiency is considered as an important figure of merit and has significant implications on the overall performance of the system. Low efficient power systems means large amounts of power being dissipated in a form of heat, resulting in one or more of the following implications:

1. Cost of energy increases due to increased consumption.
2. Additional design complications might be imposed, especially regarding the design of device heat sinks.
3. Additional components such as heat sinks increase cost, size, and weight of the system, resulting in low power density.
4. High power dissipation forces the switch to operate at low switching frequency, resulting in limited bandwidth, slow response, and most importantly, the size and weight of magnetic components (inductors and transformers), and capacitors remain large. Therefore, it is always desired to operate switches at very high frequencies. But, we will show later that as the switching frequency increases, the average switching power dissipation increases. Hence, a trade-off must be made between reduced size, weight, and cost of components vs reduced switching power dissipation, which means inexpensive low switching frequency devices.
5. Reduced component and device reliability.

For more than forty years, it has been shown that in order to achieve high efficiency, switching (mechanical or electrical) is the best possible way to accomplish this. However, unlike mechanical switches, electronic switches are far more superior because of their speed and power handling capabilities as well as reliability.

We should note that the advantages of using switches don't come at no cost. Because of the nature of switch currents and voltages (square waveforms), normally high order harmonics are generated in the system. To reduce these harmonics, additional input and output filters are normally added to the system. Moreover, depending on the device type and power electronic circuit topology used, driver circuit control and circuit protection can significantly increase the complexity of the system and its cost.

EXAMPLE 4.1 The purpose of this example is to investigate the efficiency of four different power circuits whose functions are to take in power from 24 volts dc source and deliver a 12 volts dc output to a 6 Ω resistive load. In other words, the tasks of these circuits are to serve as *dc transformer* with a ratio of 2:1. The four circuits are shown in Fig. 4.1a–d representing voltage divider circuit, zener-regulator, transistor linear regulator, and switching circuit, respectively. The objective is to calculate the efficiency of those four power electronic circuits.

SOLUTION.

Voltage Divider DC Regulator The first circuit is the simplest forming a voltage divider with $R = R_L = 6\,\Omega$ and $V_o = 12$ volts. The efficiency defined as the ratio of the average load power, P_L, to the average input power, P_{in}

$$\eta = \frac{P_L}{P_{in}}\%$$

$$= \frac{R_L}{R_L + R}\% = 50\%$$

In fact efficiency is simply $V_o/V_{in}\%$. As the output voltage becomes smaller, the efficiency decreases proportionally.

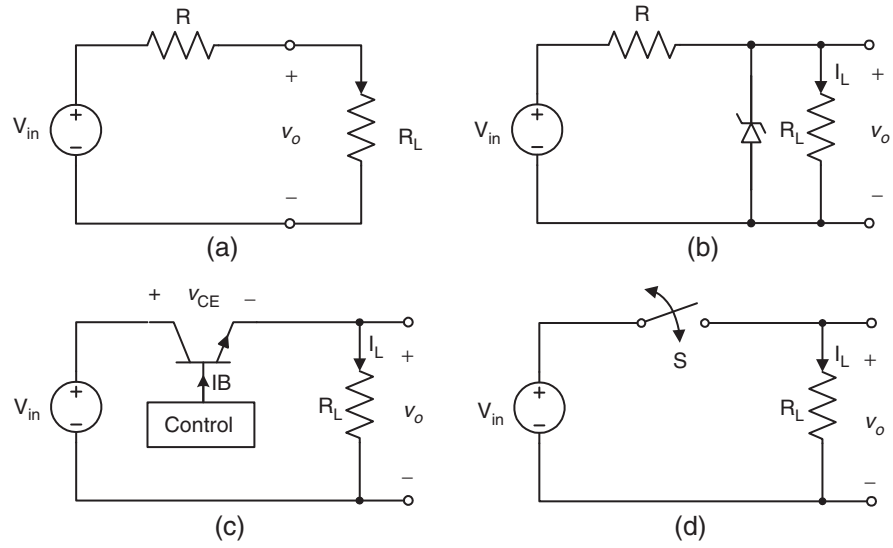
Zener DC Regulator Since the desired output is 12 V, we select a zener diode with zener breakdown $V_Z = 12$ V. Assume the zener diode has the *i–v* characteristic shown in Fig. 4.1e since $R_L = 6\,\Omega$, the load current, I_L, is 2 A. Then we calculate R for $I_Z = 0.2$ A (10% of the load current). This results in $R = 5.27\,\Omega$. Since the input power is $P_{in} = 2.2\,\text{A} \times 24\,\text{V} = 52.8\,\text{W}$ and the output power is $P_{out} = 24\,\text{W}$. The efficiency of


FIGURE 4.1   (a) Voltage divider; (b) zener regulator; (c) transistor regulator; (d) switching circuit; (e) *i–v* zener diode characteristics; and (f) switching waveform for S and corresponding output waveform.

the circuit is given by,

$$\eta = \frac{24\,\text{W}}{52.8\,\text{W}}\%$$

$$= 45.5\%$$

Transistor DC Regulator   It is clear from Fig. 4.1c that for $V_o = 12\,\text{V}$, the collector emitter voltage must be around $12\,\text{V}$. Hence, the control circuit must provide base current, I_B to put the transistor in the active mode with $V_{CE} \approx 12\,\text{V}$. Since the load current is $2\,\text{A}$, then collector current is approximately $2\,\text{A}$ (assume small I_B). The total power dissipated in the transistor can be approximated by the following equation:

$$P_{diss} = V_{CE}I_C + V_{BE}I_B$$

$$\approx V_{CE}I_C \approx 12 \times 2 = 24\,\text{watts}$$

Therefore, the efficiency of the circuit is 50%.

Switching DC Regulator   Let us consider the switching circuit of Fig. 4.1d by assuming the switch is ideal and periodically turned *on* and *off* is shown in Fig. 4.1f. The output voltage waveform is shown in Fig. 4.1f. Even though the output voltage is not constant or pure dc, its average value is given by,

$$V_{o,ave} = \frac{1}{T} \int_0^{T_0} V_{in}\,dt = V_{in}D$$

where D is the duty ratio equals the ratio of the on-time to the switching period. For $V_{o,ave} = 12\,\text{V}$, we set $D = 0.5$, i.e. the switch has a duty cycle of 0.5 or 50%. In case, the average output power is $48\,\text{W}$ and the average input power is also $48\,\text{W}$, resulting in 100% efficiency! This is of course because we assumed the switch is ideal. However, let us assume a BJT switch is used in the above circuit with $V_{CE,sat} = 1\,\text{V}$ and I_B is small, then the average power loss across the switch is approximately $2\,\text{W}$, resulting in overall efficiency of 96%. Of course the switching circuit given in this example is over simplified, since the switch requires additional driving circuitry that was not shown, which also dissipates some power. But still, the example illustrates that high efficiency can be acquired by switching power electronic circuits when compared to the efficiency of linear power electronic circuits. Also, the difference between the linear circuit in Figs. 4.1b and c and the switched circuit of Fig. 4.1d is that the power delivered to the load in the later case in pulsating between zero and $96\,\text{watts}$. If the application calls for constant power delivery with little output voltage ripple, then an LC filter must be added to smooth out the output voltage.

The final observation is regarding what is known as load regulation and line regulation. The line regulation is defined as the ratio between the change in output voltage, ΔV_o, with respect to the change in the input voltage ΔV_{in}. This is a very important parameter in power electronics since the dc input voltage is obtained from a rectified line voltage that normally changes by $\pm 20\%$. Therefore, any off-line power electronics circuit must have a limited or specified range of line regulation. If we assume the input voltage in Figs. 4.1a,b is changed by $2\,\text{V}$, i.e. $\Delta V_{in} = 2\,\text{V}$, with R_L unchanged, the corresponding change in the output voltage ΔV_o is $1\,\text{V}$ and $0.55\,\text{V}$, respectively. This is considered very poor line regulation. Figures 4.1c,d have much better line and load regulations since the closed-loop control compensate for the line and load variations.

4.3 General Switching Characteristics

4.3.1 The Ideal Switch

It is always desired to have the power switches perform as close as possible to the ideal case. Device characteristically speaking, for a semiconductor device to operate as an ideal switch, it must possess the following features:

1. No limit on the amount of current (known as forward or reverse current) the device can carry when in the conduction state (*on*-state);
2. No limit on the amount of the device-voltage ((known as forward or reverse blocking voltage) when the device is in the non-conduction state (*off*-state);
3. Zero *on*-state voltage drop when in the conduction state;
4. Infinite *off*-state resistance, i.e. zero leakage current when in the non-conduction state; and
5. No limit on the operating speed of the device when changes states, i.e. zero rise and fall times.

The switching waveforms for an ideal switch is shown in Fig. 4.2, where i_{sw} and v_{sw} are the current through and the voltage across the switch, respectively.

Both during the switching and conduction periods, the power loss is zero, resulting in a 100% efficiency, and with no switching delays, an infinite operating frequency can be achieved. In short, an ideal switch has infinite speed, unlimited power handling capabilities, and 100% efficiency. It must be noted that it is not surprising to find semiconductor-switching devices that can almost, for all practical purposes, perform as ideal switches for number of applications.
FIGURE 4.2 Ideal switching current, voltage, and power waveforms.

4.3.2 The Practical Switch

The practical switch has the following switching and conduction characteristics:

1. Limited power handling capabilities, i.e. limited conduction current when the switch is in the *on*-state, and limited blocking voltage when the switch is in the *off*-state.
2. Limited switching speed that is caused by the finite turn-*on* and turn-*off* times. This limits the maximum operating frequency of the device.
3. Finite *on*-state and *off*-state resistance's i.e. there exists forward voltage drop when in the *on*-state, and reverse current flow (leakage) when in the off-state.
4. Because of characteristics 2 and 3 above, the practical switch experiences power losses in the on and the off states (known as conduction loss), and during switching transitions (known as switching loss). Typical switching waveforms of a practical switch are shown in Fig. 4.3a.

The average switching power and conduction power losses can be evaluated from these waveforms. We should point out the exact practical switching waveforms vary from one device to another device, but Fig. 4.3a is a reasonably good representation. Moreover, other issues such as temperature dependence,

power gain, surge capacity, and over voltage capacity must be considered when addressing specific devices for specific applications. A useful plot that illustrates how switching takes place from *on* to *off* and vice versa is what is called *switching trajectory*, which is simply a plot of i_{sw} vs v_{sw}. Figure 4.3b shows several switching trajectories for the ideal and practical cases under resistive loads.

EXAMPLE 4.2 Consider a linear approximation of Fig. 4.3a as shown in Fig. 4.4a: (a) Give a possible circuit implementation using a power switch whose switching waveforms are shown in Fig. 4.4a, (b) Derive the expressions for the instantaneous switching and conduction power losses and sketch them, (c) Determine the total average power dissipated in the circuit during one switching frequency, and (d) The maximum power.

SOLUTION. (a) First let us assume that the turn-on time, t_{on}, and turn-off time, t_{off}, the conduction voltage V_{ON}, and the leakage current, I_{OFF}, are part of the switching characteristics of the switching device and have nothing to do with circuit topology.

When the switch is *off*, the blocking voltage across the switch is V_{OFF} that can be represented as a dc voltage source of value V_{OFF} reflected somehow across the switch during the *off*-state. When the switch is *on*, the current through the switch equals I_{ON}, hence, a dc current is needed in series with the switch when it is in the *on*-state. This suggests that when the switch turns *off* again, the current in series with the switch must be diverted somewhere else (this process is known as *commutation*). As a result, a second switch is needed to carry the main current from the switch being investigated when it's switched *off*. However, since i_{sw} and v_{sw} are linearly related as shown in Fig. 4.4b, a resistor will do the trick and a second switch is not needed. Figure 4.4 shows a one-switch implementation with S, the switch and R represents the switched-load.

(b) The instantaneous current and voltage waveforms during the transition and conduction times are given as follows

$$i_{sw}(t) = \begin{cases} \dfrac{t}{t_{ON}}(I_{ON} - I_{OFF}) + I_{OFF} & 0 \le t \le t_{ON} \\ I_{ON} & t_{ON} \le t \le T_s - t_{OFF} \\ -\dfrac{t - T_s}{t_{OFF}}(I_{ON} - I_{OFF}) + I_{OFF} & T_s - t_{OFF} \le t \le T_s \end{cases}$$

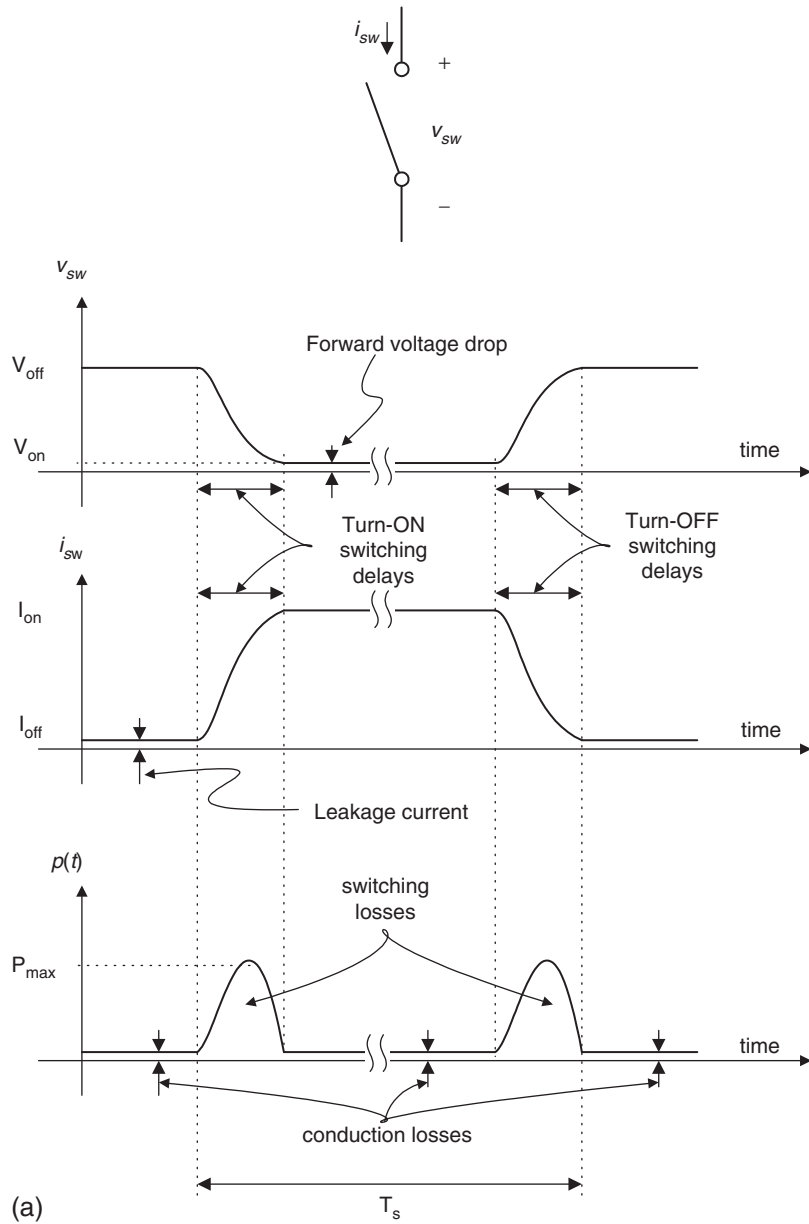
$$v_{sw}(t) = \begin{cases} -\dfrac{V_{OFF} - V_{ON}}{t_{ON}} \\ \quad \times (t - t_{ON}) + V_{ON} & 0 \le t \le t_{ON} \\ V_{ON} & t_{ON} \le t \le T_s - t_{OFF} \\ \dfrac{V_{OFF} - V_{ON}}{t_{OFF}} \\ \quad \times \left(t - (T_s - t_{OFF})\right) + V_{ON} & T_s - t_{OFF} \le t \le T_s \end{cases}$$


FIGURE 4.3 (a) Practical switching current, voltage, and power waveforms and (b) switching trajectory.
FIGURE 4.4   Linear approximation of typical current and voltage switching waveforms.

It can be shown that if we assume $I_{ON} \gg I_{OFF}$ and $V_{OFF} \gg V_{ON}$, then the instantaneous power, $p(t) = i_{sw} v_{sw}$ can be given as follows,

$$
p(t) = \begin{cases}
-\dfrac{V_{OFF} I_{ON}}{t_{ON}^2}(t - t_{ON})\, t & 0 \le t \le t_{ON} \\[2mm]
V_{ON} I_{ON} & t_{ON} \le t \le T_s - t_{OFF} \\[2mm]
-\dfrac{V_{OFF} I_{ON}}{t_{OFF}^2}(t - (T_s - t_{OFF}))\,(t - T_s) & T_s - t_{OFF} \le t \le T_s
\end{cases}
$$

Figure 4.4c shows a plot of the instantaneous power where the maximum power during turn-on and off is $V_{OFF} I_{ON}/4$.

(c) The total average dissipated power is given by

$$
\begin{aligned}
P_{ave} &= \frac{1}{T_s}\int_0^{T_s} p(t)\,dt = \frac{1}{T_s}\Bigg[\int_0^{t_{ON}} -\frac{V_{OFF} I_{ON}}{t_{ON}^2}(t - t_{ON})t\, dt \\[2mm]
&\quad + \int_{t_{ON}}^{T_s - t_{OFF}} V_{ON} I_{ON}\, dt \\[2mm]
&\quad + \int_{T_s - t_{OFF}}^{T_s} -\frac{V_{OFF} I_{ON}}{t_{OFF}^2}(t - (T_s - t_{OFF}))(t - T_s)\, dt \Bigg]
\end{aligned}
$$

The evaluation of the above integral gives

$$P_{ave} = \frac{V_{OFF}I_{ON}}{T_s}\left(\frac{t_{ON} + t_{OFF}}{6}\right)$$
$$+ \frac{V_{ON}I_{ON}}{T_s}(T_s - t_{OFF} - t_{ON})$$

The first expression represents the total switching loss, whereas the second expression represents the total conduction loss over one switching cycle. We notice that as the frequency increases, the average power increases linearly. Also the power dissipation increases with the increase in the forward conduction current and the reverse blocking voltage.

(d) The maximum power occurs at the time when the first derivative of $p(t)$ during switching is set to zero, i.e.

$$\left.\frac{dp(t)}{dt}\right|_{t=t_{max}} = 0$$

solve the above equation for t_{max}, we obtain values at turn on and off, respectively,

$$t_{max} = \frac{t_{rise}}{2}$$

$$t_{max} = T - \frac{t_{fall}}{2}$$

Solving for the maximum power, we obtain

$$P_{max} = \frac{V_{off}I_{on}}{4}$$

FIGURE 4.5 Device symbols: (a) n-channel enhancement-mode; (b) p-channel enhancement-mode; (c) n-channel depletion-mode; and (d) p-channel depletion-mode.

4.4 The Power MOSFET

Unlike the bipolar junction transistor (BJT), the MOSFET device belongs to the *Unipolar Device family, since it uses only the majority carriers in conduction.* The development of the metal oxide semiconductor technology for microelectronic circuits opened the way for developing the power metal oxide semiconductor field effect transistor (MOSFET) device in 1975. Selecting the most appropriate device for a given application is not an easy task, requiring knowledge about the device characteristics, its unique features, innovation, and engineering design experience. Unlike low power (signal devices), power devices are more complicated in structure, driver design, and understanding of their operational *i–v* characteristics. This knowledge is very important for power electronics engineer to design circuits that will make these devices close to ideal. The device symbol for a p- and n-channel enhancement and depletion types are shown in Fig. 4.5. Figure 4.6 shows the *i–v* characteristics for the

n-channel enhancement-type MOSFET. It is the fastest power switching device with switching frequency more than 1 MHz, with voltage power ratings up to 1000 V and current rating as high as 300 A.

MOSFET regions of operations will be studied shortly.

4.4.1 MOSFET Structure

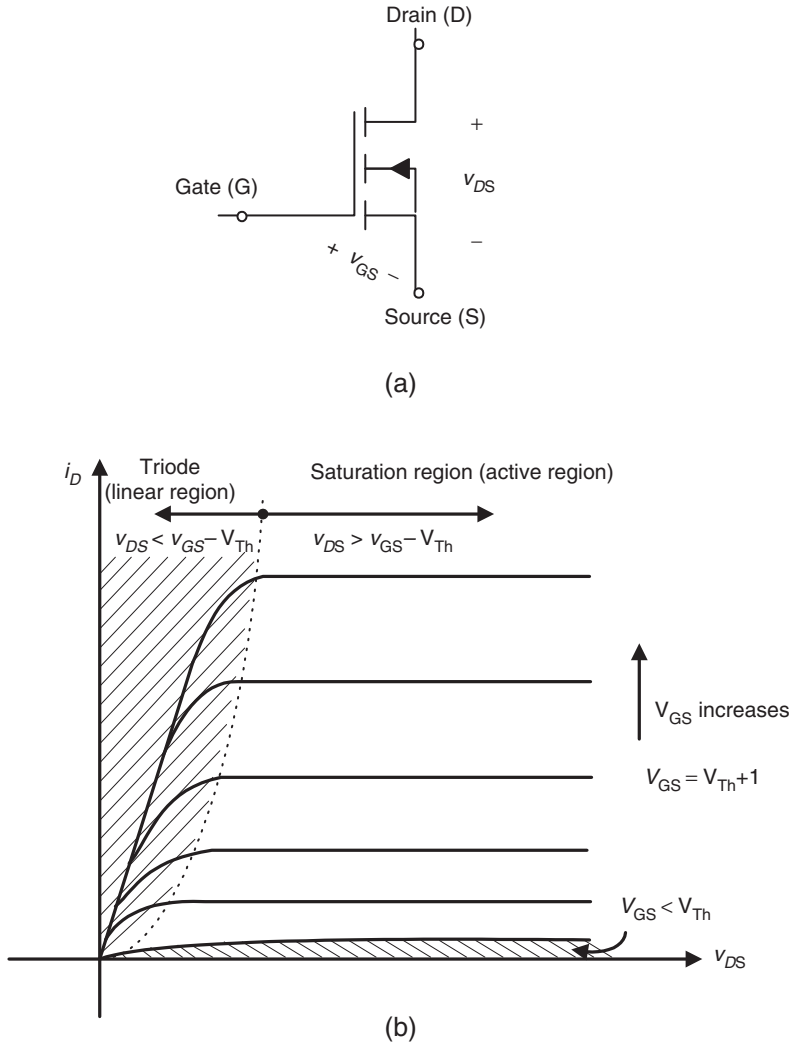
Unlike the lateral channel MOSFET devices used in many IC technology in which the gate, source, and drain terminals are located in the same surface of the silicon wafer, power MOSFET use vertical channel structure in order to increase the device power rating [1]. In the vertical channel structure, the source and drain are in opposite side of the silicon waver. Figure 4.7a shows vertical cross-sectional view for a power MOSFET. Figure 4.7b shows a more simplified representation. There are several discrete types of the vertical structure power MOSFET available commercially today such as V-MOSFET,


FIGURE 4.6   (a) n-Channel enhancement-mode MOSFET and (b) its i_D vs v_{DS} characteristics.

U-MOSFET, D-MOSFET, and S-MOSFET [1, 2]. The P–N junction between p-base (also referred to as body or bulk region) and the n-drift region provide the forward voltage blocking capabilities. The source metal contact is connected directly to the p-base region through a break in the n$^+$ source region in order to allow for a fixed potential to p-base region during the normal device operation. When the gate and source terminal are set the same potential ($V_{GS} = 0$), no channel is established in the p-base region, i.e. the channel region remain unmodulated. The lower doping in the n-drift region is needed in order to achieve higher drain voltage blocking capabilities. For the drain–source current, I_D, to flow, a conductive path must be established between the n$^+$ and n$^-$ regions through the p-base diffusion region.

A. On-state Resistance   When the MOSFET is in the on-state (triode region), the channel of the device behaves like a

constant resistance, $R_{DS(on)}$, that is linearly proportional to the change between v_{DS} and i_D as given by the following relation:

$$R_{DS(ON)} = \frac{\partial v_{DS}}{\partial i_D}\Big|_{V_{GS}=Constant} \tag{4.1}$$

The total conduction (on-state) power loss for a given MOSFET with forward current I_D and on-resistance $R_{DS(on)}$ is given by,

$$P_{on,diss} = I_D^2 R_{DS(on)} \tag{4.2}$$

The value of $R_{DS(on)}$ can be significant and it varies between tens of milliohms and a few ohms for low-voltage and high-voltage MOSFETS, respectively. The *on*-state resistance is an important data sheet parameter, since it determines the forward voltage drop across the device and its total power losses.

(b)

FIGURE 4.7 (a) Vertical cross-sectional view for a power MOSFET and (b) simplified representation.

(a)

(b)

FIGURE 4.8 (a) MOSFET Internal body diode and (b) implementation of a fast body diode.

Unlike the current-controlled bipolar device, which requires base current to allow the current to flow in the collector, the power MOSFET device is a voltage-controlled unipolar device and requires only a small amount of input (gate) current. As a result, it requires less drive power than the BJT. However, it is a non-latching current like the BJT i.e. a gate source voltage must be maintained. Moreover, since only majority carriers contribute to the current flow, MOSFETs surpass all other devices in switching speed with switching speeds exceeding a few megahertz. Comparing the BJT and the MOSFET, the BJT has higher power handling capabilities and smaller switching speed, while the MOSFET device has less power handling capabilities and relatively fast switching speed. The MOSFET device has higher *on*-state resistor than the bipolar transistor. Another difference is that the BJT parameters are more sensitive to junction temperature when compared to the MOSFET, and unlike the BJT, MOSFET devices do not suffer from second breakdown voltages, and sharing current in parallel devices is possible.

B. Internal Body Diode The modern power MOSFET has an internal diode called a body diode connected between the source and the drain as shown in Fig. 4.8a. This diode provides a reverse direction for the drain current, allowing a bi-directional switch implementation. Even though the MOSFET body diode has adequate current and switching speed ratings, in some power electronic applications that require the use of ultra-fast diodes, an external fast recovery diode is added in anti-parallel fashion after blocking the body diode by a slow recovery diode as shown in Fig. 4.8b.

C. Internal Capacitors Another important parameter that effect the MOSFET's switching behavior is the parasitic capacitance between the device's three terminals, namely, gate-to-source, C_{gs}, gate-to-drain, C_{gd}, and drain-to-source (C_{ds}) capacitance as shown in Fig. 4.9a. Figure 4.9b shows the physical representation of these capacitors. The values of these capacitances are non-linear and a function of device structure, geometry, and bias voltages. During turn on, capacitor C_{gd} and C_{gs} must be charged through the gate, hence, the design

FIGURE 4.9 (a) Equivalent MOSFET representation including junction capacitances and (b) representation of this physical location.

In power electronics, the aim is to use power-switching devices to operate at higher and higher frequencies. Hence, size and weight associated with the output transformer, inductors, and filter capacitors will decrease. As a result, MOSFETs are used extensively in power supply design that requires high switching frequencies including switching and resonant mode power supplies and brushless dc motor drives. Because of its large conduction losses, its power rating is limited to a few kilowatts. Because of its many advantages over the BJT devices, modern MOSFET devices have received high market acceptance.

4.4.2 MOSFET Regions of Operation

Most of the MOSFET devices used in power electronics applications are of the n-channel, enhancement-type like that which is shown in Fig. 4.6a. For the MOSFET to carry drain current, a channel between the drain and the source must be created. This occurs when the gate-to-source voltage exceeds the device threshold voltage, V_{Th}. For $v_{GS} > V_{Th}$, the device can be either in the triode region, which is also called "constant resistance" region, or in the saturation region, depending on the value of v_{DS}. For given v_{GS}, with small $v_{DS}(v_{DS} < v_{GS} - V_{Th})$, the device operates in the triode region(saturation region in the BJT), and for larger $v_{DS}(v_{DS} > v_{GS} - V_{Th})$, the device enters the saturation region (active region in the BJT). For $v_{GS} < V_{Th}$, the device turns off, with drain current almost equals zero. Under both regions of operation, the gate current is almost zero. This is why the MOSFET is known as a voltage-driven device, and therefore, requires simple gate control circuit.

The characteristic curves in Fig. 4.6b show that there are three distinct regions of operation labeled as triode region, saturation region, and cut-off-region. When used as a switching device, only triode and cut-off regions are used, whereas, when it is used as an amplifier, the MOSFET must operate in the saturation region, which corresponds to the active region in the BJT.

The device operates in the cut-off region (off-state) when $v_{GS} < V_{Th}$, resulting in no induced channel. In order to operate the MOSFET in either the triode or saturation region, a channel must first be induced. This can be accomplished by applying gate-to-source voltage that exceeds V_{Th}, i.e.

of the gate control circuit must take into consideration the variation in this capacitance (Fig. 4.9b). The largest variation occurs in the gate-to-drain capacitance as the drain-to-gate voltage varies. The MOSFET parasitic capacitance are given in terms of the device data sheet parameters C_{iss}, C_{oss}, and C_{rss} as follows,

$$C_{gd} = C_{rss}$$

$$C_{gs} = C_{iss} - C_{rss}$$

$$C_{ds} = C_{oss} - C_{rss}$$

where C_{rss} = small-signal reverse transfer capacitance.
   C_{iss} = small-signal input capacitance with the drain and source terminals are shorted.
   C_{oss} = small-signal output capacitance with the gate and source terminals are shorted.

The MOSFET capacitances C_{gs}, C_{gd}, and C_{ds} are non-linear and function of the dc bias voltage. The variations in C_{oss} and C_{iss} are significant as the drain-to-source and gate-to-source voltages cross zero, respectively. The objective of the drive circuit is to charge and discharge the gate-to-source and gate-to-drain parasitic capacitance to turn *on* and *off* the device, respectively.

$$v_{GS} > V_{Th}$$

Once the channel is induced, the MOSFET can either operate in the triode region (when the channel is continuous with no pinch-off, resulting in the drain current proportioned to the channel resistance) or in the saturation region (the channel pinches off, resulting in constant I_D). The gate-to-drain bias voltage (v_{GD}) determines whether the induced channel enter pinch-off or not. This is subject to the following restriction.

For triode mode of operation, we have

$$v_{GD} > V_{Th}$$

$$v_{GD} < V_{Th}$$

And for the saturation region of operation,

Pinch-off occurs when $v_{GD} = V_{Th}$.

In terms of v_{DS}, the above inequalities may be expressed as follows:

1. For triode region of operation

$$v_{DS} < v_{GS} - V_{Th} \quad \text{and} \quad v_{GS} > V_{Th} \qquad (4.3)$$

2. For saturation region of operation

$$v_{DS} > v_{GS} - V_{Th} \quad \text{and} \quad v_{GS} > V_{Th} \qquad (4.4)$$

3. For cut-off region of operation

$$v_{GS} < V_{Th} \qquad (4.5)$$

It can be shown that drain current, i_D, can be mathematically approximated as follows:

$$i_D = K[2(v_{GS} - V_{Th})v_{DS} - v_{DS}^2] \quad \text{Triode Region} \qquad (4.6)$$

$$i_D = K(v_{GS} - V_{Th})^2 \qquad \text{Saturation Region} \quad (4.7)$$

where, $\quad K = \dfrac{1}{2}\mu_n C_{OX}\left(\dfrac{W}{L}\right)$

$\quad \mu_n \;\;= $ electron mobility
$\quad C_{OX} = $ oxide capacitance per unit area
$\quad L \;\;\;= $ length of the channel
$\quad W \;\;= $ width of the channel.

Typical values for the above parameters are given in the PSPICE model discussed later. At the boundary between the saturation (active) and triode regions, we have,

$$v_{DS} = v_{GS} - V_{Th} \qquad (4.8)$$

Resulting in the following equation for i_D,

$$i_D = kv_{DS}^2 \qquad (4.9)$$

The input transfer characteristics curve for i_D and v_S. v_{GS} is when the device is operating in the saturation region shown in Fig. 4.10.

The large signal equivalent circuit model for a n-channel enhancement-type MOSFET operating in the saturation mode
FIGURE 4.10   Input transfer characteristics for a MOSFET device when operating in the saturation region.
FIGURE 4.11   Large signal equivalent circuit model.

is shown in Fig. 4.11. The drain current is represented by a current source as the function of V_{Th} and v_{GS}.

If we assume that once the channel is pinched-off, the drain–source current will no longer be constant but rather depends on the value of v_{DS} as shown in Fig. 4.12. The increased value of v_{DS} results in reduced channel length, resulting in a phenomenon known as channel-length modulation [3, 4]. If the v_{DS}–i_D lines are extended as shown in Fig. 4.12, they all intercept the v_{DS}-axis at a single point labeled $-1/\lambda$, where λ is a positive constant MOSFET parameter. The term $(1 + \lambda v_{DS})$ is added to the i_D equation in order to account for the increase in i_D due to the channel-length modulation, i.e. i_D is given by,

$$i_D = k(v_{GS} - V_{Th})^2(1 + \lambda v_{DS}) \quad \text{Saturation Region} \quad (4.10)$$

From the definition of the r_o given in Eq. (4.1), it is easy to show the MOSFET output resistance which can be expressed as follows:

$$r_o = \frac{1}{\lambda k(v_{GS} - V_{Th})} \qquad (4.11)$$

If we assume the MOSFET is operating under small signal condition, i.e. the variation in v_{GS} on i_D vs v_{GS} is in the
FIGURE 4.12   MOSFET characteristics curve including output resistance.

neighborhood of the dc operating point Q at i_D and v_{GS} as shown in Fig. 4.13. As a result, the i_D current source can be represented by the product of the slope g_m and v_{GS} as shown in Fig. 4.14.

4.4.3   MOSFET Switching Characteristics

Since the MOSFET is a majority carrier transport device, it is inherently capable of a high frequency operation [5–8]. But still the MOSFET has two limitations:

1. High input gate capacitances.
2. Transient/delay due to carrier transport through the drift region.

As stated earlier the input capacitance consists of two components: the gate-to-source and gate-to-drain capacitances. The input capacitances can be expressed in terms of the device

FIGURE 4.14   Small-signal equivalent circuit including MOSFET output resistance.

junction capacitances by applying Miller theorem to Fig. 4.15a. Using Miller theorem, the total input capacitance, C_{in}, seen between the gate-to-source is given by,

$$C_{in} = C_{gs} + (1 + g_m R_L)C_{gd} \qquad (4.12)$$

The frequency response of the MOSFET circuit is limited by the charging and discharging times of C_{in}. Miller effect is inherent in any feedback transistor circuit with resistive load that exhibits a feedback capacitance from the input and output. The objective is to reduce the feedback gate-to-drain resistance. The output capacitance between the drain-to-source, C_{ds}, does not affect the turn-on and turn-off MOSFET switching characteristics. Figure 4.16 shows how C_{gd} and C_{gs} vary under increased drain-source, v_{Ds}, voltage.

FIGURE 4.13   Linearized i_D vs v_{GS} curve with operating dc point (Q).
FIGURE 4.15   (a) Small-signal model including parasitic capacitances and (b) equivalent circuit using Miller theorem.
FIGURE 4.16   Variation of C_{gd} and C_{gs} as a function of v_{DS}.

In power electronics applications, the power MOSFETs are operated at high frequencies in order to reduce the size of the magnetic components. In order to reduce the switching losses, the power MOSFETs are maintained in either the on-state (conduction state) or the off-state (forward blocking) state.

It is important we understand the internal device behavior; therefore, the parameters that govern the device transition from the on-state and off-states. To investigate the on and off switching characteristics, we consider the simple power electronic circuit shown in Fig. 4.17a under inductive load.

The fly back diode D is used to pick up the load current when the switch is off. To simplify the analysis we will assume the load inductance is L_0 large enough so that the current through it is constant as shown in Fig. 4.17b.

A. Turn-on Analysis   Let us assume initially the device is off, the load current, I_0, flows through D as shown in the Fig. 4.18a $v_{GG} = 0$. The voltage $v_{DS} = V_{DD}$ and $i_G = i_D$. At $t = t_0$, the voltage v_{GG} is applied as shown in Fig. 4.19a. The voltage across C_{GS} starts charging through R_G. The gate–source voltage, v_{GS}, controls the flow of the drain-to-source current i_D. Let us assume that for $t_0 \leq t < t_1$, $v_{GS} < V_{Th}$, i.e. the MOSFET remains in the cut-off region with $i_D = 0$, regardless of v_{DS}. The time interval (t_1, t_0) represents the delay turn-on time needed to change C_{GS} from zero to V_{Th}. The expression for the time interval $\Delta t_{10} = t_1 - t_0$ can be obtained as follows:

The gate current is given by,

$$i_G = \frac{v_{GG} - v_{GS}}{R_G}$$

$$= i_{C_{GS}} + i_{C_{GD}}$$

$$= C_{GS}\frac{dv_{GS}}{dt} - C_{GD}\frac{d(v_G - v_D)}{dt} \qquad (4.13)$$

where v_G and v_D are gate-to-ground and drain-to-ground voltages, respectively.
(a)
(b)

FIGURE 4.17 (a) Simplified equivalent circuit used to study turn-on and turn-off characteristics of the MOSFET and (b) simplified equivalent circuit.

Since we have $v_G = v_{GS}$, $v_D = +V_{DD}$, then i_G is given by

$$i_G = C_{GS}\frac{dv_{GS}}{dt} + C_{GD}\frac{dv_{GS}}{dt} = (C_{GS} + C_{GD})\frac{dv_{GS}}{dt} \qquad (4.14)$$

From Eqs. (4.13) and (4.14), we obtain,

$$\frac{V_{GG} - v_{GS}}{R_G} = (C_{GS} + C_{GD})\frac{dv_{GS}}{dt} \qquad (4.15)$$

Solving Eq. (4.15) for $v_{GS}(t)$ for $t > t_0$ with $v_{GS}(t_0) = 0$, we obtain,

$$v_{GS}(t) = V_{GG}(1 - e^{(t-t_0)/\tau}) \qquad (4.16)$$
(a)
(b)

FIGURE 4.18 Equivalent modes: (a) MOSFET is in the off-state for $t < t_0$, $v_{GG} = 0$, $v_{DS} = V_{DD}$, $i_G = 0$, $i_D = 0$; (b) MOSFET in the off-state with $v_{GS} < V_{Th}$ for $t_1 > t > t_0$; (c) $v_{GS} > V_{Th}$, $i_D < I_0$ for $t_1 < t < t_2$; (d) $v_{GS} > V_{Th}$, $i_D = I_0$ for $t_2 \le t < t_3$; and (e) $V_{GS} > V_{Th}$, $i_D = I_o$ for $t_3 \le t < t_4$.
(c)
(d)
(e)

FIGURE 4.18 *continued*

where,

$$\tau = R_G(C_{GS} + C_{GD})$$

The gate current, i_G, is given by,

$$i_G = \frac{v_{GG} - v_{GS}}{R_G}$$

$$i_G = \frac{V_{GG}}{R_G} e^{-(t-t_0)/\tau}$$

(4.17)

As long as $v_{GS} < V_{Th}$, i_D remains zero. At $t = t_1$, v_{GS} reaches V_{Th} causing the MOSFET to start conducting. Waveforms for i_G and v_{GS} are shown in Fig. 4.19. The time interval $(t_1 - t_0)$ is given by,

$$\Delta t_{10} = t_1 - t_0 = -\tau \ln\left(1 - \frac{V_{Th}}{V_{GG}}\right)$$

Δt_{10} represents the first delay interval in the turn-on process.

For $t > t_1$ with $v_{GS} > V_{Th}$, the device starts conducting and its drain current is given as a function of v_{GS} and V_{Th}. In fact i_D starts flowing exponentially from zero as shown in Fig. 4.19d. Assume the input transfer characteristics for the MOSFET is limited as shown in Fig. 4.20 with slope of g_m that is given by

$$g_m = \frac{(\partial i_D/\partial v_{GS})}{I_D} = \frac{2\sqrt{I_{DSS}I_D}}{V_{Th}}$$

(4.18)

The drain current can be approximately given as follows:

$$i_D(t) = g_m(v_{GS} - V_{Th})$$

(4.19)

As long as $i_D(t) < I_0$, D remains on and $v_{DS} = V_{DD}$ as shown in Fig. 4.18c.

The equation for $v_{GS}(t)$ remains the same as in Eq. (4.16), hence, Eq. (4.19) results in $i_D(t)$ given by,

$$i_D(t) = g_m(V_{GG} - V_{Th}) - g_m V_{GG} e^{-(t-t_1)/\tau}$$

(4.20)

The gate current continues to decrease exponentially as shown in Fig. 4.19c. At $t = t_2$, i_D reaches its maximum value of I_0, turning D off. The time interval $\Delta t_{21} = (t_2 - t_1)$ is obtained from Eq. (4.20) by setting $i_D(t_2) = I_0$.

$$\Delta t_{21} = \tau \ln\frac{g_m V_{GG}}{g_m(V_{GG} - V_{Th}) - I_0}$$

(4.21)

For $t > t_2$, the diode turns off and $i_D \approx I_0$ as shown in Fig. 4.18d. Since the drain current is nearly a constant, then
FIGURE 4.19   Turn-on waveform switiching.
FIGURE 4.20 Input transfer characteristics.

the gate–source voltage is also constant according to the input transfer characteristic of the MOSFET, i.e.

$$i_D = g_m(v_{GS} - V_{Th}) \approx I_0 \qquad (4.22)$$

Hence,

$$v_{GS}(t) = \frac{I_0}{g_m} + V_{Th} \qquad (4.23)$$

At $t = t_2$, $i_G(t)$ is given by,

$$i_G(t_2) = \frac{V_{GG} - v_{GS}(t_2)}{V_{Th}} = \frac{V_{GG} - (I_0/g_m) - V_{Th}}{V_{Th}} \qquad (4.24)$$

Since the time constant τ is very small, it is safe to assume $v_{GS}(t_2)$ reaches its maximum, i.e.

$$v_{GS}(t_2) \approx V_{GG}$$

and

$$i_G(t_2) \approx 0$$

For $t_2 \leq t < t_3$, the diode turns off the load current I_0 (drain current i_D), which starts discharging the drain-to-source capacitance.

Since v_{GS} is constant, the entire gate current flows through C_{GD}, resulting in the following relation,

$$i_G(t) = i_{C_{GD}}$$

$$= C_{GD}\frac{d(v_G - v_D)}{dt}$$

Since v_G is constant and $v_s = 0$, we have

$$i_G(t) = -C_{GD}\frac{dv_{DS}}{dt}$$

$$= -\frac{V_{GG} - V_{Th}}{R_G}$$

Solving for $v_{DS}(t)$ for $t > t_2$, with $v_{DS}(t_2) = V_{DD}$, we obtain

$$v_{DS}(t) = -\frac{V_{GG} - V_{Th}}{R_G C_{GD}}(t - t_2) + V_{DD} \quad \text{For } t > t_2 \quad (4.25)$$

This is a linear discharge of C_{GD} as shown in Fig. 4.19e

The time interval $\Delta t_{32} = (t_3 - t_2)$ is determined by assuming that at $t = t_3$, the drain-to-source voltage reaches its minimum value determined by its on resistance, $v_{DS}(ON)$ i.e. $v_{DS(ON)}$ is given by,

$$v_{DS(ON)} \approx I_0 r_{DS(ON)}$$

$$= \text{constant}$$

For $t > t_3$, the gate current continues to charge C_{GD} and since v_{DS} is constant, v_{GS} starts charging at the same rate as in interval $t_0 \leq t < t_1$, i.e.

$$v_{GS}(t) = V_{GG}(1 - e^{-(t-t_3)/\tau})$$

The gate voltage keeps increasing exponentially until $t = t_3$ when it reaches V_{GG}, at which $i_G = 0$ and the device fully turns on as shown in Fig. 4.18e.

The equivalent circuit model when the MOSFET is completely turned on is for $t > t_1$. At this time, the capacitors C_{GS} and C_{GD} are charged with V_{GG} and $(I_0 r_{ds(ON)-V_{GG}})$, respectively.

The time interval $\Delta t_{32} = (t_3 - t_2)$ is obtained by evaluating v_{DS} at $t = t_3$ as follows

$$v_{DS}(t_3) = -\frac{V_{GG} - V_{Th}}{R_G C_{GD}}(t_3 - t_2) + V_{DD} \qquad (4.26)$$

$$= I_0 r_{DS(ON)}$$

Hence, $\Delta t_{32} = (t_3 - t_2)$ is given by,

$$\Delta t_{32} = t_3 - t_2 = R_G C_{GD}\frac{(V_{DD} - I_D r_{DS(ON)})}{V_{GG} - V_{Th}} \qquad (4.27)$$

The total delay in turning on the MOSFET is given by

$$t_{ON} = \Delta t_{10} + \Delta t_{21} + \Delta t_{32} \qquad (4.28)$$

Notice the MOSFET sustains high voltage and current simultaneously during intervals Δt_{21} and Δt_{32}. This results in large power dissipation during turn on, that contributes to the overall switching losses. The smaller the R_G, the smaller Δt_{21} and Δt_{32} become.

B.   Turn-off Characteristics   To study the turn-off character-
istic of the MOSFET, we will consider Fig. 4.17b again by
assuming the MOSFET is ON and in steady state at $t > t_0$ with
the equivalent circuit of Fig. 4.18e. Therefore, at $t = t_0$ we have
the following initial conditions.

$$v_{DS}(t_0) = I_D r_{DS(ON)}$$

$$v_{GS}(t_0) = V_{GG}$$

$$i_{DS}(t_0) = I_0$$

$$i_G(t_0) = 0 \tag{4.29}$$

$$v_{C_{GS}}(t_0) = V_{GG}$$

$$v_{C_{GD}}(t_0) = V_{GG} - I_0 r_{DS(ON)}$$

At $t = t_0$, the gate voltage, $v_{GG}(t)$ is reduced to zero as shown in
Fig. 4.21a. The equivalent circuit at $t > t_0$ is shown in Fig. 4.22a.

If we assume the drain-to-source voltage remains constant,
C_{GS} and C_{GD} are discharging through R_G as governed by the
following relations

$$i_G = \frac{-v_G}{R_G} = i_{C_{GS}} + i_{C_{GD}}$$

$$= C_{GS}\frac{dv_{GS}}{dt} + C_{GD}\frac{dv_{GD}}{dt}$$

Since v_{DS} is assumed constant, then i_G becomes,

$$i_G = \frac{-v_{GS}}{R_G}$$

$$= (C_{GS} + C_{GD})\frac{dv_{GS}}{dt} \tag{4.30}$$

Hence, evaluating for v_{GS} for $t \geq t_0$, we obtain

$$v_{GS}(t) = v_{GS}(t_0)e^{-(t-t_0)/\tau} \tag{4.31}$$

where,

$$v_{GS}(t_0) = v_{GG}$$
$$\tau = (C_{GS} + C_{GD})R_G$$

As v_{GS} continues to decrease exponentially, drawing current
from C_{GD} will reach a constant value at which drain current is
fixed, i.e. $I_D = I_0$. From the input transfer characteristics, the
value of v_{GS} when $I_D = I_0$ is given by,

$$v_{GS} = \frac{I_0}{g_m} + V_{Th} \tag{4.32}$$

The time interval $\Delta t_{10} = t_1 - t_0$ can be obtained easily by
setting Eq. (4.31) to (4.32) at $t = t_1$.

The gate current during the $t_2 \leq t < t_1$ is given by

$$i_G = -\frac{V_{GG}}{R_G} - e^{-(t-t_0)/\tau} \tag{4.33}$$

Since, for t_2-t_1, the gate-to-source voltage is constant and
equals $v_{GS}(t_1) = (I_0/g_m) + V_{Th}$ as shown in Fig. 4.21b, then
the entire gate current is being drawn from C_{GD}, hence,

$$i_G = C_{GD}\frac{dv_{GD}}{dt} = C_{GD}\frac{d(v_{GS} - v_{DS})}{dt} = -C_{GD}\frac{dv_{DS}}{dt}$$

$$= \frac{v_{GS}(t_1)}{R_G} = \frac{1}{R_G}\left(\frac{I_0}{g_m} + V_{Th}\right)$$

Assuming i_G constant at its initial value at $t = t_1$, i.e.

$$i_G = \frac{v_{GS}(t_1)}{R_G} = \frac{1}{R_G}\left(\frac{I_0}{g_m} + V_{Th}\right)$$

Integrating both sides of the above equation from t_1 to t with
$v_{DS}(t_1) = -v_{DS(ON)}$, we obtain,

$$v_{DS}(t) = v_{DS(ON)} + \frac{1}{R_G C_{GD}}\left(\frac{I_0}{g_m} + V_{Th}\right)(t - t_1) \tag{4.34}$$

hence, v_{DS} charges linearly until it reaches V_{DD}.

At $t = t_2$, the drain-to-source voltage becomes equal to
V_{DD}, forcing D to turn on as shown in Fig. 4.22c.

The drain-to-source current is obtained from the transfer
characteristics and given by

$$i_{DS}(t) = g_m(v_{GS} - V_{Th})$$

where $v_{GS}(t)$ is obtained from the following equation

$$i_G = -\frac{v_{GS}}{R_G} = (C_{GS} + C_{GD})\frac{dv_{GS}}{dt} \tag{4.35}$$

Integrate both sides from t_2 to t with $v_{GS}(t_2) = (I_0/g_m) + V_{Th}$,
we obtain the following expression for $v_{GS}(t)$,

$$v_{GS}(t) = \left(\frac{I_0}{g_m} + V_{Th}\right)e^{-(t-t_2)/\tau} \tag{4.36}$$

Hence the gate current and drain-to-source current are
given by,

$$i_G(t) = \frac{-1}{R_G}\left(\frac{I_0}{g_m} + V_{Th}\right)e^{-(t-t_2)/\tau} \tag{4.37}$$

$$i_{DS}(t) = g_m V_{Th}(e^{-(t-t_2)/\tau} - 1) + I_0 e^{-(t-t_2)/\tau} \tag{4.38}$$

The time interval between $t_2 \leq t < t_3$ is obtained by
evaluating $v_{GS}(t_3) = V_{Th}$, at which the drain current becomes
FIGURE 4.21   Turn-off switching waveforms.

approximately zero and the MOSFET turn off hence,

$$v_{GS}(t_3) = V_{Th}$$

$$= \left(\frac{I_0}{g_m} + V_{Th}\right) e^{-(t_3 - t_2)/\tau}$$

Solving for $\Delta t_{32} = t_3 - t_2$ we obtain,

$$\Delta t_{32} = t_3 - t_2 = \tau \ln\left(1 + \frac{I_0}{V_{Th}g_m}\right) \quad (4.39)$$

For $t > t_3$, the gate voltage continues to decrease exponentially to zero, at which the gate current becomes zero and C_{GD} charges to $-V_{DD}$. Between t_3 and t_4, I_D discharges to zero as shown in the equivalent circuit Fig. 4.22d.

The total turn-off time for the MOSFET is given by,

$$t_{off} = \Delta t_{10} + \Delta t_{21} + \Delta t_{32} + \Delta t_{43}$$

$$\approx \Delta t_{21} + \Delta t_{32} \quad (4.40)$$

The time intervals that most effect the power dissipation are Δt_{21} and Δt_{32}. It is clear that in order to reduce

the MOSFET t_{on} and t_{off} times, the gate–drain capacitance must be reduced. Readers are encouraged to see the reference by Baliga for detailed discussion on the turn-on and turn-off characteristics of the MOSFET and to explore various fabrication methods.

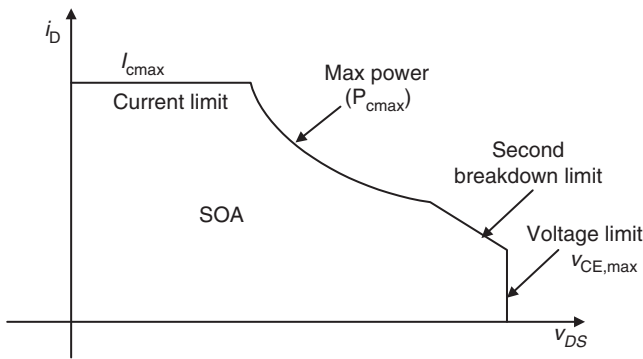
C. Safe Operation Area   The safe operation area (SOA) of a device provides the current and voltage limits. The device must handle to avoid destructive failure. Typical SOA for a MOSFET device is shown in Fig. 4.23. The maximum current limit while the device is on is determined by the maximum


FIGURE 4.23   Safe operation area for MOSFET.
FIGURE 4.25   The on-state resistance as a fraction of temperature.

power dissipation

$$P_{diss,ON} = I_{DS(ON)} R_{DS(ON)}$$

As the drain–source voltage starts increasing, the device starts leaving the on-state and enters the saturation (linear) region. During the transition time, the device exhibits large voltage and current simultaneously. At higher drain–source voltage values that approach the avalanche breakdown it is observed that power MOSFET suffers from second breakdown phenomenon. The second breakdown occurs when the MOSFET is in the blocking state (off) and a further increase in v_{DS} will cause a sudden drop in the blocking voltage. The source of this phenomenon in MOSFET is caused by the presence of a parasitic n-type bipolar transistor as shown in Fig. 4.24.

The inherent presence of the body diode in the MOSFET structure makes the device attractive to application in which bi-directional current flow is needed in the power switches.
FIGURE 4.24   MOSFET equivalent circuit including the parasitic BJT.

Today's commercial MOSFET devices have excellent high operating temperatures. The effect of temperature is more prominent on the on-state resistance as shown in Fig. 4.25.

As the on-state resistance increases, the conduction losses also increase. This large $v_{DS(ON)}$ limits the use of the MOSFET in high voltage applications. The use of silicon carbide instead of silicon has reduced $v_{DS(ON)}$ by many folds.

As the device technology keeps improving in terms of improving switch speeds, increased power handling capabilities, it is expected that the MOSFET will continue to replace BJTs in all types of power electronics systems.

4.4.4 MOSFET PSPICE Model

The PSPICE simulation package has been used widely by electrical engineers as an essential software tool for circuit design. With the increasing number of devices available in the market place, PSPICE allows for the accurate extraction and understanding of various device parameters and their variation effect on the overall design prior to their fabrication. Today's PSPICE library is rich with numerous commercial MOSFET models. This section will give a brief overview of how the MOSFET model is implemented in PSPICE. A brief overview of the PSPICE modeling of the MOSFET device will be given here.

A. PSPICE Static Model   There are four different types of MOSFET models that are also known as *levels*. The simplest MOSFET model is called LEVEL1 model and is shown in Fig. 4.26 [9, 10].

LEVEL2 model uses the same parameters as LEVEL1, but it provides a better model for Ids by computing the model coefficients KP, VTO, LAMBDA, PHI, and GAMMA directly from the geometrical, physical, and technological parameters [10]. LEVEL3 is used to model the short-channel devices and LEVEL4 represents the Berkeley Short-channel IGFET model (BSIM-model).
FIGURE 4.26   PSPICE LEVEL1 MOSFET static model.

The triode region, $v_{GS} > V_{Th}$ and $v_{DS} < v_{GS}$ and $v_{DS} < v_{GS} - V_{Th}$ the drain current is given by,

$$i_D = \frac{K_P}{2} \frac{W}{L - 2X_{jl}} \left(v_{GS} - V_{Th} - \frac{v_{DS}}{2} \right) v_{DS}(1 + \lambda v_{DS})$$

(4.41)

In the saturation (linear) region, where $v_{GS} > V_{Th}$ and $v_{DS} > v_{GS} - V_{Th}$, the drain current is given by

$$I_D = \frac{K_P}{2} \frac{W}{L - 2X_{jl}} (V_{GS} - V_{Th})^2 (1 + \lambda V_{DS})$$

(4.42)

where K_P is the transconductance and X_{jl} is the lateral diffusion.

The threshold voltage, V_{Th}, is given by,

$$V_{Th} = V_{T0} + \partial \left(\sqrt{2\phi_p - V_{BS}} - \sqrt{2\phi_p} \right)$$

(4.43)

where,

V_{T0} = Zero-bias threshold voltage.
δ = Body-effect parameter.
ϕ_p = Surface inversion potential.

Typically, $X_{ij} \ll L$ and $\lambda \approx 0$.

The term $(1 + \lambda V_{DS})$ is included in the model as empirical connection to model the effect of the output conductance when the MOSFET is operating in triode region. λ is known as the channel-length modulation parameter.

When the bulk and source terminals are connected together, i.e. $V_{BS} = 0$, the device threshold voltage equals the zero-bias threshold voltage, i.e.

$$V_{Th} = V_{T0}$$

V_{T0} is positive for the n-channel enhancement-mode devices and negative for the n-channel depletion-mode devices.

The parameters K_P, V_{T0}, δ, ϕ are electrical parameters that can be either specified directly in the MODEL statement under the Pspice keywords KP, VTO, GAMMA, and PHI, respectively, as shown in Table 4.1. They also can be calculated when the geometrical and physical parameters are known. The two-substrate currents that flow from the bulk to the source, I_{BS} and from the bulk to the drain, I_{BD} are simply diode currents, which are given by,

$$I_{BS} = I_{SS} \left(e^{-(V_{BS}/V_T)} - 1 \right)$$

(4.44)

$$I_{BD} = I_{DS} \left(e^{-(V_{BD}/V_T)} - 1 \right)$$

(4.45)

where I_{SS} and I_{DS} are the substrate source and substrate drain saturation currents. These currents are considered equal and given as I_S in the MODEL statement with a default value of 10^{-14} A. Where the equation symbols and their corresponding PSPICE parameter names are shown in Table 4.1.

In PSPICE, a MOSFET device is described by two statements: the first statement start with the letter M and the

TABLE 4.1 PSPICE MOSFET parameters

Symbol	Name	Description	Default	Units
(a) Device dc and parasitic parameters				
Level	LEVEL	Model type (1, 2, 3, or 4)	1	–
V_{TO}	VTO	Zero-bias threshold voltage	0	V
λ	LAMDA	Channel-length modulation [1,2*]	0	v^{-1}

α_F	AF	Flicker noise exponent	0	–

*These numbers indicate that this parameter is available in this level number, otherwise it is available in all levels.

second statement starts with .Model that defines the model used in the first statement. The following syntax is used:

```
M<device_name><Drain_node_number>
<Gate_node_number>
<Source_node_number><Substrate_node number>
<Model_name>
* [<param_1>=<value_1><param_2>=<value_2> ....]
.MODEL <Model_name><type_name>
[(<param_1>=<value_1>
<param_2>=<value_2> .....]
```

where the starting letter "M" in M<device_name> statement indicates that the device is a MOSFET and <device_name>is a user specified label for the given device, the <Model_name> is one of the hundreds of device models specified in the PSPICE library, <Model_name> the same name specified in the device name statement, <type_name> is either NMOS of PMOS, depending on whether the device is n-channel or p-channel MOS, respectively, that follows by optional list of parameter types and their values. The length *L* and the width *W* and other parameters can be specified in the M<device_name>, in the .MODEL or .OPTION statements. User may select not to include any value, and PSPICE will use the specified default values in the model. For normal operation (physical construction of the MOS devices), the source and bulk substrate nodes must be connected together. In all the PSPICE library files, a default parameter values for L, W, AS, AD, PS, PD, NRD, and NDS are included, hence, user should not specify such values in the device "M" statement or in the OPTION statement.

The power MOSFET device PSPICE models include relatively complete static and dynamic device characteristics given in the manufacturing data sheet. In general, the following effects are specified in a given PSPICE model: dc transfer curves, on-resistance, switching delays, and gate drive characteristics and reverse-mode "body-diode" operation. The device characteristics that are not included in the model are noise, latch-ups, maximum voltage, and power ratings. Please see OrCAD Library Files.

> **EXAMPLE 4.3** Let us consider an example of using IRF MOSFET that was connected as shown in Fig. 4.27.
>
> It was decided that the device should have a blocking voltage (V_{DSS}) of 600 V and drain current, i_d, of 3.6 A. The device selected is IRF CC30 with case TO220. This device is listed in PSPICE library under model number IRFBC30 as follows:

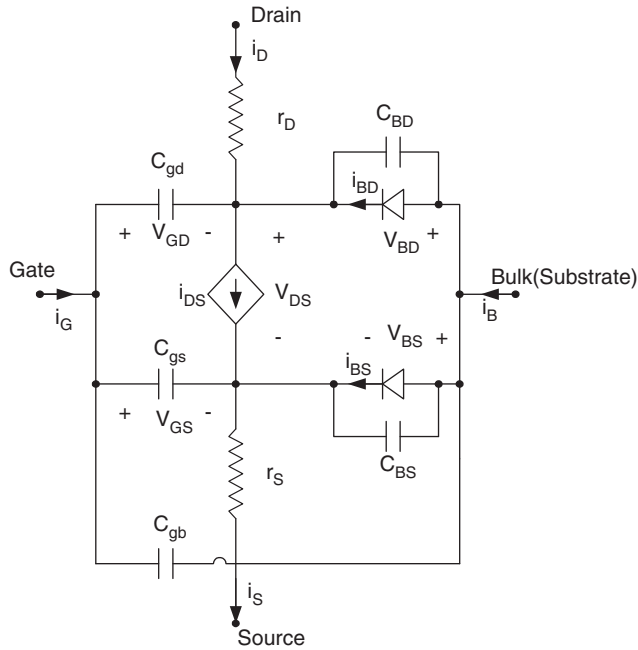
4.4.5 MOSFET Large-signal Model

The equivalent circuit of Fig. 4.28 includes five device parasitic capacitances. The capacitors C_{GB}, C_{GS}, C_{GD}, represent the charge-storage effect between the gate terminal and the bulk, source, and drain terminals, respectively. These are non-linear two-terminal capacitors expressed as function of *W*, *L*, C_{ox}, V_{GS}, V_{T0}, V_{DS}, and C_{GBO}, C_{GSO}, C_{GDO}, where the capacitors C_{GBO}, C_{GSO}, C_{GDO} are outside the channel region, known as overlap capacitances, that exist between the gate electrode and the other three terminals, respectively. Table 4.1 shows the list of PSPICE MOSFET capacitance parameters and their default values. Notice that the PSPICE overlap capacitors keywords (C_{GBO}, C_{GSO}, C_{GDO}) are proportional either to the MOSFET width or length of the channel as follows:

$$C_{GBO} = \frac{C_{GBO}}{L}$$

$$C_{GSO} = \frac{C_{GSO}}{W} \qquad (4.46)$$


$$C_{GDO} = \frac{C_{GDO}}{W}$$

FIGURE 4.28 Large-signal model for the n-channel MOSFET.

FIGURE 4.29 Small-signal equivalent circuit model for MOSFET.

In the triode region, $v_{GS} > v_{DS} - V_{Th}$, the terminal capacitors are given by,

$$C_{GS} = L_W C_{OX} \left[1 - \left(\frac{v_{GS} - v_{DS} - V_{Th}}{2(v_{GS} - V_{Th}) - V_{DS}} \right)^2 \right] + C_{GSO}$$

$$C_{GD} = L_W C_{OX} \left[1 - \left(\frac{v_{GS} - V_{Th}}{2(v_{GS} - V_{Th}) - v_{DS}} \right)^2 \right] + C_{GDO}$$

$$C_{GB} = C_{GBO} L \qquad (4.47)$$

In the saturation (linear) region, we have

$$C_{GS} = \frac{2}{3} L_W C_{OX} + C_{GSO}$$

$$C_{GB} = C_{GB0} L \qquad (4.48)$$

$$C_{GD} = C_{GD0}$$

where C_{OX} is the per-unit-area oxide capacitance given by,

$$C_{OX} = \frac{K_{OX} E_0}{T_{OX}}$$

K_{OX} = Oxide's relative dielectric constant.
E_0 = Free space dielectric constant equals
        8.854×10^{-12} F/m.
T_{OX} = Oxide's thickness layer given as T_{OX} in Table 4.1.

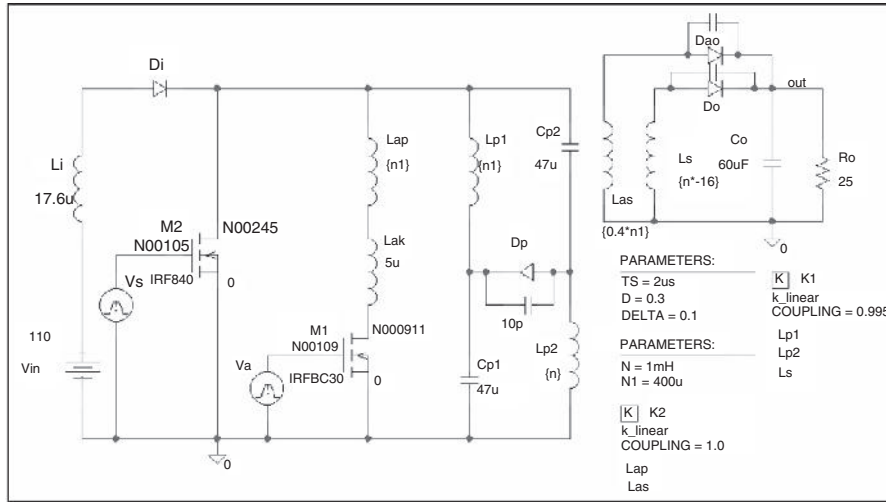
Finally, the diffusion and junction region capacitances between the bulk-to-channel (drain and source) are modeled by C_{BD} and C_{BS} across the two diodes. Because for almost all power MOSFETs, the bulk and source terminals are connected together and at zero potential, diodes D_{BD} and D_{BS} don't have forward bias, resulting in very small conductance values, i.e. small diffusion capacitances. The small-signal model for MOSFET devices is given in Fig. 4.29.

EXAMPLE 4.4 Figure 4.30a shows an example of a soft-switching power factor connection circuit that has two MOSFETs. Its PSPICE simulation waveforms are shown in Fig. 4.30b.

Table 4.2 shows the PSPICE code for Fig. 4.30a.

4.4.6 Current MOSFET Performance

The current focus of MOSFET technology development is much more broad than power handling capacity and switching speed; the size, packaging, and cooling of modern MOSFET technology is a major focus. Of course, the development of higher power and efficiency is still paramount, but as modern electronics have become increasingly smaller, the packaging and cooling of power circuits has become more important. It has been indicated by manufacturers that many of their modern MOSFETs are not limited by their semiconductor, but by the packaging. If the MOSFET cannot properly disperse heat, the device will become overheated, which will lead to failure.

An example of modern MOSFET technology is the DirectFET surface mounted MOSFET manufactured by International Rectifier. Part number IRF6662, for example, can handle 47 A at 100 V, while consuming a board space of


(a)
(b)

FIGURE 4.30   (a) Example of power electronic circuit and (b) PSPICE simulation waveforms.
5 × 6 mm, and being only 0.6 mm thick. This switch is efficient at frequencies greater than 1 MHz, and the packaging can dissipate over 50% more heat than traditional surface mounted MOSFETs of similar power ratings. The power density of this switch is many times the power density of similarly rated devices made by International Rectifier in the past. One major factor in the performance gain of this product line is dual-sided cooling. By designing the package to mount to the board through a large contact patch, and by using materials with high heat conductivity, the switch has a very high surface area vs volume ratio, which allows for the heat to be dissipated through the top heat sink as well as through the circuit board.

Another example of manufacturers that are focusing on packaging and cooling to increase the performance of their products is Vishay's PolarPAK and PowerPAK. These devices have a 65% smaller board surface area than traditional SO-8 packages. Also, the thermal conductivity of the package is 88%

greater than traditional devices. The PolarPAK device increases the performance by cooling the part from the top and the bottom of the package. These advances in packaging and cooling have allowed the devices to have power densities greater than $250\,\text{W/mm}^3$ as well, while maintaining high efficiencies into the megahertz.

Another important characteristic of any solid-state device is the expected service life. For MOSFETs, manufacturers have indicated that the mean time before failure (MTBF) approximately decreases by 50% for every 10°C that the operational temperature increases. For this reason, the current

High freq. – low power	10 V	0.7 A	200 MHz	7 W	21

advancement in cooling and packaging has a direct effect on the longevity of the components. While there are definite increases in device longevity every year, the easiest way to have a large impact on the life of the device is to keep the temperature down.

As development continues, MOSFETs will become smaller, more efficient, higher power density, and higher frequency of operation. As such, MOSFETs will continue to expand into applications that typically use other forms of power switches.

4.5 Future Trends in Power Devices

As stated earlier, depending on the applications, the power range processed in power electronic range is very wide, from hundreds of milliwatts to hundreds of megawatts, therefore, it is very difficult to find a single switching device type to cover all power electronic applications. Today's available power devices have tremendous power and frequency rating range as well as diversity. Their forward current ratings range from a few amperes to a few kiloamperes, blocking voltage rating ranges from a few volts to a few of kilovolts, and switching frequency ranges from a few hundred of hertz to a few megahertz as illustrated in Table 4.3. This table illustrates the relative comparison between available power semiconductor devices. We only give relative comparison because there is no straightforward technique that gives ranking of these devices. As we accumulate this table, devices are still being developed very rapidly with higher current, voltage ratings, and switching frequency.

It is expected that improvement in power handling capabilities and increasing frequency of operation of power devices will continue to drive the research and development in semiconductor technology. From power MOSFET to power MOS-IGBT and to power MOS-controlled thyristors, power rating has consistently increased by a factor of 5 from one type to another. Major research activities will focus on obtaining new device structure based on MOS-BJT technology integration to rapidly increase power ratings. It is expected that the power MOS-BJT technology will capture more than 90% of the total power transistor market.

The continuing development of power semiconductor technology has resulted in power systems with driver circuit, logic and control, device protection, and switching devices being designed and fabricated on a single-chip. Such power IC modules are called "smart power" devices. For example, some of today's power supplies are available as IC's for use in low-power applications. No doubt the development of smart power devices will continue in the near future, addressing more power electronic applications.

TABLE 4.3   Comparison of power semiconductor devices

Device type	Year made available	Rated voltage	Rated current	Rated frequency	Rated power	Forward voltage
Thyristor (SCR)	1957	6 kV	3.5 kA	500 Hz	100's MW	1.5–2.5 V
Triac	1958	1 kV	100 A	500 Hz	100's kW	1.5–2 V
GTO	1962	4.5 kV	3 kA	2 kHz	10's MW	3–4 V
BJT (Darlington)	1960s	1.2 kV	800 A	10 kHz	1 MW	1.5–3 V
MOSFET	1976	500 V	50 A	1 MHz	100 kW	3–4 V
IGBT	1983	1.2 kV	400 A	20 kHz	100's kW	3–4 V
SIT		1.2 kV	300 A	100 kHz	10's kW	10–20 V
SITH		1.5 kV	300 A	10 kHz	10's kW	2–4 V
MCT	1988	3 kV	2 kV	20–100 kHz	10's MW	1–2 V

5.1 Introduction

The insulated gate bipolar transistor (IGBT), which was introduced in early 1980s, is becoming a successful device because of its superior characteristics. IGBT is a three-terminal power semiconductor switch used to control the electrical energy. Many new applications would not be economically feasible without IGBTs. Prior to the advent of IGBT, power bipolar junction transistors (BJT) and power metal oxide field effect transistors (MOSFET) were widely used in low to medium power and high-frequency applications, where the speed of gate turn-off thyristors was not adequate. Power BJTs have good on-state characteristics but have long switching times especially at turn-off. They are current-controlled devices with small current gain because of high-level injection effects and wide base width required to prevent reach-through breakdown for high blocking voltage capability. Therefore, they require complex base drive circuits to provide the base current during on-state, which increases the power loss in the control electrode.

On the other hand power MOSFETs are voltage-controlled devices, which require very small current during switching period and hence have simple gate drive requirements. Power MOSFETs are majority carrier devices, which exhibit very high switching speeds. But the unipolar nature of the power

MOSFETs causes inferior conduction characteristics as the voltage rating is increased above 200 V. Therefore their on-state resistance increases with increasing breakdown voltage. Furthermore, as the voltage rating increases the inherent body diode shows inferior reverse recovery characteristics, which leads to higher switching losses.

In order to improve the power device performance, it is advantageous to have the low on-state resistance of power BJTs with an insulated gate input like that of a power MOSFET. The Darlington configuration of the two devices shown in Fig. 5.1 has superior characteristics as compared to the two discrete devices. This hybrid device could be gated like a power MOSFET with low on-state resistance because the majority of the output current is handled by the BJT. Because of the low current gain of BJT, a MOSFET of equal size is required as a driver. A more powerful approach to obtain the maximum benefits of the MOS gate control and bipolar current conduction is to integrate the physics of MOSFET and BJT within the same semiconductor region. This concept gave rise to the commercially available IGBTs with superior on-state characteristics, good switching speed and excellent safe operating area. Compared to power MOSFETs the absence of the integral body diode can be considered as an advantage or disadvantage depending on the switching speed and current requirements. An external fast recovery diode or a diode in the same package
FIGURE 5.1 Hybrid Darlington configuration of MOSFET and BJT.

can be used for specific applications. The IGBTs are replacing MOSFETs in high-voltage applications with lower conduction losses. They have on-state voltage and current density comparable to a power BJT with higher switching frequency. Although they exhibit fast turn-on, their turn-off is slower than a MOSFET because of current fall time. The IGBTs have considerably less silicon area than similar rated power MOSFETs. Therefore by replacing power MOSFETs with IGBTs, the efficiency is improved and cost is reduced. IGBT is also known as conductivity modulated FET (COMFET), insulated gate transistor (IGT), and bipolar-mode MOSFET.

As soft switching topologies offer numerous advantages over the hard switching topologies, their use is increasing in the industry. By the use of soft-switching techniques, IGBTs can operate at frequencies up to hundreds of kilohertz. The IGBTs behave differently under soft switching condition as opposed to hard switching conditions. Therefore, the device tradeoffs involved in soft switching circuits are different than those in hard switching case. Application of IGBTs in high power converters subjects them to high-transient electrical stress such as short circuit and turn-off under clamped inductive load and therefore robustness of IGBTs under stress conditions is an important requirement. Traditionally, there has been limited interaction between device manufacturers and power electronic circuit designers. Therefore, shortcomings of device reliability are observed only after the devices are used in actual circuits. This significantly slows down the process of power electronic system optimization. The development time can be

significantly reduced if all issues of device performance and reliability are taken into consideration at the design stage. As high stress conditions are quite frequent in circuit applications, it is extremely cost efficient and pertinent to model the IGBT performance under these conditions. However, development of the model can follow only after the physics of device operation under stress conditions imposed by the circuit is properly understood. Physically based process and device simulations are a quick and cheap way of optimizing the IGBT. The emergence of mixed mode circuit simulators in which semiconductor carrier dynamics is optimized within the constraints of circuit level switching is a key design tool for this task.

5.2 Basic Structure and Operation

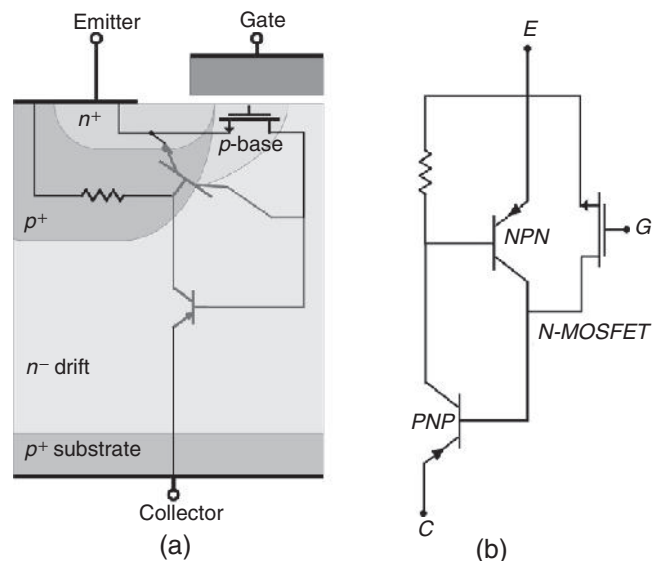
The vertical cross section of a half cell of one of the parallel cells of an n-channel IGBT shown in Fig. 5.2 is similar to that of a double diffused power MOSFET (DMOS) except for a p^+ layer at the bottom. This layer forms the IGBT collector and a pn junction with n^- drift region, where conductivity modulation occurs by injecting minority carriers into the drain drift region of the vertical MOSFET. Therefore, the current density is much greater than a power MOSFET and the forward voltage drop is reduced. The p^+ substrate, n^- drift layer, and p^+ emitter constitute a BJT with a wide base region and hence small current gain. The device operation can be explained by a BJT with its base current controlled by the voltage applied to the MOS gate. For simplicity, it is assumed that the emitter terminal is connected to the ground potential. By applying a negative voltage to the collector, the pn junction between the p^+ substrate and


FIGURE 5.2 IGBT: (a) half-cell vertical cross section and (b) equivalent circuit model.

the n^- drift region is reverse biased which prevents any current flow and the device is in its reverse blocking state. If the gate terminal is kept at ground potential but a positive potential is applied to the collector, the pn junction between the p-base and n^- drift region is reverse biased. This prevents any current flow and the device is in its forward blocking state until the open base breakdown of the pnp transistor is reached.

When a positive potential is applied to the gate and exceeds the threshold voltage required to invert the MOS region under the gate an n channel is formed, which provides a path for electrons to flow into the n^- drift region. The pn junction between the p^+ substrate and n^- drift region is forward biased and holes are injected into the drift region. The electrons in the drift region recombine with these holes to maintain space charge neutrality and the remaining holes are collected at the emitter, causing a vertical current flow between the emitter and collector. For small values of collector potential and a gate voltage larger than the threshold voltage the on-state characteristics can be defined by a wide base power BJT. As the current density increases, the injected carrier density exceeds the low doping of the base region and becomes much larger than the background doping. This conductivity modulation decreases the resistance of the drift region, and therefore IGBT has a much greater current density than a power MOSFET with reduced forward voltage drop. The base–collector junction of the pnp BJT cannot be forward biased, and therefore this transistor will not operate in saturation. But when the potential drop across the inversion layer becomes comparable to the difference between the gate voltage and threshold voltage, channel pinch-off occurs. The pinch-off limits the electron current and as a result the holes injected from the p^+ layer. Therefore, base current saturation causes the collector current to saturate.

Typical forward characteristics of an IGBT as a function of gate potential and IGBT transfer characteristics are shown in Fig. 5.3. The transfer characteristics of IGBT and MOSFET are similar. The IGBT is in the off-state if the gate–emitter potential is below the threshold voltage. For gate voltages greater than the threshold voltage, the transfer curve is linear over most of the drain current range. Gate-oxide breakdown and the maximum IGBT drain current limit the maximum gate–emitter voltage.

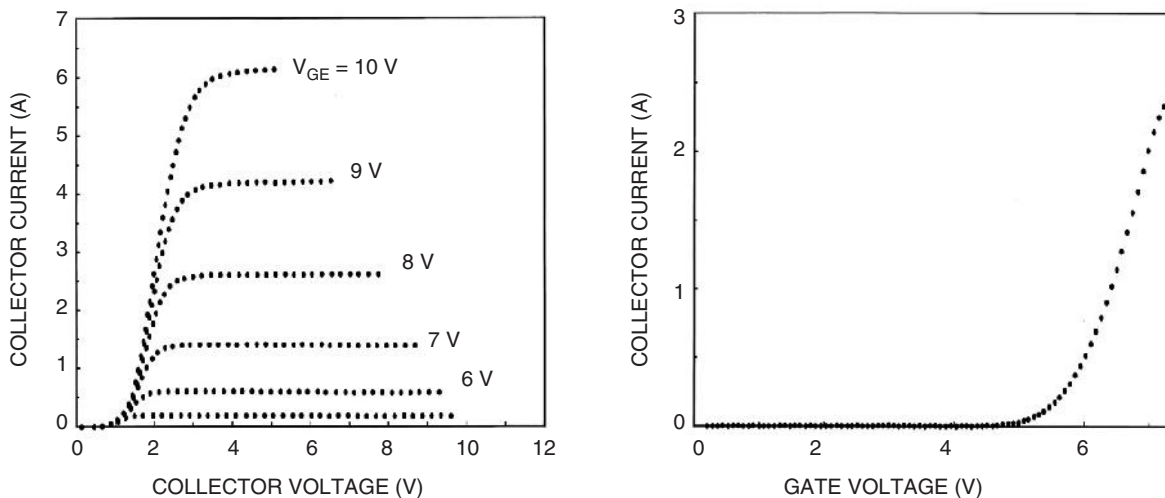
To turn-off the IGBT, gate is shorted to the emitter to remove the MOS channel and the base current of the pnp transistor. The collector current is suddenly reduced because the electron current from channel is removed. Then the excess carriers in the n^- drift region decay by electron–hole recombination, which causes a gradual collector current decay. In order to keep the on-state voltage drop low, the excess carrier lifetime must be kept large. Therefore, similar to the other minority carrier devices there is a tradeoff between on-state losses and faster turn-off switching times. In the punch-through (PT) IGBT structure of Fig. 5.4 the switching time is reduced by use of a heavily doped n buffer layer in the drift region near the collector. Because of much higher doping density in the buffer layer, the injection efficiency of the collector junction and the minority carrier lifetime in the base region is reduced. The smaller excess carrier lifetime in the buffer layer sinks the excess holes. This speeds up the removal of holes from the drift region and therefore decreases the turn-off time. Non-punch-through (NPT) IGBTs have higher carrier lifetimes and low doped shallow collector region, which affect their electrical characteristics. In order to prevent punch through, NPT IGBTs have a thicker drift region, which results in a higher base transit time. Therefore in NPT structure carrier lifetime is kept more than that of a PT structure, which causes conductivity modulation of the drift region and reduces the on-state voltage drop.


FIGURE 5.3 IGBT: (a) forward characteristics and (b) transfer characteristics.
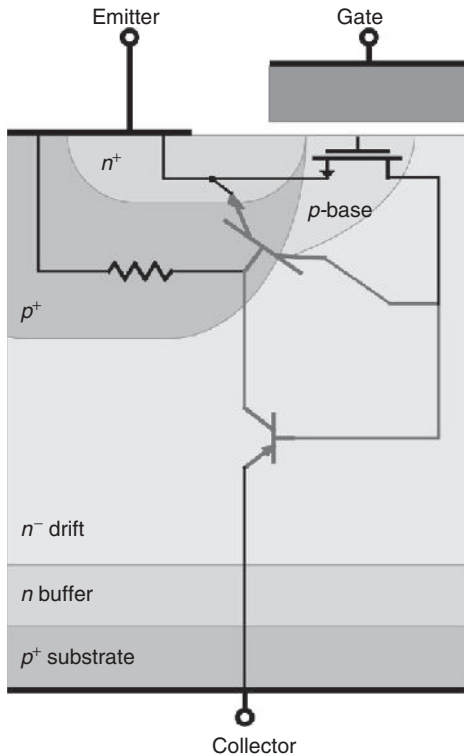

FIGURE 5.4   Punch-through (PT) IGBT structure.

5.3 Static Characteristics

In the IGBT structure of Fig. 5.2, if a negative voltage is applied to the collector, the junction between the p$^+$ substrate and n$^-$ drift region becomes reverse biased. The drift region is lightly doped and the depletion layer extends principally into the drift region. An open base transistor exists between the p$^+$ substrate, n$^-$ drift region, and the p-base region. The doping concentration (N_D) and thickness of the n$^-$ drift region (W_D) are designed to avoid the breakdown of this structure. The width of the drift region affects the forward voltage drop and therefore, should be optimized for a desired breakdown voltage. The thickness of the drift region (W_D) is chosen equal to the sum of one diffusion length (L_p) and the width of the depletion layer at maximum applied voltage (V_{max}).

$$W_D = \sqrt{\frac{2\varepsilon_s V_{max}}{qN_D}} + L_P \qquad (5.1)$$

When the gate is shorted to the emitter, no channel exists under the gate. Therefore, if a positive voltage is applied to the collector the junction between the p-base and n$^-$ drift region is reverse biased and only a small leakage current flows through IGBT. Similar to a MOSFET the depletion layer extends into the p-base and n$^-$ drift region. The p-base doping concentration, which also controls the threshold voltage is chosen to

avoid punch through of the p-base to n$^+$ emitter. In ac circuit applications, which require identical forward and reverse blocking capability the drift region thickness of the symmetrical IGBT shown in Fig. 5.2 is designed by use of Eq. (5.1) to avoid reach through of the depletion layer to the junction between the p$^+$ collector and the n$^-$ drift region. When IGBT is used in dc circuits, which do not require reverse blocking capability a highly doped n buffer layer is added to the drift region near the collector junction to form a PT IGBT. In this structure, the depletion layer occupies the entire drift region and the n buffer layer prevents reach through of the depletion layer to the p$^+$ collector layer. Therefore the required thickness of the drift region is reduced, which reduces the on-state losses. But the highly doped n buffer layer and p$^+$ collector layer degrade the reverse blocking capability to a very low value. Therefore on-state characteristics of a PT IGBT can be optimized for a required forward blocking capability while the reverse blocking capability is neglected.

When a positive voltage is applied to the gate of an IGBT, an MOS channel is formed between the n$^+$ emitter and the n$^-$ drift region. Therefore a base current is provided for the parasitic pnp BJT. By applying a positive voltage between the collector and emitter electrodes of an n type IGBT, minority carriers (holes) are injected into the drift region. The injected minority carriers reduce the resistivity of the drift region and reduce the on-state voltage drop resulting in a much higher current density compared to a power MOSFET.

If the shorting resistance between the base and emitter of the npn transistor is small, the n$^+$ emitter p-base junction does not become forward biased and therefore the parasitic npn transistor is not active and can be deleted from the equivalent IGBT circuit. The analysis of the forward conduction characteristics of an IGBT is possible by the use of two equivalent circuit approaches. The model based on a PiN rectifier in series with a MOSFET, shown in Fig. 5.5b is easy to analyze and gives a reasonable understanding of the IGBT operation. But this model does not account for the hole current component flowing into the p-base region. The junction between the p-base and the n$^-$ drift region is reverse biased. This requires that the free carrier density be zero at this junction, and therefore results in a different boundary condition for IGBT compared to those for PiN rectifier. The IGBT conductivity modulation in the drift region is identical to the PiN rectifier near the collector junction, but it is less than a PiN rectifier near the p-base junction. Therefore, the model based on a bipolar pnp transistor driven by a MOSFET in Fig. 5.5a gives a more complete description of the conduction characteristics.

Analyzing the IGBT operation by the use of these models shows that IGBT has one diode drop due to the parasitic diode. Below the diode knee voltage, there is negligible current flow due to the lack of minority carrier injection from the collector. Also by increasing the applied voltage between the gate and emitter, the base of the internal bipolar transistor is supplied by more base current, which results in an increase in the collector
FIGURE 5.5 IGBT equivalent circuits: (a) BJT/MOSFET and (b) PiN/MOSFET.

FIGURE 5.6 Components of on-state voltage drop within the IGBT structure.

current. The IGBT current shows saturation due to the pinch-off of the MOS channel. This limits the input base current of the bipolar transistor. The MOS channel of the IGBT reverse biases the collector–base junction and forces the bipolar pnp transistor to operate in its active region. The drift region is in high-level injection at the required current densities and wider n^- drift region results in higher breakdown voltage.

Because of the very low gain of the pnp BJT, the driver MOSFET in the equivalent circuit of the IGBT carries a major portion of the total collector current. Therefore, the IGBT on-state voltage drop as is shown in Fig. 5.6 consists of voltage drop across the collector junction, drift region, and MOSFET portion. The low value of the drift region conductivity modulation near the p-base junction causes a substantial drop across the junction field effect transistor (JFET) resistance of the MOSFET (V_{JFET}) in addition to the voltage drop across the channel resistance (V_{ch}) and the accumulation layer resistance (V_{acc}).

$$V_{CE(on)} = V_{p^+n} + V_{drift} + V_{MOSFET} \qquad (5.2)$$

$$V_{MOSFET} = V_{ch} + V_{JFET} + V_{acc} \qquad (5.3)$$

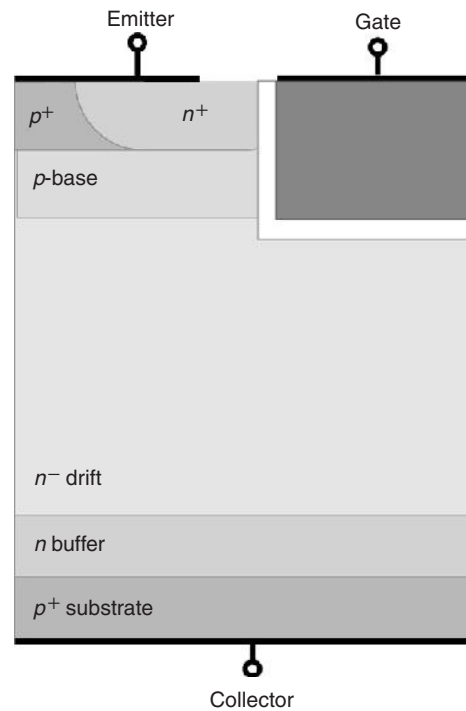
When the lifetime in the n^- drift region is large, the gain of the pnp bipolar transistor is high and its collector current is much larger than the MOSFET current and therefore, the voltage drop across the MOSFET component of IGBT is a small fraction of the total voltage drop. When lifetime control techniques are used to increase the switching speed, the current gain of the bipolar transistor is reduced and a greater portion of the current flows through the MOSFET channel and therefore the voltage drop across the MOSFET increases. In order to decrease the resistance of the MOSFET current path, trench IGBTs can be used as shown in Fig. 5.7. Extending the trench gate below the p-base and n^- drift region junction forms a channel between the n^+ emitter and the n^- drift region. This eliminates the JFET and accumulation layer resistance


FIGURE 5.7 Trench IGBT structure.

and therefore reduces the voltage drop across the MOSFET component of IGBT, which results in a superior conduction characteristics. By the use of trench structure, the IGBT cell density and latching current density are also improved.

5.4 Dynamic Switching Characteristics

5.4.1 Turn-on Characteristics

The switching waveforms of an IGBT in a clamped inductive circuit are shown in Fig. 5.8. The L/R time constant of the inductive load is assumed to be large compared to the switching frequency and therefore, can be considered as a constant current source I_{on}. The IGBT turn-on switching performance is dominated by its MOS structure. During $t_{d(on)}$, the gate current charges the constant input capacitance with a constant slope until the gate–emitter voltage reaches the threshold voltage $V_{GE(th)}$ of the device. During t_{ri}, load current is transferred from the diode into the device and increases to its steady-state value.

The gate voltage rise time and IGBT transconductance determine the current slope and results as t_{ri}. When the gate–emitter voltage reaches $V_{GE(Ion)}$, which will support the steady-state collector current, collector–emitter voltage starts to decrease. After this there are two distinct intervals, during
FIGURE 5.8 IGBT turn-on waveforms in a clamped inductive load circuit.

IGBT turn-on. In the first interval, the collector to emitter voltage drops rapidly as the gate–drain capacitance C_{gd} of the MOSFET portion of IGBT discharges. At low collector–emitter voltage C_{gd} increases. A finite time is required for high-level injection conditions to set in the drift region. The pnp transistor portion of IGBT has a slower transition to its on-state than the MOSFET. The gate voltage starts rising again only after the transistor comes out of its saturation region into the linear region, when complete conductivity modulation occurs and the collector–emitter voltage reaches its final on-state value.

5.4.2 Turn-off Characteristics

Turn-off begins by removing the gate–emitter voltage. Voltage and current remain constant until the gate voltage reaches $V_{GE(Ion)}$, required to maintain the collector steady-state current as shown in Fig. 5.9. After this delay time $(t_{d(off)})$ the collector voltage rises, while the current is held constant. The gate resistance determines the rate of collector voltage rise. As the MOS channel turns off, collector current decreases sharply during t_{fi1}. The MOSFET portion of IGBT determines the turn-off delay time $t_{d(off)}$ and the voltage rise time t_{rv}. When the collector voltage reaches the bus voltage, the freewheeling diode starts to conduct.

However the excess stored charge in the n⁻ drift region during on-state conduction, must be removed for the device to turn-off. The high minority carrier concentration stored in the n⁻ drift region supports the collector current after the MOS channel is turned off. Recombination of the minority carriers in the wide base region gradually decreases the collector current and results in a current tail. Since there is no access to the base of the pnp transistor, the excess minority carriers cannot be removed by reverse biasing the gate. The t_{fi2} interval is long because the excess carrier lifetime in this region is normally kept high to reduce the on-state voltage drop. Since the collector–emitter voltage has reached the bus voltage in this interval, a significant power loss occurs which increases with frequency. Therefore, the current tail limits the IGBT operating frequency and there is a tradeoff between the on-state losses and faster switching times. For an on-state current of I_{on}, the magnitude of the current tail, and the time required for the collector current to decrease to 10% of its on-state value, turn-off (t_{off}) time, are approximated as:

$$I_c(t) = \alpha_{pnp} I_{on} e^{-t/\tau_{HL}} \tag{5.4}$$

$$t_{off} = \tau_{HL} \ln(10\alpha_{pnp}) \tag{5.5}$$

where

$$\alpha_{pnp} = \sec h\left(\frac{l}{L_a}\right) \tag{5.6}$$

is the gain of the bipolar pnp transistor, l is the undepleted base width, and L_a is the ambipolar diffusion length and it
FIGURE 5.9 Switching waveforms during IGBT clamped inductive load turn-off.

is assumed that the high level lifetime (τ_{HL}) is independent of the minority carrier injection during the collector current decay.

Lifetime-control techniques are used to reduce the lifetime (τ_{HL}) and the gain of the bipolar transistor (α_{pnp}). As a result, the magnitude of the current tail and t_{off} decrease. But the conductivity modulation decreases, which increases the on-state voltage drop in the drift region. Therefore, higher speed IGBTs have a lower current rating. Thermal diffusion of impurities such as gold and platinum introduces recombination centers, which reduce the lifetime. The device can also be irradiated with high-energy electrons to generate recombination centers. Electron irradiation introduces a uniform distribution of defects, which results in reduction of lifetime in the entire wafer and affects the conduction properties of the device. Another method of lifetime control is proton implantation, which can place defects at a specific depth. Therefore, it is possible to have a localized control of lifetime to improve the tradeoff between the on-state voltage and switching speed of the device. The turn-off loss can be minimized by curtailing the current tail as a result of speeding up the recombination

process in the portion of the drift region, which is not swept by the reverse bias.

5.4.3 Latch-up of Parasitic Thyristor

A portion of minority carriers injected into the drift region from the collector of an IGBT flows directly to the emitter terminal. The negative charge of electrons in the inversion layer attracts the majority of holes and generates the lateral component of hole current through the p-type body layer as shown in Fig. 5.10. This lateral current flow develops a voltage drop across the spreading resistance of the p-base region, which forward biases the base–emitter junction of the npn parasitic BJT. By designing a small spreading resistance, the voltage drop is lower than the built-in potential and therefore the parasitic thyristor between the p$^+$ collector region, n$^-$ drift region, p-base region, and n$^+$ emitter does not latch-up. Larger values of on-state current density produce a larger voltage drop, which causes injection of electrons from the emitter region into the p-base region and hence turns on the npn transistor. When this occurs the pnp transistor will turn-on,

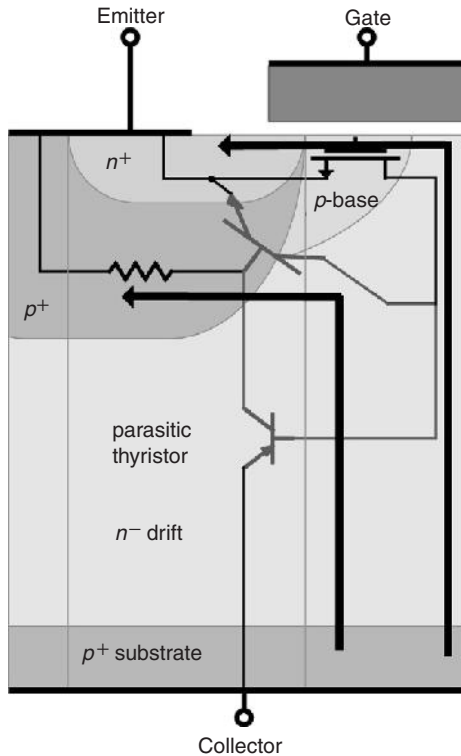
Emitter   Gate


FIGURE 5.10   On-state current flow paths in an IGBT structure.

therefore the parasitic thyristor will latch-up and the gate loses control over the collector current.

Under dynamic turn-off conditions the magnitude of the lateral hole current flow increases and latch-up can occur at lower on-state currents compared to the static condition. The parasitic thyristor latches up when the sum of the current gains of the npn and pnp transistors exceeds one. When the gate voltage is removed from IGBT with a clamped inductive load, its MOSFET component turns off and reduces the MOSFET current to zero very rapidly. As a result the drain–source voltage rises rapidly and is supported by the junction between the n^- drift region and the p-base region. The drift region has a lower doping and therefore the depletion layer extends more in the drift region. As a result the current gain of the pnp transistor portion, α_{pnp} increases and a greater portion of the injected holes into the drift region will be collected at the junction of p-base and n^- drift regions. Therefore, the magnitude of the lateral hole current increases, which increases the lateral voltage drop. As a result the parasitic thyristor will latch-up even if the on-state current is less than the static latch-up value.

Reducing the gain of the npn or pnp transistors can prevent the parasitic thyristor latch-up. A reduction in the gain of the pnp transistor increases the IGBT on-state voltage drop. Therefore in order to prevent the parasitic thyristor latch-up, it is better to reduce the gain of the npn transistor component of IGBT. Reduction of carrier lifetime, use of buffer layer, and use

of deep p^+ diffusion improve the latch-up immunity of IGBT. But inadequate extent of the p^+ region may fail to prevent the device from latch-up. Also care should be taken that the p^+ diffusion does not extend into the MOS channel because this causes an increase in the MOS threshold voltage.

5.5 IGBT Performance Parameters

The IGBTs are characterized by certain performance parameters. The manufacturers specify these parameters, which are described below, in the IGBT data sheet. The important ratings of IGBTs are values, which establish either a minimum or maximum limiting capability or limiting condition. The IGBTs cannot be operated beyond the maximum or minimum rating's value, which are determined for a specified operating point and environment condition.

Collector–Emitter blocking voltage (BV_{CES}): This parameter specifies the maximum off-state collector–emitter voltage when the gate and emitter are shorted. Breakdown is specified at a specific leakage current and varies with temperature by a positive temperature coefficient.

Emitter–Collector blocking voltage (BV_{ECS}): This parameter specifies the reverse breakdown of the collector–base junction of the pnp transistor component of IGBT.

Gate–Emitter voltage (V_{GES}): This parameter determines the maximum allowable gate–emitter voltage, when collector is shorted to emitter. The thickness and characteristics of the gate-oxide layer determine this voltage. The gate voltage should be limited to a much lower value to limit the collector current under fault conditions.

Continuous collector current (I_C): This parameter represents the value of the dc current required to raise the junction to its maximum temperature, from a specified case temperature. This rating is specified at a case temperature of 25°C and maximum junction temperature of 150°C. Since normal operating condition cause higher case temperatures, a plot is given to show the variation of this rating with case temperature.

Peak collector repetitive current (I_{CM}): Under transient conditions, the IGBT can withstand higher peak currents compared to its maximum continuous current, which is described by this parameter.

Maximum power dissipation (P_D): This parameter represents the power dissipation required to raise the junction temperature to its maximum value of 150°C, at a case temperature of 25°C. Normally a plot is provided to show the variation of this rating with temperature.

Junction temperature (T_j): Specifies the allowable range of the IGBT junction temperature during its operation.

Clamped inductive load current (I_{LM}): This parameter specifies the maximum repetitive current that IGBT can turn-off under a clamped inductive load. During IGBT turn-on, the reverse recovery current of the freewheeling diode in parallel with the inductive load increases the IGBT turn-on switching loss.

Collector–Emitter leakage current (I_{CES}): This parameter determines the leakage current at the rated voltage and specific temperature when the gate is shorted to emitter.

Gate–Emitter threshold voltage ($V_{GE(th)}$): This parameter specifies the gate–emitter voltage range, where the IGBT is turned on to conduct the collector current. The threshold voltage has a negative temperature coefficient. Threshold voltage increases linearly with gate-oxide thickness and as the square root of the p-base doping concentration. Fixed surface charge at the oxide–silicon interface and mobile ions in the oxide shift the threshold voltage.

Collector–Emitter saturation voltage ($V_{CE(SAT)}$): This parameter specifies the collector–emitter forward voltage drop and is a function of collector current, gate voltage, and temperature. Reducing the resistance of the MOSFET channel and JFET region, and increasing the gain of the pnp bipolar transistor can minimize the on-state voltage drop. The voltage drop across the MOSFET component of IGBT, which provides the base current of the pnp transistor is reduced by a larger channel width, shorter channel length, lower threshold voltage, and wider gate length. Higher minority carrier lifetime and a thin n-epi region cause high carrier injection and reduce the voltage drop in the drift region.

Forward transconductance (g_{FE}): Forward transconductance is measured with a small variation on the gate voltage, which linearly increases the IGBT collector current to its rated current at 100°C. The transconductance of an IGBT is reduced at currents much higher than its thermal handling capability. Therefore, unlike the bipolar transistors, the current handling capability of IGBTs is limited by thermal consideration and not by its gain. At higher temperatures, the transconductance starts to decrease at lower collector currents. Therefore, these features of transconductance protects the IGBT under short circuit operation.

Total gate charge (Q_G): This parameter helps to design a suitable size gate drive circuit and approximately calculate its losses. Because of the minority carrier behavior of device, the switching times cannot be approximately calculated by the use of gate charge value. This parameter varies as a function of the gate–emitter voltage.

Turn-on delay time (t_d): It is defined as the time between 10% of gate voltage and 10% of the final collector current.

Rise time (t_r): It is the time required for the collector current to increase to 90% of its final value from 10% of its final value.

Turn-off delay time ($t_{d(off)}$): It is the time between 90% of gate voltage and 10% of final collector voltage.

Fall time (t_f): It is the time required for the collector current to drop from 90% of its initial value to 10% of its initial value.

Input capacitance (C_{ies}): It is the measured gate–emitter capacitance when collector is shorted to emitter. The input capacitance is the sum of the gate–emitter and the miller capacitance. The gate–emitter capacitance is much larger than the miller capacitance.

Output capacitance (C_{oes}): It is the capacitance between collector and emitter when gate is shorted to the emitter, which has the typical pn junction voltage dependency.

Reverse transfer capacitance (C_{res}): It is the miller capacitance between gate and collector, which has a complex voltage dependency.

Safe operating area (SOA): The safe operating area determines the current and voltage boundary within which the IGBT can be operated without destructive failure. At low currents the maximum IGBT voltage is limited by the open base transistor breakdown. The parasitic thyristor latch-up limits the maximum collector current at low voltages. The IGBTs immune to static latch-up may be vulnerable to dynamic latch-up. Operation in short circuit and inductive load switching are conditions that would subject an IGBT to a combined voltage and current stress. Forward biased safe operating area (FBSOA) is defined during the turn-on transient of the inductive load switching when both electron and hole current flow in the IGBT in the presence of high voltage across the device. The reverse biased safe operating area (RBSOA) is defined during the turn-off transient, where only hole current flows in the IGBT with high voltage across it.

If the time duration of simultaneous high voltage and high current is long enough, the IGBT failure will occur because of thermal breakdown. But if this time duration is short, the temperature rise due to power dissipation will not be enough to cause thermal breakdown. Under this condition the avalanche breakdown occurs at voltage levels lower than the breakdown voltage of the device. Compared to the steady-state forward blocking condition the much larger charge in the drift region causes a higher electric field and narrower depletion region at the p-base and n⁻ drift junction. Under RBSOA conditions there is no electron in the space charge region, and therefore there is a larger increase in electric field than the FBSOA condition.

The IGBT SOA is indicated in Fig. 5.11. Under short-switching times the rectangular SOA shrinks by increase in
FIGURE 5.11 IGBT safe operating area (SOA).

the duration of on-time. Thermal limitation is the reason for smaller SOA and the lower limit is set by dc operating conditions. The device switching loci under hard switching (dashed lines) and zero voltage or zero current switching (solid lines) is also indicated in Fig. 5.11. The excursion is much wider for switch-mode hard-switching applications than for the soft-switching case, and therefore a much wider SOA is required for hard-switching applications. Presently IGBTs are optimized for hard-switching applications. In soft-switching applications the conduction losses of IGBT can be optimized at the cost of smaller SOA. In this case the p-base doping can be adjusted to result in a much lower threshold voltage and hence forward voltage drop. But in hard-switching applications, the SOA requirements dominate over forward voltage drop and switching time. Therefore, the p-base resistance should be reduced, which causes a higher threshold voltage. As a result, the channel resistance and forward voltage drop will increase.

5.6 Gate Drive Requirements

The gate drive circuit acts as an interface between the logic signals of the controller and the gate signals of the IGBT, which reproduces the commanded switching function at a higher power level. Non-idealities of the IGBT such as finite voltage and current rise and fall times, turn-on delay, voltage and current overshoots, and parasitic components of the circuit cause differences between the commanded and real waveforms. Gate drive characteristics affect the IGBT non-idealities. The MOSFET portion of the IGBT drives the base of the pnp transistor and therefore the turn-on transient and losses is greatly affected by the gate drive.

Due to lower switching losses, soft-switched power converters require gate drives with higher power ratings. The IGBT gate drive must have sufficient peak current capability to provide the required gate charge for zero current switching and zero voltage switching. The delay of the input signal to the gate drive should be small compared to the IGBT switching period and therefore, the gate drive speed should be designed properly to be able to use the advantages of faster switching speeds of the new generation IGBTs.

5.6.1 Conventional Gate Drives

The first IGBT gate drives used fixed passive components and were similar to MOSFET gate drives. Conventional gate drive circuits use a fixed gate resistance for turn-on and turn-off as shown in Fig. 5.12. The turn-on gate resistor R_{gon} limits the maximum collector current during turn-on, and the turn-off gate resistor R_{goff} limits the maximum collector–emitter voltage. In order to decouple the dv_{ce}/dt and di_c/dt control, an external capacitance C_g can be used at the gate, which increases the time constant of the gate circuit and reduces the di_c/dt as shown in Fig. 5.13. But C_g does not affect the dv_{ce}/dt
FIGURE 5.12   Gate drive circuit with independent turn-on and turn-off resistors.
FIGURE 5.13   External gate capacitor for decoupling dv_{ce}/dt and di_c/dt during switching transient.

transient, which occurs during the miller plateau region of the gate voltage.

5.6.2 New Gate Drive Circuits

In order to reduce the delay time required for the gate voltage to increase from V_{gg-} to $V_{ge}(th)$, the external gate capacitor can be introduced in the circuit only after V_{ge} reaches $V_{ge}(th)$ as is shown in Fig. 5.14, where the collector current rise occurs. The voltage tail during turn-on transient is not affected by this method. In order to prevent shoot through caused by accidental turn-on of IGBT due to noise, a negative gate voltage is required during off-state. Low gate impedance reduces the effect of noise on gate.

During the first slope of the gate voltage turn-on transient, the rate of charge supply to the gate determines the collector current slope. During the miller effect zone of the turn-on transient the rate of charge supply to the gate determines the collector voltage slope. Therefore, the slope of the collector current, which is controlled by the gate resistance, strongly affects the turn-on power loss. Reduction in switching power loss requires low gate resistance. But the collector current slope also determines the amplitude of the conducted electromagnetic interference (EMI) during turn-on switching transient. Lower EMI generation requires higher values of gate resistance. Therefore, in conventional gate drive circuits by selecting

an optimum value for R_g, there is a tradeoff between lower switching losses and lower EMI generation.

But the turn-off switching of IGBT depends on the bipolar characteristics. Carrier lifetime determines the rate at which the minority carriers stored in the drift region recombine. The charge removed from the gate during turn-off has small influence on minority carrier recombination. The tail current and di/dt during turn-off, which determine the turn-off losses, depend mostly on the amount of stored charge and the minority carriers lifetime. Therefore, the gate drive circuit has a minor influence on turn-off losses of the IGBT, while it affects the turn-on switching losses.

The turn-on transient is improved by use of the circuit shown in Fig. 5.15. The additional current source increases the gate current during the tail voltage time, and therefore reduces the turn-on loss. The initial gate current is determined by $V_{gg}+$ and R_{gon}, which are chosen to satisfy device electrical specifications and EMI requirements. After the collector current reaches its maximum value, the miller effect occurs and the controlled current source is enabled to increase the gate current to increase the rate of collector voltage fall. This reduces the turn-on switching loss. Turn-off losses can only be reduced during the miller effect and MOS turn-off portion of the turn-off transient, by reducing the gate resistance. But this increases the rate of change of collector voltage, which strongly affects the IGBT latching current and RBSOA. During the turn-off
FIGURE 5.14   A circuit for reducing the turn-on delay.
FIGURE 5.15   Schematic circuit of an IGBT gate drive circuit.

period, the turn-off gate resistor R_{goff} determines the maximum rate of collector voltage change. After the device turns off, turning on transistor T_1 prevents the spurious turn-on of IGBT by preventing the gate voltage to reach the threshold voltage.

5.6.3 Protection

Gate drive circuits can also provide fault protection of IGBT in the circuit. The fault protection methods used in IGBT converters are different from their gate turn-off thyristor (GTO) counterparts. In a GTO converter, a crowbar is used for protection and as a result there is no current limiting. When the short circuit is detected the control circuit turns on all the GTO switches in the converter, which results in the opening of a fuse or circuit breaker on the dc input. Therefore, series di/dt snubbers are required to prevent rapid increase of the fault current and the snubber inductor has to be rated for large currents in the fault condition. But IGBT has an important ability to intrinsically limit the current under over-current and short circuit fault conditions. However, the value of the fault current can be much larger than the nominal IGBT current. Therefore, IGBT has to be turned off rapidly after the fault occurs. The magnitude of the fault current depends on the positive gate bias voltage V_{gg+}. A higher V_{gg+} is required to reduce conduction loss in the device, but this leads to larger fault currents. In order to decouple the tradeoff limitation between conduction loss and fault current level, a protection circuit can reduce the gate voltage when a fault occurs. But this does not limit the peak value of the fault current, and therefore, a fast fault detection circuit is required to limit the peak value of the fault current. Fast integrated sensors in the gate drive circuit are essential for proper IGBT protection.

Various methods have been studied to protect IGBTs under fault conditions. One of the techniques uses a capacitor to reduce the gate voltage when the fault occurs. But depending on the initial condition of the capacitor and its value the IGBT current may reduce to zero and then turned on again. Another method is to softly turn-off the IGBT after the fault and to reduce the over-voltage due to di_c/dt. Therefore the over-voltage on IGBT caused by the parasitic inductance is limited while turning off large currents. The most common method of IGBT protection is the collector voltage monitoring or desat detection. The monitored parameter is the collector–emitter voltage, which makes fault detection easier compared to measuring the device current. But voltage detection can be activated only after the complete turn-on of IGBT. If the fault current increases slowly due to large fault inductance, the fault detection is difficult because the collector–emitter voltage will not change significantly. In order to determine whether the current that is being turned off is over-current or nominal current, the miller voltage plateau level can be used. This method can be used to initiate soft turn-off and reduce the over-voltage during over-currents.

Special sense IGBTs have been introduced at low power levels with a sense terminal to provide a current signal proportional to the IGBT collector current. A few active device cells are used to mirror the current carried by the other cells. But unfortunately, sense IGBTs are not available at high power levels and there are problems related to the higher conduction losses in the sense device. The most reliable method to detect an over-current fault condition is to introduce a current sensor in series with the IGBT. The additional current sensor makes the power circuit more complex and may lead to parasitic bus inductance, which results in higher over-voltages during turn-off.

After the fault occurs, the IGBT has to be safely turned off. Due to large di_c/dt during turn-off, the over-voltage can be very large. Therefore, many techniques have been investigated to obtain soft turn-off. The most common method is to use large turn-off gate resistor when the fault occurs. Another method to reduce the turn-off over-voltage is to lower the fault current level by reducing the gate voltage before initiating the turn-off. A resistive voltage divider can be used to reduce the gate voltage during fault turn-off. For example, the gate voltage reduction can be obtained by turning on simultaneously R_{goff} and R_{gon} in the circuit of Fig. 5.12. Another method is to switch a capacitor into the gate and rapidly discharge the gate during the occurrence of a fault. To prevent the capacitor from charging back up to the nominal on-state gate voltage, a large capacitor should be used, which may cause a rapid gate discharge. Also a zener can be used in the gate to reduce the gate voltage after a fault occurs. But the slow transient behavior of the zener leads to large initial peak fault current. The power dissipation during a fault determines the time duration that the fault current can flow in the IGBT without damaging it. Therefore, the IGBT fault endurance capability is improved by the use of fault current limiting circuits to reduce the power dissipation in the IGBT under fault conditions.

5.7 Circuit Models

High-quality IGBT model for circuit simulation is essential for improving the efficiency and reliability in the design of power electronic circuits. Conventional models for power semiconductor devices simply described an abrupt or linear switching behavior and a fixed resistance during the conduction state. Low switching frequencies of power circuits made it possible to use these approximate models. But moving to higher switching frequencies to reduce the size of a power electronic system requires high-quality power semiconductor device models for circuit simulation.

The n-channel IGBT consists of a pnp bipolar transistor whose base current is provided by an n-channel MOSFET, as is shown in Fig. 5.1. Therefore, the IGBT behavior is determined by the physics of the bipolar and MOSFET devices.

Several effects dominate the static and dynamic device characteristics. The influence of these effects on low-power semiconductor device is negligible and therefore they cannot be described by standard device models. The conventional circuit models were developed to describe the behavior of low power devices, and therefore were not adequate to be modified for IGBT. The reason is that the bipolar transistor and MOSFET in the IGBT have a different behavior compared to their low-power counterparts and have different structures.

The present available models have different levels of accuracy at the expense of speed. Circuit issues such as switching losses and reliability are strongly dependent on the device and require accurate device models. But simpler models are only adequate for system oriented issues such as the behavior of an electric motor driven by a pulse width modulation (PWM) converter. Finite element models have high accuracy, but are slow and require internal device structure details. Macro models are fast but have low accuracy, which depends on the operating point. Recently commercial circuit simulators have introduced one-dimensional physics-based models, which offer a compromise between the finite element models and macro models. The Hefner model and the Kraus model are such examples that have been implemented in Saber and there has been some effort to implement them in PSPICE. The Hefner model depends on the redistribution of charge in the drift region during transients. The Kraus model depends on the extraction of charge from the drift region by the electric field and emitter back injection.

The internal BJT of the IGBT has a wide base, which is lightly doped to support the depletion region to have high blocking voltages. The excess carrier lifetime in the base region is low to have fast turn-off. But low power bipolar transistors have high excess carrier lifetime in the base, narrow base, and high current gain. A finite base transit time is required for a change in the injected base charge to change the collector current. Therefore, quasi-static approximation cannot be used at high speeds and the transport of carriers in the base should be described by ambipolar transport theory.

5.7.1 Input and Output Characteristics

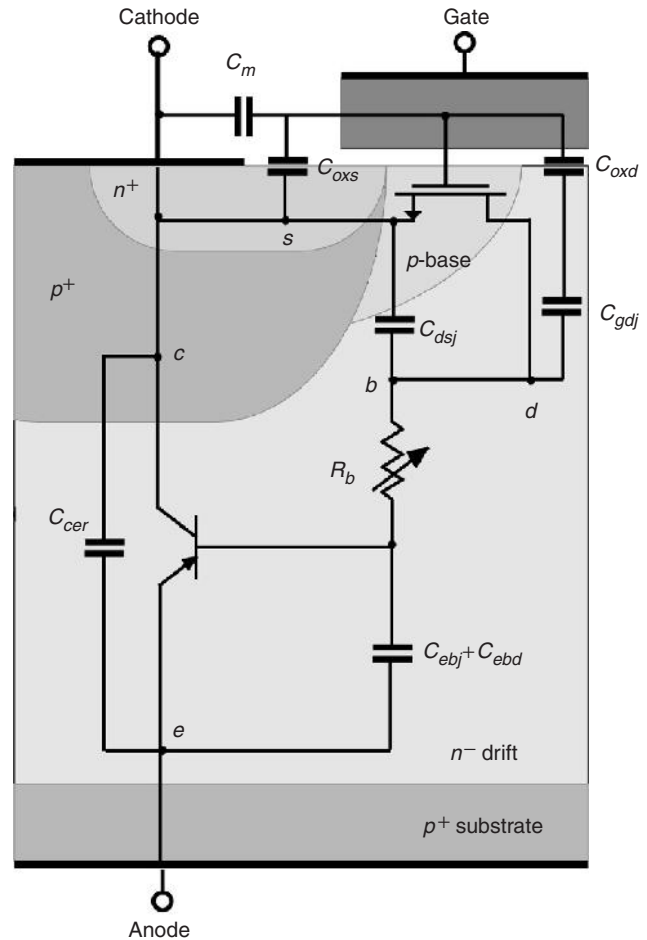
The bipolar and MOSFET components of a symmetric IGBT are shown in Fig. 5.16. The components between the emitter (e), base (b), and collector (c) terminals correspond to the bipolar transistor and those between gate (g), source (s), and drain (d) are associated with MOSFET. The combination of the drain–source and gate–drain depletion capacitances is identical to the base–collector depletion capacitance, and therefore they are shown for the MOSFET components. The gate-oxide capacitance of the source overlap (C_{oxs}) and source metallization capacitance (C_m) form the gate–source capacitance (C_{gs}). When the MOSFET is in its linear region the gate-oxide capacitance of the drain overlap (C_{oxd}) forms the gate–drain capacitance (C_{gd}). In the saturation region of


FIGURE 5.16 Symmetric IGBT half cell.

MOSFET the equivalent series connection of gate–drain overlap oxide capacitance and the depletion capacitance of the gate–drain overlap (C_{gdj}) forms the gate–drain miller capacitance. The gate–drain depletion width and the drain–source depletion width are voltage dependent, which has the same effect on the corresponding capacitances.

The most important capacitance in IGBT is the capacitance between the input terminal (g) and output terminal (a), because the switching characteristics is affected by this feedback.

$$C_{ga} \frac{dQ_g}{dv_{ga}} = C_{ox} \frac{dv_{ox}}{dv_{ga}} \qquad (5.7)$$

C_{ox} is determined by the oxide thickness and device area. The accumulation, depletion, and inversion states below the gate cause different states of charge and therefore different capacitance values.

The stored charge in the lightly doped wide base of the bipolar component of IGBT causes switching delays and switching losses. The standard quasi-static charge description

is not adequate for IGBT because it assumes that the charge distribution is a function of the IGBT terminal voltage. But the stored charge density ($P(x,t)$) changes with time and position and therefore the ambipolar diffusion equation must be used to describe the charge variation.

$$\frac{dP(x,t)}{dt} = -\frac{P(x,t)}{\tau_a} + D_a\frac{d^2P(x,t)}{dx^2} \qquad (5.8)$$

The slope of the charge carrier distribution determines the sum of electron and hole currents. The non-quasi-static behavior of the stored charge in the base of the bipolar component of IGBT results in the collector–emitter redistribution capacitance (C_{cer}). This capacitance dominates the output capacitance of IGBT during turn-off and describes the rate of change of base–collector depletion layer with the rate of change of base–collector voltage. But the base–collector displacement current is determined by the gate–drain (C_{gdj}) and drain–source (C_{dsj}) capacitance of the MOSFET component.

5.7.2 Implementing the IGBT Model into a Circuit Simulator

Usually a netlist is used in a circuit simulator such as Saber to describe an electrical circuit. Each component of the circuit is defined by a model template with the component terminal connection and the model parameters values. While Saber libraries provide some standard component models, the models can be generated by implementing the model equations in a defined saber template. Electrical component models of IGBT are defined by the current through each component element as a function of component variables, such as terminal and internal node voltages and explicitly defined variables. The circuit simulator uses the Kirchhoff's current law to solve for electrical component variables such that the total current into each node is equal to zero, while satisfying the explicitly defined component variables needed to describe the state of the device.

The IGBT circuit model is generated by defining the currents between terminal nodes as a non-linear function of component variables and their rate of change. An IGBT circuit model is shown in Fig. 5.17. Compared to Fig. 5.16, the bipolar transistor is replaced by the two base and collector current sources. There is a distributed voltage drop due to diffusion and drift in the base regions. The drift terms in the ambipolar diffusion equation depends on base and collector currents. Therefore, both of these currents generate the resistive voltage drop V_{ae} and R_b is placed at the emitter-terminal in the IGBT circuit model. The capacitance of the emitter–base junction (C_{eb}) is implicitly defined by the emitter–base voltage as a function of base charge. I_{ceb} is the emitter–base capacitor current which defines the rate of change of the base charge. The current through the collector–emitter redistribution capacitance (I_{ccer}) is part of the collector current, which in contrast to
FIGURE 5.17 IGBT circuit model.

I_{css} depends on the rate of change of the base–emitter voltage. I_{bss} is part of the base current that does not flow through C_{eb} and does not depend on rate of change of base–collector voltage.

Impact ionization causes carrier multiplication in the high electric field of the base–collector depletion region. This carrier multiplication generates an additional base–collector current component (I_{mult}), which is proportional to I_c, I_{mos}, and the multiplication factor. The resulting Saber IGBT model should be able to describe accurately the experimental results for the range of static and dynamic conditions where IGBT operates. Therefore, the model can be used to describe the steady-state and dynamic characteristics under various circuit conditions.

The present available models have different levels of accuracy at the expense of speed. Circuit issues such as switching losses and reliability are strongly dependent on the device and require accurate device models. But simpler models are adequate for system oriented issues such as the behavior of an electric motor driven by a PWM converter. Finite element models have high accuracy, but are slow and require internal device structure details. Macro models are fast but have low accuracy, which depends on the operating point. Recently commercial circuit simulators have introduced one-dimensional

physics-based models, which offer a compromise between the finite element models and macro models.

5.8 Applications

Power electronics evolution is a result of the evolution of power semiconductor devices. Applications of power electronics are still expanding in industrial and utility systems. A major challenge in designing power electronic systems is a simultaneous operation at high power and high-switching frequency. The advent of IGBTs has revolutionized power electronics by extending the power and frequency boundary. During the last decade, the conduction and switching losses of IGBTs has been reduced in the process of transition from the first to the third generation IGBTs. The improved charcteristics of the IGBTs have resulted in higher switching speed and lower energy losses. High voltage IGBTs are expected to take the place of high voltage GTO thyristor converters in the near future. To advance the performance beyond the third generation IGBTs, the fourth generation devices will require exploiting fine-line lithographic technology and employing the trench technology used to produce power MOSFETs with very low on-state resistance. Intelligent IGBT or intelligent power module (IPM) is an attractive power device integrated with circuits to protect against over-current, over-voltage, and over-heat. The main

application of IGBT is for use as a switching component in inverter circuits, which are used in both power supply and motor-drive applications. The advantages of using IGBT in these converters are simplicity and modularity of the converter, simple gate drive, elimination of snubber circuits due to the square SOA, lower switching loss, improved protection characteristics in case of over-current and short circuit fault, galvanic isolation of the modules, and simpler mechanical construction of the power converter. These advantages have made the IGBT the preferred switching device in the power range below 1 MW.

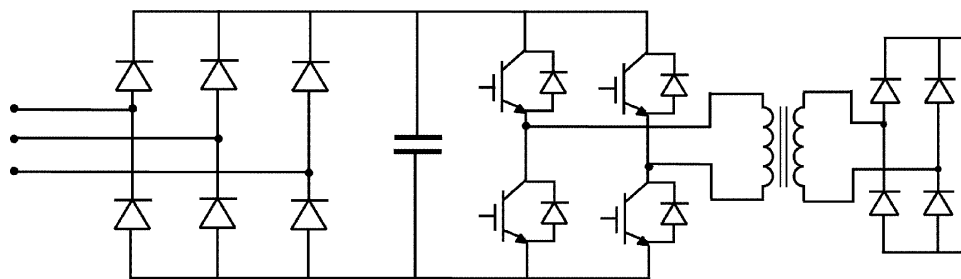
Power supply applications of IGBTs include uninterruptible power supplies (UPS) as is shown in Fig. 5.18, constant voltage, constant frequency power supplies, induction heating systems, switch mode power supplies, welders (Fig. 5.19), cutters, traction power supplies, and medical equipment (CT, X-ray). Low noise operation, small size, low cost, and high accuracy are chracteristics of the IGBT converters in these applications. Examples of motor-drive applications include variable voltage, variable frequency inverter as is shown in Fig. 5.20. The IGBTS have been recently introduced at high voltage and current levels, which has enabled their use in high power converters utilized for medium voltage motor drives. The improved characteristics of the IGBTs have introduced power converters in megawatt power applications such as traction drives. One of the critical issues in realizing high power
FIGURE 5.18   Constant voltage, constant frequency inverter (UPS).


FIGURE 5.19   IGBT welder.
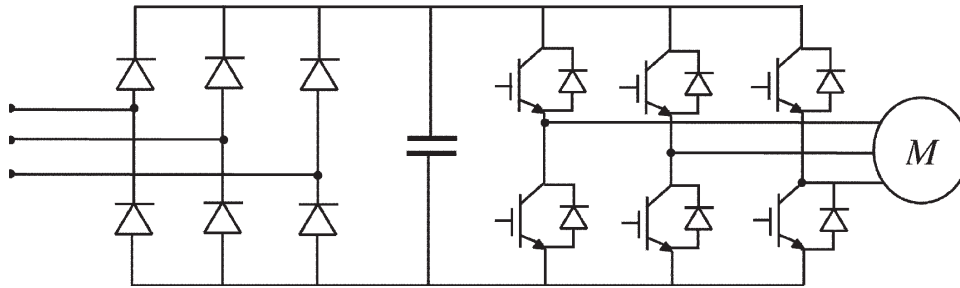

FIGURE 5.20 Variable voltage, variable frequency inverter (PWM).

converters is the reliability of the power switches. The devices used in these applications must be robust and capable of withstanding faults long enough for a protection scheme to be activated. The hard switching voltage source power converter is the most commonly used topology. In this switch-mode operation, the switches are subjected to high switching stresses and high switching power loss that increases linearly with the switching frequency of the PWM. The resulting switching loci in the v_t–i_t plane is shown by the dotted lines in Fig. 5.11. Because of simultaneous large switch voltage and large switch current, the switch must be capable of withstanding high switching stresses with a large SOA. The requirement of being able to withstand large stresses results in design compromises in other characteristics of the power semiconductor device. Often forward voltage drop and switching speed are sacrificed for enhanced short circuit capability. Process parameters of the IGBT such as threshold voltage, carrier lifetime, and the device thickness can be varied to obtain various combinations of SOA, on-state voltage, and switching time. However, there is very little overlap in the optimum combination for more than one performance parameter. Therefore, improved performance in one parameter is achieved at the cost of other parameters.

In order to reduce the size, the weight, and the cost of circuit components used in a power electronics converter very high-switching frequencies of the order of few megahertz are being contemplated. In order to be able to increase the switching frequency, the problems of switch stresses, switching losses, and the EMI associated with switch-mode applications need to be overcome. Use of soft-switching converters reduces the problems of high dv/dt and high di/dt by the use of external inductive and capacitive components to shape the switching trajectory of device. The device switching loci resulting from soft switching is shown in Fig. 5.11, where significant reduction in switching stress can be noticed. The traditional snubber circuits achieves this goal without the added control complexity, but the power dissipation in these snubber circuits can be large and limit the switching frequency of the converter. Also passive components significantly add to the size, weight, and cost of the converter at high power levels. Soft switching uses lossless resonant circuits, which overcomes the problem

of power loss in the snubber circuit, but increases the conduction loss. Resonant transition circuits eliminate the problem of high peak device stress in the soft-switched converters. The main drawback of these circuits is the increased control complexity required to obtain the resonant switching transition. The large number of circuit variables that have to be sensed in such power converters can affect their reliability. Short circuit capability no longer being the primary concern, designers can push the performance envelope for their circuits until the device becomes the limiting factor once again.

The transient response of the conventional volts/hertz induction motor drive is sluggish, because both torque and flux are functions of stator voltage and frequency. Use of vector or field oriented control methods makes the performance of the induction motor drive almost identical to that of a separately excited dc motor. Therefore, the transient response is like a dc machine, where torque and flux can be controlled in a decoupled manner. Vector controlled induction motors with shaft encoders or speed sensors have been widely applied in combination with voltage source PWM inverters using IGBT modules. According to the specification of the new products, vector controlled induction motor drive systems ranging from kilowatts to megawatts provide a broad range of speed control, constant torque operation, and high starting torque.

Because of their simple gate drives and modular packaging, IGBTs lead to simpler construction of power electronic circuits. This feature has lead to a trend to standardize and modularize power electronic circuits. Simplification of the overall system design and construction and significant cost reduction are the main implications of this approach. With these goals the power electronics building block (PEBB) program has been introduced, where the entire power electronic converter system is reduced to a single block. Similar modular power electronic blocks are commercially available at low power levels in the form of power integrated circuits. At higher power levels, these blocks have been realized in the form of intelligent power modules and power blocks. But these high power modules do not encompass the entire power electronic systems like motor drives and UPS. The aim of the PEBB program is to realize the whole power handling system within standardized blocks. A PEBB is a universal power processor that changes any

electrical power input to any desired form of voltage, current, and frequency output. A PEBB is a single package with a multi-function controller that replaces the complex power electronic circuits with a single device and therefore reduces the development and design costs of the complex power circuits and simplifies the development and design of large electric power systems.

The applications of power electronics are varied and various applications have their own specific design requirement. There is a wide choice of available power devices. Because of physical, material, and design limitations, none of the presently available devices behave as an ideal switch, which should block arbitrarily large forward and reverse voltages with zero current in the off-state, conduct arbitrarily large currents with zero voltage drop in the on-state, and have negligible switching time and power loss. Therefore, power electronic circuits should be designed by considering the capabilities and limitations of available devices. Traditionally there has been limited interaction between device manufacturers and circuit designers. Therefore, manufacturers have been fabricating generic power semiconductor devices with inadequate consideration of the specific applications where the devices are used. The diverse nature of power electronics does not allow the use of generic power semiconductor devices in all applications as it leads to non-optimal systems. Therefore, the devices and circuits need to be optimized at the application level. Soft-switching topologies offer numerous advantages over conventional hard-switching applications such as reduced switching stress and EMI, and higher switching speed at reduced power loss. The IGBTs behave dissimilarly in the two circuit conditions. As a result, devices optimized for hard switching conditions do not necessarily give the best possible performance when used in soft switching circuits. In order to extract maximum system performance, it is necessary to develop IGBTs suited for specific applications. These optimized devices need to be manufacturable and cost effective in order to be commercially viable.

6.1 Introduction

Thyristors are usually three-terminal devices that have four layers of alternating *p*-type and *n*-type material (i.e. three *p*–*n* junctions) comprising its main power handling section. In contrast to the linear relation which exists between load and control currents in a transistor, the thyristor is bistable. The control terminal of the thyristor, called the gate (*G*) electrode, may be connected to an integrated and complex structure as a part of the device. The other two terminals, called the anode (*A*) and cathode (*K*), handle the large applied potentials (often of both polarities) and conduct the major current through the thyristor. The anode and cathode terminals are connected in series with the load to which power is to be controlled.

Thyristors are used to approximate ideal closed (no voltage drop between anode and cathode) or open (no anode current flow) switches for control of power flow in a circuit. This differs from low-level digital switching circuits that are designed to deliver two distinct small voltage levels while conducting small currents (ideally zero). Thyristor circuits must have the capability of delivering large currents and be able

to withstand large externally applied voltages. All thyristor types are controllable in switching from a forward-blocking state (positive potential applied to the anode with respect to the cathode, with correspondingly little anode current flow) into a forward-conduction state (large forward anode current flowing, with a small anode–cathode potential drop). Most thyristors have the characteristic that after switching from a forward-blocking state into the forward-conduction state, the gate signal can be removed and the thyristor will remain in its forward-conduction mode. This property is termed "latching" and is an important distinction between thyristors and other types of power electronic devices. Some thyristors are also controllable in switching from forward-conduction back to a forward-blocking state. The particular design of a thyristor will determine its controllability and often its application.

Thyristors are typically used at the highest energy levels in power conditioning circuits because they are designed to handle the largest currents and voltages of any device technology (systems approximately with voltages above 1 kV or currents above 100 A). Many medium-power circuits (systems operating at less than 1 kV or 100 A) and particularly

low-power circuits (systems operating below 100 V or several amperes) generally make use of power bipolar transistors, power metal oxide semiconductor field effect transistors (MOSFETs) or insulated gate bipolar transistors (IGBTs) as the main switching elements because of the relative ease in controlling them. IGBT technology, however, continues to improve and multiple silicon die are commonly packaged together in a module. These modules are replacing thyristors in applications operating up to 3 kV that require controllable turn-off because of easier gate-drive requirements. Power diodes are used throughout all levels of power conditioning circuits and systems for component protection and wave shaping.

A thyristor used in some ac power circuits (50 or 60 Hz in commercial utilities or 400 Hz in aircraft) to control ac power flow can be made to optimize internal power loss at the expense of switching speed. These thyristors are called phase-control devices, because they are generally turned from a forward-blocking into a forward-conducting state at some specified phase angle of the applied sinusoidal anode–cathode voltage waveform. A second class of thyristors is used in association with dc sources or in converting ac power at one amplitude and frequency into ac power at another amplitude and frequency, and must generally switch on and off relatively quickly. A typical application for the second class of thyristors is in converting a dc voltage or current into an ac voltage or current. A circuit that performs this operation is often called an inverter, and the associated thyristors used are referred to as inverter thyristors.

There are four major types of thyristors: (i) the silicon-controlled rectifier (SCR); (ii) the gate turn-off thyristor (GTO) and its close relative the integrated gate commutated thyristor (IGCT); (iii) the MOS-controlled thyristor (MCT) and its various forms; and (iv) the static induction thyristor (SITh). MCTs are so-named because many parallel enhancement mode, MOSFET structures of one charge type are integrated into the thyristor for turn-on and many more MOSFETs of the other charge type are integrated into the thyristor for turn-off. A SITh or field-controlled thyristor (FCTh), has essentially the same construction as a power diode with a gate structure that can pinch-off anode current flow. Although MCTs, derivative forms of the MCT and SIThs have the advantage of being essentially voltage-controlled devices (i.e. little control current is required for turn-on or turn-off, and therefore require simplified control circuits attached to the gate electrode), they are currently only found in niche applications such as pulse power. Detailed discussion of variations of MCTs and SIThs, as well as additional references on these devices are discussed by Hudgins in [1]. Other types of thyristors include the Triac (a pair of anti-parallel SCRs integrated together to form a bi-directional current switch) and the programmable unijunction transistor (PUT).

The SCRs and GTOs are designed to operate at all power levels. These devices are primarily controlled using electrical signals (current), though some types are made to be controlled using optical energy (photons) for turn-on. Subclasses of SCRs and GTOs are reverse conducting types and symmetric structures that block applied potentials in the reverse and forward polarities. Other variations of GTOs are the gate-commutated turn-off thyristor (GCT), commonly available as the IGCT, and the bi-directional controlled thyristor (BCT). Most power converter circuits incorporating thyristors make use of SCRs, GTOs, or IGCTs, and hence the chapter will focus on these devices, though the basics of operation are applicable to all thyristor types.

All power electronic devices must be derated (e.g. power dissipation levels, current conduction, voltage blocking, and switching frequency must be reduced), when operating above room temperature (defined as approximately 25°C). Bipolar-type devices have thermal runaway problems, in that if allowed to conduct unlimited current, these devices will heat up internally causing more current to flow, thus generating more heat, and so forth until destruction. Devices that exhibit this behavior are *pin* diodes, bipolar transistors, and thyristors.

Almost all power semiconductor devices are made from silicon (Si). Research and development continues in developing other types of devices in silicon carbide (SiC), gallium nitride (GaN), and related material systems. However, the physical description and general behavior of thyristors is unimportant to the semiconductor material system used, though the discussion and any numbers cited in the chapter will be associated with Si devices.

6.2 Basic Structure and Operation

Figure 6.1 shows a conceptual view of a typical thyristor with the three *p–n* junctions and the external electrodes labeled. Also shown in the figure is the thyristor circuit symbol used in electrical schematics.

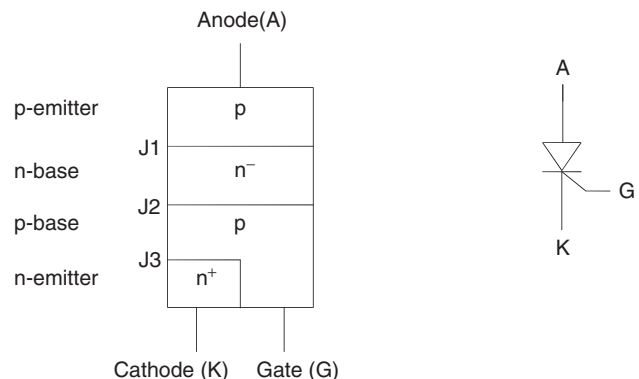

FIGURE 6.1 Simple cross section of a typical thyristor and the associated electrical schematic symbols.

A high-resistivity region, *n*-base, is present in all thyristors. It is this region, the *n*-base and associated junction, J_2 of Fig. 6.1, which must support the large applied forward voltages that occur when the switch is in its off- or forward-blocking state (non-conducting). The *n*-base is typically doped with impurity phosphorous atoms at a concentration of 10^{13} to 10^{14} cm^{-3}. The *n*-base can be tens to hundreds of micrometer thick to support large voltages. High-voltage thyristors are generally made by diffusing aluminum or gallium into both surfaces to create *p*-doped regions forming deep junctions with the *n*-base. The doping profile of the *p*-regions ranges from about 10^{15} to 10^{17} cm^{-3}. These *p*-regions can be up to tens of micrometer thick. The cathode region (typically only a few micrometer thick) is formed by using phosphorous atoms at a doping density of 10^{17} to 10^{18} cm^{-3}.

The higher the forward-blocking voltage rating of the thyristor, the thicker the *n*-base region must be. However, increasing the thickness of this high-resistivity region results in slower turn-on and turn-off (i.e. longer switching times and/or lower frequency of switching cycles because of more stored charge during conduction). For example, a device rated for a forward-blocking voltage of 1 kV will, by its physical construction, switch much more slowly than one rated for 100 V. In addition, the thicker high-resistivity region of the 1 kV device will cause a larger forward voltage drop during conduction than the 100 V device carrying the same current. Impurity atoms, such as platinum or gold, or electron irradiation are used to create charge-carrier recombination sites in the thyristor. The large number of recombination sites reduces the mean carrier lifetime (average time that an electron or hole moves through the Si before recombining with its opposite charge-carrier type). A reduced carrier lifetime shortens the switching times (in particular the turn-off or recovery time) at the expense of increasing the forward-conduction drop. There are other effects associated with the relative thickness and layout of the various regions that make up modern thyristors, but the major tradeoff between forward-blocking voltage rating and switching times, and between forward-blocking voltage rating and forward-voltage drop during conduction should be kept in mind. (In signal-level electronics an analogous tradeoff appears as a lowering of amplification (gain) to achieve higher operating frequencies, and is often referred to as the gain-bandwidth product.)

Operation of thyristors is as follows. When a positive voltage is applied to the anode (with respect to cathode), the thyristor is in its forward-blocking state. The center junction, J_2 (see Fig. 6.1) is reverse biased. In this operating mode the gate current is held to zero (open circuit). In practice, the gate electrode is biased to a small negative voltage (with respect to the cathode) to reverse bias the GK-junction J_3 and prevent charge-carriers from being injected into the *p*-base. In this condition only thermally generated leakage current flows through the device and can often be approximated as zero in value (the actual value of the leakage current is typically many orders of magnitude lower than the conducted current in the on-state). As long as the forward applied voltage does not exceed the value necessary to cause excessive carrier multiplication in the depletion region around J_2 (avalanche breakdown), the thyristor remains in an off-state (forward-blocking). If the applied voltage exceeds the maximum forward-blocking voltage of the thyristor, it will switch to its on-state. However, this mode of turn-on causes non-uniformity in the current flow, is generally destructive, and should be avoided.

When a positive gate current is injected into the device, J_3 becomes forward biased and electrons are injected from the *n*-emitter into the *p*-base. Some of these electrons diffuse across the *p*-base and get collected in the *n*-base. This collected charge causes a change in the bias condition of J_1. The change in bias of J_1 causes holes to be injected from the *p*-emitter into the *n*-base. These holes diffuse across the *n*-base and are collected in the *p*-base. The addition of these collected holes in the *p*-base acts the same as gate current. The entire process is regenerative and will cause the increase in charge carriers until J_2 also becomes forward biased and the thyristor is latched in its on-state (forward-conduction). The regenerative action will take place as long as the gate current is applied in sufficient amount and for a sufficient length of time. This mode of turn-on is considered to be the desired one as it is controlled by the gate signal.

This switching behavior can also be explained in terms of the two-transistor analog shown in Fig. 6.2. The two transistors are regeneratively coupled so that if the sum of their forward current gains (α's) exceeds unity, each drives the other into saturation. Equation 6.1 describes the condition necessary for the thyristor to move from a forward-blocking state into the forward-conduction state. The forward current gain (expressed as the ratio of collector current to emitter current) of the *pnp* transistor is denoted by α_p, and that of the *npn* as α_n. The α's are current dependent and increase slightly as the current increases. The center junction J_2 is reverse biased under forward applied voltage (positive, v_{AK}). The associated electric field in the depletion region around the junction can result

FIGURE 6.2 Two-transistor behavioral model of a thyristor.

in significant carrier multiplication, denoted as a multiplying factor M on the current components, I_{co} and i_G.

$$i_A = \frac{MI_{co} + M\alpha_n i_G}{1 - M(\alpha_n + \alpha_p)} \qquad (6.1)$$

In the forward-blocking state, the leakage current I_{co} is small, both α's are small, and their sum is less than unity. Gate current increases the current in both transistors, increasing their α's. Collector current in the *npn* transistor acts as base current for the *pnp*, and analogously, the collector current of the *pnp* acts as base current driving the *npn* transistor. When the sum of the two α's equals unity, the thyristor switches to its on-state (latches). This condition can also be reached, without any gate current, by increasing the forward applied voltage so that carrier multiplication ($M \gg 1$) at J_2 increases the internal leakage current, thus increasing the two α's. A third way to increase the α's exists by increasing the device (junction) temperature. Increasing the temperature causes a corresponding increase in the leakage current I_{co} to the point where latching can occur. The typical manifestation of this temperature dependence is to cause an effective lowering of the maximum blocking voltage that can be sustained by the thyristor.

Another way to cause a thyristor to switch from forward-blocking to forward-conduction exists. Under a forward applied voltage, J_2 is reverse biased while the other two junctions are forward-biased in the blocking mode. The reverse-biased junction of J_2 is the dominant capacitance of the three and determines the displacement current that flows. If the rate of increase in the applied v_{AK} (dv_{AK}/dt) is sufficient, it will cause a significant displacement current through the J_2 capacitance. This displacement current can initiate switching similar to an externally applied gate current. This dynamic phenomenon is inherent in all thyristors and causes there to be a limit (dv/dt) to the time rate of applied v_{AK} that can be placed on the device to avoid uncontrolled switching. Alterations to the basic thyristor structure can be produced that increase the dv/dt limit and will be discussed in Section 6.4.

Once the thyristor has moved into forward-conduction, any applied gate current is superfluous. The thyristor is latched and, for SCRs, cannot be returned to a blocking mode by using the gate terminal. Anode current must be commutated away from the SCR for a sufficient time to allow stored charge in the device to recombine. Only after this recovery time has occurred, can a forward voltage be reapplied (below the dv/dt limit of course) and the SCR again be operated in a forward-blocking mode. If the forward voltage is reapplied before sufficient recovery time has elapsed, the SCR will move back into forward-conduction. For GTOs and IGCTs, a large applied reverse gate current (typically in the range of 10–50% of the anode current for GTOs, and 100% of the anode current for IGCTs) applied for a sufficient time can remove enough charge near the GK junction to cause it to turn-off. This interrupts the base current to the *pnp* transistor, leaving the *pnp* open-base, causing thyristor turn-off. This is similar in principle to use negative base current to quickly turn-off a traditional bipolar transistor.

6.3 Static Characteristics

6.3.1 Current–Voltage Curves for Thyristors

A plot of the anode current (i_A) as a function of anode–cathode voltage (v_{AK}) is shown in Fig. 6.3. The forward-blocking mode is shown as the low-current portion of the graph (solid curve around operating point "1"). With zero gate current and positive v_{AK}, the forward characteristic in the off- or blocking-state is determined by the center junction J_2, which is reverse biased. At operating point "1" very little current flows (I_{co} only) through the device. However, if the applied voltage exceeds the forward-blocking voltage, the thyristor switches to its on- or conducting-state (shown as operating point "2") because of carrier multiplication (M in Eq. (6.1)). The effect of gate current is to lower the blocking voltage at which switching takes place. The thyristor moves rapidly along the negatively-sloped portion of the curve until it reaches a stable operating point determined by the external circuit (point "2"). The portion of the graph indicating forward-conduction shows the large values of i_A that may be conducted at relatively low values of v_{AK}, similar to a power diode.

As the thyristor moves from forward-blocking to forward-conduction, the external circuit must allow sufficient anode current to flow to keep the device latched. The minimum anode current that will cause the device to remain in forward-conduction as it switches from forward-blocking is called the

FIGURE 6.3 Static characteristic *i–v* curve typical of thyristors.

latching current I_L. If the thyristor is already in forward-conduction and the anode current is reduced, the device can move its operating mode from forward-conduction back to forward-blocking. The minimum value of anode current necessary to keep the device in forward-conduction after it has been operating at a high anode current value is called the holding current I_H. The holding current value is lower than the latching current value as indicated in Fig. 6.3.

The reverse thyristor characteristic, quadrant III of Fig. 6.3, is determined by the outer two junctions (J_1 and J_3), which are reverse biased in this operating mode (applied v_{AK} is negative). Symmetric thyristors are designed so that J_1 will reach reverse breakdown due to carrier multiplication at an applied reverse potential near the forward breakdown value (operating point "3" in Fig. 6.3). The forward- and reverse-blocking junctions are usually fabricated at the same time with a very long diffusion process (10–50 h) at high temperatures (>1200°C). This process produces symmetric blocking properties. Wafer edge termination processing causes the forward-blocking capability to be reduced to about 90% of the reverse-blocking capability. Edge termination is discussed below. Asymmetric devices are made to optimize forward-conduction and turn-off properties, and as such reach reverse breakdown at a lower voltage than that applied in the forward direction. This is accomplished by designing the asymmetric thyristor with a much thinner n-base than is used in symmetric structures. The thin n-base leads to improved properties such as lower forward drop and shorter switching times. Asymmetric devices are generally used in applications when only forward voltages (positive, v_{AK}) are to be applied (including many inverter designs).

The form of the gate-to-cathode i–v characteristic of SCRs, GTOs and IGCTs is similar to that of a diode. With positive gate bias, the gate–cathode junction is forward biased and permits the flow of a large current in the presence of a low voltage drop. When negative gate voltage is applied to an SCR, the gate–cathode junction is reverse biased and prevents the flow of current until the avalanche breakdown voltage is reached. In a GTO or IGCT, a negative gate voltage is applied to provide a low impedance path for anode current to flow out of the device instead of out the cathode. In this way the cathode region (base–emitter junction of the equivalent *npn* transistor) turns off, thus pulling the equivalent *npn* transistor out of conduction. This causes the entire thyristor to return to its blocking state. The problem with the GTO and IGCT is that the gate-drive circuitry is typically required to sink 10–50% (for the GTO) or 100% (for the IGCT) of the anode current to achieve turn-off.

6.3.2 Edge and Surface Terminations

Thyristors are often made with planar diffusion technology to create the cathode region. Formation of these regions creates cylindrical curvature of the metallurgical gate–cathode junction. Under reverse bias, the curvature of the associated depletion region results in electric field crowding along the curved section of the p^+ diffused region. The field crowding seriously reduces the breakdown potential below that expected for the bulk semiconductor. A floating field ring, an extra p diffused region with no electrical connection at the surface, is often added to modify the electric field profile and thus reduce it to a value below or at the field strength in the bulk. An illustration of a single floating field ring is shown in Fig. 6.4. The spacing, W, between the main anode region and the field ring is critical. Multiple rings can also be employed to further modify the electric field in high-voltage rated thyristors.

Another common method for altering the electric field at the surface is by using a field plate as shown in cross section in Fig. 6.5. By forcing the potential over the oxide to be the same as at the surface of the p^+ region, the depletion region can be extended so that the electric field intensity is reduced near the curved portion of the diffused p^+ region. A common practice is to use field plates with floating field rings to obtain optimum breakdown performance.

High-voltage thyristors are made from single wafers of Si and must have edge terminations other than floating field rings or field plates to promote bulk breakdown and limit
FIGURE 6.4 Cross section showing a floating field ring to decrease the electric field intensity near the curved portion of the main anode region (left-most p^+ region).
FIGURE 6.5 Cross section showing a field plate used to reduce the electric field intensity near the curved portion of the p^+-region (anode).
FIGURE 6.6 Cross section of a thyristor showing the negative bevel (upper p–n^- and p–n^+ junctions) and positive bevel (lower p–n^- junction) used for edge termination of large-area devices.

leakage current at the surface. Controlled bevel angles can be created using lapping and polishing techniques during production of large-area thyristors. Two types of bevel junctions can be created: (i) a positive bevel defined as one in which the junction area decreases when moving from the highly-doped to the lightly-doped side of the depletion region and (ii) a negative bevel defined as one in which the junction area increases when moving from the highly-doped to the lightly-doped side of the depletion region. In practice, the negative bevel must be lapped at an extremely shallow angle to reduce the surface field below the field intensity in the bulk. All positive bevel angles between 0 and 90° result in a lower surface field than in the bulk. Figure 6.6 shows the use of a positive bevel for the J_1 junction and a shallow negative bevel for the J_2 and J_3 junctions on a thyristor cross section to make maximum use of the Si area for conduction and still reduce the surface electric field. Further details of the use of beveling, field plates, and field rings can be found in Ghandi [2] and Baliga [3].

6.3.3 Packaging

Thyristors are available in a wide variety of packages, from small plastic ones for low-power (i.e. TO-247), to stud-mount packages for medium-power, to press-pack (also called flat-pack) for the highest power devices. The press-packs must be mounted under pressure to obtain proper electrical and thermal contact between the device and the external metal electrodes. Special force-calibrated clamps are made for this purpose. Large-area thyristors cannot be directly attached to the large copper pole piece of the press-pack because of the difference in the coefficient of thermal expansion (CTE), hence the use of a pressure contact for both anode and cathode. Figure 6.7 shows typical thyristor stud-mount and press-pack packages.

Many medium power thyristors are appearing in modules where a half- or full-bridge (and associated anti-parallel diodes) is put together in one package. A power module package should have five characteristics:

   i) electrical isolation of the baseplate from the semiconductor;
   ii) good thermal performance;
   iii) good electrical performance;
   iv) long life/high reliability; and
   v) low cost.

Electrical isolation of the baseplate from the semiconductor is necessary in order to contain both halves of a phase leg in one package as well as for convenience (modules switching different phases can be mounted on one heatsink) and safety (heatsinks can be held at ground potential).

Thermal performance is measured by the maximum temperature rise in the Si die at a given power dissipation level with a fixed heat sink temperature. The lower the die temperature, the better the package. A package with a low thermal resistance from junction-to-sink can operate at higher power densities for the same temperature rise or lower temperatures for the same power dissipation than a more thermally resistive package. While maintaining low device temperature is generally preferable, temperature variation affects majority carrier and bipolar devices differently. Roughly speaking, in a bipolar device such as a thyristor, switching losses increase and

FIGURE 6.7 Examples of thyristor packaging: stud-mount (left) and press-pack/capsule (right).

TABLE 6.1   Thermal conductivity of thyristor package materials

| Material	Thermal conductivity (W/m·K) at 300 K
Silicon	150
Copper (baseplate and pole pieces)	390–400
AlN substrate	170

60/40 solder (Pb/Sn eutectic)	25

conduction losses decrease with increasing temperature. In a majority carrier device, such as a MOSFET, conduction losses increase with increasing temperature. The thermal conductivity of typical materials used in thyristor packages is shown in Table 6.1.

Electrical performance refers primarily to the stray inductance in series with the die, as well as the capability of mounting a low-inductance bus to the terminals. Another problem is the minimization of capacitive cross-talk from one switch to another, which can cause an abnormal on-state condition by charging the gate of an off-state switch, or from a switch to any circuitry in the package (as would be found in a hybrid power module). Capacitive coupling is a major cause of electromagnetic interference (EMI). As the stray inductance of the module and the bus sets a minimum switching loss for the device – because the switch must absorb the stored inductive energy – it is very important to minimize inductance within the module. Reducing the parasitic inductance reduces the high-frequency ringing during transients that is another cause of radiated electromagnetic interference. Since stray inductance can cause large peak voltages during switching transients, minimizing it helps to maintain the device within its safe area of operation.

Long life and high reliability are primarily attained through minimization of thermal cycling, minimization of ambient temperature, and proper design of the transistor stack. Thermal cycling fatigues material interfaces because of coefficient of thermal expansion (CTE) mismatch between dissimilar materials. As the materials undergo temperature variation, they expand and contract at different rates which stresses the interface between the layers and can cause interface deterioration (e.g. cracking of solder layers or wire debonding). Chemical degradation processes such as dendrite growth and impurity migration are accelerated with increasing temperature, so keeping the absolute temperature of the device low, as well as minimizing the temperature changes to which it is subjected is important. Typical CTE values for common package materials are given in Table 6.2.

Low cost is achieved in a variety of ways. Both manufacturing and material costs must be taken into account when designing a power module. Materials that are difficult to machine or process, even if they are relatively cheap in raw form (molybdenum, for example), should be avoided. Manufacturing processes that lower yield also drive up costs. In addition, a part that is very reliable can reduce future costs by reducing the need for repair and replacement.

The basic half-bridge module has three power terminals: plus, minus and phase. Advanced modules differ from traditional high power commercial modules in several ways. The baseplate is metallized aluminum nitride (AlN) ceramic rather than the typical 0.125" thick nickel-plated copper baseplate with a soldered metallized ceramic substrate for electrical isolation. This AlN baseplate stack provides a low thermal resistance from die to heatsink. The copper terminal power busses are attached by solder to the devices in a wirebond-free, low-inductance, low-resistance, device interconnect configuration. The balance of the assembly is typical for module manufacturing with attachment of shells, use of dielectric gels, and hard epoxies and adhesive to seal the finished module. Details of the thermal performance of modules and advanced modules can be found in Beker *et al.* [4] and Godbold *et al.* [5].

6.4 Dynamic Switching Characteristics

The time rate of rise of anode current (*di/dt*) during turn-on and the time rate of rise of anode–cathode voltage (*dv/dt*) during turn-off are important parameters to control for ensuring proper and reliable operation. All thyristors have maximum limits for *di/dt* and *dv/dt* that must not be exceeded. Devices capable of conducting large currents in the on-state, are necessarily made with large surface areas through which the current flows. During turn-on, localized areas of a device (near the gate region) begin to conduct current. The initial turn-on of an SCR is shown in Fig. 6.8. The cross section illustrates how injected gate current flows to the nearest cathode region, causing this portion of the *npn* transistor to begin conducting. The *pnp* transistor then follows the *npn* into conduction such that anode current begins flowing only in a small portion of the

FIGURE 6.8 Top view and associated cross section of gate–cathode periphery showing initial turn-on region in a center-fired thyristor.

applications, the entire cathode region is never fully in conduction. Prevention of *di/dt* failure can be accomplished if the rate of increase of conduction area exceeds the *di/dt* rate such that the internal junction temperature does not exceed a specified critical temperature (typically approximately 350°C). This critical temperature decreases as the blocking voltage increases. Adding series inductance to the thyristor to limit *di/dt* below its maximum usually causes circuit design problems.

Another way to increase the *di/dt* rating of a device is to increase the amount of gate–cathode periphery. Inverter SCRs (so-named because of their use in high-frequency power converter circuits that convert dc to ac, i.e. invert) are designed so that there is a large amount of gate edge adjacent to a significant amount of cathode edge. A top surface view of two typical gate–cathode patterns, found in large thyristors, is shown in Fig. 6.9. An inverter SCR often has a stated maximum *di/dt* limit of approximately 2000 A/μs. This value has been shown to be conservative [6], and by using excessive gate current under certain operating conditions, an inverter SCR can be operated reliably at 10,000 A/μs–20,000 A/μs.

A GTO takes the interdigitation of the gate and cathode to the extreme (Fig. 6.9, left). In Fig. 6.10 a cross section of a GTO shows the amount of interdigitation. A GTO often has cathode islands that are formed by etching the Si. A metal plate can be placed on the top to connect the individual cathodes into a large arrangement of electrically parallel cathodes. The gate metallization is placed so that the gate surrounding each cathode is electrically in parallel as well. This construction not only allows high *di/dt* values to be reached, as in an inverter SCR, but also provides the capability to turn-off the anode current by shunting it away from the individual cathodes and out of the gate electrode upon reverse biasing of the gate. During turn-off, current is decreasing while voltage across the device is increasing. If the forward voltage becomes too high while sufficient current is still flowing, then the device will drop back into its conduction mode instead of completing its turn-off cycle. Also, during turn-off, the power dissipation can

cathode region. If the local current density becomes too large (in excess of several thousand amperes per square centimeter), then self-heating will damage the device. Sufficient time (referred to as plasma spreading time) must be allowed for the entire cathode area to begin conducting before the localized currents become too high. This phenomenon results in a maximum allowable rate of rise of anode current in a thyristor and is referred to as a *di/dt* limit. In many high-frequency

FIGURE 6.9 Top view of typical interdigitated gate–cathode patterns used for thyristors.
FIGURE 6.10 Cross section of a GTO showing the cathode islands and interdigitation with the gate (*p*-base).

FIGURE 6.11 Two-transistor equivalent circuit showing the addition of a resistive shunt path for anode current.

become excessive if the current and voltage are simultaneously too large. Both of these turn-off problems can damage the device as well as other portions of the circuit.
Another switching problem that occurs is associated primarily with thyristors, though other power electronic devices suffer some degradation of performance from the same problem. This problem is that thyristors can self-trigger into a forward-conduction mode from a forward-blocking mode if the rate of rise of forward anode–cathode voltage is too large. This triggering method is due to displacement current through the associated junction capacitances (the capacitance at J_2 dominates because it is reverse biased under forward applied voltage). The displacement current contributes to the leakage current I_{co}, shown in Eq. (6.1). The SCRs, GTOs and IGCTs, therefore, have a maximum dv/dt rating that should not be exceeded (typical values are 100–1000 V/μs). Switching into a reverse-conducting from a reverse-blocking state, due to an applied reverse dv/dt, is not possible because the values of the reverse α's of the equivalent transistors can never be made large enough to cause the necessary feedback (latching) effect. An external capacitor is often placed between the anode and cathode of the thyristor to help control the dv/dt experienced. Capacitors and other components that are used to form such protection circuits, known as snubbers, may be found in all power semiconductor devices.

6.4.1 Cathode Shorts

As the temperature in the thyristor increases above 25°C, the minority carrier lifetime and the corresponding diffusion lengths in the *n*- and *p*-bases increase. This leads to an increase in the α's of the equivalent transistors. Discussion of the details of the minority carrier diffusion length and its role in determining the current gain factor α can be found in Sze [7]. Referring to Eq. (6.1), it is seen that a lower applied bias will give a carrier multiplication factor M sufficient to switch the device from forward-blocking into conduction, because of this increase of the α's with increasing temperature. Placing a shunt resistor in parallel with the base–emitter junction of the equivalent *npn* transistor (shown in Fig. 6.11) will result in an effective current gain, α_{neff}, that is lower than α_n, as given by
FIGURE 6.12 Cross section showing cathode shorts and the resulting resistive shunt path for anode current.

Eq. (6.2), where v_{GK} is the applied gate–cathode voltage, R_s is the equivalent lumped value for the distributed current shunting structure, and the remaining factors form the appropriate current factor based on the applied bias and characteristics of the gate–cathode junction. The shunt current path is implemented by providing intermittent shorts, called cathode shorts, between the *p*-base (gate) region and the n^+-emitter (cathode) region in the thyristor as illustrated in Fig. 6.12. The lumped shunt resistance value is in the range of 1–15 Ω as measured from gate to cathode.

$$\alpha_{neff} = \alpha_n \left(\frac{1}{1 + (v_{GK}\alpha_n)/(R_s i_0 \ exp(qv_{GK}/kT))} \right) \quad (6.2)$$

Low values of anode current (e.g. those associated with an increase in temperature under forward-blocking conditions) will flow through the shunt path to the cathode contact, bypassing the n^+-emitter and keeping the device out of its forward-conduction mode. As the anode current becomes

large, the potential drop across the shunt resistance will be sufficient to forward bias the gate–cathode junction, J_3, and bring the thyristor into forward-conduction. The cathode shorts also provide a path for displacement current to flow without forward biasing J_3. The *dv/dt* rating of the thyristor is thus improved as well as the forward-blocking characteristics by using cathode shorts. However, the shorts do cause a lowering of cathode current handling capability because of the loss of some of the cathode area (n^+-region) to the shorting pattern, an increase in the necessary gate current to obtain switching from forward-blocking to forward-conduction, and an increase in complexity of manufacturing of the thyristor. The loss of cathode area due to the shorting-structure is from 5 to 20%, depending on the type of thyristor. By careful design of the cathode short windows to the *p*-base, the holding current can be made lower than the latching current. This is important so that the thyristor will remain in forward-conduction when used with varying load impedances.

6.4.2 Anode Shorts

A further increase in forward-blocking capability can be obtained by introducing anode shorts in addition to the cathode shorts. This reduces α_p in a similar manner that cathode shorts reduce α_n. An illustration of this is provided in Fig. 6.13. In this structure both J_1 and J_3 are shorted (anode and cathode shorts), so that the forward-blocking capability of the thyristor is completely determined by the avalanche breakdown characteristics of J_2. Anode shorts will result in the complete loss of reverse-blocking capability and is only suitable for thyristors used in asymmetric circuit applications.
FIGURE 6.13 Cross section showing integrated cathode and anode shorts.

6.4.3 Amplifying Gate

The cathode-shorting structure will reduce the gate sensitivity dramatically. To increase this sensitivity and yet retain the
FIGURE 6.14 Cross section showing the amplifying gate structure in a thyristor.

benefits of the cathode-shorts, a structure called an amplifying gate (or regenerative gate) is used, as shown in Fig. 6.14 (and Fig. 6.9, right). When the gate current (1) is injected into the *p*-base through the pilot-gate contact, electrons are injected into the *p*-base by the n^+-emitter with a given emitter injection efficiency. These electrons traverse through the *p*-base (the time taken for this process is called the transit time) and accumulate near the depletion region. This negative charge accumulation leads to injection of holes from the anode. The device then turns on after a certain delay, dictated by the *p*-base transit time, and the pilot anode current (2) begins to flow through a small region near the pilot-gate contact as shown in Fig. 6.14.

This flow of pilot anode current corresponds to the initial sharp rise in the anode current waveform (phase I), as shown in Fig. 6.15. The device switching then goes into phase II, during which the anode current remains fairly constant, suggesting that the resistance of the region has reached its lower limit. This is due to the fact that the pilot anode current (2) takes a finite time to traverse through the *p*-base laterally and become the gate current for the main cathode area. The n^+-emitters start to inject electrons which traverse the *p*-base vertically and after a certain finite time (transit time of the *p*-base) reach the depletion region. The total time taken by the lateral traversal of pilot anode current and the electron transit time across the *p*-base is the reason for observing this characteristic phase II interval. The width of the phase II interval is comparable to the switching delay, suggesting that the *p*-base transit time is of primary importance. Once the main cathode region turns on, the resistance of the device decreases and the anode current begins to rise again (transition from phase II to III). From this time onward in the switching cycle, the plasma spreading velocity will dictate the rate at which the conduction area will increase. The current density during phase I and II can be quite large, leading to a considerable increase in the local temperature and device failure. The detailed effect of the amplifying gate on the anode current rise will only be noticed at high levels of
FIGURE 6.15 Turn-on waveforms showing the effect of the amplifying gate in the anode current rise.

FIGURE 6.16 Temperature effect on the anode current tail during turn-off.

di/dt (in the range of 1000 A/μs), shown in Fig. 6.15. It can be concluded that the amplifying gate will increase gate sensitivity at the expense of some *di/dt* capability, as demonstrated by Sankaran [8]. This lowering of *di/dt* capability can be somewhat off-set by an increase in gate–cathode interdigitation as previously discussed.

6.4.4 Temperature Dependencies

The forward-blocking voltage of an SCR has been shown to be reduced from 1350 V at 25°C to 950 V at −175°C in a near linear fashion [8]. Above 25°C, the forward-blocking capability is again reduced, due to changes in the minority carrier lifetime which cause the leakage current to increase and the associated breakover voltage to decrease. Several dominant physical parameters associated with semiconductor devices are sensitive to temperature variations, causing their dependent device characteristics to change dramatically. The most important of these parameters are: (i) the minority carrier lifetimes (which control the high-level injection lifetimes); (ii) the hole and electron mobilities; (iii) the impact ionization collision cross sections; and (iv) the free-carrier concentrations (primarily the ionized impurity-atom concentration). Almost all of the impurity atoms are ionized at temperatures above 0°C, and so further discussion of the temperature effects on ionization is not relevant for normal operation. As the temperature increases above 25°C, the following trends are observed: the carrier lifetimes increase, giving longer recovery times and greater switching losses; the carrier mobilities are reduced, increasing the on-state voltage drop; and at very high temperatures, the intrinsic carrier concentration becomes sufficiently high that the depletion layer will not form and the device cannot switch off. A more detailed discussion of these physical parameters is beyond the scope of this article, but references are listed for those persons interested in pursuing relevant information about temperature effects.
It is well known that charge carrier recombination events are more efficient at lower temperatures. This shows up as a larger potential drop during forward-conduction and a shorter recovery time during turn-off. A plot of the anode current during turn-off, at various temperatures, for a typical GTO is shown in Fig. 6.16.

An approximate relation between the temperature and the forward drop across the *n*-base of a thyristor is discussed in detail by Herlet [10] and Hudgins *et al.* [11]. Temperature dependent equations relating the anode current density, J_A and the applied anode–cathode voltage V_{AK} are also given in Reference [11]; these include the junction potential drops in the device, the temperature dependence of the bandgap energy, and the *n*-base potential drop. Data from measurements at forward current densities of approximately 100 A/cm^2 on a GTO rated for 1 kV symmetric blocking gives forward voltage drops of 1.7 V at –50°C and 1.8 V at 150°C.

6.5 Thyristor Parameters

Understanding of a thyristor's maximum ratings and electrical characteristics is required for proper application. Use of a manufacturer's data sheet is essential for good design practice. *Ratings* are maximum or minimum values that set limits on device capability. A measure of device performance under specified operating conditions is a *characteristic* of the device. A summary of some of the maximum ratings which must be considered when choosing a thyristor for a given application is provided in Table 6.3. Thyristor types shown in parentheses indicate a maximum rating unique to that device. Both forward and reverse repetitive and non-repetitive voltage ratings must be considered, and a properly rated device must be chosen so that the maximum voltage ratings are never exceeded. In most cases, either forward or reverse voltage

TABLE 6.3 Thyristor maximum ratings specified by manufacturers

Symbol	Description
V_{RRM}	Peak repetitive reverse voltage
V_{RSM}	Peak non-repetitive reverse voltage (transient)
$V_{R(DC)}$	DC reverse blocking voltage
V_{DRM}	Peak repetitive forward off-state voltage
V_{DSM}	Peak non-repetitive forward off-state voltage (transient)
$V_{D(DC)}$	DC forward-blocking voltage
$I_{T(RMS)}, I_{F(RMS)}$	RMS forward on-state current
$I_T(AV), I_{F(AV)}$	Average forward on-state current at specified case or junction temperature
$I_{TSM}, I_{F(TSM)}$	Peak one-cycle surge on-state current (values specified at 60 and 50 Hz)
I_{TGQ} (GTO)	Peak controllable current
$I^2 t$	Non-repetitive pulse overcurrent capability ($t = 8.3$ ms for a 60 Hz half cycle)
P_T	Maximum power dissipation
di/dt	Critical rate of rise of on-state current at specified junction temperature, gate current and forward-blocking voltage
P_{GM} (P_{FGM} for GTO)	Peak gate power dissipation (forward)
P_{RGM} (GTO)	Peak gate power dissipation (reverse)
$P_{G(AV)}$	Average gate power dissipation
V_{FGM}	Peak forward gate voltage
V_{RGM}	Peak reverse gate voltage
I_{FGM}	Peak forward gate current
I_{RGM} (GTO)	Peak reverse gate current
T_{STG}	Storage temperature
T_j	Junction operating temperature
V_{RMS}	Voltage isolation (modules)

from a knowledge of steady-state thermal resistance $R_{\Theta(J-C)}$, and the average power dissipation. For transients or surges, the transient thermal impedance ($Z_{\Theta(J-C)}$) curve must be used (provided in manufacturer's data sheets). The maximum average power dissipation P_T is related to the maximum rated operating junction temperature and the case temperature by the steady-state thermal resistance. In general, both the maximum dissipation and its derating with increasing case temperature are provided.

The number and type of thyristor characteristics specified varies widely from one manufacturer to another. Some characteristics are given only as typical values of minima or maxima, while many characteristics are displayed graphically. Table 6.4 summarizes some of the typical characteristics provided as maximum values. The maximum value means that the manufacturer guarantees that the device will not exceed the value given under the specified operating or switching conditions. A minimum value means that the manufacturer guarantees that the device will perform at least, as well as the characteristic given under the specified operating or switching conditions. Thyristor types shown in parenthesis indicate a characteristic unique to that device. Gate conditions of both voltage and current to ensure either non-triggered or triggered device operation are included. The turn-on and turn-off transients of the thyristor are characterized by switching times like the turn-off

TABLE 6.4 Typical thyristor characteristic maximum and minimum values specified by manufacturers

Symbol	Description
V_{TM}, V_{FM}	Maximum on-state voltage drop(at specified junction temperature and forward current)
I_{DRM}	Maximum forward off-state current (at specified junction temperature and forward voltage)
I_{RRM}	Maximum reverse off-state current (at specified junction temperature and reverse voltage)
dv/dt	Minimum critical rate of rise of off-state voltage at specified junction temperature and forward-blocking voltage level
V_{GT}	Maximum gate trigger voltage (at specified temperature and forward applied voltage)
V_{GD}, V_{GDM}	Maximum gate non-trigger voltage (at specified temperature and forward applied voltage)
I_{GT}	Maximum gate trigger current (at specified temperature and forward applied voltage)
T_{gt} (GTO)	Maximum turn-on time (under specified switching conditions)
T_q	Maximum turn-off time (under specified switching conditions)
t_D	Maximum turn-on delay time (for specified test)
$R_{\Theta(J-C)}$	Maximum junction-to-case thermal resistance
$R_{\Theta(C-S)}$	Maximum case-to-sink thermal resistance (interface lubricated)

transients in excess of the non-repetitive maximum ratings result in destruction of the device. The maximum root mean square (RMS) or average current ratings given are usually those which cause the junction to reach its maximum rated temperature. Because the maximum current will depend upon the current waveform and upon thermal conditions external to the device, the rating is usually shown as a function of case temperature and conduction angle. The peak single half-cycle surge-current rating must be considered, and in applications where the thyristor must be protected from damage by overloads, a fuse with an $I^2 t$ rating smaller than the maximum rated value for the device must be used. Maximum ratings for both forward and reverse gate voltage, current and power also must not be exceeded.

The maximum rated operating junction temperature T_J must not be exceeded, since device performance, in particular voltage-blocking capability, will be degraded. Junction temperature cannot be measured directly but must be calculated

time listed in Table 6.4. The turn-on transient can be divided into three intervals: (i) gate-delay interval; (ii) turn-on of initial area; and (iii) spreading interval. The gate-delay interval is simply the time between application of a turn-on pulse at the gate and the time the initial cathode area turns on. This delay decreases with increasing gate drive current and is of the order of a few microseconds. The second interval, the time required for turn-on of the initial area, is quite short, typically less than 1 μs. In general, the initial area turned on is a small percentage of the total useful device area. After the initial area turns on, conduction spreads (spreading interval or plasma spreading time) throughout the device in tens of microseconds for high-speed or thyristors. The plasma spreading time may take up to hundreds of microseconds in large-area phase-control devices.

Table 6.5 lists many of the thyristor parameters that appear as listed values or as information on graphs. The definition of each parameter and the test conditions under which they are measured are given in the table as well.

6.6 Types of Thyristors

In recent years, most development effort has gone into continued integration of the gating and control electronics into thyristor modules, and the use of MOS-technology to create gate structures integrated into the thyristor itself. Many variations of this theme are being developed and some technologies should rise above the others in the years to come. Further details concerning most of the following discussion of thyristor types can be found in [1].

6.6.1 SCRs and GTOs

The highest power handling devices continue to be bipolar thyristors. High powered thyristors are large diameter devices, some well in excess of 100 mm, and as such have a limitation on the rate of rise of anode current, a di/dt rating. The depletion capacitances around the p–n junctions, in particular the center junction J_2, limit the rate of rise in forward voltage that can be applied even after all the stored charge, introduced during conduction, is removed. The associated displacement current under application of forward voltage during the thyristor blocking state sets a dv/dt limit. Some effort in improving the voltage hold-off capability and over-voltage protection of conventional SCRs is underway by incorporating a lateral high resistivity region to help dissipate the energy during breakover. Most effort, though, is being placed in the further development of high performance GTOs and IGCTs because of their controllability and to a lesser extent in optically triggered structures that feature gate circuit isolation.

High voltage GTOs with symmetric blocking capability require thick n-base regions to support the high electric field.

The addition of an $n+$ buffer layer next to the $p+$-anode allows high voltage forward-blocking and a low forward voltage drop during conduction because of the thinner n-base required. Cylindrical anode shorts have been incorporated to facilitate excess carrier removal from the n-base during turn-off and still retain the high blocking capability. This device structure can control 200 A, operating at 900 Hz, with a 6 kV hold-off. Some of the design tradeoff between the n-base width and turn-off energy losses in these structures have been determined. A similar GTO incorporating an n^+-buffer layer and a *pin* structure has been fabricated that can control up to 1 kA (at a forward drop of 4 V) with a forward blocking capability of 8 kV. A reverse conducting GTO has been fabricated that can block 6 kV in the forward direction, interrupt a peak current of 3 kA and has a turn-off gain of about 5.

The IGCT is a modified GTO structure. It is designed and manufactured so that it commutates all of the cathode current away from the cathode region and diverts it out of the gate contact. The IGCT is similar to a GTO in structure except that it always has a low-loss n-buffer region between the n-base and p-emitter. The IGCT device package is designed to result in a very low parasitic inductance and is integrated with a specially designed gate-drive circuit. The gate drive contains all the necessary di/dt and dv/dt protection; the only connections required are a low-voltage power supply for the gate drive and an optical signal for controlling the gate. The specially designed gate drive and ring-gate package circuit allows the IGCT to be operated without a snubber circuit, and to switch with a higher anode di/dt than a similar GTO. At blocking voltages of 4.5 kV and higher the IGCT provides better performance than a conventional GTO. The speed at which the cathode current is diverted to the gate (di_{GQ}/dt) is directly related to the peak snubberless turn-off capability of the IGCT. The gate drive circuit can sink current for turn-off at di_{GQ}/dt values in excess of 7000 A/μs. This hard gate drive results in a low charge storage time of about 1 μs. The low storage time and the fail-short mode makes the IGCT attractive for high-power, high-voltage series applications; examples include high-power converters in excess of 100 MVA, static vol-ampere reactive (VAR) compensators and converters for distributed generation such as wind power.

6.6.2 MOS-controlled Thyristors

The cross section of the p-type MCT unit cell is given in Fig. 6.17. When the MCT is in its forward-blocking state and a negative gate–anode voltage is applied, an inversion layer is formed in the n-doped material that allows holes to flow laterally from the p-emitter (p-channel FET source) through the channel to the p-base (p-channel FET drain). This hole flow is the base current for the npn transistor. The n-emitter then injects electrons which are collected in the n-base, causing the p-emitter to inject holes into the n-base so that the pnp transistor is turned on and latches the MCT. The MCT is brought

TABLE 6.5 Symbols and definitions of major thyristor parameters

|		
R_θ	Thermal resistance	Specifies the degree of temperature rise per unit of power, measuring junction temperature from a specified external point. Defined when junction power dissipation results in steady-state thermal flow.
$R_{\theta(J-A)}$	Junction-to-ambient thermal resistance	The steady-state thermal resistance between the junction and ambient.
$R_{\theta(J-C)}$	Junction-to-case thermal resistance	The steady-state thermal resistance between the junction and case surface.
$R_{\theta(J-S)}$	Junction-to-sink thermal resistance	The steady-state thermal resistance between the junction and the heatsink mounting surface.
$R_{\theta(C-S)}$	Contact thermal resistance	The steady-state thermal resistance between the surface of the case and the heatsink mounting surface.
Z_θ	Transient thermal impedance	The change of temperature difference between two specified points or regions at the end of a time interval divided by the step function change in power dissipation at the beginning of the same interval causing the change of temperature difference.
$Z_{\theta(J-A)}$	Junction-to-ambient transient thermal impedance	The transient thermal impedance between the junction and ambient.
$Z_{\theta(J-C)}$	Junction-to-case transient thermal impedance	The transient thermal impedance between the junction and the case surface.
$Z_{\theta(J-S)}$	Junction-to-sink transient thermal impedance	The transient thermal impedance between the junction and the heatsink mounting surface.
T_A	Ambient temperature	It is the temperature of the surrounding atmosphere of a device when natural or forced-air cooling is used, and is not influenced by heat dissipation of the device.
T_S	Sink temperature	The temperature at a specified point on the device heatsink.
T_C	Case temperature	The temperature at a specified point on the device case.
T_J	Junction temperature	The device junction temperature rating. Specifies the maximum and minimum allowable operation temperatures.
T_{STG}	Storage temperature	Specifies the maximum and minimum allowable storage temperatures (with no electrical connections).
V_{RRM}	Peak reverse blocking voltage	Within the rated junction temperature range, and with the gate terminal open circuited, specifies the repetitive peak reverse anode to cathode voltage applicable on each cycle.
V_{RSM}	Transient peak reverse-blocking voltage	Within the rated junction temperature range, and with the gate terminal open circuited, specifies the non-repetitive peak reverse anode to cathode voltage applicable for a time width equivalent to less than 5 ms.
$V_{R(DC)}$ SCR only	dc reverse-blocking voltage	Within the rated junction temperature range, and with the gate terminal open-circuited, specifies the maximum value for dc anode to cathode voltage applicable in the reverse direction.
V_{DRM}	Peak forward-blocking voltage	Within the rated junction temperature range, and with the gate terminal open circuited (SCR), or with a specified reverse voltage between the gate and cathode (GTO), specifies the repetitive peak off-state anode to cathode voltage applicable on each cycle. This does not apply for transient off-state voltage application.
V_{DSM}	Transient peak forward-blocking voltage	Within the rated junction temperature range, and with the gate terminal open circuited (SCR), or with a specified reverse voltage between the gate and cathode (GTO), specifies the non-repetitive off-state anode to cathode voltage applicable for a time width equivalent to less than 5 ms. This gives the maximum instantaneous value for non-repetitive transient off-state voltage.
$V_{D(DC)}$	dc forward-blocking voltage	Within the rated junction temperature range, and with the gate terminal open circuited (SCR), or with a specified reverse voltage between the gate and cathode (GTO), specifies the maximum value for dc anode to cathode voltage applicable in the forward direction.
dv/dt	Critical rate of rise of off-state voltage $dv/dt = (0.632 V_D)/\tau$ V_D is specified off-state voltage τ is time constant for exponential	At the maximum rated junction temperature range, and with the gate terminal open circuited (SCR), or with a specified reverse voltage between the gate and cathode (GTO), this specifies the maximum rate of rise of off-state voltage that will not drive the device from an off-state to an on-state when an exponential off-state voltage of specified amplitude is applied to the device.
V_{TM}	Peak on-state voltage	At specified junction temperature, and when on-state current (50 or 60 Hz, half sine wave of specified peak amplitude) is applied to the device, indicates peak value for the resulting voltage drop.

TABLE 6.5—*Contd.*

$I_{T(RMS)}$	RMS on-state current	At specified case temperature, indicates the RMS value for on-state current that can be continuously applied to the device.
$I_{T(AV)}$	Average on-state current	At specified case temperature, and with the device connected to a resistive or inductive load, indicates the average value for forward-current (sine half wave, commercial frequency) that can be continuously applied to the device.
I_{TSM}	Peak on-state current	Within the rated junction temperature range, indicates the peak-value for non-repetitive on-state current (sine half wave, 50 or 60 Hz). This value indicated for one cycle, or as a function of a number of cycles.
I^2t	Current-squared time	The maximum, on-state, non-repetitive short-time thermal capacity of the device and is helpful in selecting a fuse or providing a coordinated protection scheme of the device in the equipment. This rating is intended specifically for operation less than one half cycle of a 180° (degree) conduction angle sinusoidal wave form. The off-state blocking capability cannot be guaranteed at values near the maximum I^2t.
di/dt	Critical rate of Rise of on-state current	At specified case temperature, specified off-state voltage, specified gate conditions, and at a frequency of less than 60 Hz, indicates the maximum rate of rise of on-state current which the thyristor will withstand when switching from an off-state to an on-state, when using recommended gate drive.
I_{RRM}	Peak reverse leakage current	At maximum rated junction temperature, indicates the peak value for reverse current flow when a voltage (sine half wave, 50 or 60 Hz, and having a peak value as specified for repetitive peak reverse-voltage rating) is applied in a reverse direction to the device.
I_{DRM}	Peak forward-leakage current	At maximum rated junction temperature, indicates the peak value for off-state current flow when a voltage (sine half wave, 50 or 60 Hz, and having a peak value for repetitive off-state voltage rating) is applied in a forward direction to the device. For a GTO, a reverse voltage between the gate and cathode is specified.
P_{GM} (SCR) P_{GFM} (GTO)	Peak gate power dissipation peak gate forward power dissipation	Within the rated junction temperature range, indicates the peak value for maximum allowable power dissipation over a specified time period, when the device is in forward-conduction between the gate and cathode.
$P_{G(AV)}$	Average gate power dissipation	Within the rated junction temperature range, indicates the average value for maximum allowable power dissipation when the device is forward-conducting between the gate and cathode.
P_{GRM} GTO only	Peak gate reverse power dissipation	Within the rated junction temperature range, indicates the peak value for maximum allowable power dissipation in the reverse direction between the gate and cathode, over a specified time period.
$P_{GR(AV)}$ GTO only	Average gate reverse power dissipation	Within the rated junction temperature range, indicates the average value for maximum allowable power dissipation in the reverse direction between the gate and cathode.
I_{GFM}	Peak forward gate current	Within the rated junction temperature range, indicates the peak value for forward current flow between the gate and cathode.
I_{GRM} GTO only	Peak reverse gate current	Within the rated junction temperature range, indicates peak value for reverse current that can be conducted between the gate and cathode.
V_{GRM}	Peak reverse gate voltage	Within the rated junction temperature range, indicates the peak value for reverse voltage applied between the gate and cathode.
V_{GFM}	Peak forward gate voltage	Within the rated junction temperature range, indicates the peak value for forward voltage applied between the gate and cathode.
I_{GT}	Gate current to trigger	At a junction temperature of 25°C, and with a specified off-voltage, and a specified load resistance, indicates the minimum gate dc current required to switch the thyristor from an off-state to an on-state.
V_{GT}	Gate voltage to trigger	At a junction temperature of 25°C, and with a specified off-state voltage, and a specified load resistance, indicates the minimum dc gate voltage required to switch the thyristor from an off-state to an on-state.
V_{GDM} SCR Only	Non-triggering gate voltage	At maximum rated junction temperature, and with a specified off-state voltage applied to the device, indicates the maximum dc gate voltage which will not switch the device from an off-state to an on-state.
I_{TGQ} GTO only	Gate controlled turn-off current	Under specified conditions, indicates the instantaneous value for on-current usable in gate control, specified immediately prior to device turn-off.

TABLE 6.5—*Contd.*

R_θ	Thermal resistance	Specifies the degree of temperature rise per unit of power, measuring junction temperature from a specified external point. Defined when junction power dissipation results in steady-state thermal flow.
t_{on} SCR only	Turn-on time	At specified junction temperature, and with a peak repetitive off-state voltage of half rated value, followed by device turn-on using specified gate current, and when specified on-state current of specified di/dt flows, indicated as the time required for the applied off-state voltage to drop to 10% of its initial value after gate current application. Delay time is the term used to define the time required for applied voltage to drop to 90% of its initial value following gate-current application. The time required for the voltage level to drop from 90 to 10% of its initial value is referred to as rise time. The sum of both these defines turn-on time.
T_q SCR Only	Turn-off time	Specified at maximum rated junction temperature. Device set up to conduct on-state current, followed by application of specified reverse anode-cathode voltage to quench on-state current, and then increasing the anode-cathode voltage at a specified rate of rise as determined by circuit conditions controlling the point where the specified off-state voltage is reached. Turn-off time defines the minimum time which the device will hold its off-state, starting from the time on-state current reached zero until the time forward voltage is again applied (i.e. applied anode–cathode voltage becomes positive again).
t_{gt} GTO only	Turn-on time	When applying forward current to the gate, indicates the time required to switch the device from an off-state to an on-state.
t_{qt} GTO only	Turn-off time	When applying reverse current to the gate, indicates the time required to switch the device from an on-state to an off-state.
FIGURE 6.17 Cross section of unit cell of a *p*-type MCT.

out of conduction by applying a positive gate–anode voltage. This signal creates an inversion layer that diverts electrons in the *n*-base away from the *p*-emitter and into the heavily doped *n*-region at the anode. This *n*-channel FET current amounts to a diversion of the *pnp* transistor base current so that its base–emitter junction turns off. Holes are then no longer available for collection by the *p*-base. The elimination of this hole current (*npn* transistor base current) causes the *npn* transistor to turn-off. The remaining stored charge recombines and returns the MCT to its blocking state.

The seeming variability in fabrication of the turn-off FET structure continues to limit the performance of MCTs, particularly current interruption capability, though these devices can handle two to five times the conduction current density of IGBTs. Numerical modeling and its experimental verification show that ensembles of cells are sensitive to current filamentation during turn-off. All MCT device designs suffer from the problem of current interruption capability. Turn-on is relatively simple, by comparison; both the turn-on and conduction properties of the MCT approach the one-dimensional thyristor limit.

Other variations on the MCT structure have been demonstrated, namely the emitter switched thyristor (EST) and the dual-gate emitter switched thyristor (DG-EST) [12]. These comprise integrated lateral MOSFET structures which connect a floating thyristor *n*-emitter region to an *n*+ thyristor cathode region. The MOS channels are in series with the floating *n*-emitter region, allowing triggering of the thyristor with electrons from the *n*-base and interruption of the current to initiate turn-off. The DG-EST behaves as a dual-mode device, with the two gates allowing an IGBT mode to operate during switching and a thyristor mode to operate in the on-state.
FIGURE 6.18   Cross section of a SITh or FCT.

FIGURE 6.19   Cross section of a light-triggered thyristors (LTT).

6.6.3 Static Induction Thyristors

A SITh or FCTh has a cross section similar to that shown in Fig. 6.18. Other SITh configurations have surface gate structures. The device is essentially a *pin* diode with a gate structure that can pinch-off anode current flow. High power SIThs have a sub-surface gate (buried-gate) structure to allow larger cathode areas to be utilized, and hence larger current densities are possible.

Planar gate devices have been fabricated with blocking capabilities of up to 1.2 kV and conduction currents of 200 A, while step-gate (trench-gate) structures have been produced that are able to block up to 4 kV and conduct 400 A. Similar devices with a "Verigrid" structure have been demonstrated that can block 2 kV and conduct 200 A, with claims of up to 3.5 kV blocking and 200 A conduction. Buried-gate devices that block 2.5 kV and conduct 300 A have also been fabricated. Recently there has been a resurgence of interest in these devices for fabrication in SiC.

6.6.4 Optically Triggered Thyristors

Optically gated thyristors have traditionally been used in power utility applications where series stacks of devices are necessary to achieve the high voltages required. Isolation between gate drive circuits for circuits such as static VAR compensators and high voltage dc to ac inverters (for use in high voltage dc (HVDC) transmission) have driven the development of this class of devices, which are typically available in ratings from 5 to 8 kV. The cross section is similar to that shown in Fig. 6.19, showing the photosensitive region and the amplifying gate
structures. Light-triggered thyristors (LTTs) may also integrate over-voltage protection.

One of the most recent devices can block 6 kV forward and reverse, conduct 2.5 kA average current, maintain a *di/dt* capability of 300 A/μs and a *dv/dt* capability of 3000 V/μs, with a required trigger power of 10 mW. An integrated light triggered and light quenched SITh has been produced that can block 1.2 kV and conduct up to 20 A (at a forward drop of 2.5 V). This device is an integration of a normally off buried-gate static induction photo-thyristor and a normally off *p*-channel darlington surface-gate static induction phototransistor. The optical trigger and quenching power required is less than 5 and 0.2 mW, respectively.

6.6.5 Bi-directional Thyristors

The BCT is an integrated assembly of two anti-parallel thyristors on one Si wafer. The intended applications for this switch are VAR compensators, static switches, soft starters and motor drives. These devices are rated up to 6.5 kV blocking. Cross-talk between the two halves has been minimized. A cross section of the BCT is shown in Fig. 6.20. Note that each surface has a cathode and an anode (opposite devices). The small gate–cathode periphery necessarily restricts the BCT to low-frequency applications because of its *di/dt* limit.

Low-power devices similar to the BCT, but in existence for many years, are the diac and triac. A simplified cross section of a diac is shown in Fig. 6.21. A positive voltage applied to the anode with respect to the cathode forward biases J_1, while reverse biasing J_2. J_4 and J_3 are shorted by the metal contacts. When J_2 is biased to breakdown, a lateral current flows in the p_2 region. This lateral flow forward biases the edge of J_3, causing carrier injection. The result is that the device switches into its thyristor mode and latches. Applying a reverse voltage causes the opposite behavior at each junction, but
**FIGURE 6.20**   Cross section of a bi-directional control thyristor (BCT).

FIGURE 6.21   Cross section and *i–v* plot of a diac.

FIGURE 6.22   Cross section of a triac.

with the same result. Figure 6.21 also shows the *i–v* plot for a diac.

The addition of a gate connection, to form a triac, allows the breakover to be controlled at a lower forward voltage. Figure 6.22 shows the structure for the triac. Unlike the diac, this is not symmetrical, resulting in differing forward and reverse breakover voltages for a given gate voltage. The device is fired by applying a gate pulse of the same polarity relative to MT1 as that of MT2.

6.7 Gate Drive Requirements

6.7.1 Snubber Circuits

To protect a thyristor, from a large *di/dt* during turn-on and a large *dv/dt* during turn-off, a snubber circuit is needed. A general snubber topology is shown in Fig. 6.23. The turn-on snubber is made by inductance L_1 (often $L1$ is stray inductance only). This protects the thyristor from a large *di/dt* during the turn-on process. The auxiliary circuit made by R_1 and D_1 allows the discharging of L_1 when the thyristor is turned off. The turn-off snubber is made by resistor R_2 and capacitance C_2. This circuit protects a GTO from large *dv/dt* during the turn-off process. The auxiliary circuit made by D_2 and R_2 allows the discharging of C_2 when the thyristor is turned on. The circuit of capacitance C_2 and inductance L_1 also limits the value of *dv/dt* across the thyristor during forward-blocking. In addition, L_1 protects the thyristor from reverse over-currents. R_1 and diodes D_1, D_2 are usually omitted in ac circuits with converter-grade thyristors. A similar second set of *L, C* and *R* may be used around this circuit in HVDC applications.

6.7.2 Gate Circuits

It is possible to turn on a thyristor by injecting a current pulse into its gate. This process is known as gating, triggering or firing the thyristor. The most important restrictions are on the maximum peak and duration of the gate pulse current.

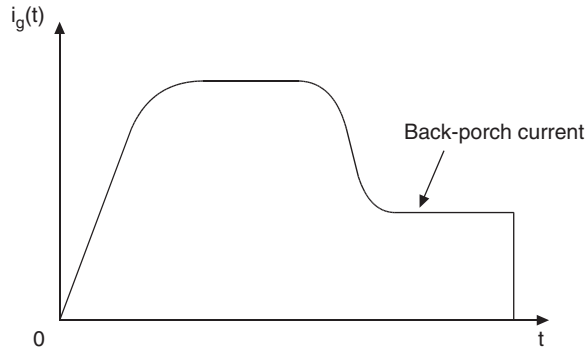
FIGURE 6.23   Turn-on (top elements) and turn-off (bottom elements) snubber circuits for thyristors.


FIGURE 6.24 Gate current waveform showing large initial current followed by a suitable back-porch value.

In order to allow a fast turn-on, and a correspondingly large anode *di/dt* during the turn-on process, a large gate current pulse is supplied during the initial turn-on phase with a large di_G/dt. The gate current is kept on, at lower value, for some times after the thyristor turned on in order to avoid unwanted turn-off of the device; this is known as the "back-porch" current. A shaped gate current waveform of this type is shown in Fig. 6.24.

Figure 6.25 shows typical gate *i–v* characteristics for the maximum and minimum operating temperatures. The dashed line represents the minimum gate current and corresponding gate voltage needed to ensure that the thyristor will be triggered at various operating temperatures. It is also known as the locus of minimum firing points. On the data sheet it is possible find a line representing the maximum operating power of the thyristor gating internal circuit. The straight line, between V_{GG} and

V_{GG}/R_G, represents the current voltage characteristic of the equivalent trigger circuit. If the equivalent trigger circuit line intercepts the two gate *i–v* characteristics for the maximum and minimum operating temperatures between where they intercept the dashed lines (minimum gate current to trigger and maximum gate power dissipation), then the trigger circuit is able to turn-on the thyristor at any operating temperature without destroying or damaging the device.

In order to keep the power circuit and the control circuit electrically unconnected, the gate signal generator and the gate of the thyristor are often connected through a transformer. There is a transformer winding for each thyristor, and in this way unwanted short circuits between devices are avoided. A general block diagram of a thyristor gate-trigger circuit is shown in Fig. 6.26. This application is for a standard bridge configuration often used in power converters.

Another problem can arise if the load impedance is high, particularly if the load is inductive and the supply voltage is low. In this situation, the latching current may not be reached during the trigger pulse. A possible solution to this problem could be the use of a longer current pulse. However, such a solution is not attractive because of the presence of the isolation transformer. An alternative solution is the generation of a series of short pulses that last for the same duration as a single long pulse. A single short pulse, a single long pulse and a series of short pulses are shown in Fig. 6.27. Reliable gating of the thyristor is essential in many applications.

There are many gate trigger circuits that use optical isolation between the logic-level electronics and a drive stage (typically MOSFETs) configured in a push–pull output. The dc power supply voltage for the drive stage is provided through
FIGURE 6.25 Gate *i–v* curve for a typical thyristor.

FIGURE 6.27   Multiple gate pulses used as an alternative to one long current pulse.
FIGURE 6.28   Typical layout of an IGCT gate drive.

transformer isolation. Many device manufacturers supply drive circuits available on printed circuit (PC) boards or diagrams of suggested circuits.

IGCT gate drives consist of an integrated module to which the thyristor is connected via a low-inductance mounting; an example is given in Fig. 6.28. Multiple MOSFETs and capacitors connected in parallel may be used to source or sink the necessary currents to turn the device on or off. Logic in the module controls the gate drive from a fiber-optic trigger input, and provides diagnostic feedback from a fiber-optic output. A simple power supply connection is also required.

6.8 PSpice Model

Circuit simulators such as Spice and PSpice are widely used as tools in the design of power systems. For this purpose equivalent circuit models of thyristors have been developed. A variety of models have been proposed with varying degrees of complexity and accuracy. Frequently the simple two-transistor model described in Section 6.2 is used in PSpice. This simple structure, however, cannot model the appropriate negative-differential-resistance (NDR) behavior as the thyristor moves from forward-blocking to forward-conduction. Few other models for conventional thyristors have been reported. A PSpice model for a GTO has been developed by Tsay *et al.* [13], which captures much of thyristor behavior, such as the static *i–v* curve shown in Fig. 6.3, dynamic characteristics (turn-on and turn-off times), device failure modes (e.g. current crowding due to excessive *di/dt* at turn-on and spurious turn-on due to excessive *dv/dt* at turn-off), and thermal effects. Specifically, three resistors are added to the two-transistor model to create the appropriate behavior.

The proposed two-transistor, three-resistor model (2T-3R) is shown in Fig. 6.29. This circuit exhibits the desired NDR behavior. Given the static *i–v* characteristics for an SCR or GTO, it is possible to obtain similar curves from the model by choosing appropriate values for the three resistors and for the forward current gains α_p and α_n of the two transistors. The process of curve fitting can be simplified by keeping in mind that resistor R_1 tends to affect the negative slope of the *i–v* characteristic, resistor R_2 tends to affect the value of the holding current I_H and resistor R_3 tends to affect the value of the forward breakdown voltage V_{FBD}. When modeling thyristors with cathode or anode shorts, as described in Section 6.4, the presence of these shorts determines the values of R_1 and R_2,
respectively. In the case of a GTO or IGCT, an important device characteristic is the so-called turn-off gain $K_{off}=I_A/|I_G|$, i.e. the ratio of the anode current to the negative gate current required to turn-off the device. An approximate formula relating the turn-off gain to the α's of the two transistors is given by,

$$K_{off} = \frac{\alpha_n}{\alpha_n + \alpha_p - 1} \tag{6.3}$$

The ability of this model to predict dynamic effects depends on the dynamics included in the transistor models. If transistor junction capacitances are included, it is possible to model the *dv/dt* limit of the thyristor. Too high a value of dv_{AK}/dt will cause significant current to flow through the J_2 junction capacitance. This current acts like gate current and can turn on the device.

This model does not accurately represent spatial effects such as current crowding at turn-on (the *di/dt* limit), when only part of the device is conducting, and, in the case of a GTO, current crowding at turn-off, when current is extracted from the gate to turn-off the device. Current crowding is caused by the location of the gate connection with respect to the conducting area of the thyristor and by the magnetic field generated by the changing conduction current. To model these effects, Tsay *et al.* [13] propose a multi-cell circuit model, in which the device is discretized in a number of conducting cells, each having the structure of Fig. 6.29. This model, shown in Fig. 6.30, takes into account the mutual inductive coupling, the delay in the gate turn-off signal due to positions of the cells relative to the gate connection, and non-uniform gate- and cathode-contact resistance. In particular, the *RC* delay circuits (series *R* with a shunt *C* tied to the cathode node) model the time delays between the gate triggering signals due to the position of the cell with respect to the gate connection; coupled inductors, *M*, model magnetic coupling between cells; resistors, R_{KC}, model non-uniform contact resistance; and resistors, R_{GC}, model gate contact resistances. The various circuit elements in the model can be estimated from device geometry and measured electrical characteristics. The choice of the number of cells is a tradeoff between accuracy and complexity. Example values of the *RC* delay network, R_{GC}, R_{KC}, and *M* are given in Table 6.6.

Other GTO thyristor models have been developed which offer improved accuracy at the expense of increased complexity. The model by Tseng *et al.* [14] includes charge storage

FIGURE 6.29 A two-transistor, three-resistor model for SCRs and GTOs.

TABLE 6.6 Element values for each cell of a multi-cell GTO model

| Model component	Symbol	Value
Delay resistor	R	1 $\mu\Omega$
Delay capacitor	C	1 nF
Mutual coupling inductance	M	10 nH
Gate contact resistance	R_{GC}	1 mΩ
Cathode contact resistance	R_{KC}	1 mΩ

FIGURE 6.30   Thyristor multi-cell circuit model containing eight cells.

effects in the *n*-base, and its application to a multi-cell model, as in Fig. 6.30, has been demonstrated successfully. Models for the IGCT, based on the lumped-charge approach [15] and the Fourier-based solution of the ambipolar diffusion equation (ADE) [16], have also been developed.

6.9 Applications

The most important application of thyristors is for line-frequency phase-controlled rectifiers. This family includes several topologies, of which one of the most important is used to construct HVDC transmission systems. A single-phase controlled rectifier is shown in Fig. 6.31.

The use of thyristors instead of diodes allows the average output voltage to be controlled by appropriate gating of the thyristors. If the gate signals to the thyristors were continuously applied, the thyristors in Fig. 6.31 would behave as diodes. If no gate currents are supplied they behave as open circuits. Gate current can be applied any time (phase delay) after the forward voltage becomes positive. Using this phase-control feature, it is possible to produce an average dc output voltage less than the average output voltage obtained from an uncontrolled diode rectifier.

FIGURE 6.31   Single-phase controlled rectifier circuit.

6.9.1 DC–AC Utility Inverters

Three-phase converters can be made in different ways, according to the system in which they are employed. The basic circuit used to construct these topologies – the three-phase controlled rectifier – is shown in Fig. 6.32.
FIGURE 6.32 A three-phase controlled bridge circuit used as a basic topology for many converter systems.

Starting from this basic configuration, it is possible to construct more complex circuits in order to obtain high-voltage or high-current outputs, or just to reduce the output ripple by constructing a multi-phase converter. One of the most important systems using the topology shown in Fig. 6.32 as a basic circuit is the HVDC system represented in Fig. 6.33. This system is made by two converters, a transmission line, and two ac systems. Each converter terminal is made of two poles. Each pole is made by two six-pulse line-frequency converters connected through Δ-Y and Y-Y transformers in order to obtain a twelve-pulse converter and a reduced output ripple. The filters

are required to reduce the current harmonics generated by the converter.

When a large amount of current and relatively low voltage is required, it is possible to connect in parallel, using a specially designed inductor, two six-pulse line-frequency converters connected through Δ-Y and Y-Y transformers. The special inductor is designed to absorb the voltage between the two converters, and to provide a pole to the load. This topology is shown in Fig. 6.34. This configuration is often known as a twelve-pulse converter. Higher pulse numbers may also be found.

6.9.2 Motor Control

Another important application of thyristors is in motor control circuits. Historically thyristors have been used heavily in traction, although most new designs are now based on IGBTs. Such motor control circuits broadly fall into four types: i) chopper control of a dc motor from a dc supply; ii) single- or three-phase converter control of a dc motor from an ac supply; iii) inverter control of an ac synchronous or induction machine from a dc supply and iv) cycloconverter control of an ac machine from an ac supply. An example of a GTO chopper is given in Fig. 6.35. L_1, R_1, D_1, and C_1 are the turn-on snubber; R_2, D_2, and C_2 are the turn-off snubber; finally R_3 and D_3 form the snubber for the freewheel diode D_3. A thyristor cycloconverter is shown in Fig. 6.36; the waveforms show the fundamental component of the output voltage for one phase. Three double converters are used to produce a three-phase

**FIGURE 6.33** A HVDC transmission system.

FIGURE 6.34 Parallel connection of two six-pulse converters for high current applications.

FIGURE 6.35 GTO chopper for dc motor control.

FIGURE 6.36 Cycloconverter for control of large ac machines.

variable-frequency, variable voltage sinusoidal output for driving ac motors. However, the limited frequency range (less than a third of the line frequency) restricts the application to large, low-speed machines at high powers.

A single- or three-phase thyristor converter (controlled rectifier) may be used to provide a variable dc supply for controlling a dc motor. Such a converter may also be used as the front end of a three-phase induction motor drive. The variable voltage, variable frequency motor drive requires a dc supply, which is supplied by the thyristor converter. The drive may use a square-wave or PWM voltage source inverter (VSI), or a current source inverter (CSI). Figure 6.37 shows a square-wave or PWM VSI with a controlled rectifier on the input side. The switch block inverter may be made of thyristors (usually GTOs or IGCTs) for high power, although most new designs now use IGBTs. Low-power motor controllers generally use IGBT inverters.

In motor control, thyristors are also used in CSI topologies. When the motor is controlled by a CSI, a controlled rectifier is also needed on the input side. Figure 6.38 shows a typical CSI inverter. The capacitors are needed to force the current in the thyristors to zero at each switching event. This is not needed when using GTOs. This inverter topology does not need any additional circuitry to provide the regenerative braking (energy recovery when slowing the motor). Historically, two back-to-back connected line-frequency thyristor converters have been employed to allow bi-directional power flow, and thus regenerative braking. Use of anti-parallel GTOs with symmetric blocking capability, or the use of diodes in series with each asymmetric GTO, reduces the number of power devices needed, but greatly increases the control complexity.

6.9.3 VAR Compensators and Static Switching Systems

Thyristors are also used to switch capacitors or inductors in order to control the reactive power in the system. Such arrangements may also be used in phase-balancing circuits for

FIGURE 6.37 PWM or square-wave inverter with a controlled rectifier input.

FIGURE 6.38 CSI on the output section of a motor drive system using capacitors for power factor correction.

balancing the load fed from a three-phase supply. Examples of these circuits are shown in Fig. 6.39. These circuits act as static VAR controllers. The topology represented on the left of Fig. 6.39 is called a thyristor-controlled inductor (TCI) and it acts as a variable inductor where the inductive VAR supplied can be varied quickly. Because the system may require either inductive or capacitive VAR compensation, it is possible to connect a bank of capacitors in parallel with a TCI. The topology shown on the right of Fig. 6.39 is called a thyristor-switched capacitor (TSC). Capacitors can be switched out by blocking

the gate pulse of all thyristors in the circuit. The problem of this topology is the voltage across the capacitors at the thyristor turn-off. At turn-on the thyristor must be gated at the instant of the maximum ac voltage to avoid large over-currents. Many recent SVCs have used GTOs.

A similar application of thyristors is in solid-state fault current limiters and circuit breakers. In normal operation, the thyristors are continuously gated. However, under fault conditions they are switched rapidly to increase the series impedance in the load and to limit the fault current. Key advantages are the flexibility of the current limiting, which is independent of the location of the fault and the change in load impedance, the reduction in fault level of the supply, and a smaller voltage sag during a short-circuit fault.

A less important application of thyristors is as a static transfer switch, used to improve the reliability of uninterruptible power supplies (UPS) as shown in Fig. 6.40. There are two modes of using the thyristors. The first leaves the load permanently connected to the UPS system and in case of emergency disconnects the load from the UPS and connects it directly to the power line. The second mode is opposite to the first one. Under normal conditions the load is permanently connected to the power line, and in event of a line outage, the load is disconnected from the power line and connected to the UPS system.

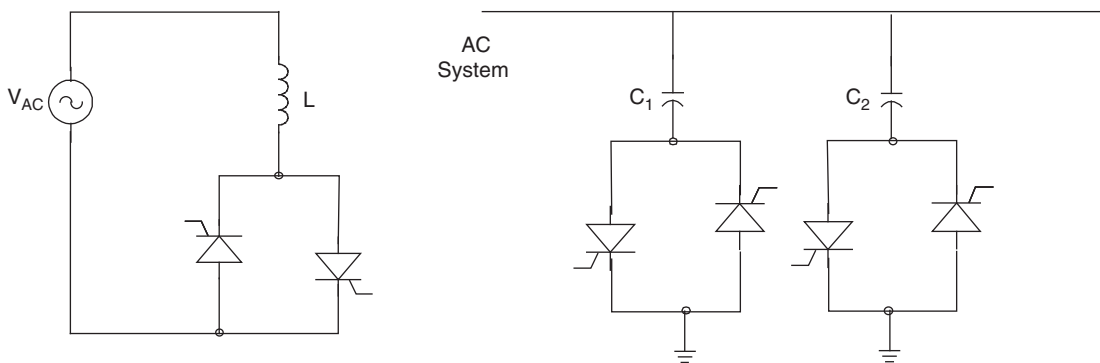

**FIGURE 6.39** Per phase TCI and TSC system.

**FIGURE 6.40**   Static transfer switch used in an UPS system.

FIGURE 6.41   Basic dimmer circuit used in lighting control.

6.9.4 Lighting Control Circuits

An important circuit used in lighting control is the dimmer, based on a triac and shown in Fig. 6.41. The *R–C* network applies a phase shift to the gate voltage, delaying the triggering of the triac. Varying the resistance, controls the firing angle of the triac and therefore the voltage across the load. The diac is used to provide symmetrical triggering for the positive and negative half-cycles, due to the non-symmetrical nature of the triac. This ensures symmetrical waveforms and elimination of even harmonics. An *L–C* filter is often used to reduce any remaining harmonics.

Gate Turn-off Thyristors

Muhammad H. Rashid, Ph.D.

Electrical and Computer Engineering, University of West Florida, 11000 University Parkway, Pensacola, Florida 32514-5754, USA

7.1 Introduction

A gate turn-off thyristor (known as a GTO) is a three terminal power semiconductor device. GTOs belong to a thyristor family having a four-layer structure. GTOs also belong to a group of power semiconductor devices that have the ability for full control of on- and off-states via the control terminal (gate). To fully understand the design, development and operation of the GTO, it is easier to compare with the conventional thyristor. Like a conventional thyristor, applying a positive gate signal to its gate terminal can turn-on to a GTO. Unlike a standard thyristor, a GTO is designed to turn-off by applying a negative gate signal.

GTOs are of two types: asymmetrical and symmetrical. The asymmetrical GTOs are the most common type on the market. This type of GTOs is normally used with a anti-parallel diode and hence high reverse blocking capability is not available. The reverse conducting is accomplished with an anti-parallel diode integrated onto the same silicon wafer. The symmetrical type of GTOs has an equal forward and reverse blocking capability.

7.2 Basic Structure and Operation

The symbol of a GTO is shown in Fig. 7.1a. A high degree of interdigitation is required in GTOs in order to achieve efficient turn-off. The most common design employs the cathode area separated into multiple segments (cathode fingers) arranged in concentric rings around the device center. The internal structure is shown in Fig. 7.1b. A common contact disc pressed against the cathode fingers connects the fingers together. It is important that all the fingers turns off simultaneously, otherwise the current may be concentrated into a fewer fingers which are likely to be damaged due to over heating.

The high level of gate interdigitation also results in a fast turn-on speed and a high di/dt performance of the GTOs. The most remote part of a cathode region is not more than 0.16 mm from a gate edge and hence the whole GTO can conduct within about 5 μs with sufficient gate drive and the turn-on losses can be reduced. However, the interdigitation reduces the available emitter area so the low frequency average current rating is less than for a standard thyristor with an equivalent diameter.

The basic structure of a GTO consists of a four-layer-PNPN semiconductor device, which is very similar in construction to a thyristor. It has several design features which allow it to be turned on and off by reversing the polarity of the gate signal. The most important differences are that the GTO has long narrow emitter fingers surrounded by gate electrodes and no cathode shorts.

The turn-on mode is similar to a standard thyristor. The injection of the hole current from the gate forward biases the cathode p-base junction causing electron emission from the cathode. These electrons flow to the anode and induce hole injection by the anode emitter. The injection of holes and electrons into the base regions continues until charge
FIGURE 7.1   GTO structure.

multiplication effects bring the GTO into conduction. This is shown in Fig. 7.2a. As with a conventional thyristor only the area of cathode adjacent to the gate electrode is turned on initially, and the remaining area is brought into conduction by plasma spreading. However, unlike the thyristor, the GTO consists of many narrow cathode elements, heavily interdigitated with the gate electrode, and therefore the initial turned-on area is very large and the time required for plasma spreading is small. The GTO, therefore, is brought into conduction very rapidly and can withstand a high turn-on di/dt.

In order to turn-off a GTO, the gate is reversed biased with respect to the cathode and holes from the anode are extracted from the p-base. This is shown in Fig. 7.2b. As a result a voltage drop is developed in the p-base region, which eventually reverse biases the gate cathode junction cutting off the injection of electrons. As the hole extraction continues, the p-base is further depleted, thereby squeezing the remaining conduction area. The anode current then flows through the

most remote areas from the gate contacts, forming high current density filaments. This is the most crucial phase of the turn-off process in GTOs, because high density filaments leads to localized heating which can cause device failure unless these filaments are extinguished quickly. An application of higher negative gate voltage may aid in extinguishing the filaments rapidly. However, the breakdown voltage of the gate-cathode junction limits this method.

When the excess carrier concentration is low enough for carrier multiplication to cease, the device reverts to the forward blocking condition. At this point although the cathode current has stopped flowing, anode-to-gate current continues to flow supplied by the carriers from n-base region stored charge. This is observed as a tail current that decays exponentially as the remaining charge concentration is reduced by recombination process. The presence of this tail current with the combination of high GTO off-state voltage produces substantial power losses. During this transition period, the electric field in the n-base region is grossly distorted due to the presence of the charge carriers and may result in premature avalanche breakdown. The resulting impact ionization can cause device failure. This phenomenon is known as "dynamic avalanche." The device regains its steady-state blocking characteristics when the tail current diminishes to leakage current level.

7.3 GTO Thyristor Models

One-dimensional two-transistor model of GTOs is shown in Fig. 7.3. The device is expected to yield the turn-off gain g given by

$$A_g = \frac{I_A}{I_G} = \frac{\alpha_{npn}}{\alpha_{pnp} + \alpha_{npn} - 1} \tag{7.1}$$

FIGURE 7.2   Turn-on and turn-off of GTOs.

FIGURE 7.3   Two-transistor model representing the GTO thyristor.

where I_A is the anode current and I_G the gate current at turn-off, and α_{npn} and α_{pnp} are the common-base current gains in the NPN and PNP transistors sections of the device. For a non-shorted device, the charge is drawn from the anode and regenerative action commences, but the device does not latch on (remain on when the gate current is removed) until

$$\alpha_{npn} + \alpha_{pnp} \geq 1 \qquad (7.2)$$

This process takes a short period while the current and the current gains increase until they satisfy Eq. (7.2). For anode-shorted devices, the mechanism is similar but the anode short impairs the turn-on process by providing a base–emitter short thus reducing the PNP transistor gain, which is shown in Fig. 7.4. The composite PNP gain of the emitter-shorted structure is given as follows

$$\alpha_{pnp}(\text{composite}) = \alpha_{pnp}\left(\frac{1 - V_{be}}{R_{Sanode}}\right) \qquad (7.3)$$

where V_{be} = emitter base voltage (generally 0.6 V for injection of carriers), and R_S is the anode short resistance. The anode emitter injects when the voltage around it exceed 0.06 V, and therefore the collector current of the NPN transistor flowing through the anode shorts influences turn-on.

The GTO remains in a transistor state if the load circuit limits the current through the shorts.

7.4 Static Characteristics

7.4.1 On-state Characteristics

In the on-state the GTO operates in a similar manner to the thyristor. If the anode current remains above the holding current level then positive gate drive may be reduced to zero and the GTO will remain in conduction. However, as a result of the turn-off ability of the GTO, it does posses a higher holding current level than the standard thyristor, and in addition, the cathode of the GTO thyristor is sub-divided into small finger elements to assist turn-off. Thus, if the GTO thyristor anode current transiently dips below the holding current level, localized regions of the device may turn-off, thus forcing a high anode current back into the GTO at a high rate of rise of anode current after this partial turn-off. This situation could be potentially destructive. It is recommended, therefore, that the positive gate drive is not removed during conduction but is held at a value $I_{G(ON)}$, where $I_{G(ON)}$ is greater than the maximum critical trigger current (I_{GT}) over the expected operating temperature range of the GTO thyristor.

Figure 7.5 shows the typical on-state V–I characteristics for a 4000 A, 4500 V GTO from Dynex range of GTOs [1] at junction temperatures of 25°C and 125°C. The curves can be approximated to a straight line of the form

$$V_{TM} = V_0 + IR_0 \qquad (7.4)$$

where V_0 = voltage intercept, models the voltage across the cathode and anode forward biased junctions and R_0 = on state resistance. When average and RMS values of on-state current (I_{TAV}, I_{TRMS}) are known, then the on-state power dissipation P_{ON} can be determined using V_0 and R_0. That is,

$$P_{ON} = V_0 I_{TAV} + R_0 I_{TRMS}^2 \qquad (7.5)$$

**FIGURE 7.4**   Two-transistor models of GTO structures.

FIGURE 7.5   *V–I* characteristics of GTO [see data sheet in Ref. 1].

7.4.2 Off-state Characteristics

Unlike the standard thyristor, the GTO does not include cathode emitter shorts to prevent non-gated turn-on effects due to *dv/dt* induced forward biased leakage current. In the off-state of the GTO, steps should, therefore, be taken to prevent such potentially dangerous triggering. This can be accomplished by either connecting the recommended value of resistance between the gate and the cathode (R_{GK}) or by maintaining a small reverse bias on the gate contact ($V_{RG} = -2\,\text{V}$). This will prevent the cathode emitter becoming forward biased and therefore sustain the GTO thyristor in the off state.

The peak off-state voltage is a function of resistance R_{GK}. This is shown in Fig. 7.6. Under ordinary operating conditions, GTOs are biased with a negative gate voltage of around $-15\,\text{V}$ supplied from the gate drive unit during the off-state interval. Nevertheless, provision of R_{GK} may be desirable design practice in the event of the gate-drive failure for any reason ($R_{GK} < 1.5\,\Omega$ is recommended for a large GTO). R_{GK} dissipates energy and hence adds to the system losses.

7.4.3 Rate of Rise of Off-state Voltage (dv_T/dt)

The rate of rise of off-state voltage (dv_T/dt) depends on the resistance R_{GK} connected between the gate and the cathode and the reverse bias applied between the gate and the cathode. This relationship is shown in Fig. 7.7.

7.4.4 Gate Triggering Characteristics

The gate trigger current (I_{GT}) and the gate trigger voltage (V_{GT}) are both dependent on junction temperature T_j as shown in Fig. 7.8. During the conduction state of the GTO a certain value of gate current must be supplied and this value should be larger than the I_{GT} at the lowest junction temperature at which the GTO operates. In dynamic conditions the specified I_{GT} is not sufficient to trigger the GTO switching from higher voltage and high *di/dt*. In practice a much high peak gate current I_{GM} (in order of ten times I_{GT}) at T_j min is recommended to obtain good turn-on performance.

7.5 Switching Phases

The switching process of a GTO thyristor goes through four operating phases (a) turn-on, (b) on-state, (c) turn-off, and (d) off-state.

Turn-on: A GTO has a highly interdigited gate structure with no regenerative gate. Thus it requires a large initial gate trigger pulse. A typical turn-on gate pulse and its important parameters are shown in Fig. 7.9. A minimum and maximum values of I_{GM} can be derived from the device data sheet. A value of *dig/dt* is given in device characteristics of the data sheet, against turn-on time. The rate of rise of gate current, *dig/dt* will affect the device turn-on losses. The duration of
FIGURE 7.6 GTO blocking voltage vs. R_{GK} [see data sheet in Ref. 1].
FIGURE 7.7 dV_D/dt vs. R_{GK} [see data sheet in Ref. 1].
FIGURE 7.8 GTO trigger characteristics [see data sheet in Ref. 1].

the I_{GM} pulse should not be less than half the minimum on time given in data sheet ratings. A longer period will be required if the anode current di/dt is low such that I_{GM} is maintained until a sufficient level of anode current is established.

On-state: Once the GTO is turned on, forward gate current must be continued for the whole of the conduction period. Otherwise, the device will not remain in conduction during the on-state period. If large negative di/dt or anode current reversal occurs in the circuit during the on-state, then higher

values of I_G may be required. Much lower values of I_G are, however, required when the device has heated up.

Turn-off: The turn-off performance of a GTO is greatly influenced by the characteristics of the gate turn-off circuit. Thus the characteristics of the turn-off circuit must match
FIGURE 7.9   A typical turn-on gate pulse [see data sheet in Ref. 2].
FIGURE 7.10   Anode and gate currents during turn-off [see data sheet in Ref. 2].

with the device requirements. Figure 7.10 shows the typical anode and gate currents during the turn-off. The gate turn-off process involves the extraction of the gate charge, the gate avalanche period and the anode current decay. The amount of the charge extraction is a device parameter and its value is not significantly affected by the external circuit conditions. The initial peak turn-off current and turn-off time, which are important parameters of the turning-off process, depend on the external circuit components. The device data sheet gives typical values for I_{GQ}.

The turn-off circuit arrangement of a GTO is shown in Fig. 7.11. The turn-off current gain of a GTO is low, typically 6–15. Thus, for a GTO with a turn-off gain of 10, it will require a turn-off gate current of 10 A to turn-off an on-state of 100 A. A charged capacitor C is normally used to provide the required turn-off gate current. Inductor L limits the turn-off di/dt of the gate current through the circuit formed by R_1, R_2, SW_1, and L. The gate circuit supply voltage V_{GS} should be selected to give the required value of V_{GQ}. The values of R_1 and R_2 should also be minimized.

Off-state period: During the off-state period, which begins after the fall of the tail current to zero, the gate should
FIGURE 7.11   Turn-off circuit [see data sheet in Ref. 2].
**FIGURE 7.12**   Gate-cathode resistance, R_{GK} [see data sheet in Ref. 2].

ideally remain reverse biased. This reverse bias ensures maximum blocking capability and dv/dt rejection. The reverse bias can be obtained either by keeping SW_1 closed during the whole off-state period or via a higher impedance circuit SW_2 and R_3 provided a minimum negative voltage exits. This higher impedance circuit SW_2 and R_3 must sink the gate leakage current.

In case of a failure of the auxiliary supplies for the gate turn-off circuit, the gate may be in reverses biased condition and the GTO may not be able to block the voltage. To ensure blocking voltage of the device is maintained, then a minimum gate-cathode resistance (R_{GK}) should be applied as shown in Fig. 7.12. The value of R_{GK} for a given line voltage can be derived from the data sheet.

7.6 SPICE GTO Model

A GTO may be modelled with two transistors shown in Fig. 7.3. However, a GTO model [3] consisting of two thyristors, which are connected in parallel, yield improved on-state, turn-on, and turn-off characteristics. This is shown in Fig. 7.13 with four transistors.

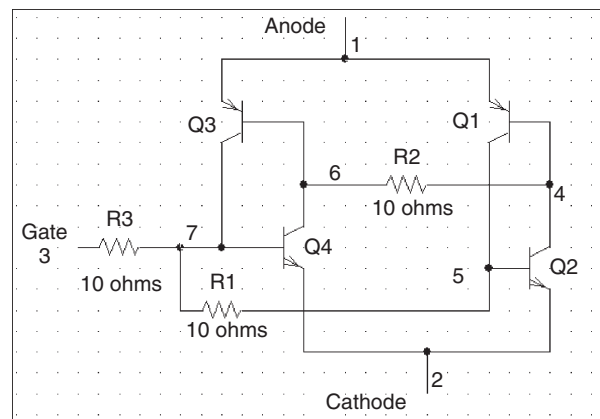
When the anode to cathode voltage, V_{AK} is positive and there is no gate voltage, the GTO model will be in the off-state like a standard thyristor. If a positive voltage (V_{AK}) is applied to the anode with respect to the cathode and no gate


FIGURE 7.13   Four-transistor GTO model.

pulse applied, $I_{B1} = I_{B2} = 0$ and therefore $I_{C1} = I_{C2} = 0$. Thus no anode current will flow, $I_A = I_K = 0$.

When a small voltage is applied to the gate, then I_{B2} is non-zero and therefore both $I_{C1} = I_{C2} = 0$ are non-zero. Thus the internal circuit will conduct and there will a current flow from the anode to the cathode.

When a negative gate pulse is applied to the GTO model, the PNP junction near to the cathode will behave as a diode. The diode will be reverse biased since the gate voltage is negative with to the cathode. Therefore the GTO will stop conduction.

When the anode-to-cathode voltage is negative, that is, the anode voltage is negative with respect to the cathode, the GTO model will act like a reverse biased diode. This is because the PNP transistor will see a negative voltage at the emitter and the NPN transistor will see a positive voltage at the emitter. Therefore both transistors will be in the off-state and hence the GTO will not conduct. The SPICE sub-circuit description of the GTO model will be as follows

| .SUBCIRCUIT	1			2	3	; GTO Sub-circuit definition

7.7 Applications

GTO thyristors find many applications such as in motor drives, induction heating [4], distribution lines [5], pulsed power [6], and Flexible AC transmission systems [7, 8].

MOS Controlled Thyristors (MCTs)

S. Yuvarajan, Ph.D.

Department of Electrical Engineering, North Dakota State University, P.O. Box 5285, Fargo, North Dakota, USA

8.1 Introduction

The efficiency, capacity, and ease of control of power converters depend mainly on the power devices employed. Power devices, in general, belong to either bipolar-junction type or field-effect type and each one has its advantages and disadvantages. The silicon controlled rectifier (SCR), also known as a thyristor, is a popular power device that has been used over the past several years. It has a high current density and a low forward voltage drop, both of which make it suitable for use in large power applications. The inability to turn-off through the gate and the low switching speed are the main limitations of an SCR. The gate turn-off (GTO) thyristor was proposed as an alternative to SCR. However, the need for a higher gate turn-off current limited its application.

The power MOSFET has several advantages such as high input impedance, ease of control, and higher switching speeds. Lower current density and higher forward drop limited the device to low-voltage and low-power applications. An effort to combine the advantages of bipolar junction and field-effect structures has resulted in hybrid devices such as the insulated gate bipolar transistor (IGBT) and the MOS controlled thyristor (MCT). While an IGBT is an improvement over a bipolar junction transistor (BJT) using a MOSFET to turn-on and turn-off current, an MCT is an improvement over a thyristor with a pair of MOSFETs to turn-on and turn-off current. The MCT overcomes several of the limitations of the existing power devices and promises to be a better switch for the future. While there are several devices in the MCT family with distinct combinations of channel and gate structures [1],

one type, called the P-channel MCT, has been widely reported and is discussed here. Because the gate of the device is referred to with respect to the anode rather than the cathode, it is sometimes referred to as a complementary MCT (C-MCT) [2]. Harris Semiconductors (Intersil) originally made the MCTs, but the MCT division was sold to Silicon Power Corporation (SPCO), which has continued the development of MCTs.

8.2 Equivalent Circuit and Switching Characteristics

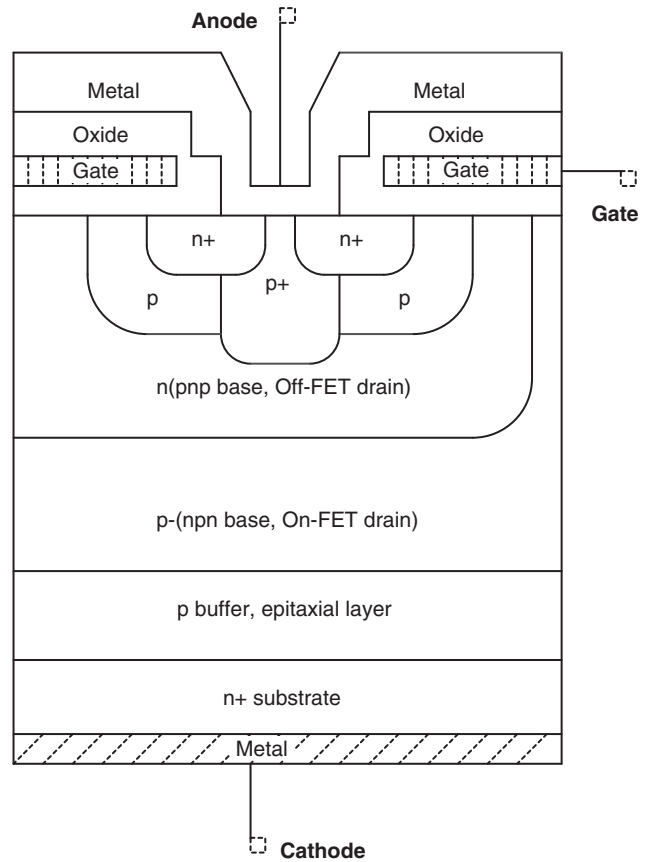
The SCR is a 4-layer *pnpn* device with a control gate, and applying a positive gate pulse turns it on when it is forward-biased. The regenerative action in the device helps to speed up the turn-on process and to keep it in the "ON" state even after the gate pulse is removed. The MCT uses an auxiliary MOS device (PMOSFET) to turn-on and this simplifies the gate control. The turn-on has all the characteristics of a power MOSFET. The turn-off is accomplished using another MOSFET


FIGURE 8.2   Cross section of an MCT unit cell.
FIGURE 8.1   Equivalent circuit and symbol of an MCT.

(NMOSFET), which essentially diverts the base current of one of the BJTs and breaks the regeneration.

The transistor-level equivalent circuit of a P-channel MCT and the circuit symbol are shown in Fig. 8.1. The cross section of a unit cell is shown in Fig. 8.2. The MCT is modeled as an SCR merged with a pair of MOSFETs. The SCR consists of the bipolar junction transistors (BJTs) Q_1 and Q_2, which are interconnected to provide regenerative feedback such that the transistors drive each other into saturation. Of the two MOSFETs, the PMOS located between the collector and emitter of Q_2 helps to turn the SCR on, and the NMOS located across the base-emitter junction of Q_2 turns it off. In the actual fabrication, each MCT is made up of a large number (~100,000) cells, each of which contains a wide-base *npn* transistor and a narrow-base *pnp* transistor. While each *pnp* transistor in a cell is provided with an N-channel MOSFET across its emitter and base, only a small percentage (~4%) of *pnp* transistors are provided with P-channel MOSFETs across their emitters and collectors. The small percentage of PMOS cells in an MCT provides just enough current for turn-on and the large number of NMOS cells provide plenty of current for turn-off.

8.2.1 Turn-on and Turn-off

When the MCT is in the forward blocking state, it can be turned on by applying a negative pulse to its gate with respect to the anode. The negative pulse turns on the PMOSFET (On-FET) whose drain current flows through the base-emitter junction of Q_1 *(npn)* thereby turning it on. The regenerative action within $Q_1 - Q_2$ turns the MCT on into full conduction within a very short time and maintains it even after the gate pulse is removed. The MCT turns on without a plasma-spreading phase giving a high *dI/dt* capability and ease of overcurrent protection. The on-state resistance of an MCT is slightly higher than that of an equivalent thyristor because of the degradation of the injection efficiency of the N^+ emitter/p-base junction. Also, the peak current rating of an MCT is much higher than its average or rms current rating.

An MCT will remain in the "ON" state until the device current is reversed or a turn-off pulse is applied to its gate. Applying a positive pulse to its gate turns off a conducting MCT. The positive pulse turns on the NMOSFET (Off-FET), thereby diverting the base current of Q_2 *(pnp)* away to the anode of the MCT and breaking the latching action of the SCR. This stops the regenerative feedback within the SCR and turns the MCT off. All the cells within the device are to be turned off at the same time to avoid a sudden increase in current density. When the Off-FETs are turned on, the SCR section is heavily shorted and this results in a high *dV/dt* rating for the MCT. The highest current that can be turned off with the application of a gate bias is called the "maximum controllable current." The MCT can be gate controlled if the device current is less than the maximum controllable current. For smaller device currents, the width of the turn-off pulse is not critical. However, for larger currents, the gate pulse has to be wider and more often has to occupy the entire off-period of the switch.

8.3 Comparison of MCT and Other Power Devices

An MCT can be compared to a power MOSFET, a power BJT, and an IGBT of similar voltage and current ratings. The operation of the devices is compared under on-state, off-state, and transient conditions. The comparison is simple and very comprehensive.

The current density of an MCT is $\approx$70% higher than that of an IGBT having the same total current [2]. During its on-state, an MCT has a lower conduction drop compared to other devices. This is attributed to the reduced cell size and the absence of emitter shorts present in the SCR within the MCT. The MCT also has a modest negative temperature coefficient at
FIGURE 8.3 Comparison of forward drop for different devices.

lower currents with the temperature coefficient turning positive at larger current [2]. Figure 8.3 shows the conduction drop as a function of current density. The forward drop of a 50-A MCT at 25 °C is around 1.1 V, while that for a comparable IGBT is over 2.5 V. The equivalent voltage drop calculated from the value of r_{DS}(ON) for a power MOSFET will be much higher. However, the power MOSFET has a much lower delay time (30 ns) compared to that of an MCT (300 ns). The turn-on of a power MOSFET can be so much faster than an MCT or an IGBT therefore, the switching losses would be negligible compared to the conduction losses. The turn-on of an IGBT is intentionally slowed down to control the reverse recovery of the freewheeling diode used in inductive switching circuits [3].

The MCT can be manufactured for a wide range of blocking voltages. Turn-off speeds of MCTs are supposed to be higher as initially predicted. The turn-on performance of Generation-2 MCTs are reported to be better compared to Generation-1 devices. Even though the Generation-1 MCTs have higher turn-off times compared to IGBTs, the newer ones with higher radiation (hardening) dosage have comparable turn-off times. At present, extensive development activity in IGBTs has resulted in high-speed switched mode power supply (SMPS) IGBTs that can operate at switching speeds $\approx$150 kHz [4]. The turn-off delay time and the fall time for an MCT are much higher compared to a power MOSFET, and they are found to increase with temperature [2]. Power MOSFETs becomes attractive at switching frequencies above 200 kHz, and they have the lowest turn-off losses among the three devices.

The turn-off safe operating area (SOA) is better in the case of an IGBT than an MCT. For an MCT, the full switching current is sustainable at $\approx$50 to 60% of the breakdown voltage rating, while for an IGBT it is about 80%. The use of capacitive snubbers becomes necessary to shape the turn-off locus

of an MCT. The addition of even a small capacitor improves the SOA considerably.

8.4 Gate Drive for MCTs

The MCT has a MOS gate similar to a power MOSFET or an IGBT and hence it is easy to control. In a PMCT, the gate voltage must be applied with respect to its anode. A negative voltage below the threshold of the On-FET must be applied to turn on the MCT. The gate voltage should fall within the specified steady-state limits in order to give a reasonably low delay time and to avoid any gate damage due to overvoltage [3]. Similar to a GTO, the gate voltage rise-time has to be limited to avoid hot spots (current crowding) in the MCT cells. A gate voltage less than -5 V for turn-off and greater than 10 V for turn-on ensures proper operation of the MCT. The latching of the MCT requires that the gate voltage be held at a positive level in order to keep the MCT turned off.

Because the peak-to-peak voltage levels required for driving the MCT exceeds those of other gate-controlled devices, the use of commercial drivers is limited. The MCT can be turned on and off using a push–pull pair with discrete NMOS–PMOS devices, which, in turn, are driven by commercial integrated circuits (ICs). However, some drivers developed by MCT manufacturers are not commercially available [3].

A Baker's clamp push–pull can also be used to generate gate pulses of negative and positive polarity of adjustable width for driving the MCT [5–7]. The Baker's clamp ensures that the push–pull transistors will be in the quasi-saturated state prior to turn-off and this results in a fast switching action. Also, the negative feedback built into the circuit ensures satisfactory operation against variations in load and temperature. A similar circuit with a push–pull transistor pair in parallel with a pair of power BJTs is available [8]. An intermediate section, with a BJT that is either cut off or saturated, provides -10 and $+15$ V through potential division.

8.5 Protection of MCTs

8.5.1 Paralleling of MCTs

Similar to power MOSFETs, MCTs can be operated in parallel. Several MCTs can be paralleled to form larger modules with only slight derating of the individual devices provided the devices are matched for proper current sharing. In particular, the forward voltage drops of individual devices have to be matched closely.

8.5.2 Overcurrent Protection

The anode-to-cathode voltage in an MCT increases with its anode current and this property can be used to develop a protection scheme against overcurrent [5, 6]. The gate pulses to the MCT are blocked when the anode current and hence the anode-to-cathode voltage exceeds a preset value. A Schmitt trigger comparator is used to allow gate pulses to the MCT when it is in the process of turning on, during which time the anode voltage is relatively large and decreasing.

8.5.2.1 Snubbers

As with any other power device, the MCT is to be protected against switching-induced transient voltage and current spikes by using suitable snubbers. The snubbers modify the voltage and current transients during switching such that the switching trajectory is confined within the safe operating area (SOA). When the MCT is operated at high frequencies, the snubber increases the switching loss due to the delayed voltage and current responses. The power circuit of an MCT chopper including an improved snubber circuit is shown in Fig. 8.4 [5, 7]. The turn-on snubber consists of L_s and D_{LS} and the turn-off snubber consists of R_s, C_s, and D_{Cs}. The series-connected turn-on snubber reduces the rate of change of the anode current dI_A/dt. The MCT does not support V_s until the current through the freewheeling diode reaches zero at turn-on. The turn-off snubber helps to reduce the peak power and the total power dissipated by the MCT by reducing the voltage across the MCT when the anode current decays to zero. The analysis and design of the snubber and the effect of the snubber on switching loss and electromagnetic interference are given in References [5] and [7]. An alternative snubber configuration for the two MCTs in an ac–ac converter has also been reported [8]. This snubber uses only one capacitor and one inductor for both the MCT switches (PMCT and NMCT) in a power-converter leg.

FIGURE 8.4 An MCT chopper with turn-on and turn-off snubbers.

8.6 Simulation Model of an MCT

The operation of power converters can be analyzed using PSPICE and other simulation software. As it is a new device, models of MCTs are not provided as part of the simulation libraries. However, an appropriate model for the MCT would be helpful in predicting the performance of novel converter topologies and in designing the control and protection circuits. Such a model must be simple enough to keep the simulation time and effort at a minimum, and must represent most of the device properties that affect the circuit operation. The PSPICE models for Harris PMCTs are provided by the manufacturer and can be downloaded from the internet. However, a simple model presenting most of the characteristics of an MCT is available [9, 10]. It is derived from the transistor-level equivalent circuit of the MCT by expanding the SCR model already reported the literature. The improved model [10] is capable of simulating the breakover and breakdown characteristics of an MCT and can be used for the simulation of high-frequency converters.

8.7 Generation-1 and Generation-2 MCTs

The Generation-1 MCTs were commercially introduced by Harris Semiconductors in 1992. However, the development of Generation-2 MCTs is continuing. In Gen-2 MCTs, each cell has its own turn-on field-effect transistor (FET). Preliminary test results on Generation-2 devices and a comparison of their performance with those of Generation-1 devices and high-speed IGBTs are available [11, 12]. The Generation-2 MCTs have a lower forward drop compared to the Generation-1 MCTs. They also have a higher *dI/dt* rating for a given value of capacitor used for discharge. During hard switching, the fall time and the switching losses are lower for the Gen-2 MCTs. The Gen-2 MCTs have the same conduction loss characteristics as Gen-1 with drastic reductions in turn-off switching times and losses [13].

Under zero-current switching conditions, Gen-2 MCTs have negligible switching losses [13]. Under zero-voltage switching, the turn-off losses in a Gen-2 device are one-half to one-fourth (depending on temperature and current level) the turn-off losses in Gen-1 devices. In all soft-switching applications, the predominant loss, namely, the conduction loss, reduces drastically allowing the use of fewer switches in a module.

8.8 N-channel MCT

The PMCT discussed in this chapter uses an NMOSFET for turn-off and this results in a higher turn-off current capability.

The PMCT can only replace a P-channel IGBT and inherits all the limitations of a P-channel IGBT. The results of a 2D simulation show that the NMCT can have a higher controllable current [13]. It is reported that NMCT versions of almost all Harris PMCTs have been fabricated for analyzing the potential for a commercial product [3]. The NMCTs are also being evaluated for use in zero-current soft-switching applications. However, the initial results are not quite encouraging in that the peak turn-off current of an NMCT is one-half to one-third of the value achievable in a PMCT. It is hoped that the NMCTs will eventually have a lower switching loss and a larger SOA as compared to PMCTs and IGBTs.

8.9 Base Resistance-controlled Thyristor [14]

The base resistance-controlled thyristor (BRT) is another gate-controlled device that is similar to the MCT but with a different structure. The Off-FET is not integrated within the *p*-base region but is formed within the n-base region. The diverter region is a shallow *p*-type junction formed adjacent to the *p*-base region of the thyristor. The fabrication process is simpler for this type of structure. The transistor level equivalent circuit of a BRT is shown in Fig. 8.5.

The BRT will be in the forward blocking state with a positive voltage applied to the anode and with a zero gate bias. The forward blocking voltage will be equal to the breakdown voltage of the open-base *pnp* transistor. A positive gate bias turns on the BRT. At low current levels, the device behaves similarly to an IGBT. When the anode current increases, the operation changes to thyristor mode resulting

FIGURE 8.5 Equivalent circuit of base resistance-controlled thyristor (BRT).

in a low forward drop. Applying a negative voltage to its gate turns off the BRT. During the turn-off process, the anode current is diverted from the N^+ emitter to the diverter. The BRT has a current tail during turn-off that is similar to an MCT or an IGBT.

8.10 MOS Turn-off Thyristor [15]

The MOS turn-off (MTO) thyristor or the MTOT is a replacement for the GTO and it requires a much smaller gate drive. It is more efficient than a GTO, it can have a maximum blocking voltage of about 9 kV, and it will be used to build power converters in the 1–20 MVA range. Silicon Power Corporation (SPCO) manufactures the device.

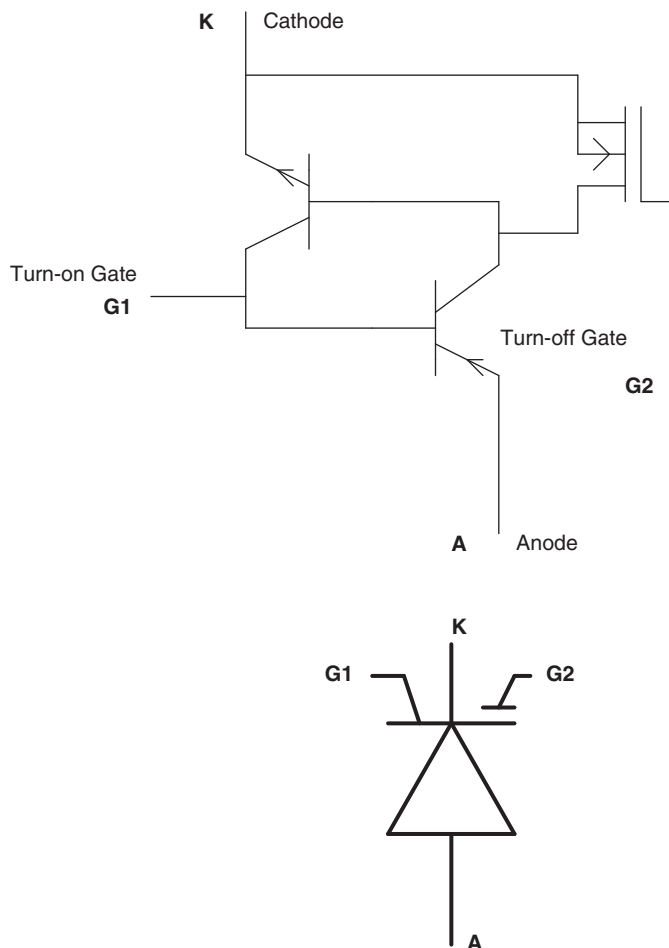
The transistor-level equivalent circuit of the MTOT (hybrid design) and the circuit symbol are shown in Fig. 8.6. Applying a current pulse at the turn-on gate (Gl), as with a conventional GTO, turns on the MTOT. The turn-on action, including


FIGURE 8.6 Equivalent circuit and symbol of a MOS turn-off (MTO) thyristor.

regeneration, is similar to a conventional SCR. Applying a positive voltage pulse to the turn-off gate (G2), as with an MCT, turns off the MTOT. The voltage pulse turns on the FET, thereby shorting the emitter and base of the *npn* transistor and breaking the regenerative action. The MTOT is a faster switch than a GTO in that it is turned off with a reduced storage time compared to a GTO. The disk-type construction allows double-side cooling.

8.11 Applications of PMCT

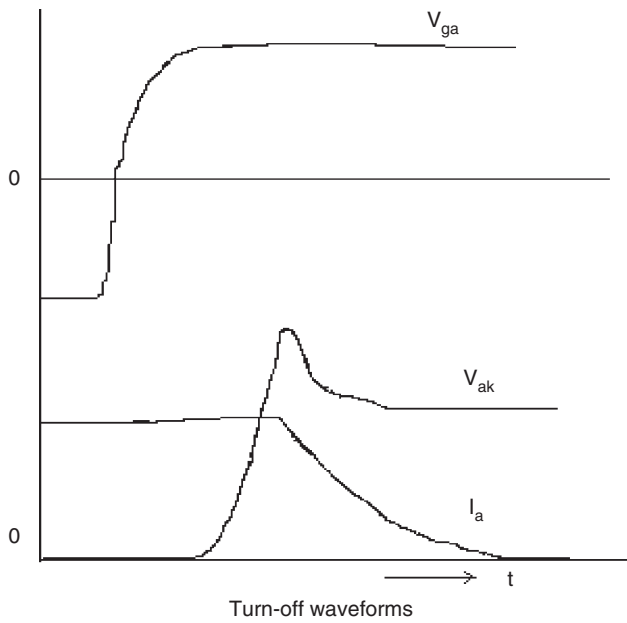
The MCTs have been used in various applications, some of which are in the area of ac-dc and ac-ac conversion where the input is 60 Hz ac. Variable power factor operation was achieved using the MCTs as a force-commutated power switch [5]. The power circuit of an ac voltage controller capable of operating at a leading, lagging, and unity power factor is shown in Fig. 8.7. Because the switching frequency is low, the switching losses are negligible. Because the forward drop is low, the conduction losses are also small. The MCTs are also used in circuit breakers.

8.11.1 Soft-switching

The MCT is intended for high-frequency switching applications where it is supposed to replace a MOSFET or an IGBT. Similar to a Power MOSFET or an IGBT, the switching losses will be high at high switching frequencies. The typical characteristics of an MCT during turn-on and turn-off under hard switching (without snubber) are shown in Fig. 8.8. During turn-on and turn off, the device current and voltage take a finite time to reach their steady-state values. Each time the device changes state, there is a short period during which the voltage and current variations overlap. This results in a transient power loss that contributes to the average power loss.

Soft-switching converters are being designed primarily to enable operation at higher switching frequencies. In these

FIGURE 8.7 Power circuit of MCT ac voltage controller.

Turn-off waveforms


Turn-on waveforms

FIGURE 8.8   The MCT turn-off and turn-on waveforms under hard switching.

converters, the power devices switch at zero voltage or zero current, thereby eliminating the need for a large safe operating area (SOA) and at the same time eliminating the switching losses entirely. The MCT converters will outperform IGBT and power MOSFET converters in such applications by giving the highest possible efficiency. In soft-switching applications, the MCT will have only conduction loss, which is

low and is close to that in a power diode with similar power ratings [12]. The Generation-1 MCTs did not turn on rapidly in the vicinity of zero anode-cathode voltage and this posed a problem in softswitching applications of an MCT. However, Generation-2 MCTs have enhanced dynamic characteristics under zero voltage soft switching [16]. In an MCT, the PMOS On-FET together with the *pnp* transistor constitute a *p*-IGBT. An increase in the number of turn-on cells (decrease in the on-resistance of the *p*-IGBT) and an enhancement of their distribution across the MCT active area enable the MCT to turn on at a very low transient voltage allowing zero voltage switching (ZVS). During zero voltage turn-on, a bipolar device such as the MCT takes more time to establish conductivity modulation. Before the device begins to conduct fully, a voltage spike appears, thus causing a modest switching loss [12]. Reducing the tail-current amplitude and duration by proper circuit design can minimize the turn-off losses in softswitching cases.

8.11.2 Resonant Converters

Resonant and quasi-resonant converters are known for their reduced switching loss [17]. Resonant converters with zero current switching are built using MCTs and the circuit of one such, a buck-converter, is shown in Fig. 8.9. The resonant commutating network consisting of L_r, C_r, auxiliary switch T_r, and diode D_r enables the MCT to turn off under zero current. The MCT must be turned off during the conduction period of D_Z. Commutating switch T_r must be turned off when the resonant current reaches zero.

A resonant dc link circuit with twelve parallel MCTs has been reported [18]. In this circuit, the MCTs switch at zero-voltage instants. The elimination of the switching loss allows operation at higher switching frequencies, which in turn increases the power density and offers better control of the spectral content. The use of MCTs with the same forward drop provides good current sharing.

FIGURE 8.9   Power circuit of MCT resonant buck converter.

The MCTs are also used in ac-resonant-link converters with pulse density modulation (PDM) [19]. The advantages of the PDM converter, such as zero-voltage switching, combined with those of the MCT make the PDM converter a suitable candidate for many ac–ac converter applications. In an ac–ac PDM converter, a low-frequency ac voltage is obtained by switching the high- frequency ac link at zero-crossing voltages. Two MCTs with reverse-connected diodes form a bidirectional switch that is used in the circuit. A single capacitor was used as a simple snubber for both MCTs in the bidirectional switch.

8.12 Conclusions

The MCT is a power switch with a MOS gate for turn-on and turn-off. It is derived from a thyristor by adding the features of a MOSFET. It has several advantages compared to modern devices like the power MOSFET and the IGBT. In particular, the MCT has a low forward drop and a higher current density which are required for high-power applications. The characteristics of Generation-2 MCTs are better than those of Generation-1 MCTs. The switching performance of Generation-2 MCTs is comparable to the IGBTs. At one time, SPCO was developing both PMCTs and NMCTs. The only product that is currently under the product list of SPCO is the voltage/current controlled Solidtron, which is a discharge switch utlizing an n-type MCT. The device features a high current and high dI/dt capability and is used in capacitor discharge applications. The data on Solidtron can be obtained at: http://www.siliconpower.com/Solidtron/Solid_home.htm.

Acknowledgment

8.13 Appendix

The following is a summary of the specifications on a 600 V/150 A PMCT made by SPC:

Peak Off-state Voltage, V_{DRM}	−600 V
Peak Reverse Voltage, V_{RRM}	+40V
Continuous Cathode Current,	
($T = +90°C$), I_{K90}	150 A
Non-repetitive Peak Cathode Current, I_{KSM}	5000 A
Peak Controllable Current, I_{KC}	300 A
Gate to Anode Voltage (Continuous), V_{GA}	±15V
Gate to Anode Voltage (Peak), V_{GAM}	±20 V
Rate of Change of Voltage ($V_{GA} =15$ V),	
dV/dt	10 kV/μs
Rate of Change of Current, di/dt	80 kA/μ
Peak Off-state Blocking Current (I_{DRM})	
($V_{KA} = -600$ V $V_{GA} = +15$ V, $Tc = +25°C$)v	200 μA
On-state Voltage (V_{TM})	
($I_K = 100$ A, $V_{GA} = -10$V $Tc = +25°C$)	1.3 V

Static Induction Devices

Bogdan M. Wilamowski, Ph.D

Alabama Microelectronics Science and Technology Center, Auburn University, Alabama, USA

9.1 Introduction

Static induction devices were invented in 1975 by J. Nishizawa [1], and for many years, Japan was the only country where static induction family devices were successfully fabricated. Static induction transistor can be considered a short channel junction field effect transistor (JFET) device operating in prepunch-through region. The number of devices in this family is increasing with time. The SIT can operate with power more than 100 kW at 100 kHz and more than 150 W at 3 GHz [2]. These devices may operate up to THz frequencies [3, 4]. Static induction transistor logic had switching energy 100 times smaller than its I^2L competitor [5, 6]. Static induction thyristor has many advantages over the traditional silicon controlled rectifier (SCR), and SID exhibits high switching speed, large reverse voltage, and low forward voltage drops [7].

9.2 Theory of Static Induction Devices

The cross section of the SIT is shown in Fig. 9.1 and its characteristics are shown in Fig. 9.2. An induced electrostatically potential barrier controls the current in static induction devices. The derivations of formulas will be done for an n-channel device, but the obtained results with a little modification can also be applied to p-channel devices. For a small electrical field existing in the vicinity of the potential barrier, the drift and diffusion currents can be approximated by

$$J_n = -qn(x)\mu_n \frac{d\varphi(x)}{dx} + qD_n \frac{dn(x)}{dx} \tag{9.1}$$

where $D_n = \mu_n V_T$ and $V_T = kT/q$. By multiplying both sides of the equation by $\exp(-\phi(x)/V_T)$ and rearranging

$$J_n \exp\left(-\frac{\varphi(x)}{V_T}\right) = qD_n \frac{d}{dx}\left[n(x)\exp\left(-\frac{\varphi(x)}{V_T}\right)\right] \tag{9.2}$$

By integrating from x_1 to x_2, one can obtain

$$J_n = qD_n \frac{n(x_2)\exp(-\varphi(x_2)/V_T) - n(x_1)\exp(-\varphi(x_1)/V_T)}{\int_{x_1}^{x_2} \exp(-\varphi(x)/V_T)\,dx} \tag{9.3}$$
FIGURE 9.1   Cross section of the static induction transistor.
FIGURE 9.2   Characteristics of the early SIT design [1].

9.3 Characteristics of Static Induction Transistor

Samples of the potential distribution in the SI devices are shown in Fig. 9.3 [7]. The vicinity of the potential barrier can be approximated using parabolic formulas (Fig. 9.4) along and across the channel [8,9].

$$\varphi(x) = \Phi\left[1 - \left(2\frac{x}{L} - 1\right)^2\right] \tag{9.6}$$

$$\varphi(y) = \Phi\left[1 - \left(2\frac{y}{W} - 1\right)^2\right] \tag{9.7}$$

Integrating Eq. (9.5) first along the channel and then across the channel yields a very simple formula for drain currents in n-channel SITs:

$$I_D = qD_pN_SZ\frac{W}{L}\exp\left(\frac{\Phi}{V_T}\right) \tag{9.8}$$

where Φ is the potential barrier height in reference to the source potential, N_S is the electron concentration at the source, W/L ratio describes the shape of the potential saddle in the vicinity of the barrier, and Z is the length of the source strip.

(a)

(b)
FIGURE 9.3   Potential distribution in SIT: (a) view from the source side and (b) view from the drain side.

With the following boundary conditions

$$\varphi(x_1) = 0; \quad n(x_1) = N_S$$

$$\varphi(x_2) = V_D; \quad n(x_2) = N_D \tag{9.4}$$

Equation (9.3) reduces to

$$J_n = \frac{qD_nN_S}{\int_{x_1}^{x_2}\exp(-\varphi(x)/V_T)dx} \tag{9.5}$$

Note that the above equations derived for SIT can also be used to find the current in any device controlled by a potential barrier, such as a bipolar transistor, an MOS transistor operating in subthreshold mode, or in a Schottky diode.
FIGURE 9.4 Potential distribution in the vicinity of the barrier approximated by parabolic shapes.

Since barrier height Φ can be a linear function of gate and drain voltages, therefore

$$I_D = qD_pN_SZ\frac{W}{L}\exp(a(V_{GS}+bV_{DS}+\Phi_0)/V_T) \quad (9.9)$$

The above equation describes characteristics of SIT for small current levels. For large current levels, the device current is controlled by the space charge of moving carriers. In one-dimensional case, the potential distribution is described by the Poisson equation:

$$\frac{d^2\varphi}{dx_2} = -\frac{\rho(x)}{\varepsilon_{Si}\varepsilon_0} = \frac{I_{DS}}{Av(x)} \quad (9.10)$$

where A is the effective device cross section and $v(x)$ is the carrier velocity. For a small electrical field $v(x)=\mu E(x)$, Eq. (9.10) results in

$$I_{DS} = \frac{9}{8}V_{DS}^2\mu\varepsilon_{Si}\varepsilon_0\frac{A}{L^3} \quad (9.11)$$

and for a large electrical field $v(x)=$ const, Eq. (9.10) results in

$$I_{DS} = 2V_{DS}v_{sat}\varepsilon_{Si}\varepsilon_0\frac{A}{L^2} \quad (9.12)$$

where L is the channel length and $v_{sat} \approx 10^{11}\mu$m/s is the carrier saturation velocity. In practical devices, the current–voltage relationship is described by an exponential relationship, Eq. (9.9), for small currents by a quadratic relationship, Eq. (9.11), and finally for large voltages by an almost linear relationship, Eq. (9.12). Static induction transistor characteristics drawn in linear and logarithmic scales are shown in Figs. 9.5 and 9.6, respectively.

FIGURE 9.5 Characteristics of the SIT drawn in a linear scale.
FIGURE 9.6 Characteristics of the SIT drawn in a logarithmic scale.

9.4 Bipolar Mode Operation of SI devices (BSIT)

The bipolar mode of operation of an SIT was first reported in 1976 by Nishizawa and Wilamowski [5, 6]. Several complex theories for the bipolar mode of operation were developed [10–14], but actually the simple formula given by Eq. (9.5) works well not only for the typical mode of the SIT operation but also for the bipolar mode of the SIT operation. Furthermore, the same formula works very well for the classical bipolar transistors. Typical characteristics of the SIT operating in normal and bipolar modes are shown in Figs. 9.7 and 9.8.
FIGURE 9.7   Small-size SIT characteristics operating in both the normal and bipolar modes, $I_D = f(V_{DS})$ with V_{GS} as a parameter.
FIGURE 9.8   Small-size SIT characteristics, operating in both the normal and bipolar modes, $I_D = f(V_{DS})$ with I_G as a parameter.

A potential barrier controls the current in the SIT, as shown in Fig. 9.9 and it is given by

$$J_n = \frac{q D_n N_S}{\int_{x_1}^{x_2} \exp\left(-\frac{\varphi(x)}{V_T}\right) dx} \tag{9.13}$$

where $\varphi(x)$ is the profile of the potential barrier along the channel.

(a)

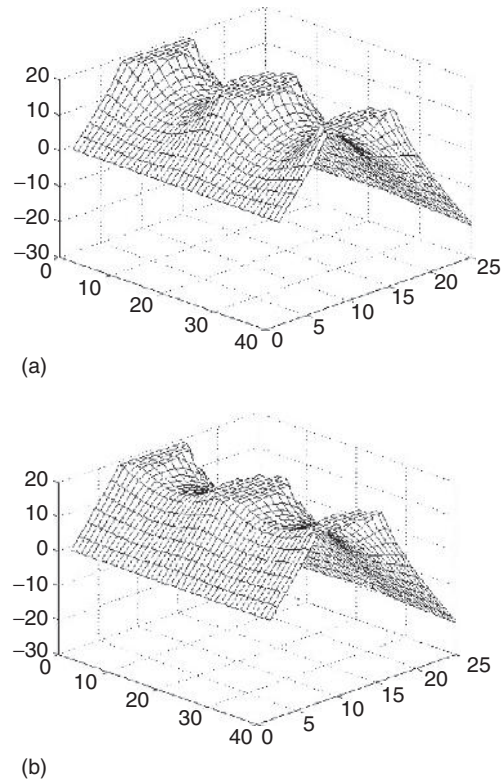
(b)


FIGURE 9.9   Potential distributions in SIT: (a) traditional and (b) with sharp potential barrier.

For example, in the case of *npn* bipolar transistors, the potential distribution across the base in reference to emitter potential at the reference impurity level $N_E = N_S$ is described by

$$\varphi(x) = V_T \ln\left(\frac{N_B(x)N_S}{n_i^2}\right) \exp\left(-\frac{V_{BE}}{V_T}\right) \tag{9.14}$$

After substituting Eq. (9.14) into Eq. (9.13), one can obtain the well-known equation for electron current injected into the base

$$J_n = \frac{q D_n n_i^2}{\int_{x_1}^{x_2} N_B(x) dx} \exp\left(\frac{V_{BE}}{V_T}\right) \tag{9.15}$$

If Eq. (9.13) is valid for SIT and BJT, then one may assume that it is also valid for the bipolar mode of operation of the SIT transistor. This is a well-known equation for the collector current in the bipolar transistor, but this time it was derived using the concept of the current flow through the potential barrier.

9.5 CMT Conductivity Modulation Transistor

The CMT conductivity modulation transistor has a unique ability of controlling ac current flow without a significant distortion of the sinusoidal waveforms of flowing current [15]. The principle of operation of the CMT is illustrated in Fig. 9.10. The potential profile of an $n^+n^-n^+$ structure is shown in Fig. 9.10a. One may notice that holes injected in the n^- region will drift to the lowest potential and will be trapped near a potential barrier. In the case of forward direction, holes would be in vicinity of the base B_1, and in the case of reverse bias, holes would be in the base B_2. The positive charge of trapped holes would lower the potential barriers near source or drain depending on the direction of applied voltages. As a consequence, larger current may flow through lowered potential barrier.

In either biasing configuration, holes are trapped by the potential well, and the number of accumulated holes in the vicinity of the potential barrier will depend upon the local recombination rate. The voltage drop across a region of hole accumulation is quite small due to the effect of conductivity modulation. In this manner, the device operation is relatively independent of the electric polarity between B_1 and B_2.

The device has the unique characteristics of allowing for proper operation for both polarities of B_1–B_2 base voltages while the controlling emitter current direction remains unchanged (see Fig. 9.10b). Also, it should be noted that in the vicinity of zero biasing, the device has extremely linear characteristics. In fact, it behaves as a variable resistor controlled by current injected by the emitter.

9.6 Static Induction Diode

The bipolar mode of operation of the SIT can also be used to obtain diodes with low forward voltage drop and negligible carrier storage effect [10, 11, 13, 16]. A static induction diode (SID) can be obtained by shorting a gate to the emitter of the SIT [17, 18]. Such diode has all the advantages of the SIT such as thermal stability and short switching time. The cross section of such diode is shown in Fig. 9.11.

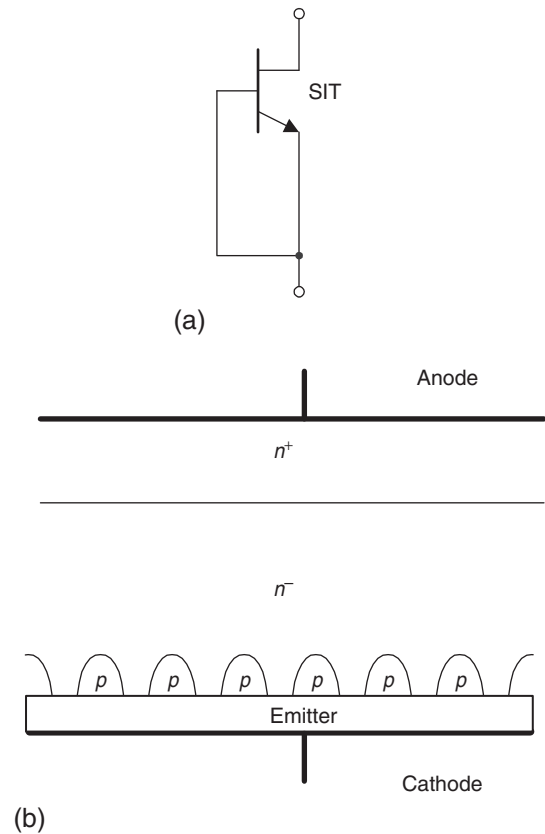
FIGURE 9.10 CMT conductivity modulation transistor: (a) band diagrams and (b) typical current–voltage characteristics.


FIGURE 9.11 Static induction diode: (a) circuit diagram and (b) cross section.
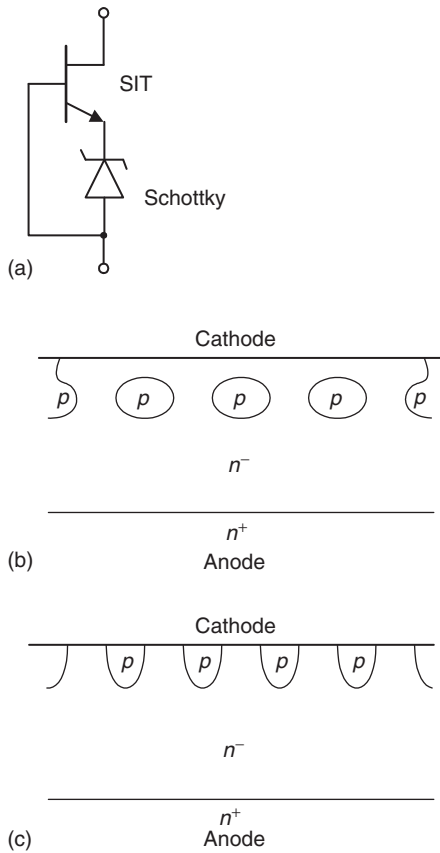

FIGURE 9.12 Schottky diode with enlarged breakdown voltages: (a) circuit diagram, (b) and (c) two cross sections of possible implementation.

The quality of the SID can be further improved with more sophisticated emitters (Fig. 9.10b,c). The SI diode with Schottky emitter was described by Wilamowski in 1983 [19] (Fig. 9.12). A similar structure was later published by Baliga [20].

9.7 Lateral Punch-Through Transistor

Fabrications of SI transistors usually require very sophisticated technology. It is much simpler to fabricate a lateral punch-through transistor, which operates on the same principle and has similar characteristics [21] (Fig. 9.13). The cross section of the LPTT is shown in Fig. 9.14.

9.8 Static Induction Transistor Logic

The static induction transistor logic (SITL) was proposed by Nishizawa and Wilamowski [5,6]. This logic circuit has almost 100 times better power-delay product than its I^2L competitor. Such drastic improvement of the power-delay product is
FIGURE 9.13 Characteristics of lateral punch-through transistor.
FIGURE 9.14 Structures of the lateral punch-through transistors: (a) simple and (b) with sharper potential barrier.
FIGURE 9.15 Cross section of SIT logic.

possible because the SITL structure has a significantly smaller junction parasitic capacitance, and also the voltage swing is reduced. Figures 9.15 and 9.16 illustrate the concept of SITL. Measured characteristics of an n-channel transistor of the static induction logic are shown in Fig. 9.17.
FIGURE 9.16   Diagrams of SIT logic.

FIGURE 9.18   Protection of bipolar transistor against deep saturation: (a) using Schottky diode and (b) using SIT.
FIGURE 9.19   Cross sections of bipolar transistors protected against deep saturation using SIT.

FIGURE 9.17   Measured characteristics of n-channel transistor of the logic circuit of Fig. 9.16.

9.9 BJT Saturation Protected by SIT

The SI transistor can also be used instead of a Schottky diode to protect a bipolar junction transistor against saturation [22]. This leads to faster switching time. The concept is shown in Figs. 9.18 and 9.19. Note that this approach is advantageous to the solution with Schottky diode since it does not require additional area on a chip and it does not introduce additional capacitance between the base and the collector. The base collector capacitance is always enlarged by the Miller effect, and this leads to slower switching in the case of the solution with the Schottky diode.

9.10 Static Induction MOS Transistor

The punch-through transistor with MOS-controlled gate was described in 1983 [23, 24]. In the illustration shown in

Fig. 9.20a, current can flow in a similar fashion as in the lateral punch-through transistor [21]. In this mode of operation, carriers are moving far from the surface with a velocity close to the saturation velocity. The real advantage of such structure is the very low gate capacitance.

Another implementation of static induction MOS transistor (SIMOS) is shown in Fig. 9.21. The buried p^+ layer is connected to the substrate, which has a large negative potential. As a result, the potential barrier is high and the emitter–drain current cannot flow. The punch-through current may start to flow when the positive voltage is applied to the gate, and hence in this way, the potential barrier is lowered. The p-implant layer is depleted, and due to the high horizontal electrical field under the gate, there is no charge accumulation under this gate. Such a transistor has several advantages over the traditional MOS transistor.

1. The gate capacitance is very small, since there is no accumulation layer under the gate.
2. Carriers are moving with a velocity close to saturation velocity.
3. Much lower substrate doping and the existing depletion layer lead to much smaller drain capacitance.

The device operates in a similar fashion as MOS transistor in subthreshold conditions, but this process occurs at much higher current levels. Such "bipolar mode" of operation may have many advantages in VLSI applications.

(b)

FIGURE 9.21 Static induction MOS structure: (a) cross section and (b) top view.

FIGURE 9.22 Space charge limiting load (SCLL).

9.11 Space Charge Limiting Load (SCLL)

Using the concept of the space charge limited current flow, as shown in Fig. 9.22, it is possible to fabricate very large resistors on a very small area. Moreover, these resistors have a very small parasitic capacitance. For example, a 50-kΩ resistor requires only several square micrometers when 2-μm feature size technology is used [7].

Depending on the value of the electrical field, the device current is described by the following two equations. For a small electrical field $v(x) = \mu E(x)$

$$I_{DS} = \frac{9}{8} V_{DS}^2 \mu \varepsilon_{Si} \varepsilon_0 \frac{A}{L^3} \qquad (9.16)$$

For a large electrical field $v(x) = \text{const}$

$$I_{DS} = 2 V_{DS} v_{sat} \varepsilon_{Si} \varepsilon_0 \frac{A}{L^2} \qquad (9.17)$$

Moreover, these resistors, which are based on the space charge limit flow, have a very small parasitic capacitance.

9.12 Power MOS Transistors

Power MOS transistors are being used for fast switching power supplies and for switching power converters. They can be driven with relatively small power, and switching frequencies could be very high. High switching frequencies lead to compact circuit implementations with small inductors and small capacitances. Basically, only two technologies, DMOS and VMOS, are used for power MOS devices as shown in Figs. 9.23 and 9.24.

A more popular structure is the DMOS shown in Fig. 9.24. This structure also uses the SIT concept. Note that for large drain voltages, the *n*-region is depleted from carriers and statically induced electrical field in the vicinity of the virtual drain is significantly reduced. As a result, this transistor may withstand
FIGURE 9.23   Cross section of the VMOS transistor.
FIGURE 9.24   Cross section of the DMOS transistor.
FIGURE 9.25   MOS and SIT equivalent to the structure of Fig. 9.24.

FIGURE 9.26   Insulated gate bipolar transistor (IGBT): (a) cross section and (b) equivalent diagram.

much larger drain voltages and also the effect of channel length modulation is significantly reduced. The later effect leads to larger output resistances of the transistor. Therefore, the drain current is less sensitive to drain voltage variations. The structure shown in Fig. 9.24 can be considered a composition of the MOS transistor and the SIT transistor as shown in Fig. 9.25.

The major disadvantage of power MOS transistors is relatively large drain series resistance and much smaller transconductance in comparison to bipolar transistors. Both of these parameters can be improved dramatically by a simple change of the type of drain, in the case of n-channel device from n-type to p-type drain. This way the integrated structure is being built

where its equivalent diagram consists of MOS transistor integrated with bipolar transistor. Such structure has β times larger transconductance (β is the current gain of bipolar transistor) and much smaller series resistance due to the conductivity modulation effect caused by holes injected into lightly doped drain region. Such device is known as insulated gate bipolar transistors (IGBT), which is shown in Fig. 9.26. Their main disadvantage is large switching time limited primarily by poor switching performance of bipolar transistor. Another difficulty is related to a possible latch-up action of four-layer $n^+ p n^- p^+$ structure. This undesired effect could be suppressed by using heavily doped p^+ region in the base of NPN structure, which leads to significant reduction of the current gain of this parasitic transistor. The gain of other PNP transistor must be kept large, so the transconductance of the entire device is large too. The IGBT transistor has breakdown voltages up to 1500 V, and turn-off times are in the range 0.1–0.5 μs. They may operate with currents above 100 A with a forward voltage drop of about 3 V.

9.13 Static Induction Thyristor

There are several special semiconductor devices dedicated to high-power applications. The most popular is thyristor known also as silicon control rectifier (SCR). This device is
FIGURE 9.27 Silicon control rectifier: (a) cross section and (b) equivalent diagram.
FIGURE 9.28 Silicon control rectifier with larger dv/dt parameter: (a) cross section and (b) equivalent diagram.

a four-layer structure as shown in Fig. 9.27a and it can be considered as two transistors *npn* and *pnp* connected as shown in Fig. 9.27b.

In normal operation mode (anode has positive potential), only one junction is reverse-biased, and it can be represented by capacitance C. A spike of anode voltage can, therefore, be obtained through capacitor C, and it can trigger SCR. This behavior is not acceptable in practical applications and therefore a different device structure is being used as shown in Fig. 9.28. Note that by shorting gate to cathode by resistor R, it is much more difficult to trigger the *npn* transistor by spike of anode voltage. This way rapid change of anode voltages is not able to trigger thyristor. Therefore, this structure has very large dv/dt parameter.

When NPN transistor is replaced with SItransistor, parameters of a thyristor can be significantly improved. For example, with breaking voltage in the range of 5 kV and current of 600 A, the switching on time can be as short as 100 ns and dv/dt parameter can be as large as 50 kV/s [16, 25].

Most of the SCRs sold in the market comprise an integrated structure composed of two or more thyristors. This structure has both large dv/dt and di/dt parameters. This structure consists of internal thyristor that significantly amplifies the gate signal.
FIGURE 9.29 Integrated structure of silicon control rectifier: (a) cross section and (b) equivalent diagram.
FIGURE 9.30 GTO-SIT: (a) cross section and (b) equivalent diagram.

The classical thyristor shown in Fig. 9.27 can be turned off by the gate voltage while integrated SCR shown in Fig. 9.29 can be only turned off by decreasing anode current to zero. Most of the SCRs sold in the market have an integrated structure composed of two or more thyristors. This structure has both large dv/dt and di/dt parameters.

9.14 Gate Turn-Off Thyristor

For dc operation, it is important to have a thyristor that can be turned off by the gate voltage. Such thyristor has a structure similar to the one shown in Fig. 9.27. However, it is important to have significantly different current gains β for *pnp* and *npn* transistors. The current gain of *npn* transistor should be as large as possible, and the current gain of *pnp* transistor should be small. The product of β_{npn} and β_{pnp} should be larger than one. This can be easily implemented using SI structure as shown in Fig. 9.30.

9.15 Summary

Several devices from the static induction family such as static induction transistor (SIT), static induction diode (SID), static induction thyristor, lateral punch-through transistor (LPTT), static induction transistor logic (SITL), static induction MOS transistor (SIMOS), and space charge limiting load (SCLL) are

described. The theory of operation of static induction devices is given for both a current controlled by a potential barrier and a current controlled by space charge. The new concept of a punch-through emitter (PTE), which operates with majority carrier transport, is presented.

Diode Rectifiers

Yim-Shu Lee and Martin H. L. Chow

Department of Electronic and Information Engineering, The Hong Kong Polytechnic, University Hung Hom, Hong Kong

10.1 Introduction

This chapter describes the application and design of diode rectifier circuits. It covers single-phase rectifier circuits, three-phase rectifier circuits, poly-phase rectifier circuits, and high-frequency rectifier circuits. The objectives of this chapter are:

- To enable the readers to understand the operation of typical rectifier circuits.
- To enable the readers to appreciate the different qualities of rectifiers required for different applications.
- To enable the reader to design practical rectifier circuits.

The high-frequency rectifier waveforms given are obtained from PSPICE simulations, which take into account the secondary effects of stray and parasitic components. In this way, the waveforms can closely resemble the real ones. These waveforms are particularly useful to help designers determine the practical voltage, current, and other ratings of high-frequency rectifiers.

10.2 Single-phase Diode Rectifiers

There are two types of single-phase diode rectifier that convert a single-phase ac supply into a dc voltage, namely, single-phase half-wave rectifiers and single-phase full-wave rectifiers. In the following subsections, the operations of these rectifier circuits are examined and their performances are analyzed and compared in a tabulated form. For the sake of simplicity, the diodes are considered to be ideal, i.e. they have zero forward voltage drop and reverse recovery time. This assumption is generally valid for the case of diode rectifiers which use the mains, a low-frequency source, as the input, and when the forward voltage drop is small compared with the peak voltage of the mains. Furthermore, it is assumed that the load is purely resistive such that the load voltage and the load current have similar waveforms. In Section 10.5, Filtering Systems in Rectifiers, the effects of inductive load and capacitive load on a diode rectifier are considered in detail.

10.2.1 Single-phase Half-wave Rectifiers

The simplest single-phase diode rectifier is the single-phase half-wave rectifier. A single-phase half-wave rectifier with resistive load is shown in Fig. 10.1. The circuit consists of only one diode that is usually fed with a secondary transformer as shown. During the positive half-cycle of the transformer secondary voltage, diode D conducts. During the negative half-cycle, diode D stops conducting. Assuming that the transformer has zero internal impedance and provides perfect sinusoidal voltage on its secondary winding, the voltage and current waveforms of resistive load R and the voltage waveform of diode D are shown in Fig. 10.2.

By observing the voltage waveform of diode D in Fig. 10.2, it is clear that the peak inverse voltage (PIV) of diode D is equal to V_m during the negative half-cycle of the transformer secondary voltage. Hence the peak repetitive reverse voltage (V_{RRM}) rating of diode D must be chosen to be higher than V_m to avoid reverse breakdown. In the positive half-cycle of the transformer secondary voltage, diode D has a forward current which is equal to the load current, therefore the peak repetitive forward current (I_{FRM}) rating of diode D must be chosen to
be higher than the peak load current, $V_m = R$, in practice. In addition, the transformer has to carry a dc current that may result in a dc saturation problem of the transformer core.

10.2.2 Single-phase Full-wave Rectifiers

There are two types of single-phase full-wave rectifier, namely, full-wave rectifiers with center-tapped transformer and bridge rectifiers. A full-wave rectifier with a center-tapped transformer is shown in Fig. 10.3. It is clear that each diode, together with the associated half of the transformer, acts as a half-wave rectifier. The outputs of the two half-wave rectifiers are combined to produce full-wave rectification in the load. As far as the transformer is concerned, the dc currents of the two half-wave rectifiers are equal and opposite, such that there is no dc current for creating a transformer core saturation problem. The voltage and current waveforms of the full-wave rectifier are shown in Fig. 10.4. By observing diode voltage waveforms v_{D1} and v_{D2} in Fig. 10.4, it is clear that the PIV of the diodes is equal to $2V_m$ during their blocking state. Hence the V_{RRM} rating of the diodes must be chosen to be higher than $2V_m$ to avoid reverse breakdown. (Note that, compared with the half-wave rectifier shown in Fig. 10.1, the full-wave rectifier has twice the dc output voltage, as shown in Section 10.2.4.) During its conducting state, each diode has a forward current which is equal to the load current, therefore the I_{FRM} rating of these diodes must be chosen to be higher than the peak load current, $V_m = R$, in practice.

Employing four diodes instead of two, a bridge rectifier as shown in Fig. 10.5 can provide full-wave rectification without using a center-tapped transformer. During the positive half-cycle of the transformer secondary voltage, the current flows to the load through diodes D_1 and D_2. During the negative half-cycle, D_3 and D_4 conduct. The voltage and current waveforms of the bridge rectifier are shown in Fig. 10.6 As with the full-wave rectifier with center-tapped transformer, the I_{FRM} rating of the employed diodes must be chosen to be higher than the peak load current, $V_m = R$. However, the PIV of the diodes is reduced from $2V_m$ to V_m during their blocking state.

10.2.3   Performance Parameters

In this subsection, the performance of the rectifiers mentioned above will be evaluated in terms of the following parameters.
FIGURE 10.6   Voltage and current waveforms of the bridge rectifier.

10.2.3.1   Voltage Relationships

The average value of the load voltage v_L is V_{dc} and it is defined as

$$V_{dc} = \frac{1}{T} \int_0^T v_L(t) \, dt \tag{10.1}$$

In the case of a half-wave rectifier, Fig. 10.2 indicates that load voltage $v_L(t) = 0$ for the negative half-cycle. Note that the angular frequency of the source $\omega = 2\pi = T$, and Eq. (10.1) can be re-written as

$$V_{dc} = \frac{1}{2\pi} \int_0^\pi V_m \sin \omega t \, d(\omega t) \tag{10.2}$$

Therefore,

$$\text{Half-wave} \quad V_{dc} = \frac{V_m}{\pi} = 0.318 V_m \tag{10.3}$$

In the case of a full-wave rectifier, Figs. 10.4 and 10.6 indicate that $v_L(t) = V_m |\sin \omega t|$ for both the positive and negative half-cycles. Hence Eq. (10.1) can be re-written as

$$V_{dc} = \frac{1}{\pi} \int_0^\pi V_m \sin \omega t \, d(\omega t) \tag{10.4}$$

Therefore,

$$\text{Full-wave} \quad V_{dc} = \frac{2V_m}{\pi} = 0.636 V_m \tag{10.5}$$

The root-mean-square (rms) value of load voltage v_L is V_L, which is defined as

$$V_L = \left[\frac{1}{T} \int_0^T v_L^2(t)\, dt \right]^{1/2} \tag{10.6}$$

In the case of a half-wave rectifier, $v_L(t) = 0$ for the negative half-cycle, therefore Eq. (10.6) can be re-written as

$$V_L = \sqrt{\frac{1}{2\pi} \int_0^\pi (V_m \sin \omega t)^2\, d(\omega t)} \tag{10.7}$$

or

$$\text{Half-wave} \quad V_L = \frac{V_m}{2} = 0.5 V_m \tag{10.8}$$

In the case of a full-wave rectifier, $v_L(t) = V_m|\sin \omega t|$ for both the positive and negative half-cycles. Hence Eq. (10.6) can be re-written as

$$V_L = \sqrt{\frac{1}{\pi} \int_0^\pi (V_m \sin \omega t)^2\, d(\omega t)} \tag{10.9}$$

or

$$\text{Full-wave} \quad V_L = \frac{V_m}{\sqrt{2}} = 0.707 V_m \tag{10.10}$$

The result of Eq. (10.10) is as expected because the rms value of a full-wave rectified voltage should be equal to that of the original ac voltage.

10.2.3.2 Current Relationships

The average value of load current i_L is I_{dc} and because load R is purely resistive it can be found as

$$I_{dc} = \frac{V_{dc}}{R} \tag{10.11}$$

The rms value of load current i_L is I_L and it can be found as

$$I_L = \frac{V_L}{R} \tag{10.12}$$

In the case of a half-wave rectifier, from Eq. (10.3)

$$\text{Half-wave} \quad I_{dc} = \frac{0.318 V_m}{R} \tag{10.13}$$

and from Eq. (10.8)

$$\text{Half-wave} \quad I_L = \frac{0.5 V_m}{R} \tag{10.14}$$

In the case of a full-wave rectifier, from Eq. (10.5)

$$\text{Full-wave} \quad I_{dc} = \frac{0.636 V_m}{R} \tag{10.15}$$

and from Eq. (10.10)

$$\text{Full-wave} \quad I_L = \frac{0.707 V_m}{R} \tag{10.16}$$

10.2.3.3 Rectification Ratio

The rectification ratio, which is a figure of merit for comparing the effectiveness of rectification, is defined as

$$\sigma = \frac{P_{dc}}{P_L} = \frac{V_{dc} I_{dc}}{V_L I_L} \tag{10.17}$$

In the case of a half-wave diode rectifier, the rectification ratio can be determined by substituting Eqs. (10.3), (10.13), (10.8), and (10.14) into Eq. (10.17).

$$\text{Half-wave} \quad \sigma = \frac{(0.318 V_m)^2}{(0.5 V_m)^2} = 40.5\% \tag{10.18}$$

In the case of a full-wave rectifier, the rectification ratio is obtained by substituting Eqs. (10.5), (10.15), (10.10), and (10.16) into Eq. (10.17).

$$\text{Full-wave} \quad \sigma = \frac{(0.636 V_m)^2}{(0.707 V_m)^2} = 81\% \tag{10.19}$$

10.2.3.4 Form Factor

The form factor (FF) is defined as the ratio of the root-mean-square value (heating component) of a voltage or current to its average value,

$$\text{FF} = \frac{V_L}{V_{dc}} \quad \text{or} \quad \frac{I_L}{I_{dc}} \tag{10.20}$$

In the case of a half-wave rectifier, the FF can be found by substituting Eqs. (10.8) and (10.3) into Eq. (10.20).

$$\text{Half-wave} \quad \text{FF} = \frac{0.5 V_m}{0.318 V_m} = 1.57 \tag{10.21}$$

In the case of a full-wave rectifier, the FF can be found by substituting Eqs. (10.16) and (10.15) into Eq. (10.20).

$$\text{Full-wave} \quad \text{FF} = \frac{0.707 V_m}{0.636 V_m} = 1.11 \tag{10.22}$$

10.2.3.5 Ripple Factor

The ripple factor (RF), which is a measure of the ripple content, is defined as

$$RF = \frac{V_{ac}}{V_{dc}} \qquad (10.23)$$

where V_{ac} is the effective (rms) value of the ac component of load voltage v_L.

$$V_{ac} = \sqrt{V_L^2 - V_{dc}^2} \qquad (10.24)$$

Substituting Eq. (10.24) into Eq. (10.23), the RF can be expressed as

$$RF = \sqrt{\left(\frac{V_L}{V_{dc}}\right)^2 - 1} = \sqrt{FF^2 - 1} \qquad (10.25)$$

In the case of a half-wave rectifier,

$$\text{Half-wave} \quad RF = \sqrt{1.57^2 - 1} = 1.21 \qquad (10.26)$$

In the case of a full-wave rectifier,

$$\text{Full-wave} \quad RF = \sqrt{1.11^2 - 1} = 0.482 \qquad (10.27)$$

10.2.3.6 Transformer Utilization Factor

The transformer utilization factor (TUF), which is a measure of the merit of a rectifier circuit, is defined as the ratio of the dc output power to the transformer volt–ampere (VA) rating required by the secondary winding,

$$TUF = \frac{P_{dc}}{V_s I_s} = \frac{V_{dc} I_{dc}}{V_s I_s} \qquad (10.28)$$

where V_s and I_s are the rms voltage and rms current ratings of the secondary transformer.

$$V_s = \frac{V_m}{\sqrt{2}} = 0.707 V_m \qquad (10.29)$$

The rms value of the transformer secondary current I_s is the same as that of the load current I_L. For a half-wave rectifier, I_s can be found from Eq. (10.14).

$$\text{Half-wave} \quad I_s = \frac{0.5 V_m}{R} \qquad (10.30)$$

For a full-wave rectifier, I_s is found from Eq. (10.16).

$$\text{Full-wave} \quad I_s = \frac{0.707 V_m}{R} \qquad (10.31)$$

Therefore, the TUF of a half-wave rectifier can be obtained by substituting Eqs. (10.3), (10.13), (10.29), and (10.30) into Eq. (10.28).

$$\text{Half-wave} \quad TUF = \frac{0.318^2}{0.707 \times 0.5} = 0.286 \qquad (10.32)$$

The poor TUF of a half-wave rectifier signifies that the transformer employed must have a 3.496 (1/0.286) VA rating in order to deliver 1 W dc output power to the load. In addition, the transformer secondary winding has to carry a dc current that may cause magnetic core saturation. As a result, half-wave rectifiers are used only when the current requirement is small.

In the case of a full-wave rectifier with center-tapped transformer, the circuit can be treated as two half-wave rectifiers operating together. Therefore, the transformer secondary VA rating, $V_s I_s$, is double that of a half-wave rectifier, but the output dc power is increased by a factor of four due to higher the rectification ratio as indicated by Eqs. (10.5) and (10.15). Therefore, the TUF of a full-wave rectifier with center-tapped transformer can be found from Eq. (10.32)

$$\text{Full-wave} \quad TUF = \frac{4 \times 0.318^2}{2 \times 0.707 \times 0.5} = 0.572 \qquad (10.33)$$

In the case of a bridge rectifier, it has the highest TUF in single-phase rectifier circuits because the currents flowing in both the primary and secondary windings are continuous sinewaves. By substituting Eqs. (10.5), (10.15), (10.29), and (10.31) into Eq. (10.28), the TUF of a bridge rectifier can be found.

$$\text{Bridge} \quad TUF = \frac{0.636^2}{(0.707)^2} = 0.81 \qquad (10.34)$$

The transformer primary VA rating of a full-wave rectifier is equal to that of a bridge rectifier since the current flowing in the primary winding is also a continuous sinewave.

10.2.3.7 Harmonics

Full-wave rectifier circuits with resistive load do not produce harmonic currents in their transformers. In half-wave rectifiers, harmonic currents are generated. The amplitudes of the harmonic currents of a half-wave rectifier with resistive load, relative to the fundamental, are given in Table 10.1. The extra loss caused by the harmonics in the resistive loaded rectifier circuits is often neglected because it is not high compared with other losses. However, with non-linear loads, harmonics can cause appreciable loss and other problems such as poor power factor and interference.

TABLE 10.1 Harmonic percentages of a half-wave rectifier with resistive load

Harmonic	2nd	3rd	4th	5th	6th	7th	8th
%	21.2	0	4.2	0	1.8	0	1.01

10.2.4 Design Considerations

In a practical design, the goal is to achieve a given dc output voltage. Therefore, it is more convenient to put all the design parameters in terms of V_{dc}. For example, the rating and turns ratio of the transformer in a rectifier circuit can be easily determined if the rms input voltage to the rectifier is in terms of the required output voltage V_{dc}.

Denote the rms value of the input voltage to the rectifier as V_s, which is equal to $0.707 V_m$. Based on this relation and Eq. (10.3), the rms input voltage to a half-wave rectifier is found as

$$\text{Half-wave} \quad V_s = 2.22 V_{dc} \quad (10.35)$$

Similarly, from Eqs. (10.5) and (10.29), the rms input voltage per secondary winding of a full-wave rectifier is found as

$$\text{Full-wave} \quad V_s = 1.11 V_{dc} \quad (10.36)$$

Another important design parameter is the V_{RRM} rating of the diodes employed.

In the case of a half-wave rectifier, from Eq. (10.3),

$$\text{Half-wave} \quad V_{RRM} = V_m = \frac{V_{dc}}{0.318} = 3.14 V_{dc} \quad (10.37)$$

In the case of a full-wave rectifier with center-tapped transformer, from Eq. (10.5),

$$\text{Full-wave} \quad V_{RRM} = 2V_m = \frac{2V_{dc}}{0.636} = 3.14 V_{dc} \quad (10.38)$$

In the case of a bridge rectifier, also from Eq. (10.5),

$$\text{Bridge} \quad V_{RRM} = V_m = \frac{V_{dc}}{0.636} = 1.57 V_{dc} \quad (10.39)$$

It is important to evaluate the I_{FRM} rating of the employed diodes in rectifier circuits.

In the case of a half-wave rectifier, from Eq. (10.13),

$$\text{Half-wave} \quad I_{FRM} = \frac{V_m}{R} = \frac{I_{dc}}{0.318} = 3.41 I_{dc} \quad (10.40)$$

In the case of full-wave rectifiers, from Eq. (10.15),

$$\text{Full-wave} \quad I_{FRM} = \frac{V_m}{R} = \frac{I_{dc}}{0.636} = 1.57 I_{dc} \quad (10.41)$$

The important design parameters of basic single-phase rectifier circuits with resistive loads are summarized in Table 10.2.

10.3 Three-phase Diode Rectifiers

It has been shown in Section 10.2 that single-phase diode rectifiers require a rather high transformer VA rating for a given dc output power. Therefore, these rectifiers are suitable only for low to medium power applications. For power output higher than 15 kW, three-phase or poly-phase diode rectifiers should be employed. There are two types of three-phase diode rectifier that convert a three-phase ac supply into a dc voltage, namely, star rectifiers and bridge rectifiers. In the following subsections,

TABLE 10.2 Important design parameters of basic single-phase rectifier circuits with resistive load

	Half-wave rectifier	Full-wave rectifier with center-tapped transformer	Full-wave bridge rectifier
Peak repetitive reverse voltage V_{RRM}	$3.14 V_{dc}$	$3.14 V_{dc}$	$1.57 V_{dc}$
RMS input voltage per transformer leg V_s	$2.22 V_{dc}$	$1.11 V_{dc}$	$1.11 V_{dc}$
Diode average current $I_{F(AV)}$	$1.00 I_{dc}$	$0.50 I_{dc}$	$0.50 I_{dc}$
Peak repetitive forward current I_{FRM}	$3.14 I_{F(AV)}$	$1.57 I_{F(AV)}$	$1.57 I_{F(AV)}$
Diode rms current $I_{F(RMS)}$	$1.57 I_{dc}$	$0.785 I_{dc}$	$0.785 I_{dc}$
Form factor of diode current $I_{F(RMS)}/I_{F(AV)}$	1.57	1.57	1.57
Rectification ratio	0.405	0.81	0.81
Form factor	1.57	1.11	1.11
Ripple factor	1.21	0.482	0.482
Transformer rating primary VA	$2.69 P_{dc}$	$1.23 P_{dc}$	$1.23 P_{dc}$
Transformer rating secondary VA	$3.49 P_{dc}$	$1.75 P_{dc}$	$1.23 P_{dc}$
Output ripple frequency f_r	$1 f_i$	$2 f_i$	$2 f_i$

the operations of these rectifiers are examined and their performances are analyzed and compared in tabulated form. For the sake of simplicity, the diodes and the transformers are considered to be ideal, i.e. the diodes have zero forward voltage drop and reverse current, and the transformers possess no resistance and no leakage inductance. Furthermore, it is assumed that the load is purely resistive, such that the load voltage and the load current have similar waveforms. In Section 10.5 Filtering Systems in Rectifier Circuits, the effects of inductive load and capacitive load on a diode rectifier are considered in detail.

10.3.1 Three-phase Star Rectifiers

10.3.1.1 Basic Three-phase Star Rectifier Circuit

A basic three-phase star rectifier circuit is shown in Fig. 10.7. This circuit can be considered as three single-phase half-wave rectifiers combined together. Therefore it is sometimes referred to as a three-phase half-wave rectifier. The diode in a particular phase conducts during the period when the voltage on that phase is higher than that on the other two phases. The voltage waveforms of each phase and the load are shown in Fig. 10.8. It is clear that, unlike the single-phase rectifier circuit, the conduction angle of each diode is $2\pi/3$, instead of π. This circuit finds uses where the required dc output voltage is relatively low and the required output current is too large for a practical single-phase system.
FIGURE 10.7   Three-phase star rectifier.

Taking phase R as an example, diode D conducts from $\pi/6$ to $5\pi/6$. Therefore, using Eq. (10.1) the average value of the output can be found as

$$V_{dc} = \frac{3}{2\pi} \int_{\pi/6}^{5\pi/6} V_m \sin\theta \, d\theta \qquad (10.42)$$

or

$$V_{dc} = V_m \frac{3}{\pi} \frac{\sqrt{3}}{2} = 0.827 V_m \qquad (10.43)$$

Similarly, using Eq. (10.6), the rms value of the output voltage can be found as

$$V_L = \sqrt{\frac{3}{2\pi} \int_{\pi/6}^{5\pi/6} (V_m \sin\theta)^2 \, d\theta} \qquad (10.44)$$
FIGURE 10.8   Waveforms of voltage and current of the three-phase star rectifier shown in Fig. 10.7.

TABLE 10.3   Important design parameters of the three-phase rectifier circuits with the resistive load

	Three-phase star rectifier	Three-phase double-star rectifier with inter-phase transformer	Three-phase bridge rectifier
Peak repetitive reverse voltage V_{RRM}	$2.092V_{dc}$	$1.06V_{dc}$	$1.05V_{dc}$
RMS input voltage per transformer leg V_s	$0.855V_{dc}$	$0.855V_{dc}$	$0.428V_{dc}$
Diode average current $I_{F(AV)}$	$0.333I_{dc}$	$0.167I_{dc}$	$0.333I_{dc}$
Peak repetitive forward current I_{FRM}	$3.63I_{F(AV)}$	$3.15I_{F(AV)}$	$3.14I_{F(AV)}$
Diode rms current $I_{F(RMS)}$	$0.587I_{dc}$	$0.293I_{dc}$	$0.579I_{dc}$
Form factor of diode current $I_{F(RMS)}/I_{F(AV)}$	1.76	1.76	1.74
Rectification ratio	0.968	0.998	0.998
Form factor	1.0165	1.0009	1.0009
Ripple factor	0.182	0.042	0.042
Transformer rating primary VA	$1.23P_{dc}$	$1.06P_{dc}$	$1.05P_{dc}$
Transformer rating secondary VA	$1.51P_{dc}$	$1.49P_{dc}$	$1.05P_{dc}$
Output ripple frequency f_r	$3f_i$	$6f_i$	$6f_i$

or

$$V_L = V_m \sqrt{\frac{3}{2\pi}\left(\frac{\pi}{3} + \frac{\sqrt{3}}{4}\right)} = 0.84V_m \qquad (10.45)$$

In addition, the rms current in each transformer secondary winding can also be found as

$$I_s = I_m \sqrt{\frac{1}{2\pi}\left(\frac{\pi}{3} + \frac{\sqrt{3}}{4}\right)} = 0.485I_m \qquad (10.46)$$

where $I_m = V_m/R$.

Based on the relationships stated in Eqs. (10.43), (10.45), and (10.46), all the important design parameters of the three-phase star rectifier can be evaluated, as listed in Table 10.3, which is given at the end of Subsection 10.3.2. Note that, as with a single-phase half-wave rectifier, the three-phase star rectifier shown in Fig. 10.7 has direct currents in the secondary windings that can cause a transformer core saturation problem. In addition, the currents in the primary do not sum

to zero. Therefore it is preferable not to have star-connected primary windings.

10.3.1.2 Three-phase Inter-star Rectifier Circuit

The transformer core saturation problem in the three-phase star rectifier can be avoided by a special arrangement in its secondary windings, known as zig-zag connection. The modified circuit is called the three-phase inter-star or zig-zag rectifier circuit, as shown in Fig. 10.9. Each secondary phase voltage is obtained from two equal-voltage secondary windings (with a phase displacement of $\pi/3$) connected in series so that the dc magnetizing forces due to the two secondary windings on any limb are equal and opposite. At the expense of extra secondary windings (increasing the transformer secondary rating factor from 1.51 to 1.74 VA/W), this circuit connection eliminates the effects of core saturation and reduces the transformer primary rating factor to the minimum of 1.05 VA/W. Apart from transformer ratings, all the design parameters of this circuit are the same as those of a three-phase star rectifier (therefore not separately listed in Table 10.3). Furthermore, a star-connected primary winding with no neutral connection
FIGURE 10.9   Three-phase inter-star rectifier.

is equally permissible because the sum of all primary phase currents is zero at all times.

10.3.1.3 Three-phase Double-star Rectifier with Inter-phase Transformer

This circuit consists essentially of two three-phase star rectifiers with their neutral points interconnected through an inter-phase transformer or reactor (Fig. 10.10). The polarities of the corresponding secondary windings in the two interconnected systems are reversed with respect to each other, so that the rectifier output voltage of one three-phase unit is at a minimum when the rectifier output voltage of the other unit is at a maximum as shown in Fig. 10.11. The function of the inter-phase transformer is to cause the output voltage v_L to be the average of the rectified voltages $v1$ and $v2$ as shown in Fig. 10.11. In addition, the ripple frequency of the output voltage is now six times that of the mains and therefore the component size of the filter (if there is any) becomes smaller. In a balanced circuit, the output currents of two three-phase units flowing in opposite directions in the inter-phase transformer winding will produce no dc magnetization current. Similarly, the dc magnetization currents in the secondary windings of two three-phase units cancel each other out.

By virtue of the symmetry of the secondary circuits, the three primary currents add up to zero at all times. Therefore, a star primary winding with no neutral connection would be equally permissible.

10.3.2 Three-phase Bridge Rectifiers

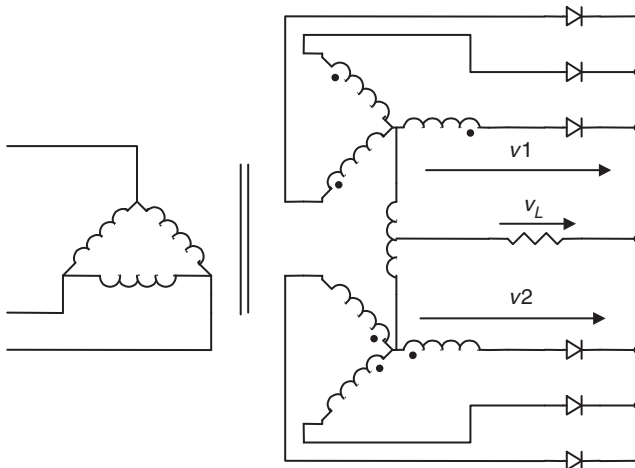
Three-phase bridge rectifiers are commonly used for high power applications because they have the highest possible transformer utilization factor for a three-phase system. The circuit of a three-phase bridge rectifier is shown in Fig. 10.12.


FIGURE 10.10   Three-phase double-star rectifier with inter-phase transformer.

The diodes are numbered in the order of conduction sequences and the conduction angle of each diode is $2\pi/3$.

The conduction sequence for diodes is 12, 23, 34, 45, 56, and 61. The voltage and the current waveforms of the three-phase bridge rectifier are shown in Fig. 10.13. The line voltage is 1.73 times the phase voltage of a three-phase star-connected source. It is permissible to use any combination of star- or delta-connected primary and secondary windings because the currents associated with the secondary windings are symmetrical.

Using Eq. (10.1) the average value of the output can be found as

$$V_{dc} = \frac{6}{2\pi} \int_{\pi/3}^{2\pi/3} \sqrt{3} V_m \sin\theta \, d\theta \qquad (10.47)$$

or

$$V_{dc} = V_m \frac{3\sqrt{3}}{\pi} = 1.654 V_m \qquad (10.48)$$

Similarly, using Eq. (10.6), the rms value of the output voltage can be found as

$$V_L = \sqrt{\frac{9}{\pi} \int_{\pi/3}^{2\pi/3} (V_m \sin\theta)^2 \, d\theta} \qquad (10.49)$$

or

$$V_L = V_m \sqrt{\frac{3}{2} + \frac{9\sqrt{3}}{4\pi}} = 1.655 V_m \qquad (10.50)$$

In addition, the rms current in each transformer secondary winding can also be found as

$$I_s = I_m \sqrt{\frac{2}{\pi}\left(\frac{\pi}{6} + \frac{\sqrt{3}}{4}\right)} = 0.78 I_m \qquad (10.51)$$

and the rms current through a diode is

$$I_D = I_m \sqrt{\frac{1}{\pi}\left(\frac{\pi}{6} + \frac{\sqrt{3}}{4}\right)} = 0.552 I_m \qquad (10.52)$$

where $I_m = 1.73 V_m/R$.

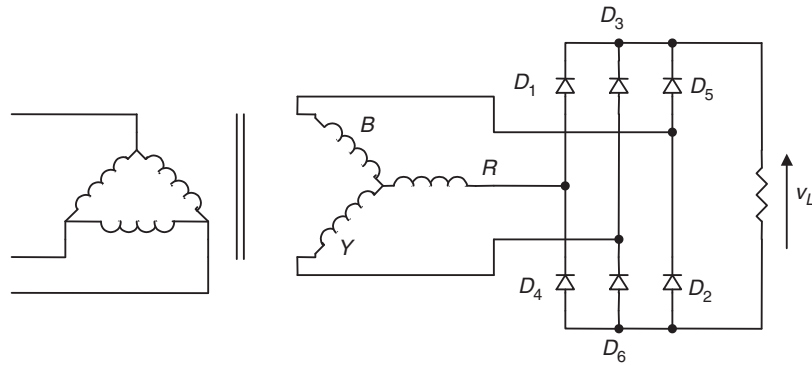
Based on Eqs. (10.48), (10.50), (10.51), and (10.52), all the important design parameters of the three-phase star rectifier can be evaluated, as listed in Table 10.3. The dc output voltage is slightly lower than the peak line voltage or 2.34 times the rms phase voltage. The V_{RRM} rating of the employed diodes is 1.05 times the dc output voltage, and the I_{FRM} rating of the employed diodes is 0.579 times the dc output current. Therefore, this three-phase bridge rectifier is very efficient and
FIGURE 10.11   Voltage waveforms of the three-phase double-star rectifier.


FIGURE 10.12   Three-phase bridge rectifier.
FIGURE 10.13   Voltage and current waveforms of the three-phase bridge rectifier.

popular wherever both dc voltage and current requirements are high. In many applications, no additional filter is required because the output ripple voltage is only 4.2%. Even if a filter is required, the size of the filter is relatively small because the ripple frequency is increased to six times the input frequency.

10.3.3 Operation of Rectifiers with Finite Source Inductance

It has been assumed in the preceding sections that the commutation of current from one diode to the next takes place instantaneously when the inter-phase voltage assumes the necessary polarity. In practice this is hardly possible, because there are finite inductances associated with the source. For the purpose of discussing the effects of the finite source inductance, a three-phase star rectifier with transformer leakage inductances is shown in Fig. 10.14, where l_1, l_2, l_3 denote the leakage inductances associated with the transformer secondary windings.

Refer to Fig. 10.15. At the time when v_{YN} is about to become larger than v_{RN}, due to leakage inductance l_1, the current in D_1 cannot fall to zero immediately. Similarly, due to the leakage inductance l_2, the current in D_2 cannot increase immediately
FIGURE 10.14 Three-phase star rectifier with the transformer leakage inductances.
FIGURE 10.15 Waveforms during commutation in Fig. 10.14.

to the full value. The result is that both the diodes conduct for a certain period, which is called the overlap (or commutation) angle. The overlap reduces the rectified voltage v_L as shown in the upper voltage waveform of Fig. 10.15. If all the leakage inductances are equal, i.e. $l_1 = l_2 = l_3 = l_c$, then the amount of reduction of dc output voltage can be estimated as $m f_i l_c I_{dc}$, where m is the ratio of the lowest-ripple frequency to the input frequency.

For example, for a three-phase star rectifier operating from a 60-Hz supply with an average load current of 50 A, the amount of reduction of the dc output voltage is 2.7 V if the leakage inductance in each secondary winding is 300 μH.

10.4 Poly-phase Diode Rectifiers

10.4.1 Six-phase Star Rectifier

A basic six-phase star rectifier circuit is shown in Fig. 10.16. The six-phase voltages on the secondary are obtained by means of a center-tapped arrangement on a star-connected three-phase winding. Therefore, it is sometimes referred to as a three-phase full-wave rectifier. The diode in a particular phase conducts during the period when the voltage on that phase is higher than that on the other phases. The voltage waveforms of each phase and the load are shown in Fig. 10.17. It is clear that, unlike the three-phase star rectifier circuit, the conduction angle of each diode is $\pi/3$, instead of $2\pi/3$. Currents flow in only one rectifying element at a time, resulting in a low average current, but a high peak to an average current ratio in the diodes and poor transformer secondary utilization. Nevertheless, the dc currents in the secondary of the six-phase star rectifier cancel in the secondary windings like a full-wave rectifier and, therefore, core saturation is not encountered. This six-phase star circuit is attractive in applications which require a low ripple factor and a common cathode or anode for the rectifiers.

By considering the output voltage provided by v_{RN} between $\pi/3$ and $2\pi/3$, the average value of the output voltage can be
FIGURE 10.16 Six-phase star rectifier.
FIGURE 10.17 Voltage waveforms of the six-phase star rectifier.

found as

$$V_{dc} = \frac{6}{2\pi} \int_{\pi/3}^{2\pi/3} V_m \sin\theta \, d\theta \qquad (10.53)$$

or

$$V_{dc} = V_m \frac{6}{\pi} \frac{1}{2} = 0.955 V_m \qquad (10.54)$$

Similarly, the rms value of the output voltage can be found as

$$V_L = \sqrt{\frac{6}{2\pi} \int_{\pi/3}^{2\pi/3} (V_m \sin\theta)^2 \, d\theta} \qquad (10.55)$$

or

$$V_L = V_m \sqrt{\frac{6}{2\pi} \left(\frac{\pi}{6} + \frac{\sqrt{3}}{4} \right)} = 0.956 V_m \qquad (10.56)$$

In addition, the rms current in each transformer secondary winding can also be found as

$$I_s = I_m \sqrt{\frac{1}{2\pi} \left(\frac{\pi}{6} + \frac{\sqrt{3}}{4} \right)} = 0.39 I_m \qquad (10.57)$$

where $I_m = V_m/R$.

Based on the relationships stated in Eqs. (10.55), (10.56), and (10.57), all the important design parameters of the six-phase star rectifier can be evaluated, as listed in Table 10.4 (given at the end of Subsection 10.4.3).

10.4.2 Six-phase Series Bridge Rectifier

The star- and delta-connected secondaries have an inherent $\pi/6$-phase displacement between their output voltages. When a star- and a delta-connected bridge rectifier are connected

TABLE 10.4 Important design parameters of the six-phase rectifier circuits with resistive load

	Six-phase star rectifier	Six-phase series bridge rectifier	Six-phase parallel bridge rectifier (with inter-phase transformer)
Peak repetitive reverse voltage V_{RRM}	$2.09 V_{dc}$	$0.524 V_{dc}$	$1.05 V_{dc}$
RMS input voltage per transformer leg V_s	$0.74 V_{dc}$	$0.37 V_{dc}$	$0.715 V_{dc}$
Diode average current $I_{F(AV)}$	$0.167 I_{dc}$	$0.333 I_{dc}$	$0.167 I_{dc}$
Peak repetitive forward current I_{FRM}	$6.28 I_{F(AV)}$	$3.033 I_{F(AV)}$	$3.14 I_{F(AV)}$
Diode rms current $I_{F(RMS)}$	$0.409 I_{dc}$	$0.576 I_{dc}$	$0.409 I_{dc}$
Form factor of diode current $I_{F(RMS)}/I_{F(AV)}$	2.45	1.73	2.45
Rectification ratio	0.998	1.00	1.00
Form factor	1.0009	1.00005	1.00005
Ripple factor	0.042	0.01	0.01
Transformer rating primary VA	$1.28 P_{dc}$	$1.01 P_{dc}$	$1.01 P_{dc}$
Transformer rating secondary VA	$1.81 P_{dc}$	$1.05 P_{dc}$	$1.05 P_{dc}$
Output ripple frequency f_r	$6 f_i$	$12 f_i$	$12 f_i$
FIGURE 10.18 Six-phase series bridge rectifier.

in series as shown in Fig. 10.18, the combined output voltage will have a doubled ripple frequency (12 times that of the mains). The ripple of the combined output voltage will also be reduced from 4.2% (for each individual bridge rectifier) to 1%. The combined bridge rectifier is referred to as a six-phase series bridge rectifier.

In the six-phase series bridge rectifier shown in Fig. 10.18, let V_m^* be the peak voltage of the delta-connected secondary. The peak voltage between the lines of the star-connected secondary is also V_m^*. The peak voltage across the load, denoted as V_m, is equal to $2V_m^* \times \cos(\pi/12)$ or $1.932V_m^*$ because there is $\pi/6$-phase displacement between the secondaries. The ripple frequency is twelve times the mains frequency. The average value of the output voltage can be found as

$$V_{dc} = \frac{12}{2\pi} \int_{5\pi/12}^{7\pi/12} V_m \sin\theta\, d\theta \qquad (10.58)$$

or

$$V_{dc} = V_m \frac{12}{\pi} \frac{\sqrt{3}-1}{2\sqrt{2}} = 0.98862 V_m \qquad (10.59)$$

The rms value of the output voltage can be found as

$$V_L = \sqrt{\frac{12}{2\pi} \int_{5\pi/12}^{7\pi/12} (V_m \sin\theta)^2\, d\theta} \qquad (10.60)$$

or

$$V_L = V_m \sqrt{\frac{12}{2\pi}\left(\frac{\pi}{12} + \frac{1}{4}\right)} = 0.98867 V_m \qquad (10.61)$$

The rms current in each transformer secondary winding is

$$I_s = I_m \sqrt{\frac{4}{\pi}\left(\frac{\pi}{12} + \frac{1}{4}\right)} = 0.807 I_m \qquad (10.62)$$

The rms current through a diode is

$$I_s = I_m \sqrt{\frac{2}{\pi}\left(\frac{\pi}{12} + \frac{1}{4}\right)} = 0.57 I_m \qquad (10.63)$$

where $I_m = V_m/R$.

Based on Eqs. (10.59), (10.61), (10.62), and (10.63), all the important design parameters of the six-phase series bridge rectifier can be evaluated, as listed in Table 10.4 (given at the end of Subsection 10.4.3).

10.4.3 Six-phase Parallel Bridge Rectifier

The six-phase series bridge rectifier described above is useful for high output voltage applications. However, for high output current applications, the six-phase parallel bridge rectifier (with an inter-phase transformer) shown in Fig. 10.19 should be used.

The function of the inter-phase transformer is to cause the output voltage v_L to be the average of the rectified voltages $v1$ and $v2$ as shown in Fig. 10.20. As with the six-phase series
FIGURE 10.19 Six-phase parallel bridge rectifier.
FIGURE 10.20   Voltage waveforms of the six-phase bridge rectifier with inter-phase transformer.

bridge rectifier, the output ripple frequency of the six-phase parallel bridge rectifier is also 12 times that of the mains. Further filtering on the output voltage is usually not required. Assuming a balanced circuit, the output currents of two three-phase units (flowing in opposite directions in the inter-phase transformer winding) produce no dc magnetization current.

All the important design parameters of the six-phase parallel rectifiers with inter-phase transformer are also listed in Table 10.4.

10.5 Filtering Systems in Rectifier Circuits

Filters are commonly employed in rectifier circuits for smoothing out the dc output voltage of the load. They are classified as inductor-input dc filters and capacitor-input dc filters. Inductor-input dc filters are preferred in high-power applications because more efficient transformer operation is obtained due to the reduction in the form factor of the rectifier current. Capacitor-input dc filters can provide volumetrically efficient operation, but they demand excessive turn-on and repetitive surge currents. Therefore, capacitor-input dc filters are suitable only for lower-power systems where close regulation is usually achieved by an electronic regulator cascaded with the rectifier.

10.5.1 Inductive-input DC Filters

The simplest inductive-input dc filter is shown in Fig. 10.21a. The output current of the rectifier can be maintained at a steady value if the inductance of L_f is sufficiently large ($\omega L_f \gg R$). The filtering action is more effective in heavy load conditions than in light load conditions. If the ripple attenuation is not sufficient even with large values of inductance, an L-section filter as shown in Fig. 10.21b can be used for further filtering. In practice, multiple L-section filters can also be employed if the requirement on the output ripple is very stringent.

For a simple inductive-input dc filter shown in Fig. 10.21a, the ripple is reduced by the factor

$$\frac{v_o}{v_L} = \frac{R}{\sqrt{R^2 + \left(2\pi f_r L_f\right)^2}} \tag{10.64}$$

where v_L is the ripple voltage before filtering, v_o is the ripple voltage after filtering, and f_r is the ripple frequency.

For the inductive-input dc filter shown in Fig. 10.21b, the amount of reduction in the ripple voltage can be estimated as

$$\frac{v_o}{v_L} = \left| \frac{1}{1 - \left(2\pi f_r\right)^2 L_f C_f} \right| \tag{10.65}$$

where f_r is the ripple frequency, if $R \gg 1/2\pi f_r C_f$.

(a)   (b)
FIGURE 10.21   Inductive-input dc filters.

10.5.1.1 Voltage and Current Waveforms of Full-wave Rectifier with Inductor-input DC Filter

Figure 10.22 shows a single-phase full-wave rectifier with an inductor-input dc filter. The voltage and current waveforms are illustrated in Fig. 10.23.
FIGURE 10.22 A full-wave rectifier with inductor-input dc filter.

When the inductance of L_f is infinite, the current through the inductor and the output voltage are constant. When inductor L_f is finite, the current through the inductor has a ripple component, as shown by the dotted lines in Fig. 10.23. If the input inductance is too small, the current decreases to zero (becoming discontinuous) during a portion of the time between the peaks of the rectifier output voltage. The minimum value of inductance required to maintain a continuous current is known as the critical inductance L_C.

10.5.1.2 Critical inductance L_C

In the case of single-phase full-wave rectifiers, the critical inductance can be found as

$$\text{Full-wave} \quad L_C = \frac{R}{6\pi f_i} \quad (10.66)$$

where f_i is the input mains frequency.

In the case of poly-phase rectifiers, the critical inductance can be found as

$$\text{Poly-phase} \quad L_C = \frac{R}{3\pi m \left(m^2 - 1\right) f_i} \quad (10.67)$$

where m is ratio of the lowest ripple frequency to the input frequency, e.g. $m = 6$ for a three-phase bridge rectifier.

10.5.1.3 Determining the Input Inductance for a Given Ripple Factor

In practice, the choice of the input inductance depends on the required ripple factor of the output voltage. The ripple voltage of a rectifier without filtering can be found by means of Fourier Analysis. For example, the coefficient of the nth harmonic component of the rectified voltage v_L shown in Fig. 10.22 can be expressed as:

$$v_{L_n} = \frac{-4V_m}{\pi \left(n^2 - 1\right)} \quad (10.68)$$

where $n = 2, 4, 8, \ldots$ etc.
FIGURE 10.23 Voltage and current waveforms of full-wave rectifier with inductor-input dc filter.

The dc component of the rectifier voltage is given by Eq. (10.5). Therefore, in addition to Eq. (10.27), the ripple factor can also be expressed as

$$RF = \sqrt{2 \sum_{n=2,4,8,} \left(\frac{1}{n^2-1}\right)^2} \qquad (10.69)$$

Considering only the lowest-order harmonic ($n = 2$), the output ripple factor of a simple inductor-input dc filter (without C_f) can be found, from Eqs. (10.64) and (10.69), as

$$\text{Filtered} \quad RF = \frac{0.4714}{\sqrt{1 + \left(4\pi f_i L_f / R\right)^2}} \qquad (10.70)$$

10.5.1.4 Harmonics of the Input Current

In general, the total harmonic distortion (THD) of an input current is defined as

$$THD = \sqrt{\left(\frac{I_s}{I_{s1}}\right)^2 - 1} \qquad (10.71)$$

where I_s is the rms value of the input current and I_{s1} and the rms value of the fundamental component of the input current. The THD can also be expressed as

$$THD = \sqrt{\sum_{n=2,3,4,} \left(\frac{I_{sn}}{I_{s1}}\right)^2} \qquad (10.72)$$

where I_{sn} is the rms value of the nth harmonic component of the input current.

Moreover, the input power factor is defined as

$$PF = \frac{I_{s1}}{I_s} \cos \phi \qquad (10.73)$$

where ϕ is the displacement angle between the fundamental components of the input current and voltage.

Assume that inductor L_f of the circuit shown in Fig. 10.22 has an infinitely large inductance. The input current is then a square wave. This input current contains undesirable higher harmonics that reduce the input power factor of the system. The input current can be easily expressed as

$$i_s = \frac{4I_m}{\pi} \sum_{n=1,3,5,} \frac{1}{n} \sin 2n\pi f_i t \qquad (10.74)$$

The rms values of the input current and its fundamental component are I_m and $4I_m/(\pi\sqrt{2})$ respectively. Therefore, the THD of the input current of this circuit is 0.484. Since the displacement angle $\phi = 0$, the power factor is $4/(\pi\sqrt{2}) = 0.9$.
FIGURE 10.24   Rectifier with input ac filter.
FIGURE 10.25   Equivalent circuit for input ac filter.

The power factor of the circuit shown in Fig. 10.22 can be improved by installing an ac filter between the source and the rectifier, as shown in Fig. 10.24.

Considering only the harmonic components, the equivalent circuit of the rectifier given in Fig. 10.24 can be found as shown in Fig. 10.25. The rms value of the nth harmonic current appearing in the supply can then be obtained using the current-divider rule,

$$I_{sn} = \left| \frac{1}{1 - \left(2n\pi f_i\right)^2 L_i C_i} \right| I_{rn} \qquad (10.75)$$

where I_{rn} is the rms value of the nth harmonic current of the rectifier.

Applying Eq. (10.73) and knowing $I_{rn}/I_{r1} = 1/n$ from Eq. (10.74), the THD of the rectifier with input filter shown in Fig. 10.24 can be found as

$$\text{Filtered} \quad THD = \sqrt{\sum_{n=3,5} \frac{1}{n^2} \left| \frac{1}{1 - \left(2n\pi f_i\right)^2 L_i C_i} \right|^2} \qquad (10.76)$$

The important design parameters of typical single-phase and three-phase rectifiers with inductor-input dc filter are listed in Table 10.5. Note that, in a single-phase half-wave rectifier, a freewheeling diode is required to be connected across the input of the dc filters such that the flow of load current can be maintained during the negative half-cycle of the supply voltage.

10.5.2 Capacitive-input DC Filters

Figure 10.26 shows a full-wave rectifier with capacitor-input dc filter. The voltage and current waveforms of this rectifier

FIGURE 10.26 Full-wave rectifier with capacitor-input dc filter.

FIGURE 10.27 Voltage and current waveforms of the full-wave rectifier with capacitor-input dc filter.

are shown in Fig. 10.27. When the instantaneous voltage of the secondary winding v_s is higher than the instantaneous value of capacitor voltage v_L, either D_1 or D_2 conducts, and the capacitor C is charged up from the transformer. When the instantaneous voltage of the secondary winding v_s falls below the instantaneous value of capacitor voltage v_L, both the diodes are reverse biased and the capacitor C is discharged through load resistance R. The resulting capacitor voltage v_L varies between a maximum value of V_m and a minimum value of $V_m - V_{r(pp)}$ as shown in Fig. 10.27. ($V_{r(pp)}$ is the peak-to-peak ripple voltage.) As shown in Fig. 10.27, the conduction angle θ_c of the diodes becomes smaller when the output-ripple voltage decreases. Consequently, the power supply and the diodes suffer from high repetitive surge currents. An LC ac filter, as shown in Fig. 10.24, may be required to improve the input power factor of the rectifier.

In practice, if the peak-to-peak ripple voltage is small, it can be approximated as

$$V_{r(pp)} = \frac{V_m}{f_r RC} \tag{10.77}$$

where f_r is the output ripple frequency of the rectifier.

Therefore, the average output voltage V_{dc} is given by

$$V_{dc} = V_m \left(1 - \frac{1}{2f_r RC} \right) \tag{10.78}$$

The rms output ripple voltage V_{ac} is approximately given by

$$V_{ac} = \frac{V_m}{2\sqrt{2}f_r RC} \tag{10.79}$$

The ripple factor RF can be found from

$$RF = \frac{1}{\sqrt{2}\left(2f_r RC - 1\right)} \tag{10.80}$$

10.5.2.1 Inrush Current

The resistor R_{inrush} in Fig. 10.26 is used to limit the inrush current imposed on the diodes during the instant when the rectifier is being connected to the supply. The inrush current can be very large because capacitor C has zero charge initially. The worst case occurs when the rectifier is connected to the supply at its maximum voltage. The worst-case inrush current can be estimated from

$$I_{inrush} = \frac{V_m}{R_{sec} + R_{ESR}} \tag{10.81}$$

where R_{sec} is the equivalent resistance looking from the secondary transformer and R_{ESR} is the equivalent series resistance (ESR) of the filtering capacitor. Hence the employed diode should be able to withstand the inrush current for a half cycle of the input voltage. In other words, the *Maximum Allowable Surge Current* (I_{FSM}) rating of the employed diodes must be higher than the inrush current. The equivalent resistance associated with the transformer windings and the filtering capacitor is usually sufficient to limit the inrush current to an acceptable level. However, in cases where the transformer is omitted, e.g. the rectifier of an off-line switch-mode supply, resistor R_{inrush} must be added for controlling the inrush current.

Consider as an example, a single-phase bridge rectifier, which is to be connected to a 120-V–60-Hz source (without transformer). Assume that the I_{FSM} rating of the diodes is 150 A for an interval of 8.3 ms. If the ESR of the filtering capacitor is zero, the value of the resistor for limiting inrush current resistance can be estimated to be 1.13 Ω using Eq. (10.81).

10.6 High-frequency Diode Rectifier Circuits

In high-frequency converters, diodes perform various functions, such as rectifying, flywheeling, and clamping. One special quality a high-frequency diode must possess is a fast switching speed. In technical terms, it must have a short reverse recovery time and a short forward recovery time.

The reverse recovery time of a diode may be understood as the time a forwardly conducting diode takes to recover to a blocking state when the voltage across it is suddenly reversed (which is known as forced turn-off). The temporary short circuit during the reverse recovery period may result in large reverse current, excessive ringing, and large power dissipation, all of which are highly undesirable.

The forward recovery time of a diode may be understood as the time a non-conducting diode takes to change to the fully-on state when a forward current is suddenly forced into it (which is known as forced turn-on). Before the diode reaches the fully-on state, the forward voltage drop during the forward recovery time can be significantly higher than the normal on-state voltage drop. This may cause voltage spikes in the circuit.

It should be interesting to note that, as far as circuit operation is concerned, a diode with a long reverse recovery time is similar to a diode with a large parasitic capacitance. A diode with a long forward recovery time is similar to a diode with a large parasitic inductance. (Spikes caused by the slow forward recovery of diodes are often wrongly thought to be caused by leakage inductance.) Comparatively, the adverse effect of a long reverse recovery time is much worse than that of a long forward recovery time.

Among commonly used diodes, the Schottky diode has the shortest forward and reverse recovery times. Schottky diodes are therefore most suitable for high-frequency applications. However, Schottky diodes have relatively low reverse breakdown voltage (normally lower than 200 V) and large leakage current. If, due to these limitations, Schottky diodes cannot be used, ultra-fast diodes should be used in high-frequency converter circuits.

Using the example of a forward converter, the operations of a forward rectifier diode, a flywheel diode, and a clamping diode will be studied in Subsection 10.6.1. Because of the difficulties encountered in the full analyses taking into account parasitic/stray/leakage components, PSpice simulations are extensively used here to study the following:

- The idealized operation of the converter.
- The adverse effects of relatively slow rectifiers (e.g. the so-called ultra-fast diodes, which are actually much slower than Schottky diodes).
- The improvement achievable by using high-speed rectifiers (Schottky diodes).
- The effects of leakage inductance of the transformer.
- The use of snubber circuits to reduce ringing.
- The operation of a practical converter with snubber circuits.

Using the example of a flyback converter, the operations of a flyback rectifier diode and a clamping diode will also be studied in Subsection 10.6.2.

The design considerations for high-frequency diode rectifier circuits will be discussed in Subsection 10.6.3. Some precautions which must be taken in the interpretation of computer simulation results are briefed in Subsection 10.6.4.

10.6.1 Forward Rectifier Diode, Flywheel Diode, and Magnetic-reset Clamping Diode in a Forward Converter

10.6.1.1 Ideal Circuit

Figure 10.28 shows the basic circuit of a forward converter. Figure 10.29 shows the idealized steady-state waveforms for continuous-mode operation (the current in L_1 being continuous). These waveforms are obtained from PSpice simulations, based on the following assumptions:

- Rectifier diode D_R, flywheel diode D_F, and magnetic-reset clamping diode D_M are ideal diodes with infinitely fast switching speed.
- Electronic switch $M1$ is an idealized MOS switch with infinitely fast switching speed and

$$\text{On-state resistance} = 0.067\,\Omega$$

$$\text{Off-state resistance} = 1\,\text{M}\Omega$$

It should be noted that PSpice does not allow a switch to have zero on-state resistance and infinite off-state resistance.

- Transformer T_1 has a coupling coefficient of 0.99999999. PSpice does not accept a coupling coefficient of 1.
- The switching operation of the converter has reached a steady state.

Referring to the circuit shown in Fig. 10.28 and the waveforms shown in Fig. 10.29, the operation of the converter can be explained as follows:

1. For $0 < t < DT$ (D is the duty cycle of the MOS switch M_1 and T is the switching period of the converter. M_1 is turned on when V1(VPULSE) is 15 V, and turned off when V1(VPULSE) is 0 V).

The switch M_1 is turned on at $t = 0$. The voltage at node 3, denoted as $V(3)$, is

$$V(3) = 0 \quad \text{for} \quad 0 < t < DT \qquad (10.82)$$

The voltage induced at node 6 of the secondary winding L_S is

$$V(6) = V_{IN}\left(N_s/N_p\right) \qquad (10.83)$$

This voltage drives a current $I(DR)$ (current through rectifier diode D_R) into the output circuit to produce the output voltage V_o. The rate of increase of $I(DR)$ is given by

$$\frac{d\,I(DR)}{dt} = \left[V_{IN}\frac{N_S}{N_P} - V_o\right]\frac{1}{L_1} \qquad (10.84)$$

where V_o is the dc output voltage of the converter.

The flywheel diode D_F is reversely biased by $V(9)$, the voltage at node 9.

$$V(9) = V_{IN}\left(N_S/N_P\right) \quad \text{for} \quad 0 < t < DT \qquad (10.85)$$

The magnetic-rest clamping diode D_M is reversely biased by the negative voltage at node 100. Assuming that L_M and L_P have the same number of turns, we have

$$V(100) = -V_{IN} \quad \text{for } 0 < t < DT \qquad (10.86)$$

A magnetizing current builds up linearly in L_P. This magnetizing current reaches the maximum value of $(V_{IN}DT)/L_P$ at $t = DT$.

FIGURE 10.28 Basic circuit of forward converter.
FIGURE 10.29   Idealized steady-state waveforms of forward converter for continuous-mode operation.

2. For $DT < t < 2DT$

The switch M_1 is turned off at $t = DT$.

The collapse of magnetic flux induces a back emf in L_M, which is equal to L_P, to turn-on the clamping diode D_M. The magnetizing current in L_M drops (from the maximum value of $(V_{IN}DT)/L_P$, as mentioned above) at the rate of V_{IN}/L_P. It reaches zero at $t = 2DT$.

The back emf induced across L_P is equal to V_{IN}. The voltage at node 3 is

$$V(3) = 2V_{IN} \quad \text{for } DT < t < 2DT \qquad (10.87)$$

The back emf across L_S forces D_R to stop conducting.

The inductive current in L_1 forces the flywheel diode D_F to conduct. $I(L1)$ (current through L_1) falls at the rate of

$$\frac{d\,I(L1)}{dt} = \frac{-V_o}{L_1} \qquad (10.88)$$

The voltage across D_R, denoted as $V(6,9)$ (the voltage at node 6 with respect to node 9), is

$$V(DR) = V(6,9)$$

$$= -V_{IN}(N_S/N_P) \quad \text{for } DT < t < 2DT \qquad (10.89)$$

3. For $2DT < t < T$

D_M stops conducting at $t = 2DT$. The voltage across L_M then falls to zero.

The voltage across L_P is zero.

$$V(3) = V_{IN} \qquad (10.90)$$

The voltage across L_S is also zero.

$$V(6) = 0 \qquad (10.91)$$

Inductive current $I(L1)$ continues to fall at the rate of

$$\frac{d\,I(L1)}{dt} = \frac{-V_o}{L_1} \qquad (10.92)$$

The switching cycle restarts when the switch M_1 is turned on again at $t = T$.

From the waveforms shown in Fig. 10.29, the following useful information (for continuous-mode operation) can be found:

- The output voltage V_o is equal to the average value of $V(9)$.

$$V_o = D\frac{N_S}{N_P}V_{IN} \qquad (10.93)$$

- The maximum current in the forward rectifying diode D_R and flywheel diode D_F is

$$I(DR)_{max} = I(DF)_{max}$$

$$= I_o + \frac{1}{2}\frac{V_o}{L_1}(1-D)\,T \qquad (10.94)$$

where $V_o = DV_{IN}(N_S/N_P)$ and I_o is the output loading current.

- The maximum reverse voltage of D_R and D_F is

$$V(DR)_{max} = V(DF)_{max}$$

$$= V(6,9)_{max} = V_{IN}\frac{N_S}{N_P} \qquad (10.95)$$

- The maximum reverse voltage of D_M is

$$V(DM)_{max} = V_{IN} \qquad (10.96)$$

- The maximum current in D_M is

$$I(DM)_{max} = DT\frac{V_{IN}}{L_P} \qquad (10.97)$$

- The maximum current in the switch $M1$, denoted as $ID(M1)$, is

$$ID(M1)_{max} = \frac{N_S}{N_P}I(DR)_{max} + I(DM)_{max}$$

$$= \frac{N_S}{N_P}\left[I_o + \frac{1}{2}\frac{V_o}{L_1}(1-D)\,T\right] + DT\frac{V_{IN}}{L_P} \qquad (10.98)$$

It should, however, be understood that, due to the non-ideal characteristics of practical components, the idealized waveforms shown in Fig. 10.29 cannot actually be achieved in the real world. In the following, the effects of non-ideal diodes and transformers will be examined.

10.6.1.2 Circuit Using Ultra-fast Diodes

Figure 10.30 shows the waveforms of the forward converter (circuit given in Fig. 10.28) when ultra-fast diodes are used as D_M, D_R, and D_F. (Note that ultra-fast diodes are actually much slower than Schottky diodes.) The waveforms are obtained by PSpice simulations, based on the following assumptions:

- D_M is an MUR460 ultra-fast diode. D_R and D_F are MUR1560 ultra-fast diodes.
- M_1 is an IRF640 MOS transistor.
- Transformer T_1 has a coupling coefficient of 0.99999999 (which may be assumed to be 1).
- The switching operation of the converter has reached a steady state.
FIGURE 10.30   Waveforms of forward converter using "ultra-fast" diodes (which are actually much slower than Schottky diodes).

It is observed that a large spike appears in the current waveforms of diodes D_R and D_F (denoted as *I(DR)* and *I(DF)* in Fig. 10.30) whenever the MOS transistor M_1 is turned on. This is due to the relatively slow reverse recovery of the flywheel diode D_F. During the reverse recovery time, the positive voltage suddenly appearing across L_S (which is equal to $V_{IN}(N_S/N_P)$) drives a large transient current through D_R and D_F. This current spike results in large current stress and power dissipation in D_R, D_F, and M_1.

A method of reducing the current spikes is to use Schottky diodes as D_R and D_F, as described below.

10.6.1.3 Circuit Using Schottky Diodes

In order to reduce the current spikes caused by the slow reverse recovery of rectifiers, Schottky diodes are now used as D_R and D_F. The assumptions made here are (referring to the circuit shown in Fig. 10.28):

- D_R and D_F are MBR2540 Schottky diodes.
- D_M is an MUR460 ultra-fast diode.
- M_1 is an IRF640 MOS transistor.
- Transformer T_1 has a coupling coefficient of 0.99999999.
- The switching operation of the converter has reached a steady state.

The new simulated waveforms are given in Fig. 10.31. It is found that, by employing Schottky diodes as D_R and D_F, the amplitudes of the current spikes in *ID(M1)*, *I(DR)*, and *I(DF)* can be reduced to practically zero. This solves the slow-speed problem of ultra-fast diodes.

10.6.1.4 Circuit with Practical Transformer

The simulation results given above in Figs. 10.29–10.31 (for the forward converter circuit shown in Fig. 10.28) are based on the assumption that transformer $T1$ has effectively no leakage inductance (with coupling coefficient $K = 0.99999999$). It is, however, found that when a practical transformer (having a slightly lower K) is used, severe ringings occur. Figure 10.32 shows some simulation results to demonstrate this phenomenon, where the following assumptions are made:

- D_R and D_F are MBR2540 Schottky diodes. D_M is an MUR460 ultra-fast diode.
- M_1 is an IRF640 MOS transistor.
- Transformer T_1 has a practical coupling coefficient of 0.996.
- The effective winding resistance of L_P is 0.1 Ω. The effective winding resistance of L_M is 0.4 Ω. The effective winding resistance of L_S is 0.01 Ω.
- The effective series resistance of the output filtering capacitor is 0.05 Ω.
- The switching operation of the converter has reached a steady state.

The resultant waveforms shown in Fig. 10.32 indicate that there are large voltage and current ringings in the circuit. These ringings are caused by the resonant circuits formed by the leakage inductance of the transformer and the parasitic capacitances of diodes and transistor.

A practical converter may therefore need snubber circuits to damp these ringings, as described below.

10.6.1.5 Circuit with Snubber Across the Transformer

In order to suppress the ringing voltage caused by the resonant circuit formed by transformer leakage inductance and the parasitic capacitance of the MOS switch, a snubber circuit, shown as R_1 and C_1 in Fig. 10.33, is now connected across the primary winding of transformer T_1. The new waveforms are shown in Fig. 10.34. Here the drain-to-source voltage waveform of the MOS transistor, $V(3)$, is found to be acceptable. However, there are still large ringing voltages across the output rectifiers ($V(6,9)$ and $V(9)$).

In order to damp the ringing voltages across the output rectifiers, additional snubber circuits across the rectifiers may therefore also be required in a practical circuit, as described below.

10.6.1.6 Practical Circuit

Figure 10.35 shows a practical forward converter with snubber circuits added also to rectifiers (R_2C_2 for D_R and R_3C_3 for D_F) to reduce the voltage ringing. Figures 10.36 and 10.37 show the resultant voltage and current waveforms. Figure 10.36 is for continuous-mode operation ($R_L = 0.35\,\Omega$), where $I(L1)$ (current in L_1) is continuous. Figure 10.37 is for discontinuous-mode operation ($R_L = 10\,\Omega$), where $I(L1)$ becomes discontinuous due to an increased value of R_L. These waveforms are considered to be acceptable.

The design considerations of diode rectifier circuits in high-frequency converters will be discussed later in Subsection 10.6.3.

10.6.2 Flyback Rectifier Diode and Clamping Diode in a Flyback Converter

10.6.2.1 Ideal Circuit

Figure 10.38 shows the basic circuit of a flyback converter. Due to its simple circuit, this type of converter is widely used in low-cost low-power applications. Discontinuous-mode operation (meaning that the magnetizing current in the transformer falls to zero before the end of each switching cycle) is often used because it offers the advantages of easy control and low diode reverse-recovery loss. Figure 10.39 shows the idealized steady-state waveforms for discontinuous-mode operation. These waveforms are obtained from PSpice simulations, based on
FIGURE 10.31   Waveforms of forward converter using Schottky (fast-speed) diodes as output rectifiers.
FIGURE 10.32   Waveforms of forward converter with practical transformer and output filtering capacitor having non-zero series effective resistance.

FIGURE 10.33   Forward converter with snubber circuit ($R_1 C_1$) across transformer.

the following assumptions:

- D_R is an idealized rectifier diode with infinitely fast switching speed.
- M_1 is an idealized MOS switch with infinitely fast switching speed and

$$\text{On-state resistance} = 0.067\,\Omega$$

$$\text{Off-state resistance} = 1\,\text{M}\,\Omega$$

- Transformer T_1 has a coupling coefficient of 0.99999999.
- The switching operation of the converter has reached a steady state.

Referring to the circuit shown in Fig. 10.38 and the waveforms shown in Fig. 10.39, the operation of the converter can be explained as follows:

1. For $0 < t < DT$
   The switch M_1 is turned on at $t = 0$.

$$V(3) = 0 \quad \text{for } 0 < t < DT$$

   The current in M_1, denoted as $ID(M1)$, increases at the rate of

$$\frac{d\,ID(M1)}{dt} = \frac{V_{IN}}{L_P} \tag{10.99}$$

   The output rectifier D_R is reversely biased.
2. For $DT < t < (D + D_2)T$
   The switching M_1 is turned off at $t = DT$.
   The collapse of magnetic flux induces a back emf in L_S to turn-on the output rectifier D_R. The initial amplitude of the rectifier current $I(DR)$, which is also denoted as $I(LS)$, can be found by equating the energy stored in the primary-winding current $I(LP)$ just before

$t = DT$ to the energy stored in the secondary-winding current $I(LS)$ just after $t = DT$:

$$\frac{1}{2}L_P\,[I\,(LP)]^2 = \frac{1}{2}L_S\,[I\,(LS)]^2 \tag{10.100}$$

$$\frac{1}{2}L_P\left[\frac{V_{IN}}{L_P}DT\right]^2 = \frac{1}{2}L_S\,[I\,(LS)]^2 \tag{10.101}$$

$$I(LS) = \sqrt{\frac{L_P}{L_S}}\,\frac{V_{IN}}{L_P}DT \tag{10.102}$$

$$I(LS) = \frac{N_P}{N_S}\,\frac{V_{IN}}{L_P}DT \tag{10.103}$$

The amplitude of $I(LS)$ falls at the rate of

$$\frac{dI(LS)}{dt} = \frac{-V_o}{L_S} \tag{10.104}$$

and $I(LS)$ falls to zero at $t = (D + D_2)T$. Since $D_2 V_o = V_{IN}\,(N_S/N_P)D$

$$D_2 = \frac{V_{IN}}{V_o}\frac{N_S}{N_P}D \tag{10.105}$$

D_2 is effectively the duty cycle of the output rectifier D_R.
3. For $(D + D_2)T < t < T$
   The output rectifier D_R is off.
   The output capacitor C_L provides the output current to the load R_L.
   The switching cycle restarts when the switch M_1 is turned on again at $t = T$.

From the waveforms shown in Fig. 10.39, the following information (for discontinuous-mode operation)
FIGURE 10.34   Waveforms of forward converter with snubber circuit across the transformer.

V_{IN} = 50 V, D_M = MUR460
D_R = MBR2540, D_F = MBR2540
M_1 = IRF640, R_1 = 24 Ω
R_2 = 10 Ω, R_3 = 10 Ω
C_1 = 3000 pF, C_2 = 10 nF, C_3 = 10 nF
C_L = 3500 μF, ESR of C_L = 0.05 Ω
L_1 = 8 μH, L_P = 0.576 mH
L_M = 0.576 mH, L_S = 0.036 mH
$N_P : N_M : N_S$ = 4: 4 : 1
Effective winding resistance of L_P = 0.1 Ω
Effective winding resistance of L_M = 0.4 Ω
Effective winding resistance of L_S = 0.01 Ω
Coupling coefficient K = 0.996
FIGURE 10.35 Practical forward converter with snubber circuits across the transformer and rectifiers.

can be obtained:

- The maximum value of the current in the switch M_1 is

$$ID(M1)_{max} = \frac{V_{IN}}{L_P}DT \tag{10.106}$$

- The maximum value of the current in the output rectifier D_R is

$$I(DR)_{max} = \frac{N_P}{N_S}\frac{V_{IN}}{L_P}DT \tag{10.107}$$

- The output voltage V_o can be found by equating the input energy to the output energy within a switching cycle.
  $V_{IN} \times$ [Charge taken from V_{IN} in a switching cycle] $= \frac{V_o^2}{R_L}T$

$$V_{IN}\left[\frac{1}{2}DT\frac{DT}{L_P}V_{IN}\right] = \frac{V_o^2}{R_L}T \tag{10.108}$$

$$V_o = \sqrt{\frac{R_L T}{2L_P}}DV_{IN} \tag{10.109}$$

- The maximum reverse voltage of D_R, $V(6,9)$ (which is the voltage at node 6 with respect to node 9), is

$$V(DR)_{max} = V(6,9)_{max} = V_{IN}\frac{N_S}{N_P} + V_o \tag{10.110}$$

10.6.2.2 Practical Circuit

When a practical transformer (with leakage inductance) is used in the flyback converter circuit shown in Fig. 10.38, there will be large ringings. In order to reduce these ringings to practically acceptable levels, snubber and clamping circuits have to be added. Figure 10.40 shows a practical flyback converter circuit where a resistor–capacitor snubber ($R_2 C_2$) is used to damp the ringing voltage across the output rectifier D_R, and a resistor–capacitor-diode clamping ($R_1 C_1 D_S$) is used to clamp the ringing voltage across the switch M_1. What the diode D_S does here is to allow the energy stored by the current in the leakage inductance to be converted to the form of a dc voltage across the clamping capacitor C_1. The energy transferred to C_1 is then dissipated slowly in the parallel resistor R_1, without ringing problems.

The simulated waveforms of the flyback converter (circuit given in Fig. 10.40) for discontinuous-mode operation are shown in Fig. 10.41, where the following assumptions are made:

- D_R and D_S are MUR460 ultra-fast diodes.
- M_1 is an IRF640 MOS transistor.
- Transformer T_1 has a practical coupling coefficient of 0.992.
- The effective winding resistance of L_P is 0.025 Ω. The effective winding resistance of L_S is 0.1 Ω.
- The effective series resistance of the output filtering capacitor C_L is 0.05 Ω.
- The switching operation of the converter has reached a steady state.

The waveforms shown in Fig. 10.40 are considered to be acceptable.

10.6.3 Design Considerations

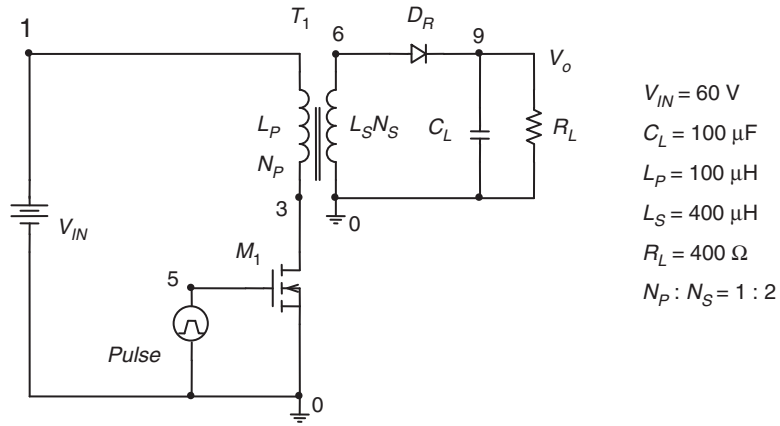
In the design of rectifier circuits, it is necessary for the designer to determine the voltage and current ratings of the diodes. The idealized waveforms and expressions for the maximum diode voltages and currents given under the heading of "Ideal circuit" above (for both forward and flyback converters) are a good starting point. However, when parasitic/stray components are also considered, the simulation results given under
FIGURE 10.36   Waveforms of practical forward converter for continuous-mode operation.
FIGURE 10.37 Waveforms of practical forward converter for discontinuous-mode operation.


FIGURE 10.38   Basic circuit of flyback converter.
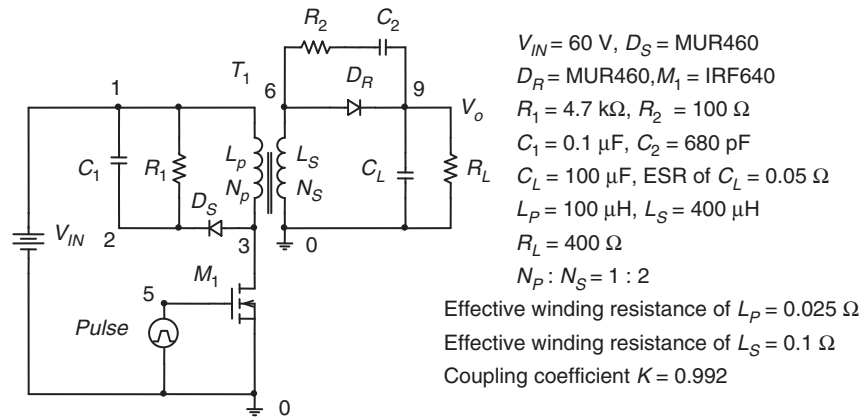
FIGURE 10.39   Idealized steady-state waveforms of flyback converter for discontinuous-mode operation.


FIGURE 10.40 Practical flyback converter circuit.
FIGURE 10.41 Waveforms of practical flyback converter for discontinuous-mode operation.

"Practical circuit" are much more useful for the determination of the voltage and current ratings of the high-frequency rectifier diodes.

Assuming that the voltage and current ratings have been determined, proper diodes can be selected to meet the requirements. The following are some general guidelines on the selection of diodes:

- For low-voltage applications, Schottky diodes should be used because they have very fast switching speed and low forward voltage drop. If Schottky diodes cannot be used, either because of their low reverse breakdown voltage or because of their large leakage current (when reversely biased), ultra-fast diodes should be used.
- The reverse breakdown-voltage rating of the diode should be reasonably higher (e.g. 10 or 20% higher) than the maximum reverse voltage, the diode is expected to encounter under the worst-case condition. However, an overly-conservative design (using a diode with much higher breakdown voltage than necessary) would result in a lower rectifier efficiency, because a diode having a higher reverse-voltage rating would normally have a larger voltage drop when it is conducting.
- The current rating of the diode should be substantially higher than the maximum current the diode is expected to carry during normal operation. Using a diode with a relatively large current rating has the following advantages:
  - It reduces the possibility of damage due to transients caused by start-up, accidental short circuit, or random turning on and off of the converter.
  - It reduces the forward voltage drop because the diode is operated in the lower current region of the *V–I* characteristic.

In some of the "high-efficiency" converter circuits, the current rating of the output rectifier can be many times larger than the actual current expected in the rectifier. In this way, a higher efficiency is achieved at the expense of a larger silicon area.

In the design of *R–C* snubber circuits for rectifiers, it should be understood that a larger *C* (and a smaller *R*) will give better damping. However, a large *C* (and a small *R*) will result in a large switching loss (which is equal to $0.5CV^2f$). As a guideline, a capacitor with five to ten times the junction capacitance of the rectifier may be used as a starting point for iterations. The value of the resistor should be chosen to provide a slightly underdamped operating condition.

10.6.4 Precautions in Interpreting Simulation Results

In using the simulated waveforms as references for design purposes, attention should be paid to the following:

- The voltage/current spikes that appear in the practically measured waveforms may not appear in the simulated waveforms. This is due to the lack of a model in the computer simulation to simulate unwanted coupling among the practical components.
- Most of the computer models of diodes, including those used in the simulations given above, do not take into account the effects of the forward recovery time. (The forward recovery time is not even mentioned in most manufacturers' data sheets.) However, it is also interesting to note that in most cases the effect of the forward recovery time of a diode is masked by that of the effective inductance in series with the diode (e.g. the leakage inductance of a transformer).

Santa María, Valparaíso, Chile

11.1 Introduction

This chapter is dedicated to single-phase controlled rectifiers, which are used in a wide range of applications. As shown in Fig. 11.1, single-phase rectifiers can be classified into two big categories:

(i) Topologies working with low switching frequency, also known as line commutated or phase controlled rectifiers.

(ii) Circuits working with high switching frequency, also known as power factor correctors (PFCs).

Line-commutated rectifiers with diodes, covered in a previous chapter of this handbook, do not allow the control of power being converted from ac to dc. This control can be achieved with the use of thyristors. These controlled rectifiers are addressed in the first part of this chapter.

In the last years, increasing attention has been paid to the control of current harmonics present at the input side of the rectifiers, originating from a very important development in the so-called PFC. These circuits use power transistors working with high switching frequency to improve the waveform quality of the input current, increasing the power factor. High power factor rectifiers can be classified in regenerative and non-regenerative topologies and they are covered in the second part of this chapter.

11.2 Line-commutated Single-phase Controlled Rectifiers

11.2.1 Single-phase Half-wave Rectifier

The single-phase half-wave rectifier uses a single thyristor to control the load voltage as shown in Fig. 11.2. The thyristor will conduct, on-state, when the voltage v_T is positive and a firing current pulse i_G is applied to the gate terminal. The control of the load voltage is performed by delaying the firing pulse by an angle α. The firing angle α is measured from the position where a diode would naturally conduct. In case of Fig. 11.2 the angle α is measured from the zero-crossing point of the supply voltage v_s. The load in Fig. 11.2 is resistive and therefore the current i_d has the same waveform of the load voltage. The thyristor goes to the non-conducting condition, off-state, when the load voltage, and consequently the current, reaches a negative value.

The load average voltage is given by

$$V_{d\alpha} = \frac{1}{2\pi} \int_{\alpha}^{\pi} V_{max} \sin(\omega t) d(\omega t) = \frac{V_{max}}{2\pi} (1 + \cos \alpha)$$

$$(11.1)$$

where V_{max} is the supply peak voltage. Hence, it can be seen from Eq. (11.1) that changing the firing angle α controls
FIGURE 11.1   Single-phase rectifier classification.
FIGURE 11.2   Single-thyristor rectifier with resistive load.

both the load average voltage and the amount of transferred power.

Figure 11.3a shows the rectifier waveforms for an *R–L* load. When the thyristor is turned on, the voltage across the inductance is

$$v_L = v_s - v_R = L\frac{di_d}{dt} \tag{11.2}$$

where v_R is the voltage in the resistance R, given by $v_R = R \cdot i_d$. If $v_s - v_R > 0$, from Eq. (11.2) holds that the load current increases its value. On the other hand, i_d decreases its value when $v_s - v_R < 0$. The load current is given by

$$i_d(\omega t) = \frac{1}{\omega L} \int_\alpha^{\omega t} v_L d\theta \tag{11.3}$$

Graphically, Eq. (11.3) means that the load current i_d is equal to zero when $A_1 = A_2$, maintaining the thyristor in conduction state even when $v_s < 0$.

When an inductive–active load is connected to the rectifier, as illustrated in Fig. 11.3b, the thyristor will be turned on if the firing pulse is applied to the gate when $v_s > E_d$. Again, the thyristor will remain in the on-state until $A_1 = A_2$. When the thyristor is turned off, the load voltage will be $v_d = E_d$.

11.2.2 Bi-phase Half-wave Rectifier

The bi-phase half-wave rectifier, shown in Fig. 11.4, uses a center-tapped transformer to provide two voltages v_1 and v_2. These two voltages are 180° out of phase with respect to the mid-point neutral *N*. In this scheme, the load is fed via thyristors T_1 and T_2 during each positive cycle of voltages v_1 and v_2, respectively, while the load current returns via the neutral *N*.

As illustrated in Fig. 11.4, thyristor T_1 can be fired into the on-state at any time while voltage $v_{T1} > 0$. The firing pulses are delayed by an angle α with respect to the instant where diodes would conduct. Also the current paths for each conduction state are presented in Fig. 11.4. Thyristor T_1 remains in the on-state until the load current tends to a negative value. Thyristor T_2 is fired into the on-state when $v_{T2} > 0$, which corresponds in Fig. 11.4 to the condition when $v_2 > 0$.

The mean value of the load voltage with resistive load is determined by

$$V_{di\alpha} = \frac{1}{\pi} \int_\alpha^\pi V_{max} \sin(\omega t) d(\omega t) = \frac{V_{max}}{\pi}(1 + \cos\alpha) \tag{11.4}$$

The ac supply current is equal to $i_{T1}(N_2/N_1)$ when T_1 is in the on-state and $-i_{T2}(N_2/N_1)$ when T_2 is in the on-state, where N_2/N_1 is the transformer turns ratio.
FIGURE 11.3 Single-thyristor rectifier with: (a) resistive-inductive load and (b) active load.

The effect of the load time constant $T_L = L/R$, on the normalized load current $i_d(t)/i_R(t)$ for a firing angle $\alpha = 0°$ is shown in Fig. 11.5. The ripple in the load current reduces as the load inductance increases. If the load inductance $L \to \infty$, then the current is perfectly filtered.

11.2.3 Single-phase Bridge Rectifier

Figure 11.6a shows a fully controlled bridge rectifier, which uses four thyristors to control the average load voltage. In addition, Fig. 11.6b shows the half-controlled bridge rectifier which uses two thyristors and two diodes.

The voltage and current waveforms of the fully controlled bridge rectifier for a resistive load are illustrated in Fig 11.7. Thyristors T_1 and T_2 must be fired on simultaneously during the positive half-wave of the source voltage v_s, to allow the conduction of current. Alternatively, thyristors T_3 and T_4 must be fired simultaneously during the negative half-wave of the source voltage. To ensure simultaneous firing, thyristors T_1 and T_2 use the same firing signal. The load voltage is similar to the voltage obtained with the bi-phase half-wave rectifier. The input current is given by

$$i_S = i_{T1} - i_{T4} \qquad (11.5)$$

and its waveform is shown in Fig. 11.7.

Figure 11.8 presents the behavior of the fully controlled rectifier with resistive–inductive load (with $L \to \infty$). The high load inductance generates a perfectly filtered current and the rectifier behaves like a current source. With continuous load current, thyristors T_1 and T_2 remain in the on-state beyond the positive half-wave of the source voltage v_s. For this reason, the load voltage v_d can have a negative instantaneous value. The firing of thyristors T_3 and T_4 has two effects:

(i) they turn-off thyristors T_1 and T_2 and
(ii) after the commutation, they conduct the load current.

This is the main reason why this type of converters are called "naturally commutated" or "line commutated" rectifiers. The supply current i_S has the square waveform, as shown in Fig. 11.9, for continuous conduction. In this case, the average load voltage is given by

$$V_{di\alpha} = \frac{1}{\pi} \int_{\alpha}^{\pi+\alpha} V_{max} \sin(\omega t) d(\omega t) = \frac{2V_{max}}{\pi} \cos \alpha \quad (11.6)$$

11.2.4 Analysis of the Input Current

Considering a very high inductive load, the input current in a bridge-controlled rectifier is filtered and presents a square waveform. In addition, the input current i_s is shifted by the firing angle α with respect to the input voltage v_s, as shown in Fig. 11.9a. The input current can be expressed as a Fourier series, where the amplitude of the different harmonics are

$$I_{smax,n} = \frac{4}{\pi} \frac{I_d}{n} \quad (n = 1, 3, 5, \dots) \qquad (11.7)$$

$$i_s = i_{T1} \cdot \frac{N_2}{N_1} \qquad\qquad i_s = -i_{T2} \cdot \frac{N_2}{N_1}$$
FIGURE 11.4   Bi-phase half-wave rectifier.
FIGURE 11.5   Effect of the load time constant over the current ripple.
FIGURE 11.6 Single-phase bridge rectifier: (a) fully controlled and (b) half-controlled.
FIGURE 11.7 Waveforms of a fully controlled bridge rectifier with resistive load.
FIGURE 11.8 Waveforms of a fully controlled bridge rectifier with resistive–inductive load ($L \to \infty$).

where n is the harmonic order. The root mean square (rms) value of each harmonic can be expressed as

$$I_{sn} = \frac{I_{smax,n}}{\sqrt{2}} = \frac{2\sqrt{2}}{\pi} \frac{I_d}{n} \qquad (11.8)$$

Thus, the rms value of the fundamental current i_{s1} is

$$I_{s1} = \frac{2\sqrt{2}}{\pi} I_d = 0.9 I_d \qquad (11.9)$$

It can be observed from Fig. 11.9a that the displacement angle ϕ_1 of the fundamental current i_{s1} corresponds to the firing angle α. Figure 11.9b shows that in the harmonic spectrum of the input current, only odd harmonics are present with
FIGURE 11.9 Input current of the single-phase controlled rectifier in bridge connection: (a) waveforms and (b) harmonics spectrum.

decreasing amplitude while the frequency increases. Finally the rms value of the input current i_s is

$$I_s = I_d \qquad (11.10)$$

The total harmonic distortion (THD) of the input current can be determined by

$$\text{THD} = \frac{\sqrt{I_s^2 - I_{s1}^2}}{I_{s1}} 100 = 48.4\% \qquad (11.11)$$

11.2.5 Power Factor of the Rectifier

The displacement factor of the fundamental current, obtained from Fig. 11.9a is

$$\cos \phi_1 = \cos \alpha \qquad (11.12)$$

In the case of non-sinusoidal currents, the active power delivered by the sinusoidal single-phase supply is

$$P = \frac{1}{T} \int_0^T v_s(t) i_s(t) dt = V_s I_{s1} \cos \phi_1 \qquad (11.13)$$

where V_s is the rms value of the single-phase voltage v_s.

The apparent power is given by

$$S = V_s I_s \qquad (11.14)$$

The power factor (PF) is defined by

$$\text{PF} = \frac{P}{S} \qquad (11.15)$$

Substitution from Eqs. (11.12), (11.13), and (11.14) in Eq. (11.15) yields

$$\text{PF} = \frac{I_{s1}}{I_s} \cos \alpha \qquad (11.16)$$

This equation shows clearly that due to the non-sinusoidal waveform of the input current, the power factor of the rectifier is negatively affected both by the firing angle α and by the distortion of the input current. In effect, an increase in the distortion of the current produces an increase in the value of I_s in Eq. (11.16), which deteriorates the power factor.

11.2.6 The Commutation of the Thyristors

Until now, the current commutation between thyristors has been considered to be instantaneous. This condition is not valid in real cases due to the presence of the line inductance L, as shown in Fig. 11.10a. During the commutation, the current through the thyristors cannot change instantaneously, and for this reason, during the commutation angle μ, all four thyristors are conducting simultaneously. Therefore, during the commutation, the following relationship for the load voltage holds

$$v_d = 0 \qquad \alpha \leq \omega t \leq \alpha + \mu \qquad (11.17)$$

The effect of the commutation on the supply current, voltage waveforms, and the thyristor current waveforms can be observed in Fig. 11.10b.

During the commutation, the following expression holds

$$L\frac{di_s}{dt} = v_s = V_{max} \sin(\omega t) \quad \alpha \leq \omega t \leq \alpha + \mu \qquad (11.18)$$

Integrating Eq. (11.18) over the commutation interval yields

$$\int_{-I_d}^{I_d} di_s = \frac{V_{max}}{L} \int_{\alpha/\omega}^{\alpha+\mu/\omega} \sin(\omega t) dt \qquad (11.19)$$

From Eq. (11.19), the following relationship for the commutation angle μ is obtained

$$\cos(\alpha + \mu) = \cos \alpha - \frac{2\omega L}{V_{max}} I_d \qquad (11.20)$$

Equation (11.20) shows that an increase of the line inductance L or an increase of the load current I_d increases the commutation angle μ. In addition, the commutation angle is affected by the firing angle α. In effect, Eq. (11.18) shows that with different values of α, the supply voltage v_s has a different instantaneous value, which produces different di_s/dt, thereby affecting the duration of the commutation.

Equation (11.17) and the waveform of Fig. 11.10b show that the commutation process reduces the average load voltage $V_{d\alpha}$. When the commutation is considered, the expression for the average load voltage is given by

$$V_{d\alpha} = \frac{1}{\pi} \int_{\alpha+\mu}^{\pi+\alpha} \sin(\omega t) d(\omega t) = \frac{V_{max}}{\pi} [\cos(\alpha + \mu) + \cos \alpha] \qquad (11.21)$$

Substituting Eq. (11.20) into Eq. (11.21) yields

$$V_{d\alpha} = \frac{2}{\pi} V_{max} \cos \alpha - \frac{2\omega L}{\pi} I_d \qquad (11.22)$$
FIGURE 11.10   The commutation process: (a) circuit and (b) waveforms.

11.2.7 Operation in the Inverting Mode

When the angle $\alpha > 90°$, it is possible to obtain a negative average load voltage. In this condition, the power is fed back to the single-phase supply from the load. This operating mode is called inverter or inverting mode, because the energy is transferred from the dc to the ac side. In practical cases, this operating mode is obtained when the load configuration is as shown in Fig. 11.11a. It must be noticed that this rectifier allows unidirectional load current flow.

Figure 11.11b shows the waveform of the load voltage with the rectifier in the inverting mode, neglecting the source inductance L.

Section 11.2.6 described how supply inductance increases the conduction interval of the thyristors by the angle μ. As shown in Fig. 11.11c, the thyristor voltage v_{T1} has a negative value during the extinction angle γ, defined by

$$\gamma = 180 - (\alpha + \mu) \tag{11.23}$$

To ensure that the outgoing thyristor will recover its blocking capability after the commutation, the extinction angle should satisfy the following restriction

$$\gamma > \omega t_q \tag{11.24}$$
FIGURE 11.11   Rectifier in the inverting mode: (a) circuit; (b) waveforms neglecting source inductance *L*; and (c) waveforms considering *L*.

where ω is the supply frequency and t_q is the thyristor turn-off time. Considering Eqs. (11.23) and (11.24) the maximum firing angle is, in practice,

$$\alpha_{max} = 180 - \mu - \gamma \qquad (11.25)$$

If the condition of Eq. (11.25) is not satisfied, the commutation process will fail, originating destructive currents.

11.2.8 Applications

Important application areas of controlled rectifiers include uninterruptible power supplies (UPS), for feeding critical loads. Figure 11.12 shows a simplified diagram of a single-phase UPS configuration, typically rated for <10 kVA. A fully controlled or half-controlled rectifier is used to generate the dc voltage for the inverter. In addition, the input rectifier acts as a battery charger. The output of the inverter is filtered before

it is fed to the load. The most important operation modes of the UPS are:

   (i) Normal mode. In this case the line voltage is present. The critical load is fed through the rectifier-inverter scheme. The rectifier keeps the battery charged.

  (ii) Outage mode. During a loss of the ac main supply, the battery provides the energy for the inverter.

 (iii) Bypass operation. When the load demands an overcurrent to the inverter, the static bypass switch is turned on and the critical load is fed directly from the mains.

The control of low power dc motors is another interesting application of controlled single-phase rectifiers. In the circuit of Fig. 11.13, the controlled rectifier regulates the armature voltage and consequently controls the motor current i_d in order to produce a required torque.

This configuration allows only positive current flow in the load. However the load voltage can be both positive
FIGURE 11.12 Application of a rectifier in single-phase UPS.
FIGURE 11.13 Two-quadrant dc drive: (a) circuit and (b) quadrants of operation.
FIGURE 11.14 Single-phase dual-converter drive: (a) connection and (b) four-quadrant operation.

and negative. For this reason, this converter works in the two-quadrant mode of operation in the plane i_d vs $V_{d\alpha}$.

A better performance can be obtained with two rectifiers in back-to-back connection at the dc terminals, as shown in Fig. 11.14a. This arrangement, known as a dual converter configuration, allows four-quadrant operation of the drive.

Rectifier I provides positive load current i_d, while rectifier II provides negative load current. The motor can work in forward powering, forward braking (regenerating), reverse powering, and reverse braking (regenerating). These operating modes are shown in Fig. 11.14b, where the torque T vs the rotor speed ω_r is illustrated.

11.3 Unity Power Factor Single-phase Rectifiers

11.3.1 The Problem of Power Factor in Single-phase Line-commutated Rectifiers

The main disadvantages of the classical line-commutated rectifiers are that (i) they produce a lagging displacement factor with respect to the voltage of the utility; (ii) they generate an important amount of input current harmonics.

These aspects have a negative influence on both power factor and power quality. In the last several years, the massive use of single-phase power converters has increased the problems of power quality in electrical systems. In effect, modern commercial buildings have 50% and even up to 90% of the demand, originated by non-linear loads, which are composed mainly by rectifiers [1]. Today it is not unusual to find rectifiers with total harmonic distortion of the current $THD_i > 40\%$, originating severe overloads in conductors and transformers.

Figure 11.15a shows a single-phase rectifier with a capacitive filter, used in much of today's low-power equipment. The input current produced by this rectifier is illustrated in Fig. 11.15b, it appears highly distorted due to the presence of the filter capacitor. This current has a harmonic content shown in Fig. 11.16 and Table 11.1, with a $THD_i = 197\%$.

The rectifier in Fig. 11.15 has a very low power factor of $PF = 0.45$, due mainly to its large harmonic content.

TABLE 11.1 Harmonic content of the current of Fig. 11.15

n	3	5	7	9	11	13	15	17	19	21
I_n/I_1 [%]	96.8	90.5	81.7	71.0	59.3	47.3	35.7	25.4	16.8	10.6

11.3.2 Standards for Harmonics in Single-phase Rectifiers

The relevance of the problems originated by harmonics in single-phase line-commutated rectifiers has motivated some agencies to introduce restrictions to these converters. The IEC 61000-3-2 Class D International Standard establishes limits to all low-power single-phase equipment having an input current with a "special wave shape" and an active input power $P \leq 600$ W. Class D equipment has an input current with a special wave shape contained within the envelope given in Fig. 11.15b. This class of equipment must satisfy certain harmonic limits, shown in Fig. 11.16. It is clear that a single-phase line-commutated rectifier with the parameters shown in Fig. 11.15a is not able to comply with the standard IEC 61000-3-2 Class D. The standard can be satisfied only by adding huge passive filters, which increases the size, weight, and cost of the rectifier. This standard has been the motivation for the development of active methods to improve the quality of the input current and, consequently, the power factor.

11.3.3 The Single-phase Boost Rectifier

One of the most important high power factor rectifiers, from a theoretical and conceptual point of view, is the so-called single-phase boost rectifier, shown in Fig. 11.17a, which is obtained from a classical non-controlled bridge rectifier, with the addition of transistor T, diode D, and inductor L.

11.3.3.1 Working Principle, Basic Concepts

In boost rectifiers, the input current $i_s(t)$ is controlled by changing the conduction state of transistor T. When transistor T is in the on-state, the single-phase power supply is short-circuited through the inductance L, as shown in Fig. 11.17b; the diode D avoids the discharge of the filter capacitor C through the transistor. The current of the inductance i_L is given by the following equation

$$\frac{di_L}{dt} = \frac{v_L}{L} = \frac{|v_s|}{L} \tag{11.26}$$

Due to the fact that $|v_s| > 0$, the on-state of transistor T always produces an increase in the inductance current i_L and consequently an increase in the absolute value of the source current i_s.

When transistor T is turned off, the inductor current i_L cannot be interrupted abruptly and flows through diode D, charging capacitor C. This is observed in the equivalent circuit of Fig. 11.17c. In this condition, the behavior of the inductor current is described by

$$\frac{di_L}{dt} = \frac{v_L}{L} = \frac{|v_s| - v_o}{L} \tag{11.27}$$

If $v_o > |v_s|$, which is an important condition for the correct behavior of the rectifier, then $|v_s| - v_o < 0$, and this means that in the off-state the inductor current decreases its instantaneous value.

11.3.3.2 Continuous Conduction Mode (CCM)

With an appropriate firing pulse sequence is applied to transistor T, the waveform of the input current i_s can be controlled to follow a sinusoidal reference, as can be observed in the positive half-wave of i_s in Fig. 11.18. This figure shows the reference
FIGURE 11.17 Single-phase boost rectifier: (a) power circuit and equivalent circuit for transistor T in; (b) on-state; and (c) off-state.
FIGURE 11.18   Behavior of the inductor current i_L: (a) waveforms and (b) transistor T gate drive signal x.

inductor current i_{Lref}, the inductor current i_L and the gate drive signal x for transistor T. Transistor T is on when $x = 1$ and it is off when $x = 0$.

Figure 11.18 clearly shows that the on- (off-) state of transistor T produces an increase (decrease) in the inductor current i_L.

Note that for low values of v_s the inductor does not have enough energy to increase the current value, for this reason it presents a distortion in their current waveform as shown in Fig. 11.18a.

Figure 11.19 presents a block diagram of the control system for the boost rectifier, which includes a proportional-integral (PI) controller, to regulate the output voltage v_o. The reference value i_{Lref} for the inner current control loop is obtained from the multiplication between the output of the voltage controller and the absolute value $|v_s(t)|$. A hysteresis controller provides a fast control for the inductor current i_L, resulting in a practically sinusoidal input current i_s.

Typically, the output voltage v_o should be at least 10% higher than the peak value of the source voltage $v_s(t)$, in order to assure good dynamic control of the current. The control works with the following strategy: a step increase in the reference voltage v_{oref} will produce an increase in the voltage error $v_{oref} - v_o$ and an increase of the output of the PI controller, which originates an increase in the amplitude of the reference

current i_{Lref}. The current controller will follow this new reference and will increase the amplitude of the sinusoidal input current i_s, which will increase the active power delivered by the single-phase power supply, producing finally an increase in the output voltage v_o.

Figure 11.20a shows the waveform of the input current i_s and the source voltage v_s. The ripple of the input current can be reduced by shortening the hysteresis width δ. The tradeoff for this improvement is an increase in the switching frequency, which is proportional to the commutation losses of the transistors. For a given hysteresis width δ, a reduction of inductance L also produces an increase in the switching frequency. As can be seen, the input current presents a third-harmonic component. This harmonic is generated by the second-harmonic component present in v_o, which is fed back through the voltage (PI) controller and multiplied by the sinusoidal waveform, generating a third-harmonic component on i_{Lref}. This harmonic contamination can be avoided by filtering the v_o measurement with a lowpass filter or a bandstop filter around $2\omega_s$. The input current obtained using the measurement filter is shown in Fig. 11.20b. Figure 11.20d confirms the reduction of the third-harmonic component.

However, in both cases, a drastic reduction in the harmonic content of the input current i_s can be observed in the frequency spectrum of Figs. 11.20c and 11.20d. This current fulfills the restrictions established by standard IEC 61000-3-2. The total harmonic distortion of the current in Fig. 11.20a is THD $= 7.46\%$, while the THD of the current of Fig. 11.20b is 4.83%, in both cases a very high power factor, over 0.99, is reached.

Figure 11.21 shows the dc voltage control loop dynamic behavior for step changes in the load. An increase in the load, at $t = 0.3$ [s], produces an initial reduction of the output voltage v_o, which is compensated by an increase in the input current i_s. At $t = 0.6$ [s] a step decrease in the load is applied. The dc voltage controller again adjusts the supply current in order to balance the active power.

11.3.3.3 Discontinuous Conduction Mode (DCM)

This PFC method is based on an active current waveform-shaping principle. There are two different approaches considering fixed and variable switching frequency, both operating principles are illustrated in Fig. 11.22.
FIGURE 11.19   Control system of the boost rectifier.
FIGURE 11.20 Input current and voltage of the single-phase boost rectifier: (a) without a filter on v_o measurement; (b) with a filter on v_o measurement; frequency spectrum; (c) without filter; and (d) with filter.
FIGURE 11.21 Response to a change in the load: (a) output-voltage v_o and (b) input current i_s.
FIGURE 11.22   Boost DCM operating principle: (a) with fixed switching frequency and (b) with variable switching frequency.

a) DCM with Fixed Switching Frequency

The current shaping strategy is achieved by combining three different conduction modes, performed over a fixed switching period T_s. At the beginning of each period the power semiconductor is turned on. During the on-state, shown in Fig. 11.23a, the power supply is short-circuited through the rectifier diodes, the inductor L, and the boost switch T. Hence, the inductor current i_L increases at a rate proportional to the instantaneous value of the supply voltage. As a result, during the on-state, the average supply current i_s is proportional to the supply voltage v_s which yields to power factor correction.

When the switch is turned off, the current flows to the load trough diode D, as shown in Fig. 11.23b. The instantaneous current value decreases (since the load voltage v_o is higher than the supply peak voltage) at a rate proportional to the difference between the supply and load voltage. Finally, the last mode, illustrated in Fig. 11.23c, corresponds to the time in which the current reaches zero value, completing the switching period T_s. Therefore, the supply current is not proportional to the voltage source during the whole control period, introducing distortion and undesirable EMI in comparison to CCM.

The duty cycle $D = t_{on}/T_s$ is determined by the control loop, in order to obtain the desired output power and to ensure operation in DCM, i.e. to reach zero current before the new switching cycle starts. The control strategy can be implemented with analog circuitry as shown in Fig. 11.24, or digitally with modern computing devices. Generally, the duty cycle is controlled with a slow control loop, maintaining the output voltage and duty cycle constant over a half-source cycle.

A qualitative example of the supply voltage and current obtained using DCM is illustrated in Fig. 11.25.

b) DCM with Variable Switching Frequency

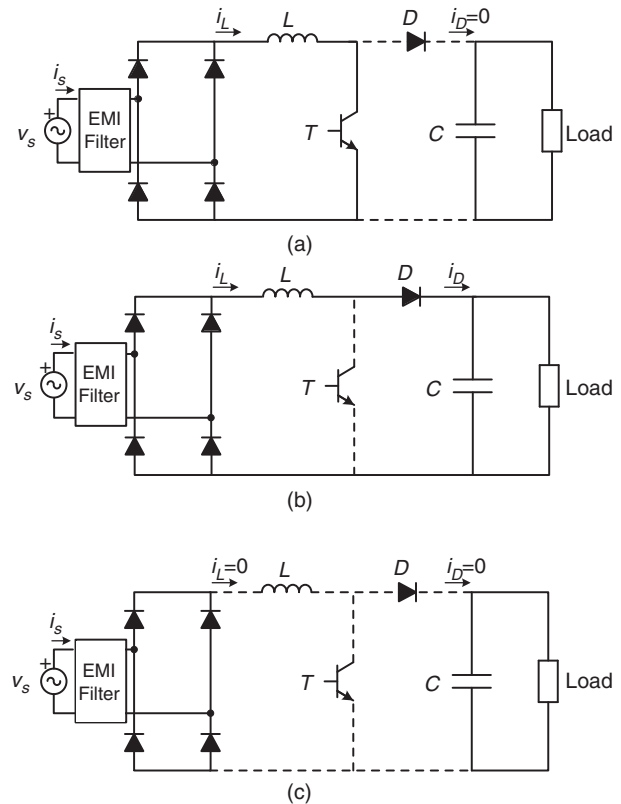
The operating principle is similar to the one used in the previous case, the main difference is that mode 3 is avoided by switching the transistor again to the on-state, immediately after the inductor current reaches zero value. This reduces


FIGURE 11.23   Boost DCM equivalent circuits: (a) mode 1: transistor on, inductor current increasing; (b) mode 2: transistor off, inductor current decreasing; and (c) mode 3: transistor off, inductor current reaches zero.

the current distortion, with the tradeoff of introducing variable switching frequency (T_s is variable) and consequently lower-order harmonic content.

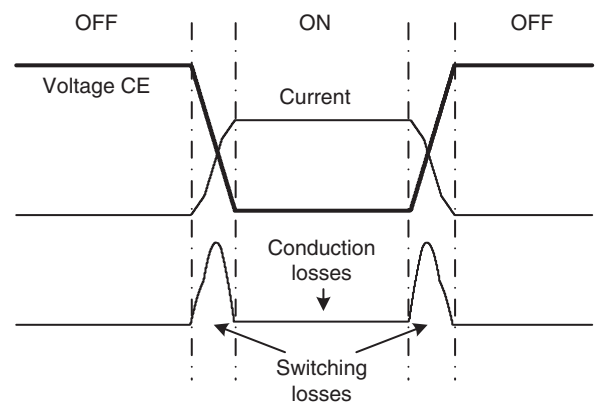
Both CCM and DCM achieve an improvement in the power factor. The DCM is more efficient since reverse-recovery losses
FIGURE 11.24 Boost DCM control circuit with fixed switching frequency.
FIGURE 11.25 Boost DCM waveforms: supply voltage, transistor control signal, and supply current.


FIGURE 11.26 Conduction and switching losses on a power switch.

of the boost diode are eliminated, however this mode introduces high-current ripple and considerable distortion and usually an important fifth-order harmonic is obtained. Therefore boost-DCM applications are limited to 300 W power levels, to meet standards and regulations. The DCM with variable switching frequency reduces this harmonic content, at expends of a wide distributed current spectrum and all related design problems.

11.3.3.4 Resonant Structures for the Boost Rectifiers

An important issue in power electronics is the power losses in power semiconductors. These losses can be classified in two groups: conduction losses and switching losses, as shown in Fig. 11.26.

The conduction losses are produced by the current through the semiconductor juncture, so these losses are unavoidable.

However, the switching losses, which are produced while the power semiconductors work in linear state during the transition from on- to off- state or from off- to on-state, can be reduced or even eliminated, if the switch (transition) occurs when: (a) the current across the power semiconductor is zero; (b) the voltage between the power terminals of the power semiconductor is zero.

This operation mode is used in the so-called *resonant* or *soft-switched* converters, which are discussed in detail in a different chapter of this handbook.

Resonant operation can also be used with the boost converter topology. In order to produce this condition, topology of Fig. 11.17 needs to be modified, by including reactive components and additional semiconductors.

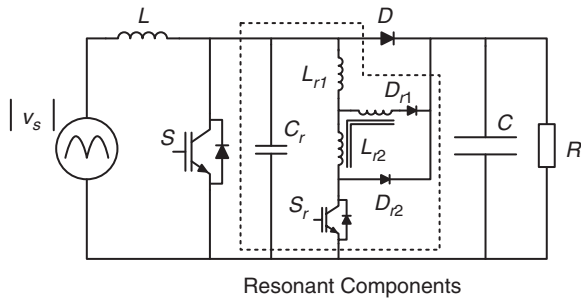
In Fig. 11.27 a resonant structure for zero current switching (ZCS) [2] is shown. As can be seen, additional resonant inductors (L_{r1}, L_{r2}), capacitors (C_r), diodes (D_{r1}, D_{r2}), and power switch (S_r) have been included.


FIGURE 11.27 Boost rectifier with ZCS.
FIGURE 11.28 Boost rectifier with ZVS.

In a similar way, in Fig. 11.28 a resonant structure for zero voltage switching (ZVS) [3] is shown. Once again, additional inductance (L_r), capacitor (C_r), and power switch (S_r) are added, note however, that diode D has been replaced by two "resonant diodes," D_{r1} and D_{r2}.

In both cases, the ZVS or ZCS condition is reached through a proper control of S_r. Other resonant topologies are described in the literature [4–6] with similar behavior.

11.3.3.5 Bridgless Boost Rectifier

The bridgless boost rectifier [7] is shown in Fig. 11.29a. This rectifier replaces the input diode rectifier by a combination of two boost rectifiers which work alternately: (a) when v_s is positive, T_1 and D_1 operate as boost rectifier 1 (Fig. 11.29b); (b) when v_s is negative, T_2 and D_2 operate as boost rectifier 2 (Fig. 11.29c);

This topology reduces the conduction losses of the rectifier [8, 9], but requires a slightly more complex control scheme, also EMI and EMC aspects must be considered.

11.3.4 Voltage Doubler PWM Rectifier

Figure 11.30a shows the power circuit of the voltage doubler pulse width modulated (PWM) rectifier, which uses two transistors T_1 and T_2 and two filter capacitors C_1 and C_2. The transistors are switched complementary to control the waveform of the input current i_s and the output dc voltage v_o. Capacitor voltages V_{C1} and V_{C2} must be higher than the peak value of the input voltage v_s to ensure the control of the input current.

The equivalent circuit of this rectifier with transistor T_1 in the on-state is shown in Fig. 11.30b. For this case, the inductor voltage dynamic equation is

$$v_L = L\frac{di_s}{dt} = v_s(t) - V_{C1} < 0 \qquad (11.28)$$

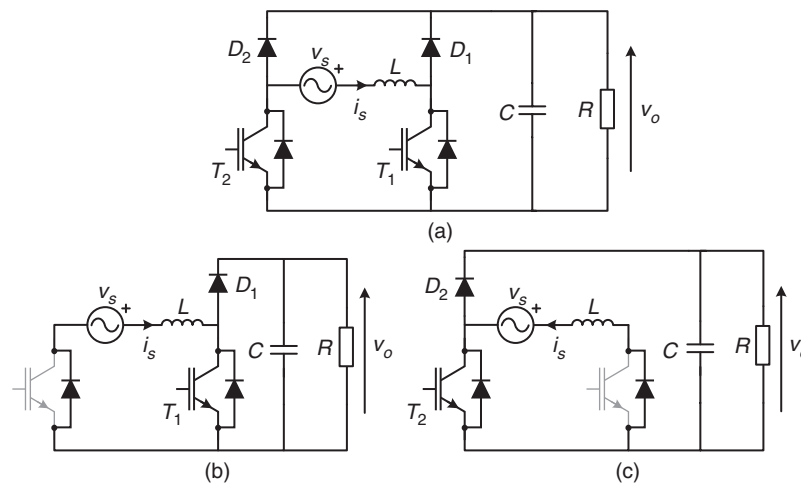
Equation (11.28) means that under this conduction state, current $i_s(t)$ decreases its value.


FIGURE 11.29 (a) Power circuit of bridgless boost rectifier; equivalent circuit when; (b) $v_s > 0$; and (c) $v_s < 0$.

(a)

(b)   (c)
FIGURE 11.30   Voltage doubler rectifier: (a) power circuit; (b) equivalent circuit with T_1 on; and (c) equivalent circuit with T_2 on.

On the other hand, the equivalent circuit of Fig. 11.30c is valid when transistor T_2 is in the conduction state, resulting in the following expression for the inductor voltage

$$v_L = L\frac{di_s}{dt} = v_s(t) + V_{C2} > 0 \qquad (11.29)$$

hence, for this condition, the input current $i_s(t)$ increases.

Therefore the waveform of the input current can be controlled by switching appropriately transistors T_1 and T_2 in a similar way as shown in Fig. 11.18a for the single-phase boost converter. Figure 11.31 shows a block diagram of the control system for the voltage doubler rectifier, which is very similar to the control scheme of the boost rectifier. This topology can present an unbalance in the capacitor voltages V_{C1} and V_{C2}, which will affect the quality of the control. This problem is solved by adding to the actual current value i_s an offset signal proportional to the capacitor's voltage difference.

Figure 11.32 shows the waveform of the input current. The ripple amplitude of this current can be reduced by decreasing the hysteresis width of the controller.

FIGURE 11.32   Waveform of the input current in the voltage doubler rectifier.

11.3.5 The PWM Rectifier in Bridge Connection

Figure 11.33a shows the power circuit of the fully controlled single-phase PWM rectifier in bridge connection, which uses four transistors with antiparallel diodes to produce a controlled dc voltage v_o. Using a bipolar PWM switching strategy, this converter may have two conduction states: (i) Transistors T_1 and T_4 in the on-state and T_2 and T_3 in the off-state; (ii) Transistors T_2 and T_3 in the on-state and T_1 and T_4 in the off-state.

In this topology, the output voltage v_o must be higher than the peak value of the ac source voltage v_s, to ensure a proper control of the input current.

Figure 11.33b shows the equivalent circuit with transistors T_1 and T_4 on. In this case, the inductor voltage is given by

$$v_L = L\frac{di_s}{dt} = v_s(t) - V_0 < 0 \qquad (11.30)$$

Therefore, in this condition a reduction of the inductor current i_s is produced.

Figure 11.33c shows the equivalent circuit with transistors T_2 and T_3 on. Here, the inductor voltage has the following expression

$$v_L = L\frac{di_s}{dt} = v_s(t) + V_0 > 0 \qquad (11.31)$$

which means an increase in the instantaneous value of the input current i_s.

FIGURE 11.31   Control system of the voltage doubler rectifier.
FIGURE 11.33 Single-phase PWM rectifier in bridge connection: (a) power circuit; (b) equivalent circuit with T_1 and T_4 on; (c) equivalent circuit with T_2 and T_3 on; (d) equivalent circuit with T_1 and T_3 or T_2 and T_4 on; and (e) waveform of the input current during regeneration.

Finally, Fig. 11.33d shows the equivalent circuit with transistors T_1 and T_3 or T_2 and T_4 are in the on-state. In this case, the input voltage source is short-circuited through inductor L, which yields

$$v_L = L\frac{di_s}{dt} = v_s(t) + V_0 > 0 \qquad (11.32)$$

Equation (11.32) implies that the current value will depend on the sign of v_s.

The waveform of the input current i_s can be controlled by appropriately switching transistors T_1–T_4 or T_2–T_3, originating a similar shape to the one shown in Fig. 11.18a for the single-phase boost rectifier.

The control strategy for the rectifier is similar to the one illustrated in Fig. 11.31, for the voltage doubler topology. The quality of the input current obtained with this rectifier is the same as presented in Fig. 11.32 for the voltage doubler configuration.

The input current waveform can be slightly improved if the state of Fig. 11.33d is used. This can be done by replacing the hysteresis current control with a more complex linear control plus a three-level PWM modulator. This method reduces

the semiconductor switching frequency and provides a more defined current spectrum.

Finally, it must be said that one of the most attractive characteristics of the fully controlled PWM converter in bridge connection and the voltage doubler is their regeneration capability. In effect, these rectifiers can deliver power from the load to the single-phase supply, operating with sinusoidal current and a high power factor of PF > 0.99. Figure 11.33e shows that during regeneration, the input current i_s is 180° out of phase with respect to the supply voltage v_s, which means operation with power factor PF ≈ -1 (PF is approximately 1 because of the small harmonic content in the input current).

11.3.6 Applications of Unity Power Factor Rectifiers

11.3.6.1 Boost Rectifier Applications

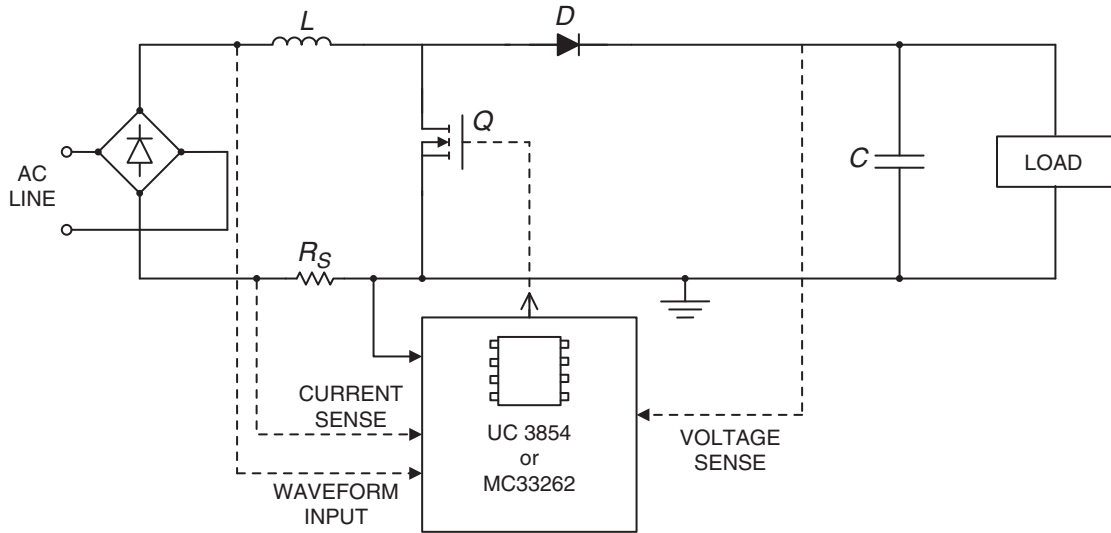
The single-phase boost rectifier has become the most popular topology for power factor correction (PFC) in general purpose power supplies. To reduce the costs, the complete control system shown in Fig. 11.19 and the gate drive circuit of the power transistor have been included in a single integrated circuit (IC), like the UC3854 [10] or MC33262, shown in Fig. 11.34.


FIGURE 11.34 Simplified circuit of a power factor corrector with control integrated circuit.
FIGURE 11.35 Functional block diagram of electronic ballast with power factor correction.

Today there is increased interest in developing high-frequency electronic ballasts to replace the classical electromagnetic ballast present in fluorescent lamps. These electronic ballasts require an ac–dc converter. To satisfy the harmonic current injection from electronic equipment and to maintain a high power quality, a high power factor rectifier can be used, as shown in Fig. 11.35 [11].

11.3.6.2 Voltage Doubler PWM Rectifier

The development of low-cost compact motor drive systems is a very relevant topic, particularly in the low-power range. Figure 11.36 shows a low-cost converter for low-power induction motor drives. In this configuration, a three-phase induction motor is fed through the converter from a single-phase power supply. Transistors T_1, T_2 and capacitors C_1, C_2
FIGURE 11.36 Low-cost induction motor drive.

constitute the voltage doubler single-phase rectifier, which controls the dc link voltage and generates sinusoidal input current, working with close-to-unity power factor [12]. On the other hand, transistors T_3, T_4, T_5, and T_6 and capacitors C_1 and C_2 constitute the power circuit of an asymmetric inverter that supplies the motor. An important characteristic of the power circuit shown in Fig. 11.36 is the capability of regenerating power to the single-phase mains.

11.3.6.3 PWM Rectifier in Bridge Connection

Distortion of the input current in the line-commutated rectifiers with capacitive filtering is particularly critical in the UPS fed from motor-generator sets. In effect, due to the higher value of the generator impedance, the current distortion can originate an unacceptable distortion on the ac voltage, which affects the behavior of the whole system. For this reason, it is very attractive to use rectifiers with low distortion in the input current.

Figure 11.37 shows the power circuit of a single-phase UPS, which has a PWM rectifier in bridge connection at the input

side. This rectifier generates a sinusoidal input current and controls the charge of the battery [13].

Perhaps the most typical and widely accepted area of application of high power factor single-phase rectifiers is in locomotive drives [14]. An essential prerequisite for proper operation of voltage source three-phase inverter drives in modern locomotives is the use of four-quadrant line-side converters, which ensure motoring and braking of the drive, with reduced harmonics in the input current. Figure 11.38 shows a simplified power circuit of a typical drive for a locomotive connected to a single-phase power supply [14], which includes a high power factor rectifier at the input.

Finally, Fig. 11.39 shows the main circuit diagram of the 300 series Shinkansen train [15]. In this application, ac power from the overhead catenary is transmitted through a transformer to single-phase PWM rectifiers, which provide the dc voltage for the inverters. The rectifiers are capable of controlling the input ac current in an approximate sine waveform and in phase with the voltage, achieving power factor close to unity on powering and on regenerative braking. Regenerative braking produces energy savings and an important operational flexibility.

Three-phase Controlled Rectifiers

Juan W. Dixon, Ph.D.

*Department of Electrical
Engineering, Pontificia
Universidad Católica de Chile
Vicuña Mackenna 4860,
Santiago, Chile*

12.1 Introduction

Three-phase controlled rectifiers have a wide range of applications, from small rectifiers to large high voltage direct current (HVDC) transmission systems. They are used for electrochemical processes, many kinds of motor drives, traction equipment, controlled power supplies and many other applications. From the point of view of the commutation process, they can be classified into two important categories: *line-commutated controlled rectifiers (thyristor rectifiers)* and *force-commutated pulse width modulated (PWM) rectifiers.*

12.2 Line-commutated Controlled Rectifiers

12.2.1 Three-phase Half-wave Rectifier

Figure 12.1 shows the three-phase half-wave rectifier topology. To control the load voltage, the half-wave rectifier uses three common-cathode thyristor arrangement. In this figure, the power supply and the transformer are assumed ideal. The thyristor will conduct (*ON* state), when the anode-to-cathode voltage v_{AK} is positive and a firing current pulse i_G is applied to the gate terminal. Delaying the firing pulse by an angle α controls the load voltage. As shown in Fig. 12.2, the firing angle α

is measured from the crossing point between the phase supply voltages. At that point, the anode-to-cathode thyristor voltage v_{AK} begins to be positive. Figure 12.3 shows that the possible range for gating delay is between $\alpha = 0°$ and $\alpha = 180°$, but because of commutation problems in actual situations, the maximum firing angle is limited to around 160°. As shown in Fig. 12.4, when the load is resistive, current i_d has the same waveform of the load voltage. As the load becomes more and more inductive, the current flattens and finally becomes constant. The thyristor goes to the non-conducting condition (*OFF* state) when the following thyristor is switched *ON*, or the current, tries to reach a negative value.

With the help of Fig. 12.2, the load average voltage can be evaluated, and is given by:

$$V_D = \frac{V_{MAX}}{\frac{2}{3}\pi} \int_{-\pi/3+\alpha}^{\pi/3+\alpha} \cos \omega t \cdot d(\omega t)$$

$$= V_{MAX} \frac{\sin \frac{\pi}{3}}{\frac{\pi}{3}} \cdot \cos \alpha \approx 1.17 \cdot V_{f-N}^{rms} \cdot \cos \alpha \qquad (12.1)$$

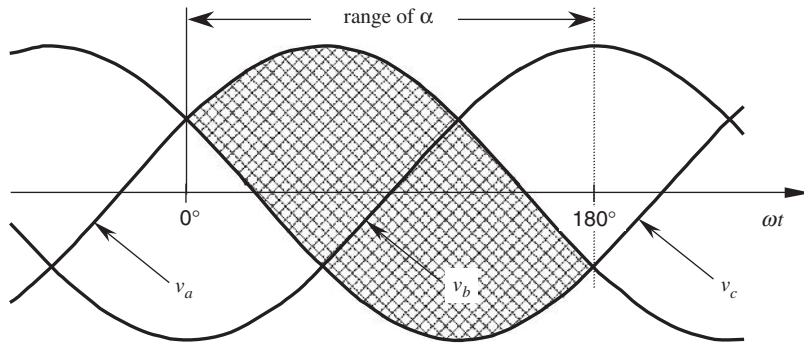
where V_{MAX} is the secondary phase-to-neutral peak voltage, V_{f-N}^{rms} its root mean square (*rms*) value and ω is the angular frequency of the main power supply. It can be seen from Eq. (12.1) that the load average voltage V_D is modified by
FIGURE 12.1   Three-phase half-wave rectifier.
FIGURE 12.2   Instantaneous *dc* voltage v_D, average *dc* voltage V_D, and firing angle α.


FIGURE 12.3   Possible range for gating delay in angle α.

changing firing angle α. When $\alpha < 90°$, V_D is positive and when $\alpha > 90°$, the average *dc* voltage becomes negative. In such a case, the rectifier begins to work as an inverter and the load needs to be able to generate power reversal by reversing its *dc* voltage.

The *ac* currents of the half-wave rectifier are shown in Fig. 12.5. This drawing assumes that the *dc* current is constant (very large L_D). Disregarding commutation overlap, each valve conducts during 120° per period. The secondary currents (and thyristor currents) present a *dc* component that is undesirable, and makes this rectifier not useful for high power applications.

The primary currents show the same waveform, but with the *dc* component removed. This very distorted waveform requires an input filter to reduce harmonics contamination.

The current waveforms shown in Fig. 12.5 are useful for designing the power transformer. Starting from:

$$VA_{prim} = 3 \cdot V^{rms}_{(prim)f-N} \cdot I^{rms}_{prim}$$

$$VA_{sec} = 3 \cdot V^{rms}_{(sec)f-N} \cdot I^{rms}_{sec} \qquad (12.2)$$

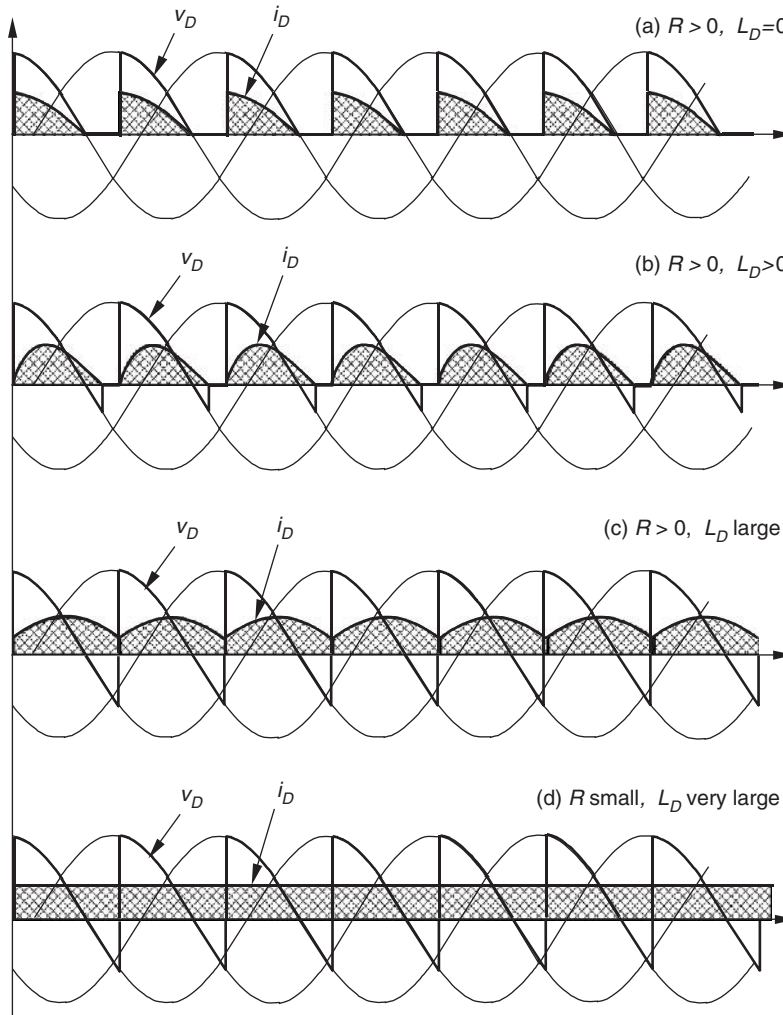
$$P_D = V_D \cdot I_D$$


FIGURE 12.4   *DC* current waveforms.

where VA_{prim} and VA_{sec} are the ratings of the transformer for the primary and secondary side respectively. Here P_D is the power transferred to the *dc* side. The maximum power transfer is with $\alpha = 0°$ (or $\alpha = 180°$). Then, to establish a relation between *ac* and *dc* voltages, Eq. (12.1) for $\alpha = 0°$ is required:

$$V_D = 1.17 \cdot V^{rms}_{(sec)f-N} \tag{12.3}$$

and:

$$V_D = 1.17 \cdot a \cdot V^{rms}_{(prim)f-N} \tag{12.4}$$

where *a* is the secondary to primary turn relation of the transformer. On the other hand, a relation between the currents is also possible to obtain. With the help of Fig. 12.5:

$$I^{rms}_{sec} = \frac{I_D}{\sqrt{3}} \tag{12.5}$$

$$I^{rms}_{prim} = a \cdot \frac{I_D\sqrt{2}}{3} \tag{12.6}$$

Combining Eqs. (12.2) to (12.6), it yields:

$$VA_{prim} = 1.21 \cdot P_D$$
$$VA_{sec} = 1.48 \cdot P_D \tag{12.7}$$

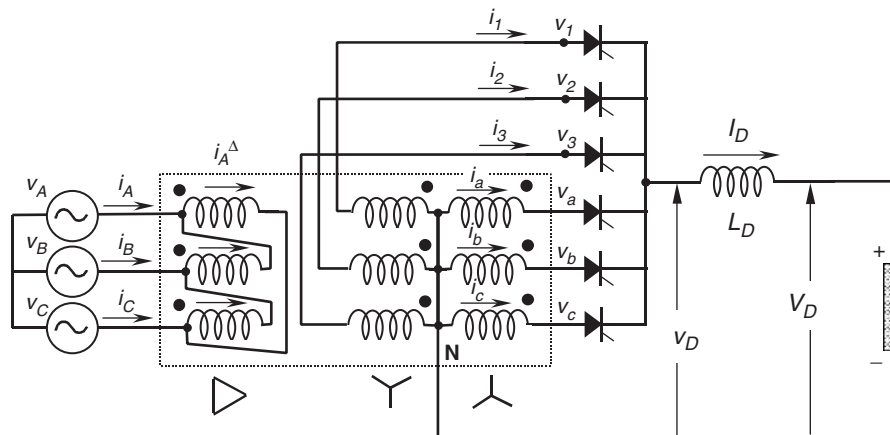
Equation (12.7) shows that the power transformer has to be oversized 21% at the primary side, and 48% at the secondary side. Then, a special transformer has to be built for this rectifier. In terms of average *VA*, the transformer needs to be 35% larger that the rating of the *dc* load. The larger rating of the secondary with respect to primary is because the secondary carries a *dc* component inside the windings. Furthermore, the transformer is oversized because the circulation of current harmonics does not generate active power. Core saturation, due to
FIGURE 12.5 *AC* current waveforms for the half-wave rectifier.


FIGURE 12.6 Six-pulse rectifier.

the *dc* components inside the secondary windings, also needs to be taken in account for iron oversizing.

12.2.2 Six-pulse or Double Star Rectifier

The thyristor side windings of the transformer shown in Fig. 12.6 form a six-phase system, resulting in a six-pulse starpoint (midpoint connection). Disregarding commutation overlap, each valve conducts only during 60° per period. The direct voltage is higher than that from the half-wave rectifier

and its average value is given by:

$$V_D = \frac{V_{MAX}}{\frac{\pi}{3}} \int\limits_{-\pi/6+\alpha}^{\pi/6+\alpha} \cos \omega t \cdot d\,(\omega t)$$

$$= V_{MAX} \frac{\sin \frac{\pi}{6}}{\frac{\pi}{6}} \cdot \cos \alpha \approx 1.35 \cdot V_{f-N}^{rms} \cdot \cos \alpha \qquad (12.8)$$

The *dc* voltage ripple is also smaller than the one generated by the half-wave rectifier, due to the absence of the third harmonic with its inherently high amplitude. The smoothing
FIGURE 12.7   *AC* current waveforms for the six-pulse rectifier.

reactor L_D is also considerably smaller than the one needed for a three-pulse (half-wave) rectifier.

The *ac* currents of the six-pulse rectifier are shown in Fig. 12.7. The currents in the secondary windings present a *dc* component, but the magnetic flux is compensated by the double star. As can be observed, only one valve is fired at a time and then this connection in no way corresponds to a parallel connection. The currents inside the delta show a symmetrical waveform with 60° conduction. Finally, due to the particular transformer connection shown in Fig. 12.6, the source currents also show a symmetrical waveform, but with 120° conduction.

Evaluation of the the rating of the transformer is done in similar fashion to the way the half-wave rectifier is evaluated:

$$VA_{prim} = 1.28 \cdot P_D$$
$$VA_{sec} = 1.81 \cdot P_D$$
(12.9)

Thus the transformer must be oversized 28% at the primary side and 81% at the secondary side. In terms of size it has an average apparent power of 1.55 times the power P_D(55% oversized). Because of the short conducting period of the valves, the transformer is not particularly well utilized.

12.2.3 Double Star Rectifier with Interphase Connection

This topology works as two half-wave rectifiers in parallel, and is very useful when high *dc* current is required. An optimal

way to reach both good balance and elimination of harmonics is through the connection shown in Fig. 12.8. The two rectifiers are shifted by 180°, and their secondary neutrals are connected through a middle-point autotransformer called "interphase transformer." The interphase transformer is connected between the two secondary neutrals and the middle point at the load return. In this way, both groups operate in parallel. Half the direct current flows in each half of the interphase transformer, and then its iron core does not become saturated. The potential of each neutral can oscillate independently, generating an almost triangular voltage waveform (v_T) in the interphase transformer, as shown in Fig. 12.9. As this converter work like two half-wave rectifiers connected in parallel, the load average voltage is the same as in Eq. (12.1):

$$V_D \approx 1.17 \cdot V_{f-N}^{rms} \cdot \cos\alpha$$
(12.10)

where V_{f-N}^{rms} is the phase-to-neutral *rms* voltage at the valve side of the transformer (secondary).

The Fig. 12.9 also shows the two half-wave rectifier voltages, related to their respective neutrals. Voltage v_{D1} represents the potential between the common cathode connection and the neutral N1. The voltage v_{D2} is between the common cathode connection and N2. It can be seen that the two instantaneous voltages are shifted, which gives as a result, a voltage v_D that is smoother than v_{D1} and v_{D2}.

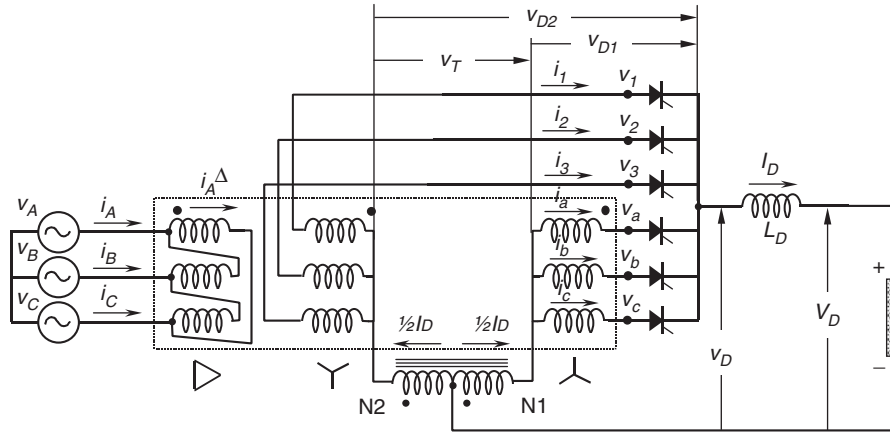
Figure 12.10 shows how v_D, v_{D1}, v_{D2}, and v_T change when the firing angle changes from $\alpha = 0°$ to 180°.


FIGURE 12.8   Double star rectifier with interphase transformer.
FIGURE 12.9   Operation of the interphase connection for $\alpha = 0°$.

The transformer rating in this case is:

$$VA_{prim} = 1.05 \cdot P_D$$

$$VA_{sec} = 1.48 \cdot P_D$$ (12.11)

And the average rating power will be 1.26 P_D, which is better than the previous rectifiers (1.35 for the half-wave rectifier and 1.55 for the six-pulse rectifier). Thus the transformer is well utilized. Figure 12.11 shows *ac* current waveforms for a rectifier with interphase transformer.

12.2.4 Three-phase Full-wave Rectifier or Graetz Bridge

Parallel connection via interphase transformers permits the implementation of rectifiers for high current applications. Series connection for high voltage is also possible, as shown in the full-wave rectifier of Fig. 12.12. With this arrangement, it can be seen that the three common cathode valves generate a positive voltage with respect to the neutral, and the three common anode valves produce a negative voltage. The result is a *dc* voltage, twice the value of the half-wave rectifier. Each half of the bridge is a three-pulse converter group. This bridge connection is a two-way connection and alternating currents flow in the valve-side transformer windings during both half periods, avoiding *dc* components into the windings, and saturation in the transformer magnetic core. These characteristics make the so-called Graetz bridge the most widely used line-commutated thyristor rectifier. The configuration does not need any special transformer and works as a six-pulse rectifier. The series characteristic of this rectifier produces a *dc* voltage twice the value of the half-wave rectifier. The load average voltage is given by:

$$V_D = \frac{2 \cdot V_{MAX}}{\frac{2}{3}\pi} \int\limits_{-\pi/3+\alpha}^{\pi/3+\alpha} \cos\omega t \cdot d\left(\omega t\right)$$

$$= 2 \cdot V_{MAX} \frac{\sin\frac{\pi}{3}}{\frac{\pi}{3}} \cdot \cos\alpha \approx 2.34 \cdot V_{f-N}^{rms} \cdot \cos\alpha \quad (12.12)$$
FIGURE 12.10   Firing angle variation from $\alpha = 0°$ to $180°$.
FIGURE 12.11   *AC* current waveforms for the rectifier with interphase transformer.

or

$$V_D = \frac{3 \cdot \sqrt{2} \cdot V_{f-f}^{sec}}{\pi} \cos \alpha \approx 1.35 \cdot V_{f-f}^{sec} \cdot \cos \alpha \qquad (12.13)$$

where V_{MAX} is the peak phase-to-neutral voltage at the secondary transformer terminals, V_{f-N}^{rms} its *rms* value,

and V_{f-f}^{sec} the *rms* phase-to-phase secondary voltage, at the valve terminals of the rectifier.

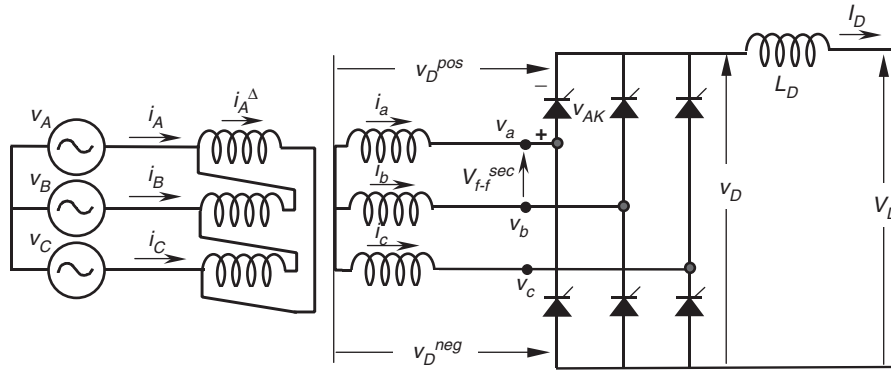
Figure 12.13 shows the voltages of each half-wave bridge of this topology, v_D^{pos} and v_D^{neg}, the total instantaneous *dc* voltage v_D, and the anode-to-cathode voltage v_{AK} in one of the bridge thyristors. The maximum value of v_{AK} is $\sqrt{3} \cdot V_{MAX}$,


FIGURE 12.12 Three-phase full-wave rectifier or Graetz bridge.
FIGURE 12.13 Voltage waveforms for the Graetz bridge.

which is the same as that of the half-wave converter and the interphase transformer rectifier. The double star rectifier presents a maximum anode-to-cathode voltage of two times V_{MAX}. Figure 12.14 shows the currents of the rectifier, which assumes that L_D is large enough to keep the *dc* current smooth. The example is for the same ΔY transformer connection shown in the topology of Fig. 12.12. It can be noted that the secondary currents do not carry any *dc* component, thereby avoiding overdesign of the windings and transformer saturation. These two figures have been drawn for a firing angle, α of approximately 30°. The perfect symmetry of the currents in all windings and lines is one of the reasons why this rectifier is the most popular of its type. The transformer rating in this case is

$$VA_{prim} = 1.05 \cdot P_D$$

$$VA_{sec} = 1.05 \cdot P_D \tag{12.14}$$

As can be noted, the transformer needs to be oversized only 5%, and both primary and secondary windings have the same rating. Again, this value can be compared with the previous rectifier transformers: $1.35P_D$ for the half-wave rectifier, $1.55P_D$ for the six-pulse rectifier, and $1.26P_D$ for the interphase transformer rectifier. The Graetz bridge makes excellent use of the power transformer.

12.2.5 Half Controlled Bridge Converter

The fully controlled three-phase bridge converter shown in Fig. 12.12 has six thyristors. As already explained here, this circuit operates as a rectifier when each thyristor has a firing angle $\alpha < 90°$ and functions as an inverter for $\alpha > 90°$. If inverter operation is not required, the circuit may be simplified by replacing three controlled rectifiers with power diodes, as in Fig. 12.15a. This simplification is economically attractive
FIGURE 12.14   Current waveforms for the Graetz bridge.
FIGURE 12.15   One-quadrant bridge converter circuits: (a) half-controlled bridge and (b) free-wheeling diode bridge.

because diodes are considerably less expensive than thyristors and they do not require firing angle control electronics.

The half controlled bridge, or "semiconverter," is analyzed by considering it as a phase-controlled half-wave circuit in series with an uncontrolled half-wave rectifier. The average *dc* voltage is given by the following equation

$$V_D = \frac{3 \cdot \sqrt{2} \cdot V_{f-f}^{sec}}{2\pi}(1 + \cos\alpha) \qquad (12.15)$$

Then, the average voltage V_D never reaches negative values. The output voltage waveforms of half-controlled bridge are similar to those of a fully controlled bridge with a free-wheeling diode. The advantage of the free-wheeling diode connection, shown in Fig. 12.15b is that there is always a path for the *dc* current, independent of the status of the *ac* line and of the converter. This can be important if the load is inductive–resistive with a large time constant, and there is an interruption in one or more of the line phases. In such a case, the load current could commutate to the free-wheeling diode.
FIGURE 12.16 Commutation process.

12.2.6 Commutation

The description of the converters in the previous sections was based upon assumption that the commutation was instantaneous. In practice this is not possible, because the transfer of current between two consecutive valves in a commutation group takes a finite time. This time, called *overlap time*, depends on the phase-to-phase voltage between the valves participating in the commutation process, and the line inductance L_S between the converter and power supply. During the overlap time, two valves conduct, and the phase-to-phase voltage drops entirely on the inductances L_S. Assuming the *dc* current I_D to be smooth and with the help of Fig. 12.16, the following relation is deduced

$$2L_S \cdot \frac{di_{sc}}{dt} = \sqrt{2} \cdot V_{f-f} \sin \omega t = v_A - v_B \qquad (12.16)$$

where i_{sc} is the current in the valve being fired during the commutation process (thyristor T2 in Fig. 12.16). This current can be evaluated, and it yields

$$i_{sc} = -\frac{\sqrt{2}}{2L_S} \cdot V_{f-f} \frac{\cos \omega t}{\omega} + C \qquad (12.17)$$

The constant "C" is evaluated through initial conditions at the instant when T2 is ignited. In terms of angle, when $\omega t = \alpha$

$$\text{when } \omega t = \alpha, \quad i_{sc} = 0$$

$$\therefore C = \frac{V_{f-f}^{sec}}{\sqrt{2} \cdot \omega L_S} \cos \alpha \qquad (12.18)$$

Replacing Eq. (12.18) in (12.17):

$$i_{sc} = \frac{V_{f-f}}{\sqrt{2} \cdot \omega L_S} \cdot (\cos \alpha - \cos \omega t) \qquad (12.19)$$

Before commutation, the current I_D was carried by thyristor T1 (see Fig. 12.16). During the commutation time, the load current I_D remains constant, i_{sc} returns through T1, and T1 is automatically switched off when the current i_{sc} reaches the value of I_D. This happens because thyristors cannot conduct in reverse direction. At this moment, the overlap time lasts and the current I_D is then conducted by T2. In terms of angle, when $\omega t = \alpha + \mu$, $i_{sc} = I_D$, where μ is defined as the "*overlap angle.*" Replacing this final condition in Eq. (12.19) yields

$$I_D = \frac{V_{f-f}^{sec}}{\sqrt{2} \cdot \omega L_S} \cdot [\cos \alpha - \cos (\alpha + \mu)] \qquad (12.20)$$

To avoid confusion in a real analysis, it has to be remembered that V_{f-f} corresponds to the secondary voltage in case of transformer utilization. For this reason, the abbreviation "sec" has been added to the phase-to-phase voltage in Eq. (12.20).

During commutation, two valves conduct at a time, which means that there is an instantaneous short circuit between the two voltages participating in the process. As the inductances of each phase are the same, the current i_{sc} produces the same voltage drop in each L_S, but with opposite sign because this current flows in reverse direction and with opposite slope in each inductance. The phase with the higher instantaneous voltage suffers a voltage drop $-\Delta v$ and the phase with the lower voltage suffers a voltage increase $+\Delta v$. This situation affects the *dc* voltage V_C, reducing its value an amount ΔV_{med}. Figure 12.17 shows the meanings of Δv, ΔV_{med}, μ, and i_{sc}.

The area ΔV_{med} showed in Fig. 12.17, represents the loss of voltage that affects the average voltage V_C, and can be evaluated through the integration of Δv during the overlap angle μ. The voltage drop Δv can be expressed as

$$\Delta v = \left(\frac{v_A - v_B}{2} \right) = \frac{\sqrt{2} \cdot V_{f-f}^{sec} \sin \omega t}{2} \qquad (12.21)$$
FIGURE 12.17 Effect of the overlap angle on the voltages and currents.

Integrating Eq. (12.21) into the corresponding period (60°) and interval (μ) and starting at the instant when the commutation begins (α)

$$\Delta V_{med} = \frac{3}{\pi} \cdot \frac{1}{2} \int_{\alpha}^{\alpha+\mu} \sqrt{2} \cdot V_{f-f}^{sec} \sin \omega t \cdot d\omega t \qquad (12.22)$$

$$\Delta V_{med} = \frac{3 \cdot V_{f-f}^{sec}}{\pi \cdot \sqrt{2}} [\cos \alpha - \cos (\alpha + \mu)] \qquad (12.23)$$

Subtracting ΔV_{med} in Eq. (12.13)

$$V_D = \frac{3 \cdot \sqrt{2} \cdot V_{f-f}^{sec}}{\pi} \cos \alpha - \Delta V_{med} \qquad (12.24)$$

$$V_D = \frac{3 \cdot \sqrt{2} \cdot V_{f-f}^{sec}}{2\pi} [\cos \alpha + \cos (\alpha + \mu)] \qquad (12.25)$$

or

$$V_D = \frac{3 \cdot \sqrt{2} \cdot V_{f-f}^{sec}}{\pi} \left[\cos \left(\alpha + \frac{\mu}{2} \right) \cos \frac{\mu}{2} \right] \qquad (12.26)$$

Equations (12.20) and (12.25) can be written as a function of the primary winding of the transformer, if there is any transformer.

$$I_D = \frac{a \cdot V_{f-f}^{prim}}{\sqrt{2} \cdot \omega L_S} \cdot [\cos \alpha - \cos (\alpha + \mu)] \qquad (12.27)$$

$$V_D = \frac{3 \cdot \sqrt{2} \cdot a \cdot V_{f-f}^{prim}}{2\pi} [\cos \alpha + \cos (\alpha + \mu)] \qquad (12.28)$$

where $a = V_{f-f}^{sec}/V_{f-f}^{prim}$. With Eqs. (12.27) and (12.28) one gets

$$V_D = \frac{3 \cdot \sqrt{2}}{\pi} \cdot a \cdot V_{f-f}^{prim} \cos \alpha - \frac{3 I_D \omega L_S}{\pi} \qquad (12.29)$$

Equation (12.29) allows a very simple equivalent circuit of the converter to be made, as shown in Fig. 12.18. It is important to note that the equivalent resistance of this circuit is not real, because it does not dissipate power.

From the equivalent circuit, regulation curves for the rectifier under different firing angles are shown in Fig. 12.19. It should be noted that these curves correspond only to an ideal situation, but helps in understanding the effect of voltage drop Δv on *dc* voltage. The commutation process and the overlap angle also affects the voltage v_a and anode-to-cathode thyristor voltage, as shown in Fig. 12.20.
FIGURE 12.18 Equivalent circuit for the converter.
FIGURE 12.19   *DC* voltage regulation curves for rectifier operation.

12.2.7 Power Factor

The displacement factor of the fundamental current, obtained from Fig. 12.14 is

$$\cos\phi_1 = \cos\alpha \tag{12.30}$$

In the case of non-sinusoidal current, the active power delivered per phase by the sinusoidal supply is

$$P = \frac{1}{T}\int_0^T v_a(t)i_a(t)dt = V_a^{rms}I_{a1}^{rms}\cos\phi_1 \tag{12.31}$$

where V_a^{rms} is the *rms* value of the voltage v_a and I_{a1}^{rms} the *rms* value of i_{a1} (fundamental component of i_a). Analog relations can be obtained for v_b and v_c.

The apparent power per phase is given by

$$S = V_a^{rms}I_a^{rms} \tag{12.32}$$

The power factor is defined by

$$PF = \frac{P}{S} \tag{12.33}$$

By substituting Eqs. (12.30), (12.31), and (12.32) into Eq. (12.33), the power factor can be expressed as follows

$$PF = \frac{I_{a1}^{rms}}{I_a^{rms}}\cos\alpha \tag{12.34}$$

This equation shows clearly that due to the non-sinusoidal waveform of the currents, the power factor of the rectifier is negatively affected by both the firing angle α and the distortion of the input current. In effect, an increase in the distortion of the current produces an increase in the value of I_a^{rms} in Eq. (12.34), which deteriorates the power factor.

12.2.8 Harmonic Distortion

The currents of the line-commutated rectifiers are far from being sinusoidal. For example, the currents generated from the Graetz rectifier (see Fig. 12.14b) have the following harmonic content

$$i_A = \frac{2\sqrt{3}}{\pi}I_D(\cos\omega t - \frac{1}{5}\cos 5\omega t + \frac{1}{7}\cos 7\omega t$$

$$- \frac{1}{11}\cos 11\omega t + \ldots) \tag{12.35}$$

Some of the characteristics of the currents, obtained from Eq. (12.35) include: (i) the absence of triple harmonics; (ii) the presence of harmonics of order $6k \pm 1$ for integer values of k; (iii) those harmonics of orders $6k + 1$ are of positive sequence; (iv) those of orders $6k - 1$ are of negative sequence; (v) the *rms* magnitude of the fundamental frequency is

$$I_1 = \frac{\sqrt{6}}{\pi}I_D \tag{12.36}$$
FIGURE 12.20   Effect of the overlap angle on v_a and on thyristor voltage v_{AK}.

and (vi) the *rms* magnitude of the *n*th harmonic is

$$I_n = \frac{I_1}{n} \qquad (12.37)$$

If either, the primary or the secondary three-phase windings of the rectifier transformer are connected in delta, the *ac* side current waveforms consist of the instantaneous differences between two rectangular secondary currents 120° apart as shown in Fig. 12.14e. The resulting Fourier series for the current in phase "a" on the primary side is

$$i_A = \frac{2\sqrt{3}}{\pi} I_D (\cos \omega t + \frac{1}{5} \cos 5\omega t - \frac{1}{7} \cos 7\omega t$$

$$- \frac{1}{11} \cos 11\omega t + \ldots) \qquad (12.38)$$

This series differs from that of a star connected transformer only by the sequence of rotation of harmonic orders $6k \pm 1$ for odd values of *k*, i.e. the 5th, 7th, 17th, 19th, etc.

12.2.9 Special Configurations for Harmonic Reduction

A common solution for harmonic reduction is through the connection of passive filters, which are tuned to trap a particular harmonic frequency. A typical configuration is shown in Fig. 12.21.

However, harmonics also can be eliminated using special configurations of converters. For example, 12-pulse configuration consists of two sets of converters connected as shown

5th   7th   11th   13th   17th to ∞
FIGURE 12.21 Typical passive filter for one phase.

in Fig. 12.22. The resultant *ac* current is given by the sum of the two Fourier series of the star connection (Eq. (12.35)) and delta connection transformers (Eq. (12.38))

$$i_A = 2\left(\frac{2\sqrt{3}}{\pi}\right) I_D (\cos \omega t - \frac{1}{11} \cos 11\omega t + \frac{1}{13} \cos 13\omega t$$

$$- \frac{1}{23} \cos 23\omega t + \ldots) \qquad (12.39)$$

The series only contains harmonics of order $12k \pm 1$. The harmonic currents of orders $6k \pm 1$ (with *k* odd), i.e. 5th, 7th, 17th, 19th, etc. circulate between the two converter transformers but do not penetrate the *ac* network.

The resulting line current for the 12-pulse rectifier, shown in Fig. 12.23, is closer to a sinusoidal waveform than previous line currents. The instantaneous *dc* voltage is also smoother with this connection.
FIGURE 12.22 12-pulse rectifier configuration.
FIGURE 12.23   Line current for the 12-pulse rectifier.
FIGURE 12.24   *DC* ripple reinjection technique for 48-pulse operation.

Higher pulse configuration using the same principle is also possible. The 12-pulse rectifier was obtained with a 30° phase shift between the two secondary transformers. The addition of further, appropriately shifted, transformers in parallel provides the basis for increasing pulse configurations. For instance, 24-pulse operation is achieved by means of four transformers with 15° phase shift, and 48-pulse operation requires eight transformers with 7.5° phase shift (transformer connections in zig-zag configuration).

Although theoretically possible, pulse numbers above 48 are rarely justified due to the practical levels of distortion found in the supply voltage waveforms. Further, the converter topology becomes more and more complicated.

An ingenious and very simple way to reach high pulse operation is shown in Fig. 12.24. This configuration is called *dc* ripple reinjection. It consists of two parallel converters connected to the load through a multistep reactor. The reactor uses a chain of thyristor-controlled taps, which are connected to symmetrical points of the reactor. By firing the thyristors located at the reactor at the right time, high-pulse operation is reached. The level of pulse operation depends on the number of thyristors connected to the reactor. They multiply the basic level of operation of the two converters. The example, is Fig. 12.24, shows a 48-pulse configuration, obtained by the multiplication of basic 12-pulse operation by four reactor thyristors. This technique also can be applied to series connected bridges.

Another solution for harmonic reduction is the utilization of active power filters. Active power filters are special pulse width modulated (PWM) converters, able to generate the harmonics the converter requires. Figure 12.25 shows a current controlled shunt active power filter.

12.2.10 Applications of Line-commutated Rectifiers in Machine Drives

Important applications for line-commutated three-phase controlled rectifiers, are found in machine drives. Figure 12.26 shows a *dc* machine control implemented with a six-pulse rectifier. Torque and speed are controlled through the armature current I_D, and excitation current I_{exc}. Current I_D is adjusted with V_D, which is controlled by the firing angle α through Eq. (12.12). This *dc* drive can operate in two quadrants: positive and negative *dc* voltage. This two-quadrant
FIGURE 12.25   Current controlled shunt active power filter.

operation allows regenerative braking when $\alpha > 90°$ and $I_{exc} < 0$.

The converter of Fig. 12.26 can also be used to control synchronous machines, as shown in Fig. 12.27. In this case, a second converter working in the inverting mode operates the machine as self-controlled synchronous motor. With this second converter, the synchronous motor behaves like a *dc* motor but has none of the disadvantages of mechanical commutation. This converter is not line commutated, but machine commutated.

The nominal synchronous speed of the motor on a 50 or 60 Hz *ac* supply is now meaningless and the upper speed limit is determined by the mechanical limitations of the rotor construction. There is disadvantage that the rotational *emfs* required for load commutation of the machine side converter are not available at standstill and low speeds. In such a case, auxiliary force commutated circuits must be used.

The line-commutated rectifier controls the torque of the machine through firing angle α. This approach gives direct torque control of the commutatorless motor and is analogous to the use of armature current control shown in Fig. 12.26 for the converter-fed *dc* motor drive.

Line-commutated rectifiers are also used for speed control of wound rotor induction motors. Subsynchronous and supersynchronous static converter cascades using a naturally commutated *dc* link converter, can be implemented. Figure 12.28 shows a supersynchronous cascade for a wound rotor induction motor, using a naturally commutated *dc* link converter.

In the supersynchronous cascade shown in Fig. 12.28, the right hand bridge operates at slip frequency as a rectifier or inverter, while the other operates at network frequency as an inverter or rectifier. Control is difficult near synchronism when slip frequency *emfs* are insufficient for natural commutation and special circuit configuration employing forced commutation or devices with a self-turn-off capability are necessary for the passage through synchronism. This kind of supersynchronous cascade works better with cycloconverters.

12.2.11 Applications in HVDC Power Transmission

High voltage direct current (HVDC) power transmission is the most powerful application for line-commutated converters that exist today. There are power converters with ratings in excess of 1000 MW. Series operation of hundreds of valves can be found in some HVDC systems. In high power and long distance applications, these systems become more economical than conventional *ac* systems. They also have some other advantages compared with *ac* systems:

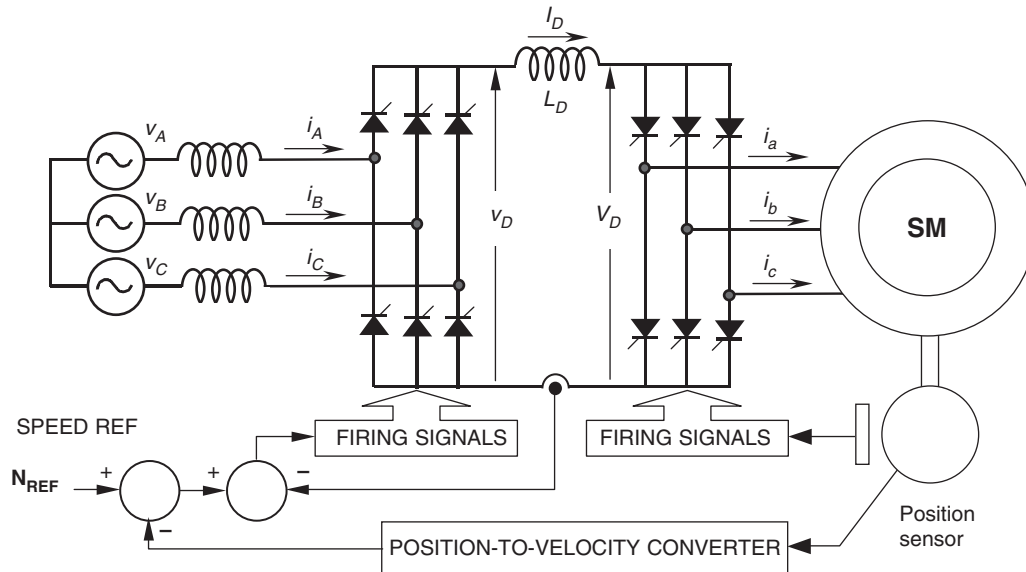
1. they can link two *ac* systems operating unsynchronized or with different nominal frequencies, that is 50 $\leftrightarrow$ 60 Hz;
FIGURE 12.26   *DC* machine drive with a six-pulse rectifier.


FIGURE 12.27   Self-controlled synchronous motor drive.
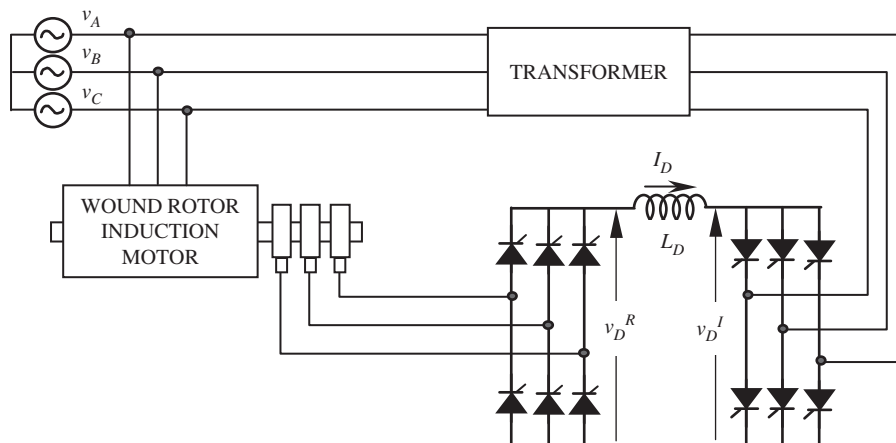

FIGURE 12.28   Supersynchronous cascade for a wound rotor induction motor.

2. they can help in stability problems related with sub-synchronous resonance in long *ac* lines;
3. they have very good dynamic behavior and can inter-rupt short-circuit problems very quickly;
4. if transmission is by submarine or underground cable, it is not practical to consider *ac* cable systems exceeding 50 km, but *dc* cable transmission systems are in service whose length is in hundreds of kilometers and even distances of 600 km or greater have been considered feasible;
5. reversal of power can be controlled electronically by means of the delay firing angles α; and
6. some existing overhead *ac* transmission lines can-not be increased. If overbuilt with or upgraded to

dc transmission can substantially increase the power transfer capability on the existing right-of-way.

The use of HVDC systems for interconnections of asyn-chronous systems is an interesting application. Some continen-tal electric power systems consist of asynchronous networks such as those for the East, West, Texas, and Quebec networks in North America, and islands loads such as that for the Island of Gotland in the Baltic Sea make good use of the HVDC interconnections.

Nearly all HVDC power converters with thyristor valves are assembled in a converter bridge of 12-pulse configuration, as shown in Fig. 12.29. Consequently, the *ac* voltages applied to each six-pulse valve group which makes up the 12-pulse
FIGURE 12.29   Typical HVDC power system: (a) detailed circuit and (b) unilinear diagram.

valve group have a phase difference of 30° which is utilized to cancel the *ac* side, 5th and 7th harmonic currents and *dc* side, 6th harmonic voltage, thus resulting in a significant saving in harmonic filters.

Some useful relations for HVDC systems include:

a) Rectifier Side:

$$P_D = V_D \cdot I_D = \sqrt{3} \cdot V_{f-f}^{prim} \cdot I_{line}^{rms} \cos \varphi \qquad (12.40)$$
$$I_P = I \cos \varphi$$

$$I_Q = I \sin \varphi$$

$$\therefore P_D = V_D \cdot I_D = \sqrt{3} \cdot V_{f-f}^{prim} \cdot I_P \qquad (12.41)$$

$$I_P = \frac{V_D \cdot I_D}{\sqrt{3} \cdot V_{f-f}^{prim}} \qquad (12.42)$$

$$I_P = \frac{a^2 \sqrt{3} \cdot V_{f-f}^{prim}}{4\pi \cdot \omega L_S} [\cos 2\alpha - \cos 2 (\alpha + \mu)] \qquad (12.43)$$

$$I_Q = \frac{a^2 \sqrt{3} \cdot V_{f-f}^{prim}}{4\pi \cdot \omega L_S} [\sin 2(\alpha + \mu) - \sin 2\alpha - 2\mu] \qquad (12.44)$$

$$I_P = I_D \frac{a\sqrt{6}}{\pi} \left[\frac{\cos \alpha + \cos (\alpha + \mu)}{2} \right] \qquad (12.45)$$

Fundamental secondary component of *I*

$$I = \frac{a\sqrt{6}}{\pi} I_D \qquad (12.46)$$

Replacing Eq. (12.46) in (12.45)

$$I_P = I \cdot \left[\frac{\cos \alpha + \cos (\alpha + \mu)}{2} \right] \qquad (12.47)$$

as $I_P = I \cos \varphi$, it yields Fig. 12.30a

$$\cos \varphi = \left[\frac{\cos \alpha + \cos (\alpha + \mu)}{2} \right] \qquad (12.48)$$

b) Inverter Side:
The same equations are applied for the inverter side, but the firing angle α is replaced by γ, where γ is

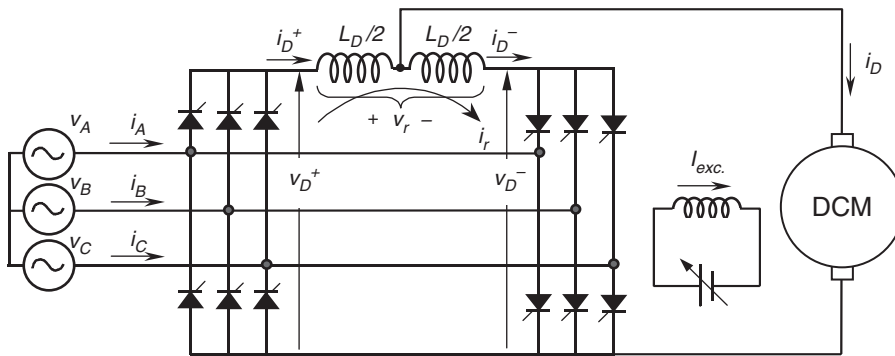
$$\gamma = 180° - (\alpha + \mu) \qquad (12.49)$$
FIGURE 12.30   Definition of angle γ for inverter side: (a) rectifier side and (b) inverter side.


FIGURE 12.31   Dual converter in a four-quadrant *dc* drive.

As reactive power always goes in the converter direction, Eq. (12.44) for inverter side becomes (Fig. 12.30b)

$$I_{QI} = -\frac{a_I^2\sqrt{3}\cdot V_{f-f_I}^{prim}}{4\pi\cdot\omega_I L_I}\left[\sin 2(\gamma+\mu_I)-\sin 2\gamma-2\mu_I\right]$$

(12.50)

12.2.12   Dual Converters

In many variable-speed drives, four-quadrant operation is required, and three-phase dual converters are extensively used in applications up to 2 MW level. Figure 12.31 shows a three-phase dual converter, where two converters are connected back-to-back.

In the dual converter, one rectifier provides the positive current to the load and the other the negative current. Due to the instantaneous voltage differences between the output

voltages of the converters, a circulating current flows through the bridges. The circulating current is normally limited by circulating reactor, L_D, as shown in Fig. 12.31. The two converters are controlled in such a way that if α^+ is the delay angle of the positive current converter, the delay angle of the negative current converter is $\alpha^- = 180° - \alpha^+$.

Figure 12.32 shows the instantaneous *dc* voltages of each converter, v_D^+ and v_D^-. Despite the average voltage V_D is the same in both the converters, their instantaneous voltage differences shown as voltage v_r, are producing the circulating current i_r, which is superimposed with the load currents i_D^+ and i_D^-.

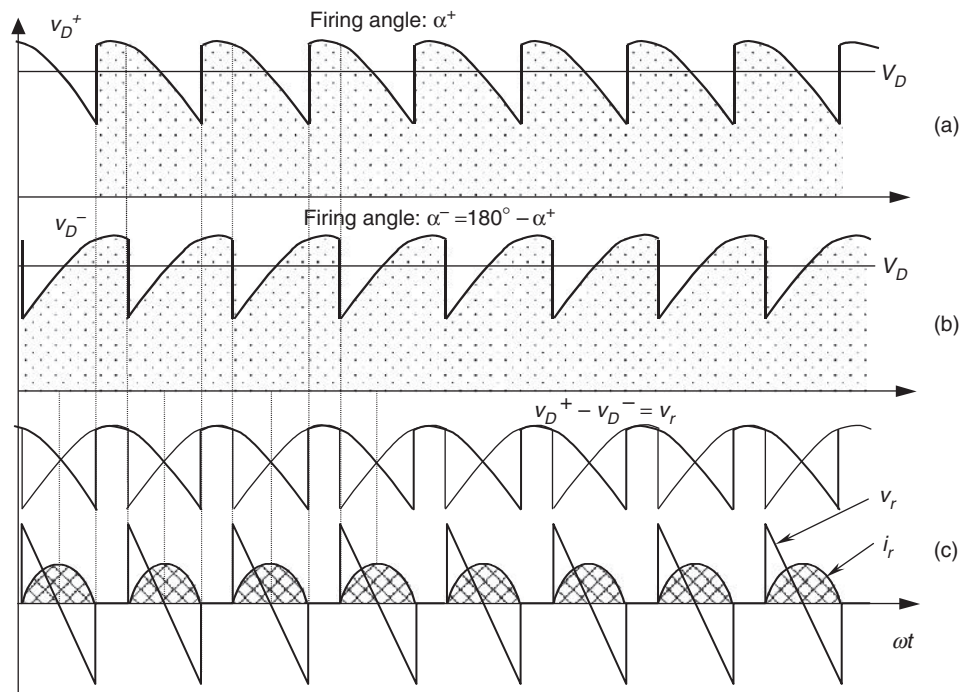
To avoid the circulating current i_r, it is possible to implement a "circulating current free" converter if a dead time of a few milliseconds is acceptable. The converter section, not required to supply current, remains fully blocked. When a current reversal is required, a logic switch-over system determines


FIGURE 12.32 Waveform of circulating current: (a) instantaneous *dc* voltage from positive converter: (b) instantaneous *dc* voltage from negative converter; and (c) voltage difference between v_D^+ and v_D^-, v_r, and circulating current i_r.

at first the instant at which the conducting converter's current becomes zero. This converter section is then blocked and the further supply of gating pulses to it is prevented. After a short safety interval (dead time), the gating pulses for the other converter section are released.

12.2.13 Cycloconverters

A different principle of frequency conversion is derived from the fact that a dual converter is able to supply an *ac* load with a lower frequency than the system frequency. If the control signal of the dual converter is a function of time, the output voltage will follow this signal. If this control signal value alters sinusoidally with the desired frequency, then the waveform depicted in Fig. 12.33a consists of a single-phase voltage with a large harmonic current. As shown in Fig. 12.33b, if the load is inductive, the current will present less distortion than voltage.

The cycloconverter operates in all four quadrants during a period. A pause (dead time) at least as small as the time required by the switch-over logic occurs after the current reaches zero, that is, between the transfer to operation in the quadrant corresponding to the other direction of current flow.

Three single-phase cycloconverters may be combined to build a three-phase cycloconverter. The three-phase cycloconverters find an application in low-frequency, high-power requirements. Control speed of large synchronous motors in the low-speed range is one of the most common applications

of three-phase cycloconverters. Figure 12.34 is a diagram for this application. They are also used to control slip frequency in wound rotor induction machines, for supersynchronous cascade (Scherbius system).

12.2.14 Harmonic Standards and Recommended Practices

In view of the proliferation of the power converter equipment connected to the utility system, various national and international agencies have been considering limits on harmonic current injection to maintain good power quality. As a consequence, various standards and guidelines have been established that specify limits on the magnitudes of harmonic currents and harmonic voltages.

The Comité Européen de Normalisation Electrotechnique (CENELEC), International Electrical Commission (IEC), and West German Standards (VDE) specify the limits on the voltages (as a percentage of the nominal voltage) at various harmonics frequencies of the utility frequency, when the equipment-generated harmonic currents are injected into a network whose impedances are specified.

According with Institute of Electrical and Electronic Engineers-519 standards (IEEE), Table 12.1 lists the limits on the harmonic currents that a user of power electronics equipment and other non-linear loads is allowed to inject into the
FIGURE 12.33 Cycloconverter operation: (a) voltage waveform and (b) current waveform for inductive load.

utility system. Table 12.2 lists the quality of voltage that the utility can furnish the user.

In Table 12.1, the values are given at the point of connection of non-linear loads. The *THD* is the total harmonic distortion given by Eq. (12.51) and *h* is the number of the harmonic.

$$THD = \frac{\sqrt{\sum_{h=2}^{\infty} I_h^2}}{I_1} \tag{12.51}$$

The total current harmonic distortion allowed in Table 12.1 increases with the value of short circuit current.

The total harmonic distortion in the voltage can be calculated in a manner similar to that given by Eq. (12.51). Table 12.2 specifies the individual harmonics and the *THD* limits on the voltage that the utility supplies to the user at the connection point.

12.3 Force-commutated Three-phase Controlled Rectifiers

12.3.1 Basic Topologies and Characteristics

Force-commutated rectifiers are built with semiconductors with gate-turn-off capability. The gate-turn-off capability allows full control of the converter, because valves can be switched *ON* and *OFF* whenever is required. This allows the commutation of the valves, hundreds of times in one period which is not possible with line-commutated rectifiers, where thyristors are switched *ON* and *OFF* only once a cycle. This feature has the following advantages: (a) the current or voltage can be modulated (PWM), generating less harmonic contamination; (b) power factor can be controlled and even

it can be made leading; and (c) they can be built as voltage source or current source rectifiers; (d) the reversal of power in thyristor rectifiers is by reversal of voltage at the *dc* link. Instead, force-commutated rectifiers can be implemented for both, reversal of voltage or reversal of current.

There are two ways to implement force-commutated three-phase rectifiers: (a) as a current source rectifier, where power reversal is by *dc* voltage reversal; and (b) as a voltage source rectifier, where power reversal is by current reversal at the *dc* link. Figure 12.35 shows the basic circuits for these two topologies.

12.3.2 Operation of the Voltage Source Rectifier

The voltage source rectifier is by far the most widely used, and because of the duality of the two topologies showed in Fig. 12.35, only this type of force-commutated rectifier will be explained in detail.

The voltage source rectifier operates by keeping the *dc* link voltage at a desired reference value, using a feedback control loop as shown in Fig. 12.36. To accomplish this task, the *dc* link voltage is measured and compared with a reference V_{REF}. The error signal generated from this comparison is used to switch the six valves of the rectifier *ON* and *OFF*. In this way, power can come or return to the *ac* source according with the *dc* link voltage requirements. The voltage V_D is measured at the capacitor C_D.

When the current I_D is positive (rectifier operation), the capacitor C_D is discharged, and the error signal ask the control block for more power from the *ac* supply. The control block takes the power from the supply by generating the appropriate PWM signals for the six valves. In this way, more current flows from the *ac* to the *dc* side and the capacitor voltage is recovered. Inversely, when I_D becomes negative (inverter operation), the capacitor C_D is overcharged and the error signal ask the control to discharge the capacitor and return power to the *ac* mains.

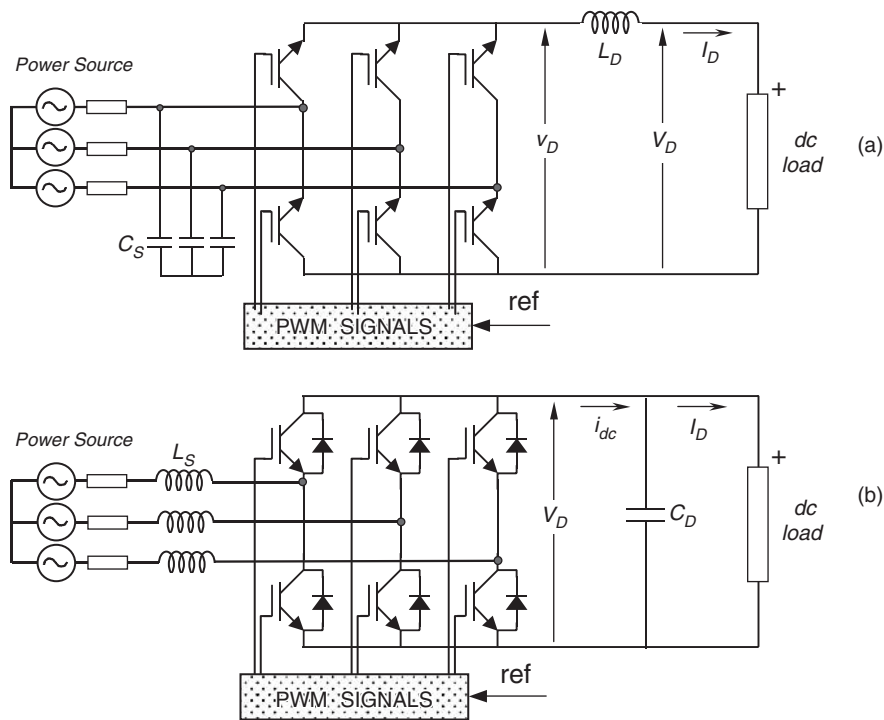
The PWM control can manage not only the active power, but also the reactive power, allowing this type of rectifier to correct power factor. In addition, the *ac* current waveforms can be maintained as almost sinusoidal, which reduces harmonic contamination to the mains supply.


FIGURE 12.35 Basic topologies for force-commutated PWM rectifiers: (a) current source rectifier and (b) voltage source rectifier.
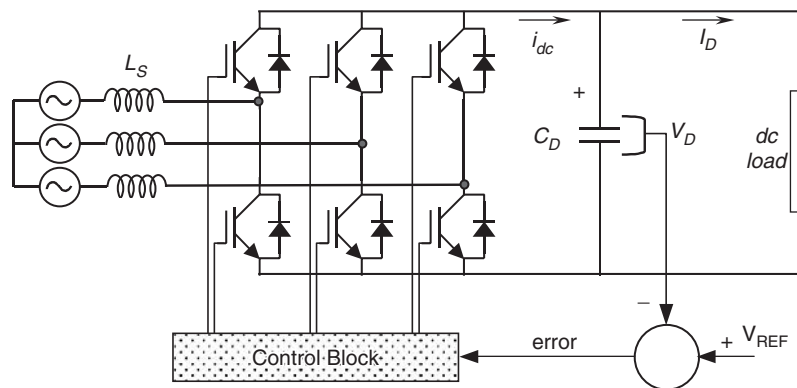

FIGURE 12.36 Operation principle of the voltage source rectifier.

The PWM consists of switching the valves *ON* and *OFF*, following a pre-established template. This template could be a sinusoidal waveform of voltage or current. For example, the modulation of one phase could be as the one shown in Fig. 12.37. This PWM pattern is a periodical waveform whose fundamental is a voltage with the same frequency of the template. The amplitude of this fundamental, called V_{MOD} in Fig. 12.37, is also proportional to the amplitude of the template.

To make the rectifier work properly, the PWM pattern must generate a fundamental V_{MOD} with the same frequency as the power source. Changing the amplitude of this fundamental and its phase shift with respect to the mains, the rectifier can

be controlled to operate in the four quadrants: leading power factor rectifier, lagging power factor rectifier, leading power factor inverter, and lagging power factor inverter. Changing the pattern of modulation, as shown in Fig. 12.38, modifies the magnitude of V_{MOD}. Displacing the PWM pattern changes the phase shift.

The interaction between V_{MOD} and V (source voltage) can be seen through a phasor diagram. This interaction permits understanding of the four-quadrant capability of this rectifier. In Fig. 12.39, the following operations are displayed: (a) rectifier at unity power factor; (b) inverter at unity power factor; (c) capacitor (zero power factor); and (d) inductor (zero power factor).
FIGURE 12.37   A PWM pattern and its fundamental V_{MOD}.
FIGURE 12.38   Changing V_{MOD} through the PWM pattern.

In Fig. 12.39, I_S is the *rms* value of the source current i_s. This current flows through the semiconductors in the way shown in Fig. 12.40. During the positive half cycle, the transistor T_N, connected at the negative side of the *dc* link is switched *ON*, and the current i_s begins to flow through T_N (i_{Tn}). The current returns to the mains and comes back to the valves, closing a loop with another phase, and passing through a diode connected at the same negative terminal of the *dc* link. The current can also go to the *dc* load (inversion) and return through another transistor located at the positive terminal of the *dc* link. When the transistor T_N is switched *OFF*, the current path is interrupted and the current begins to flow through the diode D_P, connected at the positive terminal of the *dc* link. This current, called i_{Dp} in Fig. 12.39, goes directly to the *dc* link, helping in the generation of the current i_{dc}. The current i_{dc} charges the capacitor C_D and permits the rectifier to produce *dc* power. The inductances L_S are very important in this process, because they generate an induced voltage which allows the conduction of the diode D_P. Similar operation occurs during the negative half cycle, but with T_P and D_N (see Fig. 12.40).

Under inverter operation, the current paths are different because the currents flowing through the transistors come mainly from the *dc* capacitor, C_D. Under rectifier operation,

the circuit works like a boost converter and under inverter, it works as a buck converter.

To have full control of the operation of the rectifier, their six diodes must be polarized negatively at all values of instantaneous *ac* voltage supply. Otherwise diodes will conduct, and the PWM rectifier will behave like a common diode rectifier bridge. The way to keep the diodes blocked is to ensure a *dc* link voltage higher than the peak *dc* voltage generated by the diodes alone, as shown in Fig. 12.41. In this way, the diodes remain polarized negatively, and they will conduct only when at least one transistor is switched *ON*, and favorable instantaneous *ac* voltage conditions are given. In the Fig. 12.41, V_D represents the capacitor *dc* voltage, which is kept higher than the normal diode-bridge rectification value v_{BRIDGE}. To maintain this condition, the rectifier must have a control loop like the one displayed in Fig. 12.36.

12.3.3 PWM Phase-to-phase and Phase-to-neutral Voltages

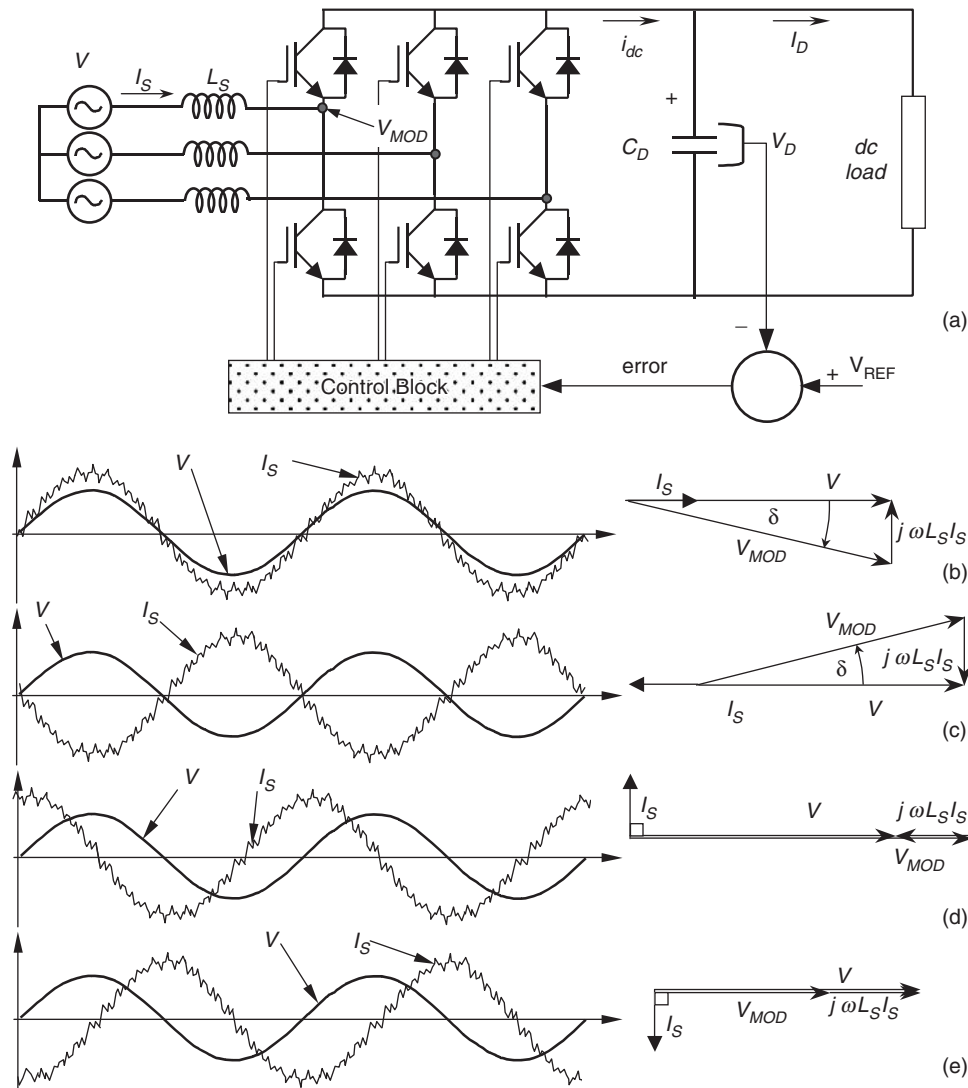
The PWM waveforms shown in the preceding figures are voltages measured between the middle point of the *dc* voltage and the corresponding phase. The phase-to-phase PWM voltages


FIGURE 12.39 Four-quadrant operation of the force-commutated rectifier: (a) the PWM force-commutated rectifier; (b) rectifier operation at unity power factor; (c) inverter operation at unity power factor; (d) capacitor operation at zero power factor; and (e) inductor operation at zero power factor.

can be obtained with the help of Eq. (12.52), where the voltage V_{PWM}^{AB} is evaluated.

$$V_{PWM}^{AB} = V_{PWM}^{A} - V_{PWM}^{B} \qquad (12.52)$$

where V_{PWM}^{A} and V_{PWM}^{B} are the voltages measured between the middle point of the *dc* voltage, and the phases *a* and *b* respectively. In a less straightforward fashion, the phase-to-neutral voltage can be evaluated with the help of Eq. (12.53).

$$V_{PWM}^{AN} = \frac{1}{3}(V_{PWM}^{AB} - V_{PWM}^{CA}) \qquad (12.53)$$

where V_{PWM}^{AN} is the phase-to-neutral voltage for phase *a*, and V_{PWM}^{jk} is the phase-to-phase voltage between phase *j* and phase *k*. Figure 12.42 shows the PWM patterns for the phase-to-phase and phase-to-neutral voltages.

12.3.4 Control of the *DC* Link Voltage

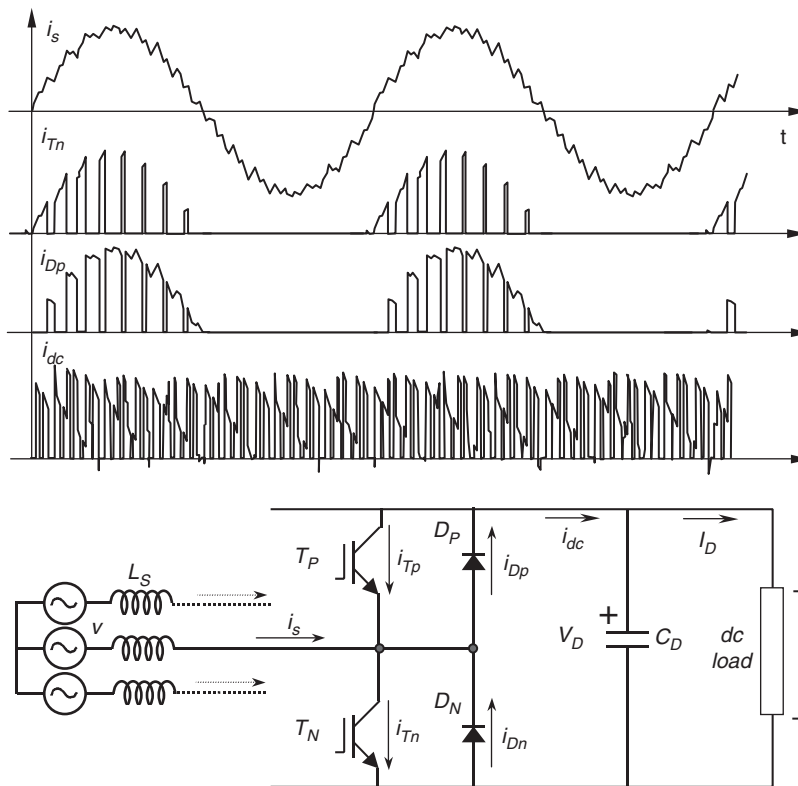
Control of the *dc* link voltage requires a feedback control loop. As already explained in Section 12.3.2, the *dc* voltage V_D is compared with a reference V_{REF}, and the error signal "e" obtained from this comparison is used to generate a template waveform. The template should be a sinusoidal waveform with the same frequency of the mains supply. This template is used to produce the PWM pattern and allows controlling


FIGURE 12.40   Current waveforms through the mains, the valves, and the *dc* link.
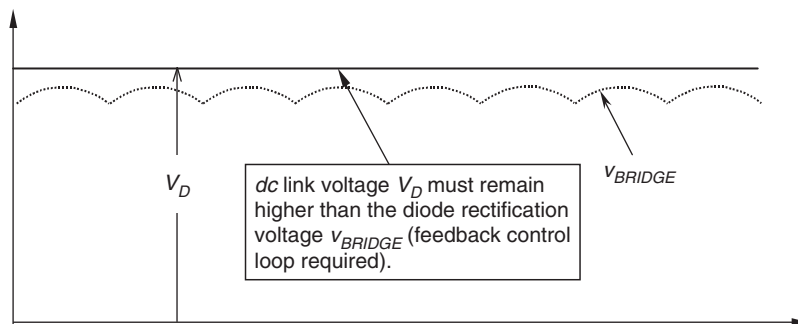

FIGURE 12.41   The *DC* link voltage condition for the operation of the PWM rectifier.

the rectifier in two different ways: (1) as a voltage-source current-controlled PWM rectifier or (2) as a voltage-source voltage-controlled PWM rectifier. The first method controls the input current, and the second controls the magnitude and phase of the voltage V_{MOD}. The current-controlled method is simpler and more stable than the voltage-controlled method, and for these reasons it will be explained first.

12.3.4.1   Voltage-source Current-controlled PWM Rectifier

This method of control is shown in the rectifier in Fig. 12.43. Control is achieved by measuring the instantaneous phase

currents and forcing them to follow a sinusoidal current reference template, I_ref. The amplitude of the current reference template, I_{MAX} is evaluated using the following equation

$$I_{MAX} = G_C \cdot e = G_C \cdot (V_{REF} - v_D) \qquad (12.54)$$

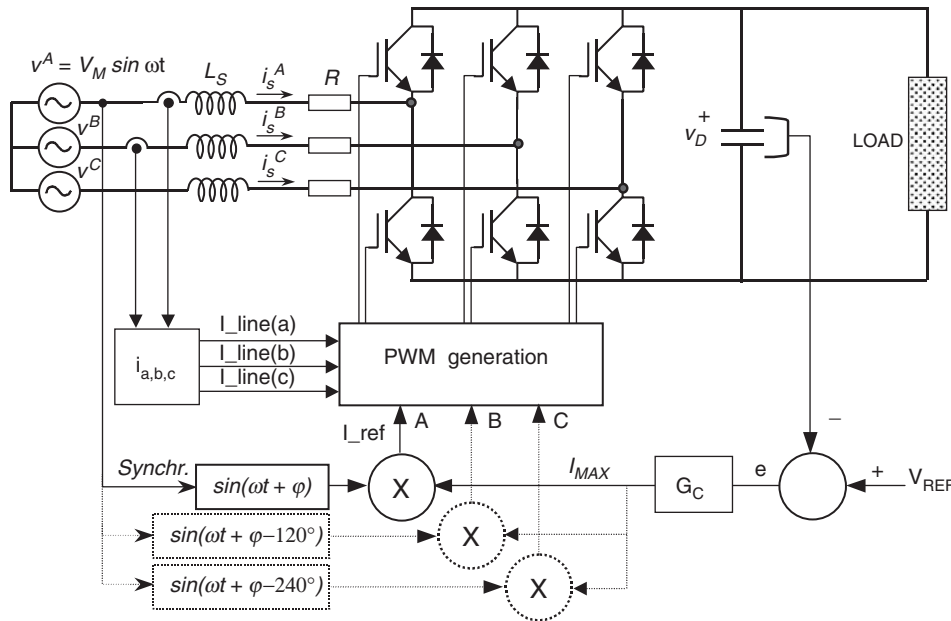
where G_C is shown in Fig. 12.43 and represents a controller such as PI, P, Fuzzy, or other. The sinusoidal waveform of the template is obtained by multiplying I_{MAX} with a sine function, with the same frequency of the mains, and with the desired phase-shift angle φ, as shown in Fig. 12.43. Further, the template must be synchronized with the power supply. After that,
FIGURE 12.42 PWM phase voltages: (a) PWM phase modulation; (b) PWM phase-to-phase voltage; and (c) PWM phase-to-neutral voltage.


FIGURE 12.43 Voltage-source current-controlled PWM rectifier.

the template has been created and is ready to produce the PWM pattern.

However, one problem arises with the rectifier because the feedback control loop on the voltage V_C can produce instability. Then it becomes necessary to analyze this problem during rectifier design. Upon introducing the voltage feedback and the G_C controller, the control of the rectifier can be represented in a block diagram in Laplace dominion, as shown in Fig. 12.44. This block diagram represents a linearization of the system around an operating point, given by the *rms* value of the input current, I_S.

The blocks $G_1(s)$ and $G_2(s)$ in Fig. 12.44 represent the transfer function of the rectifier (around the operating point) and the transfer function of the *dc* link capacitor C_D respectively.

$$G_1(s) = \frac{\Delta P_1(s)}{\Delta I_S(s)} = 3 \cdot (V \cos \varphi - 2RI_S - L_S I_S s) \quad (12.55)$$

$$G_2(s) = \frac{\Delta V_D(s)}{\Delta P_1(s) - \Delta P_2(s)} = \frac{1}{V_D \cdot C_D \cdot s} \quad (12.56)$$

where $\Delta P_1(s)$ and $\Delta P_2(s)$ represent the input and output power of the rectifier in Laplace dominion, V the *rms* value of
FIGURE 12.44   Closed-loop rectifier transfer function.

the mains voltage supply (phase-to-neutral), I_S the input current being controlled by the template, L_S the input inductance, and R the resistance between the converter and power supply. According to stability criteria, and assuming a *PI* controller, the following relations are obtained

$$I_S \leq \frac{C_D \cdot V_D}{3K_P \cdot L_S} \qquad (12.57)$$

$$I_S \leq \frac{K_P \cdot V \cdot \cos\varphi}{2R \cdot K_P + L_S \cdot K_I} \qquad (12.58)$$

These two relations are useful for the design of the current-controlled rectifier. They relate the values of *dc* link capacitor, *dc* link voltage, *rms* voltage supply, input resistance and inductance, and input power factor, with the *rms* value of the input current, I_S. With these relations the proportional and integral gains K_P and K_I can be calculated to ensure the stability of the rectifier. These relations only establish limitations for rectifier operation, because negative currents always satisfy the inequalities.

With these two stability limits satisfied, the rectifier will keep the *dc* capacitor voltage at the value of V_{REF} (*PI* controller), for all load conditions, by moving power from the *ac* to the *dc* side. Under inverter operation, the power will move in the opposite direction.

Once the stability problems have been solved and the sinusoidal current template has been generated, a modulation method will be required to produce the PWM pattern for the power valves. The PWM pattern will switch the power valves to force the input currents I_line to follow the desired current template I_ref. There are many modulation methods in the literature, but three methods for voltage-source current-controlled rectifiers are the most widely used ones: *periodical sampling* (PS), *hysteresis band* (HB), and *triangular carrier* (TC).

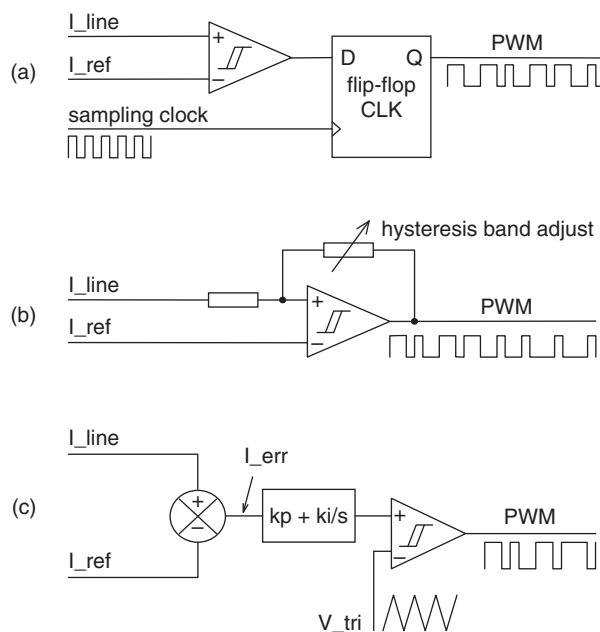
The PS method switches the power transistors of the rectifier during the transitions of a square wave clock of fixed frequency: the *periodical sampling* frequency. In each transition, a comparison between I_ref and I_line is made, and corrections take place. As shown in Fig. 12.45a, this type of control is very simple to implement: only a comparator and a D-type flip-flop are needed per phase. The main advantage of this method is that the minimum time between switching


FIGURE 12.45   Modulation control methods: (a) periodical sampling; (b) hysteresis band; and (c) triangular carrier.

transitions is limited to the period of the sampling clock. This characteristic determines the maximum switching frequency of the converter. However, the average switching frequency is not clearly defined.

The HB method switches the transistors when the error between I_ref and I_line exceeds a fixed magnitude: the *hysteresis band*. As it can be seen in Fig. 12.45b, this type of control needs a single comparator with hysteresis per phase. In this case the switching frequency is not determined, but its maximum value can be evaluated through the following equation

$$f_S^{max} = \frac{V_D}{4h \cdot L_S} \qquad (12.59)$$

where h is the magnitude of the hysteresis band.

The TC method, shown in Fig. 12.45c, compares the error between I_ref and I_line with a triangular wave. This triangular wave has fixed amplitude and frequency and is called the *triangular carrier*. The error is processed through a

proportional-integral (PI) gain stage before comparison with the TC takes place. As can be seen, this control scheme is more complex than PS and HB. The values for k_p and k_i determine the transient response and steady-state error of the TC method. It has been found empirically that the values for k_p and k_i shown in Eqs. (12.60) and (12.61) give a good dynamic performance under several operating conditions.

$$k_p = \frac{L_s \cdot \omega_c}{2 \cdot V_D} \tag{12.60}$$

$$k_i = \omega_c \cdot K_P \tag{12.61}$$

where L_S is the total series inductance seen by the rectifier, ω_c is the TC frequency, and V_D is the dc link voltage of the rectifier.

In order to measure the level of distortion (or undesired harmonic generation) introduced by these three control methods, Eq. (12.62) is defined

$$\%Distortion = \frac{100}{I_{rms}} \sqrt{\frac{1}{T} \int_T (I\_line - I\_ref)^2 \, dt} \tag{12.62}$$

In Eq. (12.62), the term I_{rms} is the effective value of the desired current. The term inside the square root gives the rms value of the error current, which is undesired. This formula measures the percentage of error (or distortion) of the generated waveform. This definition considers the ripple, amplitude, and phase errors of the measured waveform, as opposed to the *THD*, which does not take into account offsets, scalings, and phase shifts.

Figure 12.46 shows the current waveforms generated by the three aforementioned methods. The example uses an average switching frequency of 1.5 kHz. The PS is the worst, but its digital implementation is simpler. The HB method and TC
FIGURE 12.46 Waveforms obtained using 1.5 kHz switching frequency and $L_S = 13$ mH: (a) PS method; (b) HB method; (c) TC method ($K_P + K_I$); and (d) TC method (K_P only).

with PI control are quite similar, and the TC with only proportional control gives a current with a small phase shift. However, Fig. 12.47 shows that the higher the switching frequency, the closer the results obtained with the different modulation methods. Over 6 kHz of switching frequency, the distortion is very small for all methods.

12.3.4.2 Voltage-source Voltage-controlled PWM Rectifier

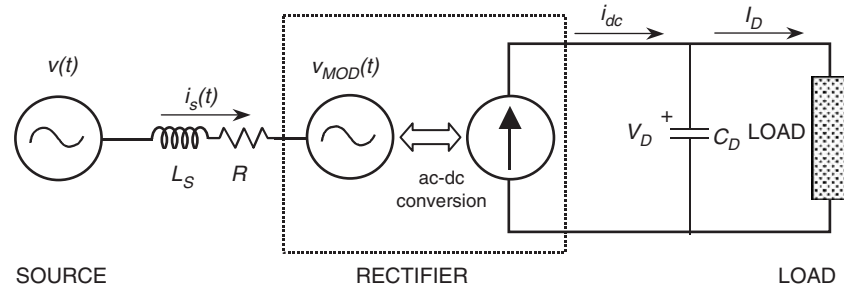
Figure 12.48 shows a one-phase diagram from which the control system for a voltage-source voltage-controlled rectifier is derived. This diagram represents an equivalent circuit of the fundamentals, that is, pure sinusoidal at the mains side and pure dc at the dc link side. The control is achieved by creating a sinusoidal voltage template V_{MOD}, which is modified in amplitude and angle to interact with the mains voltage V. In this way the input currents are controlled without measuring them. The template V_{MOD} is generated using the differential equations that govern the rectifier.
FIGURE 12.47 Distortion comparison for a sinusoidal current reference.


FIGURE 12.48 One-phase fundamental diagram of the voltage source rectifier.

The following differential equation can be derived from Fig. 12.48

$$v(t) = L_S \frac{di_s}{dt} + Ri_s + v_{MOD}(t) \qquad (12.63)$$

Assuming that $v(t) = V\sqrt{2}\sin\omega t$, then the solution for $i_s(t)$, to acquire a template V_{MOD} able to make the rectifier work at constant power factor, should be of the form

$$i_s(t) = I_{max}(t)\sin(\omega t + \varphi) \qquad (12.64)$$

Equations (12.63), (12.64), and $v(t)$ allows a function of time able to modify V_{MOD} in amplitude and phase that will make the rectifier work at a fixed power factor. Combining these equations with $v(t)$ yields

$$v_{MOD}(t) = \left[V\sqrt{2} + X_S I_{max}\sin\varphi - \left(RI_{max} + L_S \frac{dI_{max}}{dt} \right)\cos\varphi \right]\sin\omega t$$

$$- \left[X_S I_{max}\cos\varphi + \left(RI_{max} + L_S \frac{dI_{max}}{dt} \right)\sin\varphi \right]\cos\omega t$$
$$(12.65)$$

Equation (12.65) provides a template for V_{MOD}, which is controlled through variations of the input current amplitude I_{max}. Substituting the derivatives of I_{max} into Eq. (12.65) make sense, because I_{max} changes every time the dc load is modified. The term X_S in Eq. (12.65) is ωL_S. This equation can also be written for unity power factor operation. In such a case, $\cos\varphi = 1$ and $\sin\varphi = 0$.

$$v_{MOD}(t) = \left(V\sqrt{2} - RI_{max} - L_S \frac{dI_{max}}{dt} \right)\sin\omega t$$

$$- X_S I_{max}\cos\omega t \qquad (12.66)$$

With this last equation, a unity power factor, voltage source, voltage-controlled PWM rectifier can be implemented as shown in Fig. 12.49. It can be observed that Eqs. (12.65) and (12.66) have an *in-phase* term with the mains supply ($\sin\omega t$) and an *in-quadrature* term ($\cos\omega t$). These two terms allow

the template V_{MOD} to change in magnitude and phase so as to have full unity power factor control of the rectifier.

Compared with the control block of Fig. 12.43, in the voltage-source voltage-controlled rectifier of Fig. 12.49, there is no need to sense the input currents. However, to ensure stability limits as good as the limits of the current-controlled rectifier, the blocks "$-R-sL_S$" and "$-X_S$" in Fig. 12.49, have to emulate and reproduce exactly the real values of R, X_S, and L_S of the power circuit. However, these parameters do not remain constant, and this fact affects the stability of this system, making it less stable than the system showed in Fig. 12.43. In theory, if the impedance parameters are reproduced exactly, the stability limits of this rectifier are given by the same equations as used for the current-controlled rectifier seen in Fig. 12.43 (Eqs. (12.57) and (12.58)).

Under steady-state, I_{max} is constant, and Eq. (12.66) can be written in terms of phasor diagram, resulting in Eq. (12.67). As shown in Fig. 12.50, different operating conditions for the unity power factor rectifier can be displayed with this equation

$$\vec{V}_{MOD} = \vec{V} - R\vec{I}_S - jX_S\vec{I}_S \qquad (12.67)$$

With the sinusoidal template V_{MOD} already created, a modulation method to commutate the transistors will be required. As in the case of current-controlled rectifier, there are many methods to modulate the template, with the most well known the so-called *sinusoidal pulse width modulation* (SPWM), which uses a TC to generate the PWM as shown in Fig. 12.51. Only this method will be described in this chapter.

In this method, there are two important parameters to define: the amplitude modulation ratio or modulation index m, and the frequency modulation ratio p. Definitions are given by

$$m = \frac{V_{MOD}^{max}}{V_{TRIANG}^{max}} \qquad (12.68)$$

$$p = \frac{f_T}{f_S} \qquad (12.69)$$

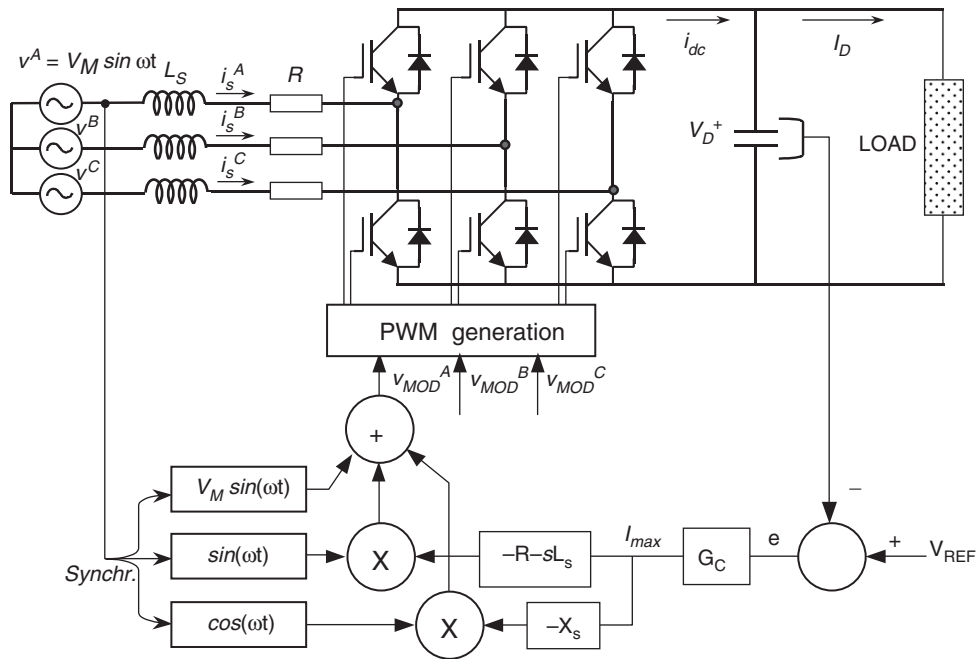
where V_{MOD}^{max} and V_{TRIANG}^{max} are the amplitudes of V_{MOD} and V_{TRIANG} respectively. On the other hand, f_S is the frequency of


FIGURE 12.49 Implementation of the voltage-controlled rectifier for unity power factor operation.
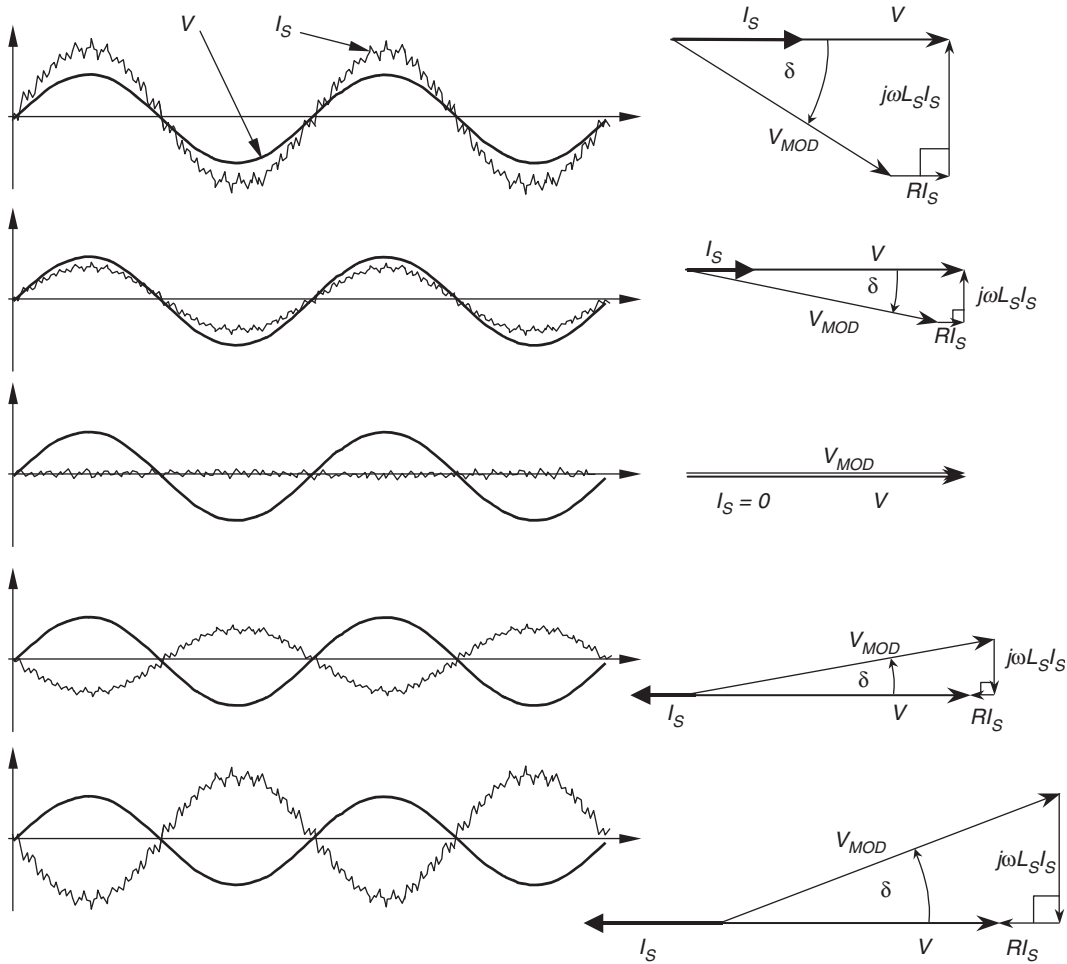

FIGURE 12.50 Steady-state operation of the unity power factor rectifier under different load conditions.

COMPARATOR
FIGURE 12.51 Sinusoidal modulation method based on TC.

the mains supply and f_T the frequency of the TC. In Fig. 12.51, $m = 0.8$ and $p = 21$. When $m > 1$ overmodulation is defined.

The modulation method described in Fig. 12.51 has a harmonic content that changes with p and m. When $p < 21$, it is recommended that synchronous PWM be used, which means that the TC and the template should be synchronized. Furthermore, to avoid subharmonics, it is also desired that p be

an integer. If p is an odd number, even harmonics will be eliminated. If p is a multiple of 3, then the PWM modulation of the three phases will be identical. When m increases, the amplitude of the fundamental voltage increases proportionally, but some harmonics decrease. Under overmodulation ($m > 1$), the fundamental voltage does not increase linearly, and more harmonics appear. Figure 12.52 shows the harmonic spectrum
FIGURE 12.52 Harmonic spectrum for SPWM modulation.
FIGURE 12.53   Current waveforms for different values of *p*.

of the three-phase PWM voltage waveforms for different values of *m*, and $p = 3k$ where *k* is an odd number.

Due to the presence of the input inductance L_S, the harmonic currents that result are proportionally attenuated with the harmonic number. This characteristic is shown in the current waveforms of Fig. 12.53, where larger *p* numbers generate cleaner currents. The rectifier that originated the currents of Fig. 12.53 has the following characteristics: $V_D = 450\ V_{dc}$, $V_{f-f}^{rms} = 220\ V_{ac}$, $L_S = 2$ mH, and input current $I_S = 80\ A_{rms}$. It can be observed that with $p > 21$ the current distortion is quite small. The value of $p = 81$ in Fig. 12.53 produces an almost pure sinusoidal waveform, and it means 4860 Hz of

switching frequency at 60 Hz or only 4.050 Hz in a rectifier operating in a 50 Hz supply. This switching frequency can be managed by MOSFETs, IGBTs, and even Power Darlingtons. Then a number $p = 81$, is feasible for today's low and medium power rectifiers.

12.3.4.3 Voltage-source Load-controlled PWM Rectifier

A simple method of control for small PWM rectifiers (up to 10–20 kW) is based on direct control of the *dc* current. Figure 12.54 shows the schematic of this control system. The fundamental voltage V_{MOD} modulated by the rectifier is produced by a fixed and unique PWM pattern, which can be carefully selected to eliminate most undesirable harmonics. As the PWM does not change, it can be stored in a permanent digital memory (ROM).

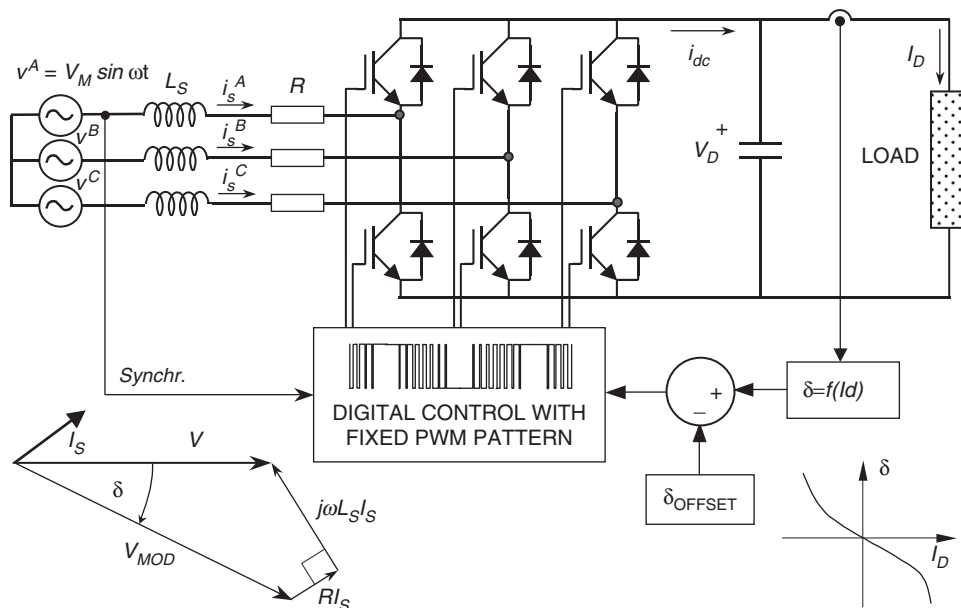
The control is based on changing the power angle δ between the mains voltage *V* and fundamental PWM voltage V_{MOD}. When δ changes, the amount of power flow transferred from the *ac* to the *dc* side also changes. When the power angle is negative (V_{MOD} lags *V*), the power flow goes from the *ac* to the *dc* side. When the power angle is positive, the power flows in the opposite direction. Then, the power angle can be controlled through the current I_D. The voltage V_D does not need to be sensed, because this control establishes a stable *dc* voltage operation for each *dc* current and power angle. With these characteristics, it is possible to find a relation between I_D and δ so as to obtain constant *dc* voltage for all load conditions.


FIGURE 12.54   Voltage-source load-controlled PWM rectifier.

This relation is given by

$$I_D = f(\delta) = \frac{V\left(\cos\delta - \frac{\omega L_S}{R}\sin\delta - 1\right)}{R\left[1 + \left(\frac{\omega L_S}{R}\right)^2\right]} \tag{12.70}$$

From Eq. (12.70) a plot and a reciprocal function $\delta = f(I_D)$ is obtained to control the rectifier. The relation between I_D and δ allows for leading power factor operation and null regulation. The leading power factor operation is shown in the phasor diagram of Fig. 12.54.

The control scheme of the voltage-source load-controlled rectifier is characterized by the following: (i) there are neither input current sensors nor *dc* voltage sensor; (ii) it works with a fixed and predefined PWM pattern; (iii) it presents very good stability; (iv) its stability does not depend on the size of the *dc* capacitor; (v) it can work at leading power factor for all load conditions; and (vi) it can be adjusted with Eq. (12.70) to work at zero regulation. The drawback appears when R in Eq. (12.70) becomes negligible, because in such a case the control system is unable to find an equilibrium point for the *dc* link voltage. That is why this control method is not applicable to large systems.

12.3.5 New Technologies and Applications of Force-commutated Rectifiers

The additional advantages of force-commutated rectifiers with respect to line-commutated rectifiers, make them better candidates for industrial requirements. They permit new applications such as rectifiers with harmonic elimination capability (active filters), power factor compensators, machine drives with four-quadrant operation, frequency links to connect 50 Hz with 60 Hz systems, and regenerative converters for traction power supplies. Modulation with very fast valves such as IGBTs permit almost sinusoidal currents to be obtained. The dynamics of these rectifiers is so fast that they can reverse power almost instantaneously. In machine drives, current source PWM rectifiers, like the one shown in Fig. 12.35a, can be used to drive *dc* machines from the three-phase supply. Four-quadrant applications using voltage-source PWM rectifiers, are extended for induction machines, synchronous machines with starting control, and special machines such as brushless-*dc* motors. Back-to-back systems are being used in Japan to link power systems with different frequencies.

12.3.5.1 Active Power Filter
Force-commutated PWM rectifiers can work as active power filters. The voltage-source current-controlled rectifier has the capability to eliminate harmonics produced by other polluting loads. It only needs to be connected as shown in Fig. 12.55.

The current sensors are located at the input terminals of the power source and these currents (instead of the rectifier currents) are forced to be sinusoidal. As there are polluting loads in the system, the rectifier is forced to deliver the harmonics that loads need, because the current sensors do not allow the harmonics going to the mains. As a result, the rectifier currents become distorted, but an adequate *dc* capacitor C_D can keep the *dc* link voltage in good shape. In this way the rectifier can do its duty, and also eliminate harmonics to the source. In addition, it also can compensate power factor and unbalanced load problems.

12.3.5.2 Frequency Link Systems
Frequency link systems permit power to be transferred form one frequency to another one. They are also useful for linking unsynchronized networks. Line-commutated converters are widely used for this application, but they have some drawbacks that force-commutated converters can eliminate. For example, the harmonic filters requirement, the poor power factor, and the necessity to count with a synchronous compensator when generating machines at the load side are absent. Figure 12.56 shows a typical line-commutated system in which a 60 Hz load is fed by a 50 Hz supply. As the 60 Hz side needs excitation to commutate the valves, a synchronous compensator has been required.

In contrast, an equivalent system with force-commutated converters is simpler, cleaner, and more reliable. It is implemented with a *dc* voltage-controlled rectifier, and another identical converter working in the inversion mode. The power factor can be adjusted independently at the two *ac* terminals, and filters or synchronous compensators are not required. Figure 12.57 shows a frequency link system with force-commutated converters.

12.3.5.3 Special Topologies for High Power Applications
High power applications require series- and/or parallel-connected rectifiers. Series and parallel operation with force-commutated rectifiers allow improving the power quality because harmonic cancellation can be applied to these topologies. Figure 12.58 shows a series connection of force-commutated rectifiers, where the modulating carriers of the valves in each bridge are shifted to cancel harmonics. The example uses sinusoidal PWM that are with TC shifted.

The waveforms of the input currents for the series connection system are shown in Fig. 12.59. The frequency modulation ratio shown in this figure is for $p = 9$. The carriers are shifted by 90° each, to obtain harmonics cancellation. Shifting of the carriers δ_T depends on the number of converters in series (or in parallel), and is given by

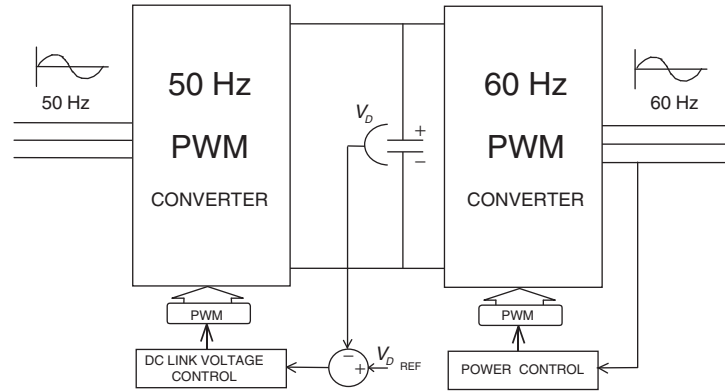
$$\delta_T = \frac{2\pi}{n} \tag{12.71}$$
FIGURE 12.55 Voltage-source rectifier with harmonic elimination capability.
FIGURE 12.56 Frequency link systems with line-commutated converters.


FIGURE 12.57   Frequency link systems with force-commutated converters.
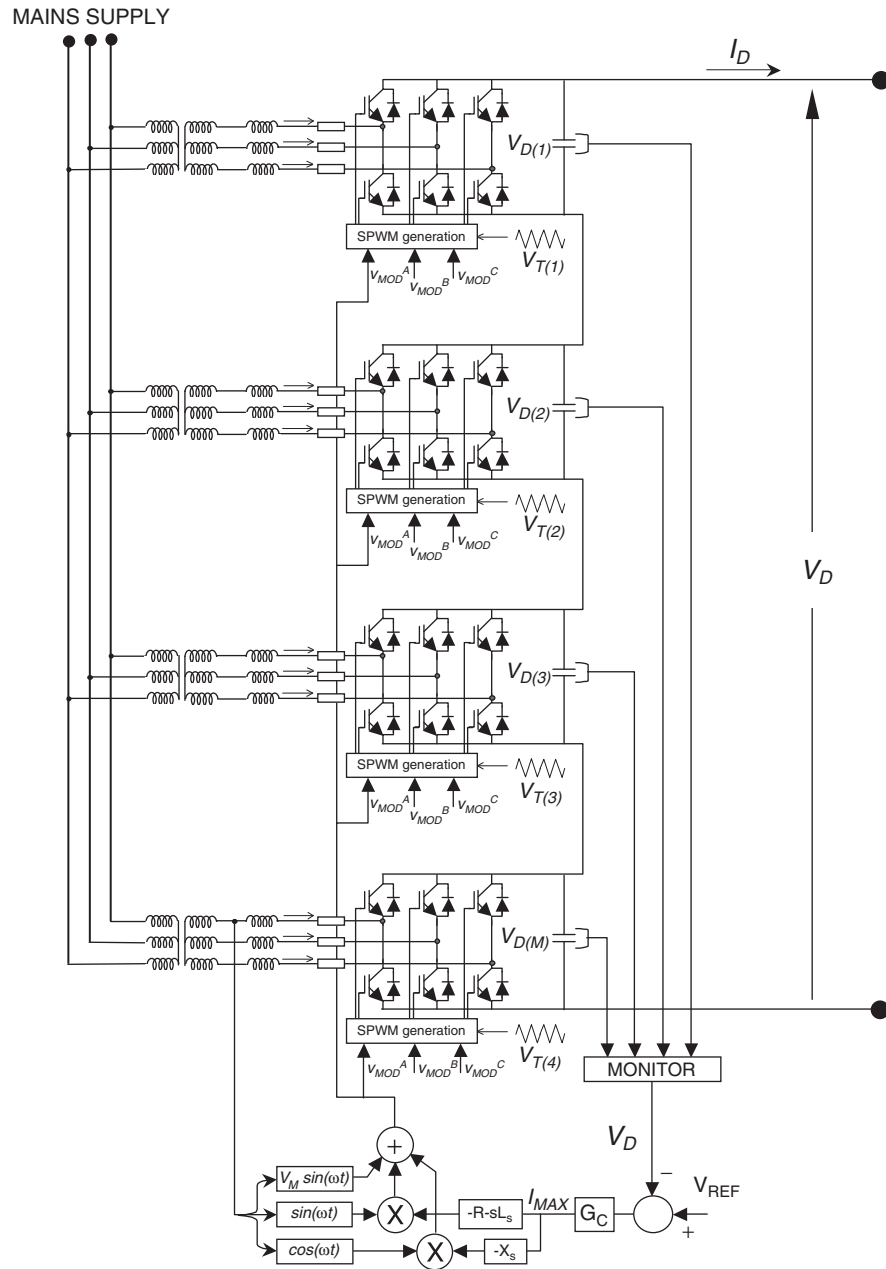

FIGURE 12.58   Series connection system with force-commutated rectifiers.
FIGURE 12.59   Input currents and carriers of the series connection system of Fig. 12.58.
FIGURE 12.60   Four converters in series and $p = 9$ compared with one converter and $p = 36$.

where n is the number of converters in series or in parallel. It can be observed that despite the low value of p, the total current becomes quite clean and clear, better than the current of one of the converters in the chain.

The harmonic cancellation with series- or parallel-connected rectifiers, using the same modulation but the carriers shifted, is quite effective. The resultant current is better with n converters and frequency modulation $p = p_1$ than with one converter and $p = n \cdot p_1$. This attribute is verified in Fig. 12.60, where the total current of four converters in series with $p = 9$ and carriers shifted, is compared with the current of only one converter and $p = 36$. This technique also allows for the use of valves with slow commutation times, such as high power GTOs. Generally, high power valves have low commutation times and hence the parallel and/or series options remain very attractive.

Another special topology for high power was implemented for Asea Brown Boveri (ABB) in Bremen. A 100 MW power converter supplies energy to the railways at $16^{2/3}$ Hz. It uses basic "H" bridges like the one shown in Fig. 12.61, connected to the load through power transformers. These transformers are connected in parallel at the converter side, and in series at the load side.

The system uses SPWM with TCs shifted, and depending on the number of converters connected in the chain of bridges, the voltage waveform becomes more and more sinusoidal. Figure 12.62 shows a back-to-back system using a chain of 12 "H" converters connected as showed in Fig. 12.61b.

The *ac* voltage waveform obtained with the topology of Fig. 12.62 is displayed in Fig. 12.63. It can be observed that the voltage is formed by small steps that depend on the number of converters in the chain (12 in this case). The current is almost perfectly sinusoidal.

Figure 12.64 shows the voltage waveforms for different number of converters connected in the bridge. It is clear that the larger the number of converters, the better the voltage.

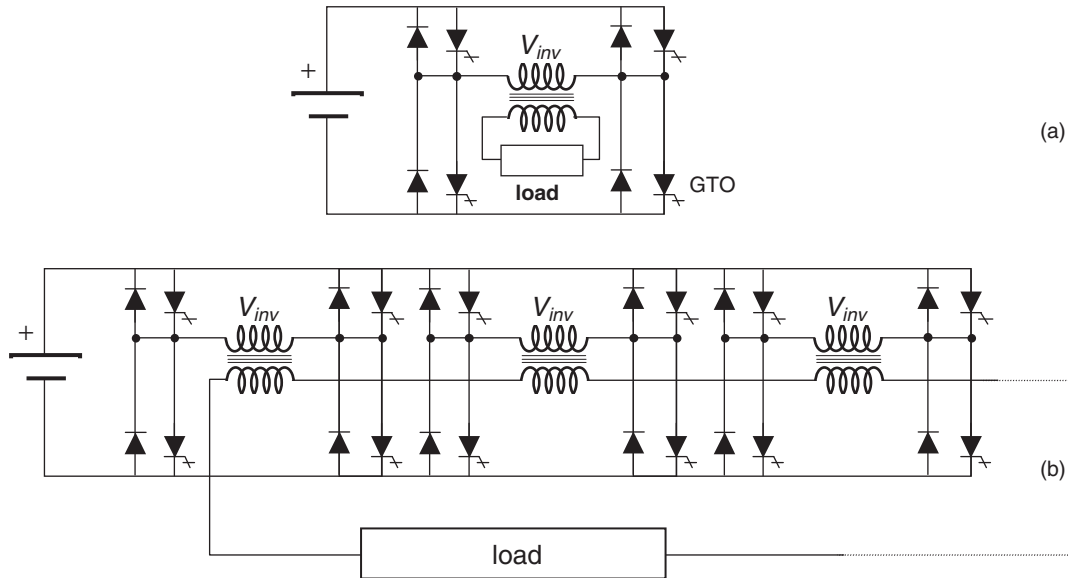
Another interesting result with this converter is that the *ac* voltages become modulated by both PWM and amplitude


FIGURE 12.61   The "H" modulator: (a) one bridge and (b) bridges connected in series at load side through isolation transformers.

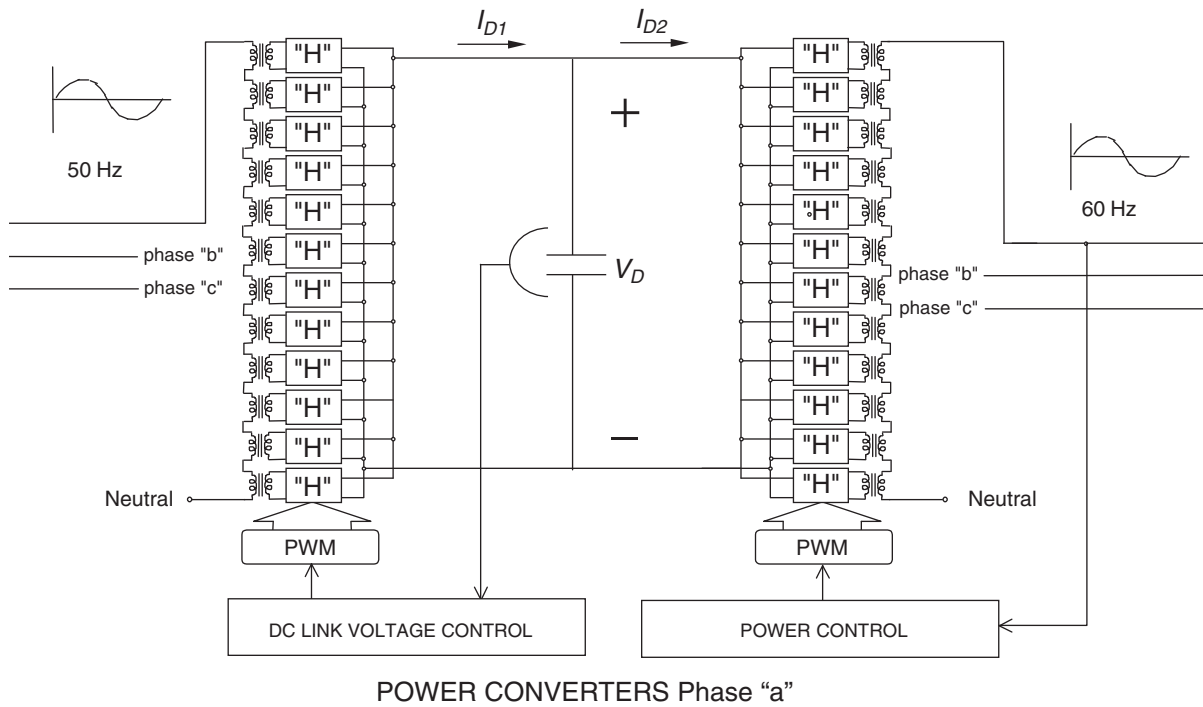
POWER CONVERTERS Phase "a"


FIGURE 12.62   Frequency link with force-commutated converters and sinusoidal voltage modulation.

modulation (AM). This is because when the pulse modulation changes, the steps of the amplitude change. The maximum number of steps of the resultant voltage is equal to the number of converters. When the voltage decreases, some steps disappear, and then the AM becomes a discrete function. Figure 12.65 shows the AM of the voltage.

12.3.5.4 Machine Drives Applications

One of the most important applications of force-commutated rectifiers is in machine drives. Line-commutated thyristor converters have limited applications because they need excitation to extinguish the valves. This limitation do not allow the use of line-commutated converters in induction machine drives.
FIGURE 12.63   Voltage and current waveforms with 12 converters.
FIGURE 12.64   Voltage waveforms with different numbers of "H" bridges in series.

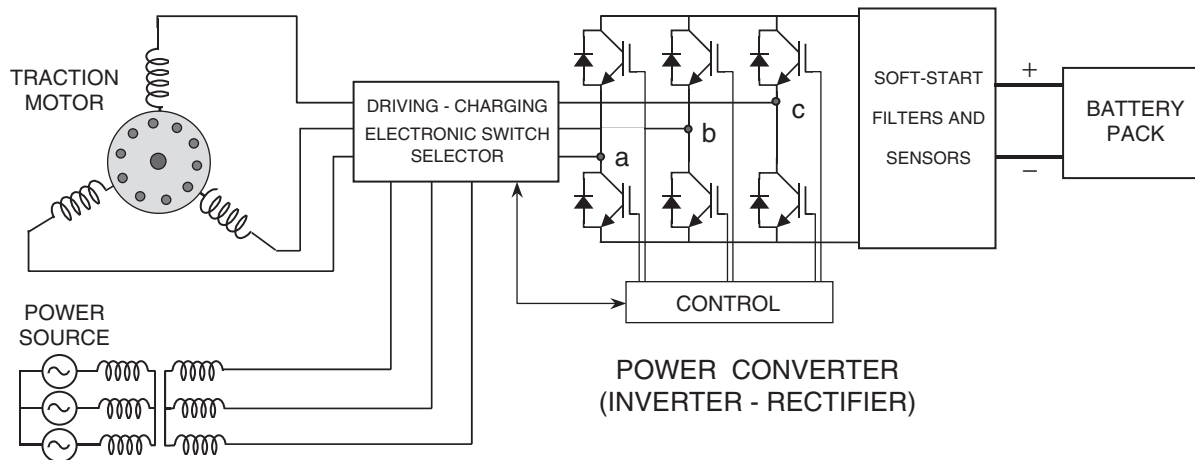
On the other hand, with force-commutated converters four-quadrant operation is achievable. Figure 12.66 shows a typical frequency converter with a force-commutated rectifier–inverter link. The rectifier side controls the *dc* link, and the inverter side controls the machine. The machine can be a synchronous, brushless *dc*, or induction machine. The reversal of both speed and power are possible with this topology. At the rectifier side, the power factor can be controlled, and even with an inductive load such as an induction machine, the source can "see" the load as capacitive or resistive. Changing the frequency of the inverter controls the machine speed, and the torque is controlled through the stator currents and
FIGURE 12.65 Amplitude modulation of the "H" bridges of Fig. 12.62.
FIGURE 12.66 Frequency converter with force-commutated converters.


FIGURE 12.67 Electric bus system with regenerative braking and battery charger.

torque angle. The inverter will become a rectifier during regenerative braking, which is possible by making slip negative in an induction machine, or by making the torque angle negative in synchronous and brushless *dc* machines.

A variation of the drive of Fig. 12.66 is found in electric traction applications. Battery powered vehicles use the inverter as a rectifier during regenerative braking, and sometimes the inverter is also used as a battery charger. In this case, the rectifier can be fed by a single-phase or three-phase system.

Figure 12.67 shows a battery-powered electric bus system. This system uses the power inverter of the traction motor as rectifier for two purposes: regenerative braking and as a battery charger fed by a three-phase power source.

12.3.5.5 Variable Speed Power Generation

Power generation at 50 or 60 Hz requires constant speed machines. In addition, induction machines are not currently
FIGURE 12.68   Variable-speed constant-frequency wind generator.
FIGURE 12.69   Voltage-source rectifier using three-level converter.

used in power plants because of magnetization problems. With the use of frequency-link force-commutated converters, variable-speed constant-frequency generation becomes possible even with induction generators. The power plant in Fig. 12.68 shows a wind generator implemented with an induction machine, and a rectifier–inverter frequency link connected to the utility. The *dc* link voltage is kept constant with the converter located at the mains side. The converter connected at the machine side controls the slip of the generator and adjusts it according to the speed of wind or power requirements. The utility is not affected by the power factor of the generator, because the two converters keep the $\cos\varphi$ of the machine independent of the mains supply. The converter at the mains side can even be adjusted to operate at leading power factor.

Varible-speed constant-frequency generation also can be used in either hydraulic or thermal plants. This allows for optimal adjustment of the efficiency-speed characteristics of the machines. In many places, wound rotor induction generators working as variable speed synchronous machines are being used as constant frequency generators. They operate in hydraulic plants that are able to store water during low demand periods. A power converter is connected at the slip rings of the generator. The rotor is then fed with variable frequency

excitation. This allows the generator to generate at different speeds around the synchronous rotating flux.

12.3.5.6 Power Rectifiers Using Multilevel Topologies

Almost all voltage source rectifiers already described are two-level configurations. Today, multilevel topologies are becoming very popular, mainly three-level converters. The most popular three-level configuration is called diode clamped converter, which is shown in Fig. 12.69. This topology is today the standard solution for high power steel rolling mills, which uses back-to-back three-phase rectifier–inverter link configuration. In addition, this solution has been recently introduced in high power downhill conveyor belts which operate almost permanently in the regeneration mode or rectifier operation. The more important advantage of three-level rectifiers is that voltage and current harmonics are reduced due to the increased number of levels.

Higher number of levels can be obtained using the same diode clamped strategy, as shown in Fig. 12.70, where only one phase of a general approach is displayed. However, this topology becomes more and more complex with the increase of number of levels. For this reason, new topologies are being
FIGURE 12.70   Multilevel rectifier using diode clamped topology.
FIGURE 12.71   27-Level rectifier for railways, using H-bridges scaled in power of three.

studied to get a large number of levels with less power transistors. One example of such of these topologies is the multistage, 27-level converter shown in Fig. 12.71. This special 27-level, four-quadrant rectifier, uses only three H-bridges per phase with independent input transformers for each H-bridge. The transformers allow galvanic isolation and power escalation to get high quality voltage waveforms, with *THD* of less than 1%.

The power scalation consists on increasing the voltage rates of each transformer making use of the "three-level" characteristics of H-bridges. Then, the number of levels is optimized when transformers are scaled in power of three. Some advantages of this 27-level topology are: (a) only one of the three H-bridges, called "main converter," manages more than 80% of the total active power in each phase and (b) this main
FIGURE 12.72   *AC* voltage waveform generated by the 27-level rectifier.

converter switches at fundamental frequency reducing the switching losses at a minimum value. The rectifier of Fig. 12.71 is a current-controlled voltage source type, with a conventional feedback control loop, which is being used as a rectifier in a subway substation. It includes fast reversal of power and the ability to produce clean *ac* and *dc* waveforms with negligible ripple. This rectifier can also compensate power factor and eliminate harmonics produced by other loads in the *ac* line. Figure 12.72 shows the *ac* voltage waveform obtained with this rectifier from an experimental prototype. If one more H-bridge is added, 81 levels are obtained, because the number of levels increases according with $N = 3^k$, where N is the number of levels or voltage steps and k the number of H-bridges used per phase.

Many other high-level topologies are under study but this matter is beyond the main topic of this chapter.

DC–DC Converters

Dariusz Czarkowski

Department of Electrical and Computer Engineering, Polytechnic University, Brooklyn, New York, USA

13.1 Introduction

Modern electronic systems require high quality, small, lightweight, reliable, and efficient power supplies. Linear power regulators, whose principle of operation is based on a voltage or current divider, are inefficient. They are limited to output voltages smaller than the input voltage. Also, their power density is low because they require low-frequency (50 or 60 Hz) line transformers and filters. Linear regulators can, however, provide a very high quality output voltage. Their main area of application is at low power levels as low drop-out voltage (LDO) regulators. Electronic devices in linear regulators operate in their active (linear) modes. At higher power levels, switching regulators are used. Switching regulators use power electronic semiconductor switches in *on* and *off* states. Since there is a small power loss in those states (low voltage across a switch in the *on* state, zero current through a switch in the *off* state), switching regulators can achieve high energy conversion efficiencies. Modern power electronic switches can operate at high frequencies. The higher the operating frequency, the smaller and lighter the transformers, filter inductors, and capacitors. In addition, dynamic characteristics of converters improve with increasing operating frequencies. The bandwidth of a control loop is usually determined by the corner frequency of the output filter. Therefore, high operating frequencies allow for achieving a faster dynamic response to rapid changes in the load current and/or the input voltage.

High-frequency electronic power processors are used in dc–dc power conversion. The functions of dc–dc converters are:

- to convert a dc input voltage V_S into a dc output voltage V_O;
- to regulate the dc output voltage against load and line variations;
- to reduce the ac voltage ripple on the dc output voltage below the required level;
- to provide isolation between the input source and the load (isolation is not always required);
- to protect the supplied system and the input source from electromagnetic interference (EMI);
- to satisfy various international and national safety standards.

The dc–dc converters can be divided into two main types: hard-switching pulse width modulated (PWM) converters, and resonant and soft-switching converters. This chapter deals with the former type of dc–dc converters. The PWM converters have been very popular for the last three decades. They are

widely used at all power levels. Topologies and properties of PWM converters are well understood and described in literature. Advantages of PWM converters include low component count, high efficiency, constant frequency operation, relatively simple control and commercial availability of integrated circuit controllers, and ability to achieve high conversion ratios for both step-down and step-up application. A disadvantage of PWM dc–dc converters is that PWM rectangular voltage and current waveforms cause turn-on and turn-off losses in semiconductor devices which limit practical operating frequencies to a megahertz range. Rectangular waveforms also inherently generate EMI.

   This chapter starts from a section on dc choppers which are used primarily in dc drives. The output voltage of dc choppers is controlled by adjusting the *on* time of a switch which in turn adjusts the width of a voltage pulse at the output. This is so called pulse-width modulation (PWM) control. The dc choppers with additional filtering components form PWM dc–dc converters. Four basic dc–dc converter topologies are presented in Sections 13.3–13.6: buck, boost, buck–boost, and Čuk converters. Popular isolated versions of these converters are also discussed. Operation of converters is explained under ideal component and semiconductor device assumptions. Section 13.7 discusses effects of non-idealities in PWM converters. Section 13.8 presents topologies for increased efficiency at low output voltage and for bidirectional power flow. Section 13.9 reviews control principles of PWM dc–dc converters. Two main control schemes, voltage-mode control and current-mode control, are described. Summary of application areas of PWM dc–dc converters is given in Section 13.10. Finally, a list of modern textbooks on power electronics is provided. These books are excellent resources for deeper exploration of the area of dc–dc power conversion.

(b)

FIGURE 13.1   DC chopper with resistive load: (a) circuit diagram and (b) output voltage waveform.

13.2 DC Choppers

A step-down dc chopper with a resistive load is shown in Fig. 13.1a. It is a series connection of a dc input voltage source V_S, controllable switch S, and load resistance R. In most cases, switch S has a unidirectional voltage blocking capabilities and unidirectional current conduction capabilities. Power electronic switches are usually implemented with power MOSFETs, IGBTs, MCTs, power BJTs, or GTOs. If an antiparallel diode is used or embedded in a switch, a switch exhibits a bidirectional current conduction property. Figure 13.1b depicts waveforms in a step-down chopper. The switch is being operated with a duty ratio D defined as a ratio of the switch *on* time to the sum of the *on* the *off* times. For a constant frequency operation,

$$D \equiv \frac{t_{on}}{t_{on} + t_{off}} = \frac{t_{on}}{T} \qquad (13.1)$$

where $T = 1/f$ is the period of the switching frequency f. The average value of the output voltage is

$$V_O = DV_S \qquad (13.2)$$

and can be regulated by adjusting duty ratio D. The average output voltage is always smaller than the input voltage, hence, the name of the converter.

   The dc step-down choppers are commonly used in dc drives. In such a case, the load is presented as a series combination of inductance L, resistance R, and back emf E as shown in Fig. 13.2a. To provide a path for a continuous inductor current flow when the switch is in the *off* state, an antiparallel diode D must be connected across the load. Since the chopper of Fig. 13.2a provides a positive voltage and a positive current to the load, it is called a first-quadrant chopper. The load voltage and current are graphed in Fig. 13.2b under assumptions that the load current never reaches zero and the load time constant $\tau = L/R$ is much greater than the period T. Average values of the output voltage and current can be adjusted by changing the duty ratio D.
FIGURE 13.2 DC chopper with RLE load: (a) circuit diagram and (b) waveforms.
FIGURE 13.3 The dc step-up chopper.

The dc choppers can also provide peak output voltages higher than the input voltage. Such a step-up configuration is presented in Fig. 13.3. It consists of dc input source V_S, inductor L connected in series with the source, switch S connecting the inductor to ground, and a series combination of diode D and load. If the switch operates with a duty ratio D, the output voltage is a series of pulses of duration $(1-D)T$ and amplitude $V_S/(1-D)$. Neglecting losses, the average value of the output voltage is V_S. To obtain an average value of the output voltage greater than V_S, a capacitor must be connected in parallel with

the load. This results in a topology of a boost dc–dc converter that is described in Section 13.4.

13.3 Step-down (Buck) Converter

13.3.1 Basic Converter

The step-down dc–dc converter, commonly known as a buck converter, is shown in Fig. 13.4a. It consists of dc input voltage source V_S, controlled switch S, diode D, filter inductor L, filter capacitor C, and load resistance R. Typical waveforms in the converter are shown in Fig. 13.4b under assumption that the inductor current is always positive. The state of the converter in which the inductor current is never zero for any period of time is called the continuous conduction mode (CCM). It can be seen from the circuit that when the switch S is commanded to the *on* state, the diode D is reverse biased. When the switch S is off, the diode conducts to support an uninterrupted current in the inductor.

The relationship among the input voltage, output voltage, and the switch duty ratio D can be derived, for instance, from the inductor voltage v_L waveform (see Fig. 13.4b). According to Faraday's law, the inductor volt–second product over a period of steady-state operation is zero. For the buck converter

$$(V_S - V_O)DT = -V_O(1 - D)T \qquad (13.3)$$

Hence, the dc voltage transfer function, defined as the ratio of the output voltage to the input voltage, is

$$M_V \equiv \frac{V_O}{V_S} = D \qquad (13.4)$$

It can be seen from Eq. (13.4) that the output voltage is always smaller than the input voltage.

The dc–dc converters can operate in two distinct modes with respect to the inductor current i_L. Figure 13.4b depicts the CCM in which the inductor current is always greater than zero. When the average value of the input current is low (high R) and/or the switching frequency f is low, the converter may enter the discontinuous conduction mode (DCM). In the DCM, the inductor current is zero during a portion of the switching period. The CCM is preferred for high efficiency and good utilization of semiconductor switches and passive components. The DCM may be used in applications with special control requirements, since the dynamic order of the converter is reduced (the energy stored in the inductor is zero at the beginning and at the end of each switching period). It is uncommon to mix these two operating modes because of different control algorithms. For the buck converter, the value

(a)

(b)
FIGURE 13.4 Buck converter: (a) circuit diagram and (b) waveforms.

of the filter inductance that determines the boundary between CCM and DCM is given by

$$L_b = \frac{(1 - D)R}{2f} \tag{13.5}$$

For typical values of $D = 0.5$, $R = 10\,\Omega$, and $f = 100\,\text{kHz}$, the boundary is $L_b = 25\,\mu\text{H}$. For $L > L_b$, the converter operates in the CCM.

The filter inductor current i_L in the CCM consists of a dc component I_O with a superimposed triangular ac component.

Almost all of this ac component flows through the filter capacitor as a current i_c. Current i_c causes a small voltage ripple across the dc output voltage V_O. To limit the peak-to-peak value of the ripple voltage below certain value V_r, the filter capacitance C must be greater than

$$C_{min} = \frac{(1 - D)\,V_O}{8 V_r L f^2} \tag{13.6}$$

At $D = 0.5$, $V_r/V_O = 1\%$, $L = 25\,\mu\text{H}$, and $f = 100\,\text{kHz}$, the minimum capacitance is $C_{min} = 25\,\mu\text{F}$.

Equations (13.5) and (13.6) are the key design equations for the buck converter. The input and output dc voltages (hence, the duty ratio D), and the range of load resistance R are usually determined by preliminary specifications. The designer needs to determine values of passive components L and C, and of the switching frequency f. The value of the filter inductor L is calculated from the CCM/DCM condition using Eq. (13.5). The value of the filter capacitor C is obtained from the voltage ripple condition Eq. (13.6). For the compactness and low conduction losses of a converter, it is desirable to use small passive components. Equations (13.5) and (13.6) show that it can be accomplished by using a high switching frequency f. The switching frequency is limited, however, by the type of semiconductor switches used and by switching losses. It should be also noted that values of L and C may be altered by effects of parasitic components in the converter, especially by the equivalent series resistance of the capacitor. The issue of parasitic components in dc–dc converters is discussed in Section 13.7.

13.3.2 Transformer Versions of Buck Converter

In many dc power supplies, a galvanic isolation between the dc or ac input and the dc output is required for safety and reliability. An economical mean of achieving such an isolation is to employ a transformer version of a dc–dc converter. High-frequency transformers are of a small size and weight and provide high efficiency. Their turns ratio can be used to additionally adjust the output voltage level. Among buck-derived dc–dc converters, the most popular are: forward converter, push–pull converter, half-bridge converter, and full-bridge converter.

A. Forward Converter

The circuit diagram of a forward converter is depicted in Fig. 13.5. When the switch S is *on*, diode D_1 conducts and diode D_2 is *off*. The energy is transferred from the input, through the transformer, to the output filter. When the switch is *off*, the state of diodes D_1 and D_2 is reversed. The dc voltage transfer function of the forward converter is

$$M_V = \frac{D}{n} \tag{13.7}$$

where $n = N_1/N_2$.
FIGURE 13.5   Forward converter.

FIGURE 13.7   Half-bridge converter.

In the forward converter, the energy-transfer current flows through the transformer in one direction. Hence, an additional winding with diode D_3 is needed to bring the magnetizing current of the transformer to zero. This prevents transformer saturation. The turns ratio N_1/N_3 should be selected in such a way that the magnetizing current decreases to zero during a fraction of the time interval when the switch is *off*.

Equations (13.5) and (13.6) can be used to design the filter components. The forward converter is very popular for low power applications. For medium power levels, converters with bidirectional transformer excitation (push–pull, half-bridge, and full-bridge) are preferred due to better utilization of magnetic components.

B. Push–Pull Converter

The PWM dc–dc push–pull converter is shown in Fig. 13.6. The switches S_1 and S_2 operate shifted in phase by $T/2$ with the same duty ratio D. The duty ratio must be smaller than 0.5. When switch S_1 is *on*, diode D_1 conducts and diode D_2 is *off*. Diode states are reversed when switch S_2 is *on*. When both controllable switches are *off*, the diodes are *on* and share equally the filter inductor current. The dc voltage transfer function of the push–pull converter is

$$M_V = \frac{2D}{n} \qquad (13.8)$$

where $n = N_1/N_2$. The boundary value of the filter inductor is

$$L_b = \frac{(1-2D)R}{4f} \qquad (13.9)$$

The filter capacitor can be obtained from

$$C_{min} = \frac{(1-2D)V_O}{32V_r Lf^2} \qquad (13.10)$$

C. Half-bridge Converter

Figure 13.7 shows the dc–dc half-bridge converter. The operation of the PWM half-bridge converter is similar to that of the push–pull converter. In comparison to the push–pull converter, the primary of the transformer is simplified at the expense of two voltage-sharing input capacitors. The half-bridge converter dc voltage transfer function is

$$M_V \equiv \frac{V_D}{V_S} = \frac{D}{n} \qquad (13.11)$$

where $D \leq 0.5$. Equations (13.9) and (13.10) apply to the filter components.

D. Full-bridge Converter

Comparing the PWM dc–dc full-bridge converter of Fig. 13.8 to the half-bridge converter, it can be seen that the input capacitors have been replaced by two controllable switches. The controllable switches are operated in pairs. When S_1 and S_4 are *on*, voltage V_S is applied to the primary of the transformer and diode D_1 conducts, With S_2 and S_3 *on*, there is voltage $-V_S$ across the primary transformer and diode D_2

FIGURE 13.6   Push–pull converter.
FIGURE 13.8   Full-bridge converter.

is *on*. With all controllable switches *off*, both diodes conduct, similarly as in the push–pull and half-bridge converters. The dc voltage transfer function of the full-bridge converter is

$$M_V \equiv \frac{V_O}{V_S} = \frac{2D}{n} \tag{13.12}$$

where $D \leq 0.5$. Values of filter components can be obtained from Eqs. (13.9) and (13.10).

It should be stressed that the full-bridge topology is a very versatile one. With different control algorithms, it is very popular in dc–ac conversion (square-wave and PWM single-phase inverters). It is also used in four-quadrant dc drives.

13.4 Step-up (Boost) Converter

Figure 13.9a depicts a step-up or a PWM boost converter. It is comprised of dc input voltage source V_S, boost inductor L, controlled switch S, diode D, filter capacitor C, and load resistance R. The converter waveforms in the CCM are presented in Fig. 13.9b. When the switch S is in the *on* state, the current in the boost inductor increases linearly. The diode D is *off* at the time. When the switch S is turned *off*, the energy stored in the inductor is released through the diode to the input RC circuit.

Using the Faraday's law for the boost inductor

$$V_S DT = (V_O - V_S)(1 - D)T \tag{13.13}$$

from which the dc voltage transfer function turns out to be

$$M_V \equiv \frac{V_O}{V_S} = \frac{1}{1 - D} \tag{13.14}$$

As the name of the converter suggests, the output voltage is always greater than the input voltage.

The boost converter operates in the CCM for $L > L_b$ where

$$L_b = \frac{(1 - D)^2 DR}{2f} \tag{13.15}$$

For $D = 0.5$, $R = 10\,\Omega$, and $f = 100\,\text{kHz}$, the boundary value of the inductance is $L_b = 6.25\,\mu\text{H}$.

As shown in Fig. 13.9b, the current supplied to the output RC circuit is discontinuous. Thus, a larger filter capacitor is required in comparison to that in the buck-derived converters to limit the output voltage ripple. The filter capacitor must provide the output dc current to the load when the diode D
FIGURE 13.9　Boost converter: (a) circuit diagram and (b) waveforms.

is *off*. The minimum value of the filter capacitance that results in the voltage ripple V_r is given by

$$C_{min} = \frac{DV_O}{V_r R f} \tag{13.16}$$

At $D = 0.5$, $V_r/V_O = 1\%$, $R = 10\,\Omega$, and $f = 100\,\text{kHz}$, the minimum capacitance for the boost converter is $C_{min} = 50\,\mu\text{F}$.

The boost converter does not have a popular transformer (isolated) version.

13.5 Buck–Boost Converter

13.5.1 Basic Converter

A non-isolated (transformerless) topology of the buck–boost converter is shown in Fig. 13.10a. The converter consists of dc input voltage source V_S, controlled switch S, inductor L, diode D, filter capacitor C, and load resistance R. With the switch *on*, the inductor current increases while the diode is maintained *off*. When the switch is turned *off*, the diode provides a path for the inductor current. Note the polarity of the diode which results in its current being *drawn from* the output.

The buck–boost converter waveforms are depicted in Fig. 13.10b. The condition of a zero volt–second product for the inductor in steady state yields

$$V_S DT = -V_O(1-D)T \qquad (13.17)$$

Hence, the dc voltage transfer function of the buck–boost converter is

$$M_V \equiv \frac{V_O}{V_S} = -\frac{D}{1-D} \qquad (13.18)$$

The output voltage V_O is negative with respect to the ground. Its magnitude can be either greater or smaller (equal at $D = 0.5$) than the input voltage as the converter's name implies.

The value of the inductor that determines the boundary between the CCM and DCM is

$$L_b = \frac{(1-D)^2 R}{2f} \qquad (13.19)$$

The structure of the output part of the converter is similar to that of the boost converter (reversed polarities being the only difference). Thus, the value of the filter capacitor can be obtained from Eq. (13.16).

13.5.2 Flyback Converter

A PWM flyback converter is a very practical isolated version of the buck–boost converter. The circuit of the flyback converter is presented in Fig. 13.11a. The inductor of the buck–boost converter has been replaced by a flyback transformer. The input dc source V_S and switch S are connected in series with the primary transformer. The diode D and the *RC* output circuit are connected in series with the secondary of the flyback transformer. Figure 13.11b shows the converter with a simple flyback transformer model. The model includes a magnetizing inductance L_m and an ideal transformer with a turns ratio $n = N_1/N_2$. The flyback transformer leakage inductances and losses are neglected in the model. It should be noted that leakage inductances, although not important from the principle of operation point of view, affect adversely switch and diode transitions. Snubbers are usually required in flyback converters.

Refer to Fig. 13.11b for the converter operation. When the switch S is *on*, the current in the magnetizing inductance increases linearly. The diode D is *off* and there is no current in the ideal transformer windings. When the switch is turned *off*, the magnetizing inductance current is diverted into the ideal transformer, the diode turns *on*, and the transformed

(a)

(b)

FIGURE 13.10 Buck–boost converter: (a) circuit diagram and (b) waveforms.
FIGURE 13.11 Flyback converter: (a) circuit diagram and (b) circuit with a transformer model showing the magnetizing inductance L_m.

magnetizing inductance current is supplied to the RC load. The dc voltage transfer function of the flyback converter is

$$M_V \equiv \frac{V_O}{V_S} = \frac{D}{n(1-D)} \qquad (13.20)$$

It differs from the buck–boost converter voltage transfer function by the turns ratio factor n. A positive sign has been obtained by an appropriate coupling of the transformer windings.

Unlike in transformer buck-derived converters, the magnetizing inductance L_m of the flyback transformer is an important design parameter. The value of the magnetizing inductance that determines the boundary between the CCM and DCM is given by

$$L_{mb} = \frac{n^2(1-D)^2 R}{2f} \qquad (13.21)$$

The value of the filter capacitance can be calculated using Eq. (13.16).

13.6 Ćuk Converter

The circuit of the Ćuk converter is shown in Fig. 13.12a. It consists of dc input voltage source V_S, input inductor L_1, controllable switch S, energy transfer capacitor C_1, diode D, filter inductor L_2, filter capacitor C, and load resistance R.
FIGURE 13.12 Ćuk converter: (a) circuit diagram and (b) waveforms.

An important advantage of this topology is a continuous current at both the input and the output of the converter. Disadvantages of the Ćuk converter include a high number of reactive components and high current stresses on the switch, the diode, and the capacitor C_1. Main waveforms in the converter are presented in Fig. 13.12b. When the switch is *on*, the diode is *off* and the capacitor C_1 is discharged by the inductor L_2 current. With the switch in the *off* state, the diode conducts currents of the inductors L_1 and L_2 whereas capacitor C_1 is charged by the inductor L_1 current.

To obtain the dc voltage transfer function of the converter, we shall use the principle that the average current through a capacitor is zero for steady-state operation. Let us assume that inductors L_1 and L_2 are large enough that their ripple current can be neglected. Capacitor C_1 is in steady state if

$$I_{L2}DT = I_{L1}(1-D)T \qquad (13.22)$$

For a lossless converter

$$P_S = V_S I_{L1} = -V_O I_{L2} = P_O \qquad (13.23)$$

Combining these two equations, the dc voltage transfer function of the Cùk converter is

$$M_V \equiv \frac{V_O}{V_S} = -\frac{D}{1-D} \qquad (13.24)$$

This voltage transfer function is the same as that for the buck–boost converter.

The boundaries between the CCM and DCM are determined by

$$L_{b1} = \frac{(1-D)R}{2Df} \qquad (13.25)$$

for L_1 and

$$L_{b2} = \frac{(1-D)R}{2f} \qquad (13.26)$$

for L_2.

The output part of the Cùk converter is similar to that of the buck converter. Hence, the expression for the filter capacitor C is

$$C_{min} = \frac{(1-D)V_O}{8V_r L_2 f^2} \qquad (13.27)$$

The peak-to-peak ripple voltage in the capacitor C_1 can be estimated as

$$V_{r1} = \frac{DV_O}{C_1 Rf} \qquad (13.28)$$

A transformer (isolated) version of the Cùk converter can be obtained by splitting capacitor C_1 and inserting a high-frequency transformer between the split capacitors.

13.7 Effects of Parasitics

The analysis of converters in Sections 13.2 through 13.6 has been performed under ideal switch, diode, and passive component assumptions. Non-idealities or parasitics of practical devices and components may, however, greatly affect some performance parameters of dc–dc converters. In this section, effects of parasitics on output voltage ripple, efficiency, and voltage transfer function of converters will be illustrated.

A more realistic model of a capacitor than just a capacitance C, consists of a series connection of capacitance C and resistance r_C. The resistance r_C is called an equivalent series resistance (ESR) of the capacitor and is due to

losses in the dielectric and physical resistance of leads and connections. Recall Eq. (13.6) which provided a value of the filter capacitance in a buck converter that limits the peak-to-peak output voltage ripple to V_r. The equation was derived under an assumption that the entire triangular ac component of the inductor current flows through a capacitance C. It is, however, closer to reality to maintain that this triangular component flows through a series connection of capacitance C and resistance r_C.

The peak-to-peak ripple voltage is independent of the voltage across the filter capacitor and is determined only by the ripple voltage of the ESR if the following condition is satisfied,

$$C \geq C_{min} = \max \left\{ \frac{1-D_{min}}{2r_C f}, \frac{D_{max}}{2r_C f} \right\} \qquad (13.29)$$

If condition (13.29) is satisfied, the peak-to-peak ripple voltage of the buck and forward converters is

$$V_r = r_C \Delta i_{Lmax} = \frac{r_C V_O (1-D_{min})}{fL} \qquad (13.30)$$

For push–pull, half-bridge, and full-bridge converters,

$$C \geq C_{min} = \max \left\{ \frac{0.5-D_{min}}{2r_C f}, \frac{D_{max}}{2r_C f} \right\} \qquad (13.31)$$

where $D_{max} \leq 0.5$. If condition (13.31) is met, the peak-to-peak ripple voltage V_r of these converters is given by

$$V_r = r_C \Delta i_{Lmax} = \frac{r_C V_O (0.5-D_{min})}{fL} \qquad (13.32)$$

Waveforms of voltage across the ESR V_{rC}, voltage across the capacitance V_C, and total ripple voltage V_r are depicted in Fig. 13.13 for three values of the filter capacitances. For the case of the top graph in Fig. 13.13, the peak-to-peak value of V_r is higher than the peak-to-peak value of V_{rC} because $C < C_{min}$. Middle and bottom graphs in Fig. 13.13 show the waveforms for $C = C_{min}$ and $C > C_{min}$, respectively. For both these cases, the peak-to-peak voltages of V_r and V_{rC} equal to each other.

Note that when the resistance r_C sets the ripple voltage V_r, the minimum value of inductance L is determined either by the boundary between the CCM and DCM according to Eq. (13.5) (buck and forward converters) or Eq. (13.9) (push–pull, half-bridge, and full-bridge converters), or by the voltage ripple condition (13.30) or (13.32).

In buck–boost and boost converters, the peak-to-peak capacitor current I_{Cpp} is equal to the peak-to-peak diode current and is given by

$$I_{Cpp} = \frac{I_O}{1-D} \qquad (13.33)$$
FIGURE 13.13 Voltage ripple waveforms V_{rC}, V_C, and V_r for a buck converter at $V_O = 12\,\text{V}$, $f = 100\,\text{kHz}$, $L = 40\,\mu\text{H}$, $r_C = 0.05\,\Omega$, and various values of C: $C = 33\,\mu\text{F}$ (top graph), $C = C_{min} = 65\,\mu\text{F}$ (middle graph), and $C = 100\,\mu\text{F}$ (bottom graph).

under condition that the inductor current ripple is much lower than the average value of the inductor current. The peak-to-peak voltage across the ESR is

$$V_{rC} = r_C I_{Cpp} = \frac{r_C I_O}{1 - D} \qquad (13.34)$$

Assuming that the total ripple voltage V_r is approximately equal to the sum of the ripple voltages across the ESR and the capacitance, the maximum value of the peak-to-peak ripple voltage across the capacitance is

$$V_{Cmax} \approx V_r - V_{rC} \qquad (13.35)$$

Finally, by analogy to Eq. (13.16), when the ESR of the filter capacitor is taken into account in the boost-type output filter, the filter capacitance should be greater than

$$C_{min} = \frac{DV_O}{V_{Cmax}Rf} \qquad (13.36)$$

Parasitic resistances, capacitances, and voltage sources affect also an energy conversion efficiency of dc–dc converters. The efficiency η is defined as a ratio of output power to the input power

$$\eta \equiv \frac{P_O}{P_S} = \frac{V_O I_O}{V_S I_S} \qquad (13.37)$$

Efficiencies are usually specified in percent. Let us consider the boot converter as an example. Under low ripple assumption, the boost converter efficiency can be estimated as

$$\eta = \frac{R(1-D)^2}{R(1-D)^2(1+(V_D/V_O)+fC_oR)+r_L+Dr_S+(1-D)r_D+D(1-D)r_C} \qquad (13.38)$$

where V_D is the forward conduction voltage drop of the diode, C_o is the output capacitance of the switch, r_L is the ESR of the inductor, and r_D is the forward *on* resistance of the diode. The term fC_oR in Eq. (13.38) represents switching losses in the converter. Other terms account for conduction losses. Losses in a dc–dc converter also contribute to a decrease in the dc voltage transfer function. The non-ideal dc voltage transfer function M_{Vn} is a product of the ideal one and the efficiency

$$M_{Vn} = \eta M_V \qquad (13.39)$$

Sample graphs for the boost converter that correspond to Eqs. (13.38) and (13.39) are presented in Fig. 13.14.

13.8 Synchronous and Bidirectional Converters

It can be observed in Eq. (13.38) that the forward voltage of a diode V_D contributes to a decrease in efficiency. This contribution is especially significant in low output voltage power supplies, e.g. 3.3 V power supplies for microprocessors or power supplies for portable telecommunication equipment. Even with a Schottky diode, which has V_D in the range of 0.4 V, the power loss in the diode can easily exceed 10% of the total power delivered to the load. To reduce conduction losses in the diode, a low on-resistance switch can be added in parallel as shown in Fig. 13.15 for a buck converter. The input switch and the switch parallel to the diode must be

(a)

(b)
FIGURE 13.14   Effects of parasitics on characteristics of a boost converter: (a) efficiency and (b) dc voltage transfer function.

FIGURE 13.15   Synchronous buck converter.

FIGURE 13.16   Bidirectional flyback converter.

usually have longer turn-off times than turn-on times, a dead time (sometimes called a blanking time) must be introduced in PWM driving signals.

The parallel combination of a controllable switch and a diode is also used in converters which allow for a current flow in both directions: from the input source to the load and from the load back to the input source. Such converters are called bidirectional power flow or simply bidirectional converters. As an example, a flyback bidirectional converter is shown in Fig. 13.16. It contains unipolar voltage and bidirectional current switch–diode combinations at both primary and secondary of the flyback transformer. When the primary switch and secondary diode operate, the current flows from the input source to the load. The converter current can also flow from the output to the input through the secondary switch and primary diode. Bidirectional arrangements can be made for buck and boost converters. A bidirectional buck converter operates as a boost converter when the current flow is from the output to the input. A bidirectional boost converter operates as a buck converter with a reversed current flow. If for any reason (for instance to avoid the DCM) the controllable switches are driven at the same time, they must be driven alternately with a sufficient dead time to avoid a shot-through current.

13.9 Control Principles

A dc–dc converter must provide a regulated dc output voltage under varying load and input voltage conditions.

turned on and off alternately. The arrangement of Fig. 13.15 is called a synchronous converter or a synchronous rectifier. Modern low-voltage MOSFETs have *on* resistances of only several milliohms. Hence, a synchronous converter may exhibit higher efficiency than a conventional one at output currents as large as tens of amperes. The efficiency is increased at an expense of more complicated driving circuitry for the switches. In particular, a special can must be exercised to avoid having both switches *on* at the same time as this would short the input voltage source. Since power semiconductor devices

The converter component values are also changing with time, temperature, pressure, etc. Hence, the control of the output voltage should be performed in a closed-loop manner using principles of negative feedback. Two most common closed-loop control methods for PWM dc–dc converters, namely, the voltage-mode control and the current-mode control, are presented schematically in Fig. 13.17.

In the voltage-mode control scheme shown in Fig. 13.17a, the converter output voltage is sensed and subtracted from an external reference voltage in an error amplifier. The error amplifier produces a control voltage that is compared to a constant-amplitude sawtooth waveform. The comparator produces a PWM signal which is fed to drivers of controllable switches in the dc–dc converter. The duty ratio of the PWM signal depends on the value of the control voltage. The frequency of the PWM signal is the same as the frequency of the sawtooth waveform. An important advantage of the voltage-mode control is its simple hardware implementation and flexibility.

The error amplifier in Fig. 13.17a reacts fast to changes in the converter output voltage. Thus, the voltage-mode control provides good load regulation, that is, regulation against variations in the load. Line regulation (regulation against variations in the input voltage) is, however, delayed because changes in the input voltage must first manifest themselves in the converter output before they can be corrected. To alleviate this problem, the voltage-mode control scheme is sometimes augmented by so-called voltage feedforward path. The feedforward path affects directly the PWM duty ratio according to variations in the input voltage. As will be explained below, the input voltage feedforward is an inherent feature of current-mode control schemes.

The current-mode control scheme is presented in Fig. 13.17b. An additional inner control loop feeds back an inductor current signal. This current signal, converted into its voltage analog, is compared to the control voltage. This modification of replacing the sawtooth wavefrom of the voltage-mode control scheme by a converter current signal significantly alters
FIGURE 13.17 Main control schemes for dc–dc converters: (a) voltage-mode control and (b) current-mode control.

the dynamic behavior of the converter. The converter takes on some characteristics of a current source. The output current in PWM dc–dc converters is either equal to the *average* value of the output inductor current (buck-derived and Čuk converters) or is a product of an *average* inductor current and a function of the duty ratio. In practical implementations of the current-mode control, it is feasible to sense the peak inductor current instead of the average value. Since the peak inductor current is equal to the peak switch current, the latter can be used in the inner loop which often simplifies the current sensor. Note that the peak inductor (switch) current is proportional to the input voltage. Hence, the inner loop of the current-mode control naturally accomplishes the input voltage feedforward technique. Among several current-mode control versions, the most popular is the constant-frequency one which requires a clock signal. Advantages of the current-mode control include: input voltage feedforward, limit on the peak switch current, equal current sharing in modular converters, and reduction in the converter dynamic order. The main disadvantage of the current-mode control is its complicated hardware which includes a need to compensate the control voltage by ramp signals (to avoid converter instability).

Among other control methods of dc–dc converters, a hysteretic (or bang-bang) control is very simple for hardware implementation. The hysteretic control results, however, in variable frequency operation of semiconductor switches. Generally, a constant switching frequency is preferred in power electronic circuits for easier elimination of electromagnetic interference and better utilization of magnetic components.

Application specific integrated circuits (ASICs) are commercially available that contain main elements of voltage- or current-mode control schemes. On a single 14 or 16-pin chip, there is error amplifier, comparator, sawtooth generator or sensed current input, latch, and PWM drivers. The switching frequency is usually set by an external *RC* network and can be varied from tens of kilohertz to a few megahertz. The controller has an oscillator output for synchronization with other converters in modular power supply systems. A constant voltage reference is generated on the chip as well. Additionally, the ASIC controller may be equipped in various diagnostic and protection features: current limiting, overvoltage and undervoltage protection, soft start, dead time in case of multiple PWM outputs, and duty ratio limiting. In several dc–dc converter topologies, e.g. buck and buck–boost, neither control terminal of semiconductor switches is grounded (so-called high-side switches). The ASIC controllers are usually designed for a particular topology and their PWM drivers may be able to drive high-side switches in low voltage applications. In high voltage applications, external PWM drivers must be used. External PWM drivers are also used for switches with high input capacitances. To take a full advantage of the input–output isolation in transformer versions of dc–dc converters, such an isolation must be also provided in the control loop.

Signal transformers or optocouplers are used for isolating feedback signals.

Dynamic characteristic of closed-loop dc–dc converters must fulfill certain requirements. To simply analysis, these requirements are usually translated into desired properties of the open loop. The open loop should provide a sufficient (typically, at least 45°) phase margin for stability, high bandwidth (about one-tenth of the switching frequency) for good transient response, and high gain (several tens of decibels) at low frequencies for small steady-state error.

The open loop dynamic characteristics are shaped by compensating networks of passive components around the error amplifier. Second or third order *RC* networks are commonly used. Since the converter itself is a part of the control loop, the design of compensating networks requires a knowledge of small-signal characteristics of the converter. There are several methods of small-signal characterization of PWM dc–dc converters. The most popular methods provide average models of converters under high switching frequency assumption. The averaged models are then linearized at an operating point to obtain small-signal transfer functions. Among analytical averaging methods, state-space averaging has been popular since late 1970s. Circuit-based averaging is usually performed using PWM switch or direct replacement of semiconductor switches by controlled current and voltage sources. All these methods can take into account converter parasitics.

The most important small-signal characteristic is the *control-to-output* transfer function T_p. Other converter characteristics that are investigated include the *input-to-output* (or *line-to-output*) voltage transfer function, also called the *open-loop dynamic line regulation* or the *audio susceptibility*, which describes the input–output disturbance transmission; the *open-loop input impedance*; and the *open-loop dynamic load regulation*. Buck-derived, boost, and buck–boost converters are second order dynamic systems; the Čuk converter is a fourth-order system. Characteristics of buck and buck-derived converters are similar to each other. Another group of converters with similar small-signal characteristics is formed by boost, buck–boost, and flyback converters. Among parasitic components, the ESR of the filter capacitor r_C introduces additional dynamic terms into transfer functions. Other parasitic resistances usually modify slightly the effective value of the load resistance. Sample characteristics below are given for non-zero r_C, neglecting other parasitics.

The control-to-output transfer function of the forward converter is

$$T_p(s) \equiv \frac{v_o(s)}{d(s)}\Big|_{v_s(s)=0} = \frac{V_I R r_C}{nL(R + r_C)}$$

$$\times \frac{s + (1/Cr_C)}{s^2 + s(CRr_C + L/LC(R + r_C)) + R/(LC(R + r_C))}$$

$$(13.40)$$

It can be seen that this transfer function has two poles and one zero. The zero is due to the filter capacitor ESR. Buck-derived converters can be easily compensated for stability with second-order controllers.

The control-to-output transfer function of the boost converter is given by

$$T_p(s) = -\frac{V_O r_C}{(1-D)(R+r_C)}$$

$$\times \frac{[s+(1/Cr_C)][s-((1-D)^2 R)/L]}{s^2 + s[((1-D)^2 CRr_C + L)/(LC(R+r_C))] + [((1-D)^2 R)/(LC(R+r_C))]}$$

$$(13.41)$$

The zero $-(1-D)^2 R/L$ is located in the right half of the s-plane. Therefore, the boost converter (as well as buck–boost and flyback converters) is a non-minimum phase system. Non-minimum phase dc–dc converters are typically compensated with third-order controllers. Step-by-step procedures for a design of compensating networks are usually given by manufacturers of ASIC controllers in application notes.

The final word of this section is on the behavior of dc–dc converters in distributed power supply systems. An important feature of closed-loop regulated dc–dc converters is that they exhibit a negative input resistance. As the load voltage is kept constant by the controller, the output power changes with the load. With slow load changes, an increase (decrease) in the input voltage results in a decrease (increase) in the input power. This negative resistance property must be carefully examined during the system design to avoid resonances.

13.10 Applications of DC–DC Converters

Step-down choppers find most of their applications in high-performance dc drive systems, e.g. electric traction, electric vehicles, and machine tools. The dc motors with their winding inductances and mechanical inertia act as filters resulting in high-quality armature currents. The average output voltage of step-down choppers is a linear function of the switch duty ratio. Step-up choppers are used primarily in radar and ignition systems. The dc choppers can be modified for two-quadrant and four-quadrant operation. Two-quadrant choppers may be a part of autonomous power supply system that contain battery packs and such renewable dc sources as photovoltaic arrays, fuel cells, or wind turbines. Four-quadrant choppers are applied in drives in which regenerative breaking of dc motors is desired, e.g. transportation systems with frequent stops. The dc choppers with inductive outputs serve as inputs to current-driven inverters.

An addition of filtering reactive components to dc choppers results in PWM dc–dc converters. The dc–dc converters can be viewed as dc transformers that deliver to the load as dc voltage or current at a different level than the input source. This dc transformation is performed by electronic switching means, not by electromagnetic means like in conventional transformers. Output voltages of dc–dc converters range from a volt for special VLSI circuits to tens of kilovolts in X-ray lamps. The most common output voltages are: 3.3 V for modern microprocessors, 5 and 12 V for logic circuits, 48 V for telecommunication equipment, and 270 V for main dc bus on airplanes. Typical input voltages include 48 V, 170 V (the peak value of a 120 V rms line), and 270 V.

Selection of a topology of dc–dc converters is determined not only by input/output voltages, which can be additionally adjusted with the turns ratio in isolated converters, but also by power levels, voltage and current stresses of semiconductor switches, and utilization of magnetic components. The low part-count flyback converter is popular in low power applications (up to 200 W). Its main deficiencies are the large size of the flyback transformer core and high voltage stress on the semiconductor switch. The forward converter is also a single switch converter. Since its core size requirements are smaller, it is popular in low/medium (up to several hundreds of watts) power applications. Disadvantages of the forward converter are in a need for demagnetizing winding and in a high voltage stress on the semiconductor switch. The push–pull converter is also used at medium power levels. Due to bidirectional excitation, the transformer size is small. An advantage of the push–pull converter is also a possibility to refer driving terminals of both switches to the ground which greatly simplifies the control circuitry. A disadvantage of the push–pull converter is a potential core saturation in a case of asymmetry. The half-bridge converter has similar range of applications as the push–pull converter. There is no danger of transformer saturation in the half-bridge converter. It requires, however, two additional input capacitors to split in half the input dc source. The full-bridge converter is used at high (several kilowatts) power and voltage levels. The voltage stress on power switches is limited to the input voltage source value. A disadvantage of the full-bridge converter is a high number of semiconductor devices.

The dc–dc converters are building blocks of distributed power supply systems in which a common dc bus voltage is converted to various other voltage according to requirements of particular loads. Such distributed dc systems are common in space stations, ships and airplanes, as well as in computer and telecommunication equipment. It is expected that modern portable wireless communication and signal processing systems will use variable supply voltages to minimize power consumption and extend battery life. Low output voltage converters in these applications utilize the synchronous rectification arrangement.

Another big area of dc–dc converter applications is related to the utility ac grid. For critical loads, if the utility grid fails, there must be a backup source of energy, e.g. a battery pack. This need for continuous power delivery gave rise to various

types of uninterruptible power supplies (UPSs). The dc–dc converters are used in UPSs to adjust the level of a rectified grid voltage to that of the backup source. Since during normal operation, the energy flows from the grid to the backup source and during emergency conditions the backup source must supply the load, bidirectional dc–dc converters are often used. The dc–dc converters are also used in dedicated battery chargers.

Power electronic loads, especially those with front-end rectifiers, pollute the ac grid with odd harmonics. The dc–dc converters are used as intermediate stages, just after a rectifier and before the load-supplying dc–dc converter, for shaping the input ac current to improve power factor and decrease the harmonic content. The boost converter is especially popular in such power factor correction (PFC) applications. Another utility grid related application of dc–dc converters is in interfaces between ac networks and dc renewable energy sources such as fuel cells and photovoltaic arrays.

In isolated dc–dc converters, multiple outputs are possible with additional secondary windings of transformers. Only one output is regulated with a feedback loop. Other outputs depend on the duty ratio of the regulated one and on their loads. A multiple-output dc–dc converter is a convenient solution in application where there is a need for one closely regulated output voltage and for one or more non-critical other output voltage levels.

DC/DC Conversion Technique and Twelve Series Luo-converters

Fang Lin Luo, Ph.D.

School of EEE, Block S1, Nanyang Technological University, Nanyang Avenue, Singapore

Hong Ye, Ph.D.

School of Biological Sciences, Block SBS, Nanyang Technological University, Nanyang Avenue, Singapore

14.1 Introduction

DC/DC converters are widely used in industrial applications and computer hardware circuits. DC/DC conversion technique has been developed very quickly. Since 1920s there have been more than 500 DC/DC converters' topologies developed. Professor Luo and Dr. Ye have systematically sorted them in six generations in 2001. They are the first-generation (classical) converters, second-generation (multi-quadrant) converters, third-generation (switched-component) converters, fourth-generation (soft-switching) converters, fifth-generation (synchronous-rectifier) converters and sixth-generation (multi-element resonant power) converters.

The first-generation converters perform in a single quadrant mode with low power range (up to around 100 W), such as buck converter, boost converter and buck–boost converter. Because of the effects of parasitic elements, the output voltage and power transfer efficiency of all these converters are restricted.

The voltage-lift (VL) technique is a popular method that is widely applied in electronic circuit design. Applying this technique effectively overcomes the effects of parasitic elements and greatly increases the output voltage. Therefore, these DC/DC converters can convert the source voltage into a higher output voltage with high power efficiency, high power density, and a simple structure.

The VL converters have high voltage transfer gains, which increase in arithmetical series stage-by-stage. Super-lift (SL) technique is more powerful to increase the converters voltage transfer gains in geometric series stage-by-stage. Even higher, ultra-lift (UL) technique is most powerful to increase the converters voltage transfer gain.

The second-generation converters perform in two- or four-quadrant operation with medium output power range (say hundreds watts or higher). Because of high power conversion, these converters are usually applied in industrial applications with high power transmission. For example, DC motor drives with multi-quadrant operation. Since most of second-generation converters are still made of capacitors and inductors, they are large.

The third-generation converters are called switched-component DC/DC converters, and made of either inductor or capacitors, which are so-called switched-inductor and switched-capacitors. They usually perform in two- or four-quadrant operation with high output power range (say thousands watts). Since they are made of only inductor or capacitors, they are small.

Switched-capacitor (SC) DC/DC converters are made of only switched-capacitors. Since switched-capacitors can be integrated into power semiconductor integrated circuits (IC) chips, they have limited size and work in high switching frequency. They have been successfully employed in the inductorless DC/DC converters and opened the way to build the converters with high power density. Therefore, they have drawn much attention from the research workers and manufacturers. However, most of these converters in the literature perform single-quadrant operation. Some of them work in the push–pull status. In addition, their control circuit and topologies are very complex, especially, for the large difference between input and output voltages.

Switched-inductor (SI) DC/DC converters are made of only inductor, and have been derived from four-quadrant choppers. They usually perform multi-quadrant operation with very simple structure. The significant advantage of these converters is its simplicity and high power density. No matter how large the difference between the input and output voltages, only one inductor is required for each SI DC/DC converter. Therefore, they are widely required for industrial applications.

The fourth-generation converters are called soft-switching converters. Soft-switching technique involves many methods implementing resonance characteristics. Popular method is resonant-switching. There are three main groups: zero-current-switching (ZCS), zero-voltage-switching (ZVS), and zero-transition (ZT) converters. They usually perform in single quadrant operation in the literature. We have developed this technique in two- and four-quadrant operation with high output power range (say thousands watts).

Multi-quadrant ZCS/ZVS/ZT converters implement ZCS/ZVS technique in four-quadrant operation. Since switches turn on and off at the moment that the current/voltage is equal to zero, the power losses during switching on and off become zero. Consequently, these converters have high power density and transfer efficiency. Usually, the repeating frequency is not very high and the converters work in a mono-resonance frequency, the components of higher order harmonics is very low. Using fast fourier transform (FFT) analysis, we obtain that the total harmonic distortion (THD) is very small. Therefore, the electromagnetic interference (EMI) is weaker, electromagnetic sensitivity (EMS) and electromagnetic compatibility (EMC) are reasonable.

The fifth-generation converters are called synchronous rectifier (SR) DC/DC Converters. Corresponding to the development of the microelectronics and computer science, the power supplies with low output voltage (5 V, 3.3 V, and $1.8 \sim 1.5$ V) and strong output current (30 A, 50 A, 100 A up to 200 A) are widely required in industrial applications and computer peripheral equipment. Traditional diode bridge rectifiers are not available for this requirement. Many prototypes of SR DC/DC converters with soft-switching technique have been developed. The SR DC/DC converters possess the technical feathers with very low voltage and strong current and high power transfer efficiency η (90%, 92% up to 95%) and high power density (22–25 W/in^3).

The sixth-generation converters are called multi-element resonant power converters (RPCs). There are eight topologies of 2-E RPC, 38 topologies of 3-E RPC, and 98 topologies of 4-E RPC. The RPCs have very high current transfer gain, purely harmonic waveform, low power losses and EMI since

they are working in resonant operation. Usually, the sixth-generation RPCs used in large power industrial applications with high output power range (say thousands watts).

The DC/DC converter family tree is shown in Fig. 14.1.

Professor F. L. Luo and Dr. H. Ye have devoted in the subject area of DC/DC conversion technique for a long time and harvested outstanding achievements. They have created **twelve** (12) series converters namely **Luo-converters** and more knowledge which are listed below:

Positive output Luo-converters;

Negative output Luo-converters;

Double output Luo-converters;

Positive/Negative output super-lift Luo-converters;

Ultra-lift Luo-converter;

Multiple-quadrant Luo-converters;

Switched capacitor multi-quadrant Luo-converters;

Multiple-lift push-pull switched-capacitor Luo-converters;

Switched-inductor multi-quadrant Luo-converters;

Multi-quadrant ZCS quasi-resonant Luo-converters;

Multi-quadrant ZVS quasi-resonant Luo-converters;

Synchronous-rectifier DC/DC Luo-converters;

Multi-element resonant power converters;

Energy factor and mathematical modeling for power DC/DC converters.

All of their research achievements have been published in the international top-journals and conferences. Many experts, including Prof. Rashid of West Florida University, Prof. Kassakian of MIT, and Prof. Rahman of Memorial University of Newfoundland are very interested in their work, and acknowledged their outstanding achievements.

In this handbook, we only show the circuit diagram and list a few parameters of each converter for readers, such as the output voltage and current, voltage transfer gain and output voltage variation ratio, and the discontinuous condition and output voltage.

After a well discussion of steady-state operation, we prepare one section to investigate the dynamic transient process of DC/DC converters. Energy storage in DC/DC converters have been paid attention long time ago, but it was not well investigated and defined. Professor Fang Lin Luo and Dr. Hong Ye have theoretically defined it and introduced new parameters: energy storage in DC/DC converters have theoretically defined it and introduced new parameters: energy factor (EF) and other variables. They have also fundamentally established the mathematical modeling and discussed the characteristics of all power DC/DC converters. They have successfully solved the traditional problems.

In this chapter, the input voltage is V_I or V_1 and load voltage is V_O or V_2. Pulse width modulated (PWM) pulse train has repeating frequency f, the repeating period is $T = 1/f$. Conduction duty is k, the switching-on period is kT, and switching-off period is $(1 - k)T$. All average values are in capital letter, and instantaneous values in small letter, e.g. V_1 and $v_1(t)$ or v_1. The variation ratio of the free-wheeling diode's

current is ζ. Voltage transfer gain is M and power transfer efficiency is η.

14.2 Fundamental, Developed, Transformer-type, and Self-lift Converters

The first-generation converters are called classical converters which perform in a single-quadrant mode and in low. Historically, the development of the first generation converters covers very long time. Many prototypes of these converters have been created. We can sort them in six categories:

- Fundamental topologies: buck converter, boost converter, and buck–boost converter.
- Developed topologies: positive output Luo-converter, negative output Luo-converter, double output Luo-converter, Cúk-converter, and single-ended primary inductance converter (SEPIC).
- Transformer-type topologies: forward converter, push–pull converter, fly-back converter, half-bridge converter, bridge converter, and ZETA.
- Voltage-lift topologies: self-lift converters, positive output Luo-converters, negative output Luo-converters, double output Luo-converters.
- Super-lift topologies: positive/negative output super-lift Luo-converters, positive/negative output cascade boost-converters.
- Ultra-lift topologies: ultra-lift Luo-converter.

14.2.1 Fundamental Topologies

Buck converter is a step-down converter, which is shown in Fig. 14.2a, the equivalent circuits during switch-on and -off periods are shown in Figs. 14.2b and c. Its output voltage and output current are

$$V_2 = kV_1 \tag{14.1}$$

and

$$I_2 = \frac{1}{k}I_1 \tag{14.2}$$

This converter may work in discontinuous mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high.

Boost converter is a step-up converter, which is shown in Fig. 14.3a, the equivalent circuits during switch-on and -off periods are shown in Figs. 14.3b and c. Its output voltage and current are

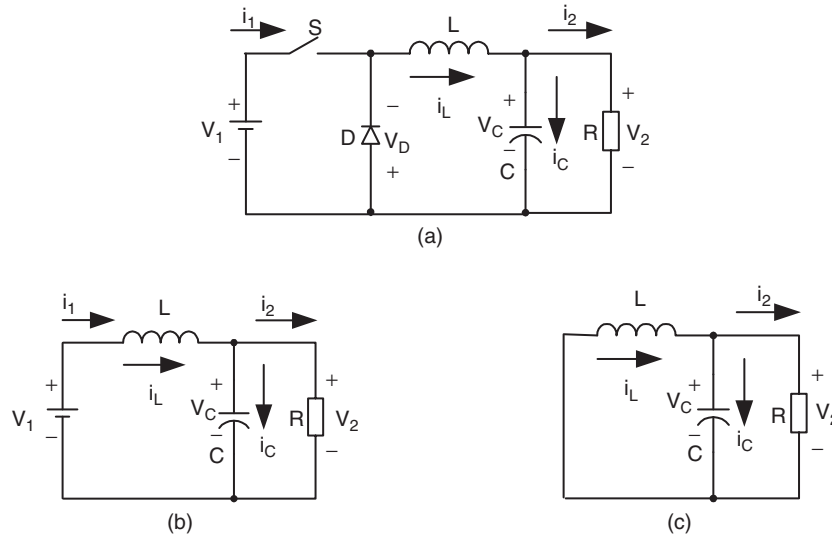
$$V_2 = \frac{1}{1 - k}V_1 \tag{14.3}$$
FIGURE 14.1   DC/DC converter family tree.


FIGURE 14.2   Buck converter: (a) circuit diagram; (b) switch-on equivalent circuit; and (c) switch-off equivalent circuit.
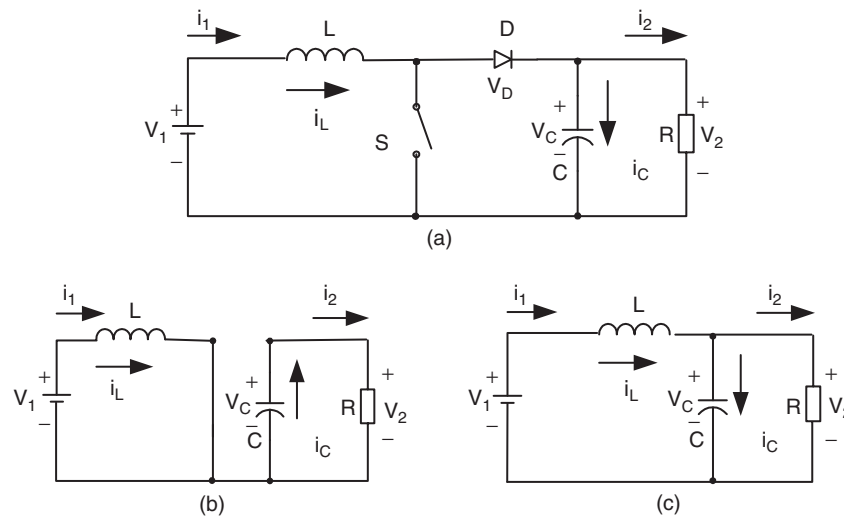

FIGURE 14.3   Boost converter: (a) circuit diagram; (b) switch-on equivalent circuit; and (c) switch-off equivalent circuit.

and

$$I_2 = (1 - k)I_1 \tag{14.4}$$

The output voltage is higher than the input voltage. This converter may work in discontinuous mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high.

Buck–boost converter is a step–down/up converter, which is shown in Fig. 14.4a, the equivalent circuits during switch-on and -off periods are shown in Figs. 14.4b and c. Its output

voltage and current are

$$V_2 = \frac{k}{1 - k} V_1 \tag{14.5}$$

and

$$I_2 = \frac{1 - k}{k} I_1 \tag{14.6}$$

When k is greater than 0.5, the output voltage can be higher than the input voltage. This converter may work in
FIGURE 14.4 Buck-boost converter: (a) circuit diagram; (b) switch-on equivalent circuit; and (c) switch-off equivalent circuit.

discontinuous mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high.

14.2.2 Developed Topologies

For convenient applications, all developed converters have output voltage and current as

$$V_2 = \frac{k}{1 - k} V_1 \tag{14.7}$$

and

$$I_2 = \frac{1 - k}{k} I_1 \tag{14.8}$$

Positive output (P/O) Luo-converter is a step-down/up converter, and is shown in Fig. 14.5. This converter may work in discontinuous mode if the frequency f is small, k is small, and inductance L is small.
FIGURE 14.5 Positive output Luo-converter.
FIGURE 14.6 Negative output Luo-converter.

Negative output (N/O) Luo-converter is shown in Fig. 14.6. This converter may work in discontinuous mode if the frequency f is small, k is small, inductance L is small, and load current is high.

Double output Luo-converter is a double output step-down/up converter, which is derived from **P/O Luo-converter** and **N/O Luo-converter**. It has two conversion paths and two output voltages V_{O+} and V_{O-}. It is shown in Fig. 14.7. If the components are carefully selected the output voltages and currents (concentrate the absolute value) obtained are

$$V_2^+ = |V_2^-| = \frac{k}{1 - k} V_1 \tag{14.9}$$

and

$$I_2^+ = \frac{1 - k}{k} I_1^+ \quad \text{and} \quad I_2^- = \frac{1 - k}{k} I_1^- \tag{14.10}$$

When k is greater than 0.5, the output voltage can be higher than the input voltage. This converter may work in discontinuous mode if the frequency f is small, k is small, inductance L is small, and load current is high.
FIGURE 14.7 Double output Luo-converter.
FIGURE 14.8 Cúk converter.
FIGURE 14.10 Forward converter.

Cúk-converter is a negative output step-down/up converter, which is derived from boost and buck converters. It is shown in Fig. 14.8.

Single-ended primary inductance converter is a positive output step-down/up converter, which is derived from boost converters. It is shown in Fig. 14.9.

FIGURE 14.9 SEPIC.

14.2.3 Transformer-type Topologies

All transformer-type converters have transformer(s) to isolate the input and output voltages. Therefore, it is easy to obtain the high or low output voltage by changing the turns ratio N, the
positive or negative polarity by changing the winding direction, and multiple output voltages by setting multiple secondary windings.

Forward converter is a step-up/down converter, which is shown in Fig. 14.10. The transformer turns ratio is N (usually $N > 1$). If the transformer has never been saturated during operation, it works as a buck converter. The output voltage and current are

$$V_O = kNV_I \tag{14.11}$$

and

$$I_O = \frac{1}{kN}I_I \tag{14.12}$$

This converter may work in discontinuous mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high.

To avoid the saturation of transformer applied in forward converters, a tertiary winding is applied. The corresponding circuit diagram is shown in Fig. 14.11.

To obtain multiple output voltages we can set multiple secondary windings. The corresponding circuit diagram is shown in Fig. 14.12.

FIGURE 14.11 Forward converter with tertiary winding.
FIGURE 14.12 Forward converter with multiple secondary windings.
FIGURE 14.13 Push–pull converter.

Push–pull converter is a step-up/down converter, which is shown in Fig. 14.13. It is not necessary to set the tertiary winding. The transformer turns ratio is N (usually $N > 1$). If the transformer has never been saturated during operation, it works as a buck converter with the conduction duty cycle $k < 0.5$. The output voltage and current are

$$V_O = 2kNV_I \tag{14.13}$$

and

$$I_O = \frac{1}{2kN}I_I \tag{14.14}$$

This converter may work in discontinuous mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high.

Fly-back converter is a high step-up converter, which is shown in Fig. 14.14. The transformer turns ratio is N (usually $N > 1$). It effectively uses the transformer leakage inductance
FIGURE 14.14 Fly-back converter.

in fly-back operation to obtain high surge voltage induced, then get high output voltage. It works likely in buck–boost operation as a buck–boost converter. Its output voltage and current are

$$V_O = \frac{kN}{1-k}V_I \tag{14.15}$$

and

$$I_O = \frac{1-k}{kN}I_I \tag{14.16}$$

Half-bridge converter is a step-up converter, which is shown in Fig. 14.15. There are two switches and one double secondary coils transformer required. The transformer turns ratio is N. It works as a half-bridge rectifier (half of V_1 inputs to primary winding) plus a buck converter circuit in secondary side. The conduction duty cycle k is set in $0.1 < k < 0.5$. Its output voltage and current are

$$V_O = 2kN\frac{V_I}{2} = kNV_I \tag{14.17}$$

and

$$I_O = \frac{1}{kN}I_I \tag{14.18}$$

This converter may work in discontinuous mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high.
FIGURE 14.15 Half-bridge converter.
FIGURE 14.16   Bridge converter.

Bridge converter is a step-up converter, which is shown in Fig. 14.16. There are four switches and one double secondary coils transformer required. The transformer turns ratio is N. It works as a full-bridge rectifier (full V_1 inputs to primary winding) plus a buck-converter circuit in secondary side. The conduction duty cycle k is set in $0.1 < k < 0.5$. Its output voltage and current are

$$V_O = 2kNV_I \qquad (14.19)$$

and

$$I_O = \frac{1}{2kN}I_I \qquad (14.20)$$

ZETA (zeta) converter is a step-up converter, which is shown in Fig. 14.17. The transformer turns ratio is N. The transformer functions as a inductor (L_1) plus a buck–boost converter plus a low-pass filter (L_2–C_2). Its output voltage and current are

$$V_O = \frac{k}{1-k}NV_I \qquad (14.21)$$

and

$$I_O = \frac{1-k}{kN}I_I \qquad (14.22)$$
FIGURE 14.17   ZETA (zeta) converter.

14.2.4 Seven (7) Self-lift DC/DC Converters

Because of the effect of the parasitic elements, the voltage conversion gain is limited. Especially, when the conduction duty k is towards unity, the output voltage is sharply reduced.

Voltage-lift technique is a popular method used in electronic circuit design. Applying this technique can effectively overcome the effect of the parasitic elements, and largely increase the voltage transfer gain. In this section, we introduce seven self-lift converters which are working in continuous mode.

- Positive output (P/O) self-lift Luo-converter;
- Reverse P/O self-lift Luo-converter;
- Negative output (N/O) self-lift Luo-converter;
- Reverse N/O self-lift Luo-converter;
- Self-lift Cúk-converter;
- Self-lift SEPIC;
- Enhanced self-lift Luo-converter.

All self-lift converters (except enhanced self-lift circuit) have the output voltage and current to be

$$V_O = \frac{1}{1-k}V_I \qquad (14.23)$$

and

$$I_O = (1-k)I_I \qquad (14.24)$$

The voltage transfer gain in continuous mode is

$$M_S = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{1}{1-k} \qquad (14.25)$$

P/O self-lift Luo-converter is shown in Fig. 14.18. The variation ratio of the output voltage v_O in continuous conduction mode (CCM) is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{8M_S}\frac{1}{f^2C_OL_2} \qquad (14.26)$$

Reverse P/O self-lift Luo-converter is shown in Fig. 14.19. The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{16M_S}\frac{1}{f^2C_OL_2} \qquad (14.27)$$
FIGURE 14.18   P/O self-lift Luo-converter.
FIGURE 14.19   Reverse P/O self-lift Luo-converter.
FIGURE 14.20   N/O self-lift Luo-converter.

N/O self-lift Luo-converter is shown in Fig. 14.20. The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 L_O C_1 C_O R} \qquad (14.28a)$$

Reverse N/O self-lift Luo-converter is shown in Fig. 14.21. The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 L_O C_1 C_O R} \qquad (14.28b)$$

Self-lift Cúk-converter is shown in Fig. 14.22. The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 L_O C_1 C_O R} \qquad (14.28c)$$
FIGURE 14.21   Reverse N/O self-lift Luo-converter.
FIGURE 14.22   Self-lift Cúk-converter.
FIGURE 14.23   Self-lift SEPIC.

Self-lift SEPIC is shown in Fig. 14.23. The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 L_O C_1 C_O R} \qquad (14.28d)$$

Enhanced self-lift Luo-converter is shown in Fig. 14.24. Its output voltage and current are

$$V_O = \frac{2-k}{1-k} V_I \qquad (14.29)$$

and

$$I_O = \frac{1-k}{2-k} I_I \qquad (14.30)$$

The voltage transfer gain in continuous mode is

$$M_S = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{1}{1-k} + 1 = \frac{2-k}{1-k} \qquad (14.31)$$
FIGURE 14.24   Enhanced self-lift Luo-converter.

TABLE 14.1   The circuit diagrams of the tapped inductor fundamental converters

	Standard converter	Switch tap	Diode to tap	Rail to tap
Buck				
Boost				
Buck–Boost				
The variation ratio of the output voltage v_O in CCM is as in Eq. (14.26)

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{8M_S} \frac{1}{f^2 C_O L_2}$$

14.2.5 Tapped Inductor (Watkins–Johnson) Converters

Tapped inductor (Watkins–Johnson) converters have been derived from fundamental converters, which circuit diagrams are shown in Table 14.1. The voltage transfer gains are shown in Table 14.2. Here the tapped inductor ratio is $n = n1/(n1 + n2)$.

14.3 Voltage-lift Luo-converters

Voltage-lift (**VL**) technique is very popular for electronic circuit design. Professor Luo and Dr. Ye have successfully applied this technique in the design of DC/DC converters, and created a

Buck–Boost	$\dfrac{k}{1-k}$	$\dfrac{k}{n(1-k)}$	$\dfrac{nk}{1-k}$	$\dfrac{k}{1-k}$

number of up-to-date converters. There are three series of Luo-converters introduced in this section:

- Positive output Luo-converters;
- Simplified positive output Luo-converters;
- Negative output Luo-converters.

14.3.1 Positive Output Luo-converters

Positive output (P/O) Luo-converters perform the voltage conversion from positive to positive voltages using the voltage lift technique. They work in the first-quadrant with large voltage amplification. Their voltage transfer gains are high. Five circuits are introduced in the literature. They are:

- Elementary circuit;
- Self-lift circuit;
- Re-lift circuit;
- Triple-lift circuit;
- Quadruple-lift circuit.

Further lift circuits can be derived from the above circuits. In all P/O Luo-Converters, we define normalized inductance $L = L_1 L_2/(L_1 + L_2)$ and normalized impedance $z_N = R/fL$.

P/O Luo-converter elementary circuit is shown in Fig. 14.25a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.25b and c. Its output voltage and current are

$$V_O = \frac{k}{1-k} V_I$$

and

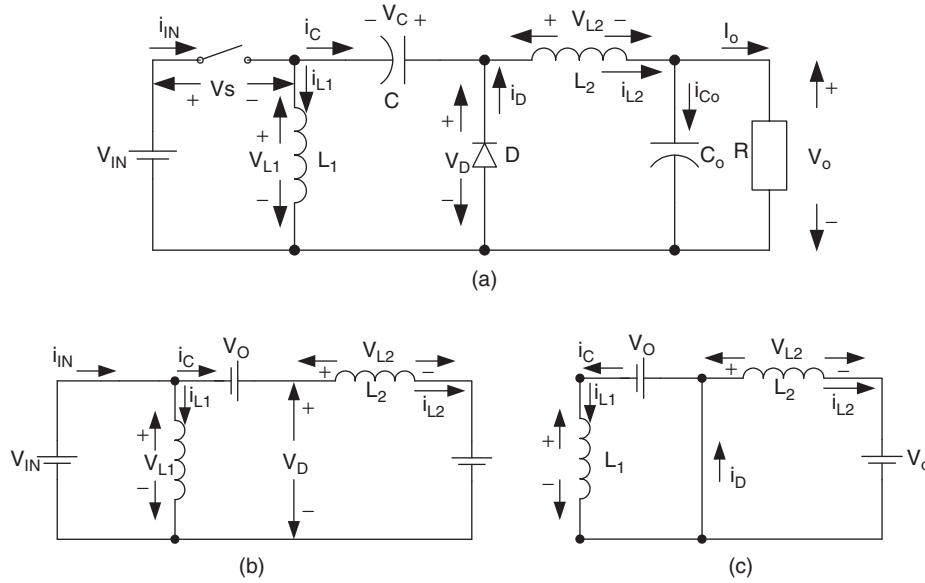
$$I_O = \frac{1-k}{k} I_I$$


FIGURE 14.25   P/O Luo-converter elementary circuit; (a) circuit diagram; (b) switch on; and (c) switch off.

The voltage transfer gain in continuous mode is

$$M_E = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{k}{1-k} \qquad (14.32)$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{16M_E} \frac{1}{f^2 C_O L_2} \qquad (14.33)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for discontinuous conduction mode (DCM) is

$$M_E \le k\sqrt{\frac{z_N}{2}} \qquad (14.34)$$

The output voltage in DCM is

$$V_O = k(1-k)\frac{R}{2fL}V_I \quad \text{with} \quad \sqrt{\frac{R}{2fL}} \ge \frac{1}{1-k} \qquad (14.35)$$

P/O Luo-converter self-lift circuit is shown in Fig. 14.26a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.26b and c. Its output voltage and current are

$$V_O = \frac{1}{1-k}V_I$$

and

$$I_O = (1-k)I_I$$

The voltage transfer gain in continuous mode is

$$M_S = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{1}{1-k} \qquad (14.36)$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{16M_S} \frac{1}{f^2 C_O L_2} \qquad (14.37)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_S \le \sqrt{k}\sqrt{\frac{z_N}{2}} \qquad (14.38)$$

The output voltage in DCM is

$$V_O = \left[1 + k^2(1-k)\frac{R}{2fL}\right]V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{R}{2fL}} \ge \frac{1}{1-k} \qquad (14.39)$$

P/O Luo-converter re-lift circuit is shown in Fig. 14.27a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.27b and c. Its output voltage and current are

$$V_O = \frac{2}{1-k}V_I$$
FIGURE 14.26   P/O Luo-converter self-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.
FIGURE 14.27   P/O Luo-converter re-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

and

$$I_O = \frac{1-k}{2} I_I$$

The voltage transfer gain in CCM is

$$M_R = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{2}{1-k} \quad (14.40)$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{16M_R} \frac{1}{f^2 C_O L_2} \quad (14.41)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_R \leq \sqrt{k z_N} \quad (14.42)$$

The output voltage in DCM is

$$V_O = \left[2 + k^2(1-k)\frac{R}{2fL}\right] V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{R}{fL}} \geq \frac{2}{1-k} \quad (14.43)$$

P/O Luo-converter triple-lift circuit is shown in Fig. 14.28a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.28b and c. Its output voltage and current are

$$V_O = \frac{3}{1-k} V_I$$

and

$$I_O = \frac{1-k}{3} I_I$$

The voltage transfer gain in CCM is

$$M_T = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{3}{1-k} \quad (14.44)$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{16M_T} \frac{1}{f^2 C_O L_2} \quad (14.45)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is
FIGURE 14.28 P/O Luo-converter triple-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

$$M_T \leq \sqrt{\frac{3kz_N}{2}} \qquad (14.46)$$

The output voltage in DCM is

$$V_O = \left[3 + k^2(1-k)\frac{R}{2fL}\right]V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{3R}{2fL}} \geq \frac{3}{1-k} \qquad (14.47)$$

P/O Luo-converter quadruple-lift circuit is shown in Fig. 14.29a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.29b and c. Its output voltage and current are

$$V_O = \frac{4}{1-k}V_I$$

and

$$I_O = \frac{1-k}{4}I_I$$

The voltage transfer gain in CCM is

$$M_Q = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{4}{1-k} \qquad (14.48)$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{16M_Q}\frac{1}{f^2 C_O L_2} \qquad (14.49)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_Q \leq \sqrt{2kz_N} \qquad (14.50)$$

The output voltage in DCM is

$$V_O = \left[4 + k^2(1-k)\frac{R}{2fL}\right]V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{2R}{fL}} \geq \frac{4}{1-k} \qquad (14.51)$$

Summary for all P/O Luo-converters:

$$M = \frac{V_O}{V_I} = \frac{I_I}{I_O}; \quad L = \frac{L_1 L_2}{L_1 + L_2}; \quad z_N = \frac{R}{fL}; \quad R = \frac{V_O}{I_O}$$

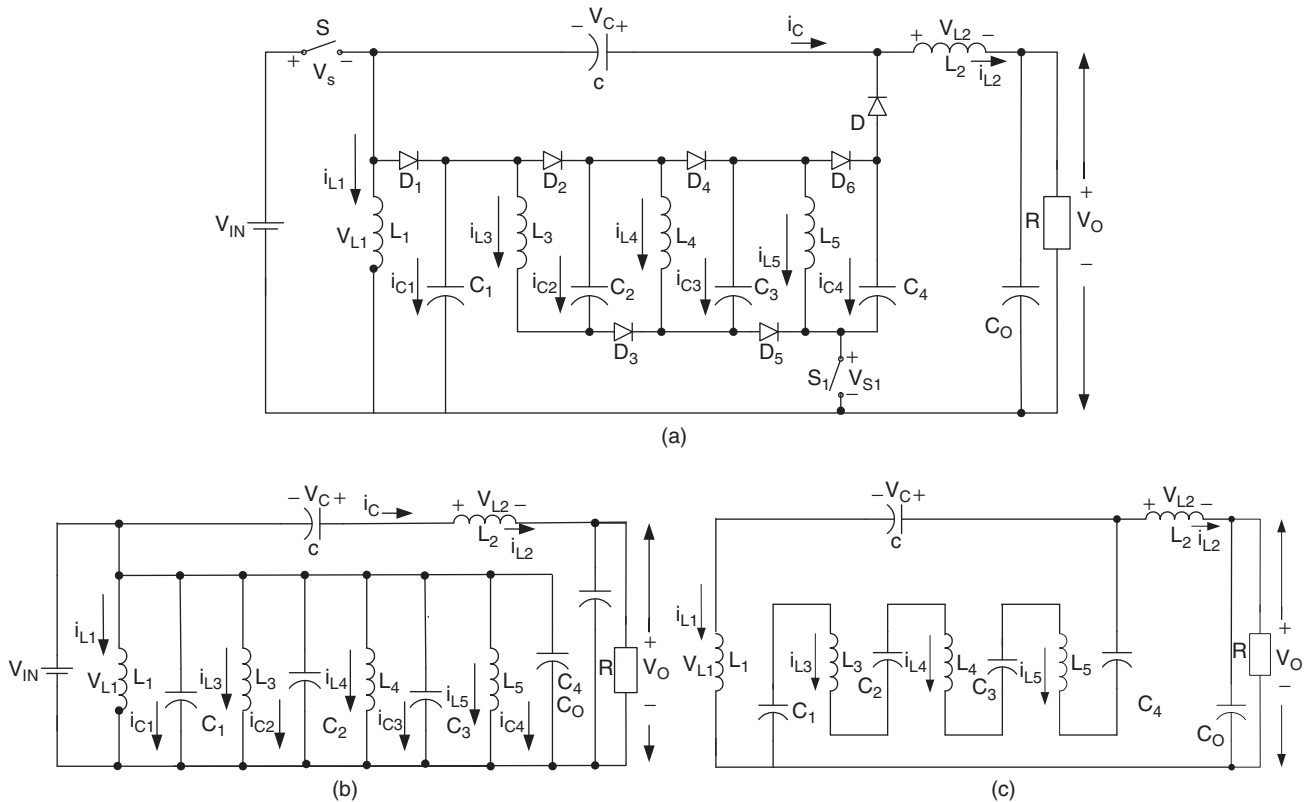
To write common formulas for all circuits parameters, we define that subscript $j = 0$ for the elementary circuit, $j = 1$


FIGURE 14.29 P/O Luo-converter quadruple-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

for the self-lift circuit, $j = 2$ for the re-lift circuit, $j = 3$ for the triple-lift circuit, $j = 4$ for the quadruple-lift circuit, and so on. The voltage transfer gain is

$$M_j = \frac{k^{h(j)}[j + h(j)]}{1 - k} \qquad (14.52)$$

The variation ratio of the output voltage is

$$\varepsilon_j = \frac{\Delta v_O/2}{V_O} = \frac{k}{16M_j} \frac{1}{f^2 C_O L_2} \qquad (14.53)$$

The condition for discontinuous conduction mode is

$$\frac{k^{[1+h(j)]}}{M_j^2} \frac{j + h(j)}{2} z_N \geq 1 \qquad (14.54)$$

The output voltage in discontinuous conduction mode is

$$V_{O-j} = \left\{ j + k^{[2-h(j)]} \frac{1 - k}{2} z_N \right\} V_I \qquad (14.55)$$

where

$$h(j) = \begin{cases} 0 & if \quad j \geq 1 \\ 1 & if \quad j = 0 \end{cases} \qquad (14.56)$$

is the **Hong** function.

14.3.2 Simplified Positive Output (S P/O) Luo-converters

Carefully check P/O Luo-converters, we can see that there are two switches required from re-lift circuit. In order to use only one switch in all P/O Luo-converters, we modify the circuits. In this section we introduce following four circuits:

- Simplified self-lift circuit;
- Simplified re-lift circuit;
- Simplified triple-lift circuit;
- Simplified quadruple-lift circuit.

Further lift circuits can be derived from the above circuits. In all S P/O Luo-converters, we define normalized impedance $z_N = R/fL$.

S P/O Luo-converter self-lift circuit is shown in Fig. 14.30a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.30b and c. Its output voltage and current are

$$V_O = \frac{1}{1 - k} V_I$$

and

$$I_O = (1 - k)I_I$$

The voltage transfer gain in CCM is

$$M_S = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{1}{1 - k} \qquad (14.57)$$
FIGURE 14.30   S P/O Luo-converter self-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 L_O C_1 C_O R} \qquad (14.58)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_S \le \sqrt{k}\sqrt{\frac{z_N}{2}} \qquad (14.59)$$

The output voltage in DCM is

$$V_O = \left[1 + k^2(1-k)\frac{R}{2fL}\right] V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{R}{2fL}} \ge \frac{1}{1-k} \qquad (14.60)$$

S P/O Luo-converter re-lift circuit is shown in Fig. 14.31a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.31b and c. Its output voltage and current are

$$V_O = \frac{2}{1-k} V_I$$

and

$$I_O = \frac{1-k}{2} I_I$$

The voltage transfer gain in CCM is

$$M_R = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{2}{1-k} \qquad (14.61)$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 L_O C_1 C_O R} \qquad (14.62)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_R \le \sqrt{k z_N} \qquad (14.63)$$

The output voltage in DCM is

$$V_O = \left[2 + k^2(1-k)\frac{R}{2fL}\right] V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{R}{fL}} \ge \frac{2}{1-k} \qquad (14.64)$$

S P/O Luo triple-lift circuit is shown in Fig. 14.32a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.32b and c. Its output voltage and current are

$$V_O = \frac{3}{1-k} V_I$$
FIGURE 14.31 S P/O Luo-converter re-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.
FIGURE 14.32 S P/O Luo-converter triple-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

and

$$I_O = \frac{1-k}{3}I_I$$

The voltage transfer gain in CCM is

$$M_T = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{3}{1-k} \qquad (14.65)$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 L_O C_1 C_O R} \qquad (14.66)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_T \le \sqrt{\frac{3kz_N}{2}} \qquad (14.67)$$

The output voltage in DCM is

$$V_O = \left[3 + k^2(1-k)\frac{R}{2fL}\right]V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{3R}{2fL}} \ge \frac{3}{1-k} \qquad (14.68)$$

S P/O Luo quadruple-lift circuit is shown in Fig. 14.33a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.33b and c. Its output voltage and current are

$$V_O = \frac{4}{1-k}V_I$$

and

$$I_O = \frac{1-k}{4}I_I$$

The voltage transfer gain in CCM is

$$M_Q = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{4}{1-k} \qquad (14.69)$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 L_O C_1 C_O R} \qquad (14.70)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_Q \le \sqrt{2kz_N} \qquad (14.71)$$

FIGURE 14.33 S P/O Luo-converter quadruple-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

The output voltage in DCM is

$$V_O = \left[4 + k^2(1-k)\frac{R}{2fL} \right] V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{2R}{fL}} \geq \frac{4}{1-k} \tag{14.72}$$

Summary for all S P/O Luo-converters:

$$M = \frac{V_O}{V_I} = \frac{I_I}{I_O}; \quad z_N = \frac{R}{fL}; \quad R = \frac{V_O}{I_O}$$

To write common formulas for all circuits parameters, we define that subscript $j = 1$ for the self-lift circuit, $j = 2$ for the re-lift circuit, $j = 3$ for the triple-lift circuit, $j = 4$ for the quadruple-lift circuit, and so on. The voltage transfer gain is

$$M_j = \frac{j}{1-k} \tag{14.73}$$

The variation ratio of the output voltage is

$$\varepsilon_j = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 L_O C_1 C_O R} \tag{14.74}$$

The condition for discontinuous mode is

$$M_j \leq \sqrt{\frac{jkz_N}{2}} \tag{14.75}$$

The output voltage in discontinuous mode is

$$V_{O-j} = \left[j + k^2(1-k)\frac{z_N}{2} \right] V_I \tag{14.76}$$

14.3.3 Negative Output Luo-converters

Negative output (N/O) Luo-converters perform the voltage conversion from positive to negative voltages using the voltage-lift technique. They work in the third-quadrant with large voltage amplification. Their voltage transfer gains are high. Five circuits are introduced in the literature. They are:

- Elementary circuit;
- Self-lift circuit;
- Re-lift circuit;
- Triple-lift circuit;
- Quadruple-lift circuit.

Further lift circuits can be derived from above circuits. In all N/O Luo-converters, we define normalized impedance $z_N = R/fL$.

N/O Luo-converter elementary circuit is shown in Fig. 14.34a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.34b and c. Its output voltage and current (the absolute value) are

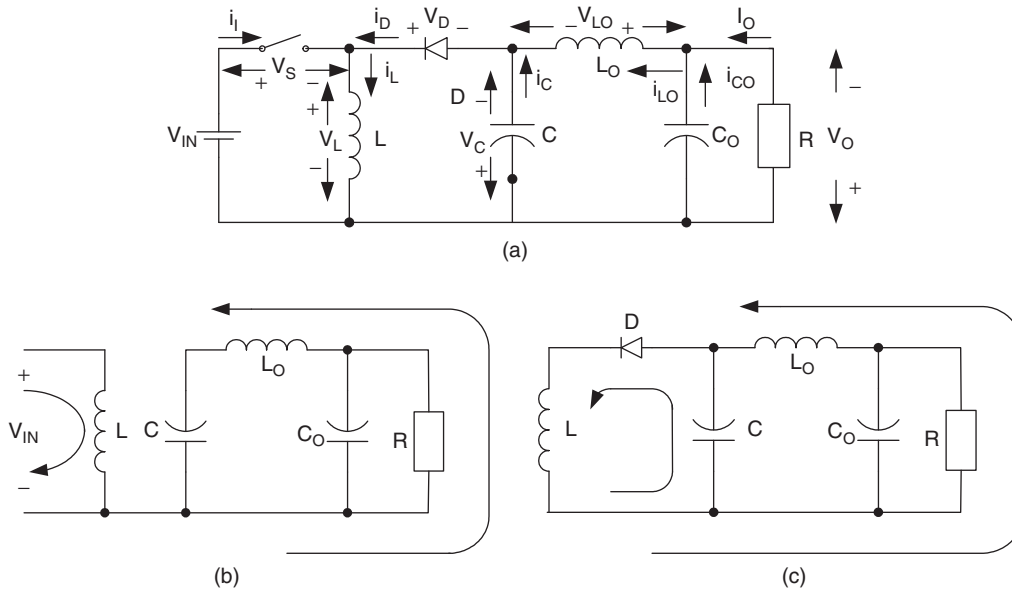
$$V_O = \frac{k}{1-k} V_I$$


FIGURE 14.34 N/O Luo-converter elementary circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

and

$$I_O = \frac{1-k}{k}I_I$$

When k is greater than 0.5, the output voltage can be higher than the input voltage.

The voltage transfer gain in CCM is

$$M_E = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{k}{1-k} \qquad (14.77)$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128}\frac{1}{f^3 CC_O L_O R} \qquad (14.78)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_E \leq k\sqrt{\frac{z_N}{2}} \qquad (14.79)$$

The output voltage in DCM is

$$V_O = k(1-k)\frac{R}{2fL}V_I \quad \text{with} \quad \sqrt{\frac{R}{2fL}} \geq \frac{1}{1-k} \qquad (14.80)$$

N/O Luo-converter self-lift circuit is shown in Fig. 14.35a. The equivalent circuits during switch-on and -off periods are

shown in Figs. 14.35b and c. Its output voltage and current (the absolute value) are

$$V_O = \frac{1}{1-k}V_I$$

and

$$I_O = (1-k)I_I$$

The voltage transfer gain in CCM is

$$M_S = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{1}{1-k} \qquad (14.81)$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128}\frac{1}{f^3 CC_O L_O R} \qquad (14.82)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_S \leq \sqrt{k}\sqrt{\frac{z_N}{2}} \qquad (14.83)$$

The output voltage in DCM is

$$V_O = \left[1 + k^2(1-k)\frac{R}{2fL}\right]V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{R}{2fL}} \geq \frac{1}{1-k} \qquad (14.84)$$
FIGURE 14.35 N/O Luo-converter self-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

N/O Luo-converter re-lift circuit is shown in Fig. 14.36a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.36b and c. Its output voltage and current (the absolute value) are

$$V_O = \frac{2}{1-k} V_I$$

and

$$I_O = \frac{1-k}{2} I_I$$

The voltage transfer gain in CCM is

$$M_R = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{2}{1-k} \tag{14.85}$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 C C_O L_O R} \tag{14.86}$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_R \le \sqrt{k z_N} \tag{14.87}$$

The output voltage in DCM is

$$V_O = \left[2 + k^2(1-k)\frac{R}{2fL} \right] V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{R}{fL}} \ge \frac{2}{1-k} \tag{14.88}$$

N/O Luo-converter triple-lift circuit is shown in Fig. 14.37a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.37b and c. Its output voltage and current (the absolute value) are

$$V_O = \frac{3}{1-k} V_I$$

and

$$I_O = \frac{1-k}{3} I_I$$

The voltage transfer gain in CCM is

$$M_T = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{3}{1-k} \tag{14.89}$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 C C_O L_O R} \tag{14.90}$$

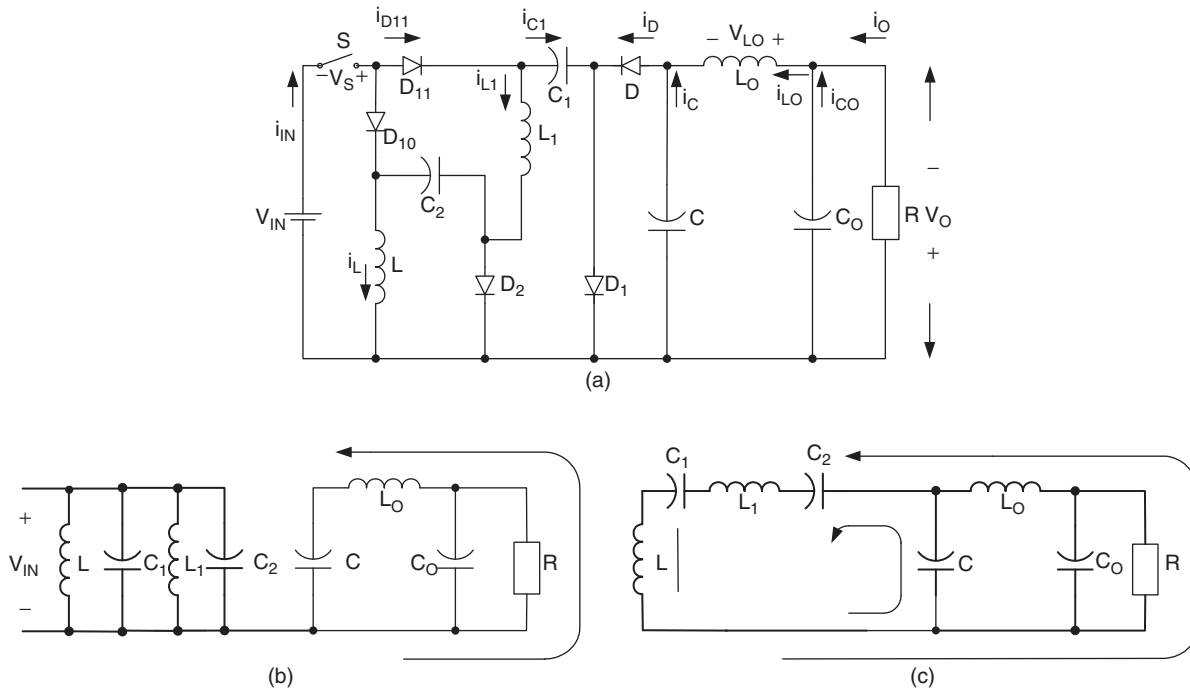
This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small,


FIGURE 14.36   N/O Luo-converter re-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.
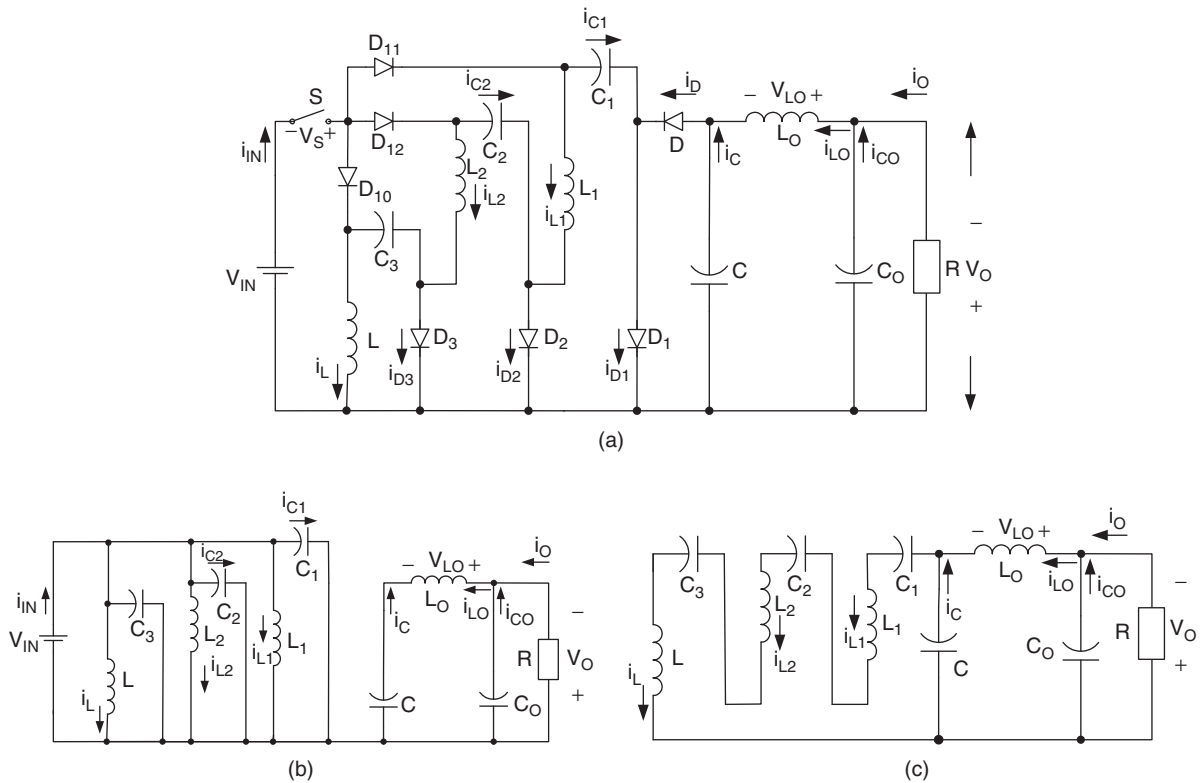

FIGURE 14.37   N/O Luo-converter triple-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

inductance L is small, and load current is high. The condition for DCM is

$$M_T \leq \sqrt{\frac{3kz_N}{2}} \tag{14.91}$$

The output voltage in DCM is

$$V_O = \left[3 + k^2(1-k)\frac{R}{2fL}\right] V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{3R}{2fL}} \geq \frac{3}{1-k} \tag{14.92}$$

N/O Luo-converter quadruple-lift circuit is shown in Fig. 14.38a. The equivalent circuits during switch-on and -off periods are shown in Figs. 14.38b and c. Its output voltage and current (the absolute value) are

$$V_O = \frac{4}{1-k} V_I$$

and

$$I_O = \frac{1-k}{4} I_I$$

The voltage transfer gain in CCM is

$$M_Q = \frac{V_O}{V_I} = \frac{I_I}{I_O} = \frac{4}{1-k} \tag{14.93}$$

The variation ratio of the output voltage v_O in CCM is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 CC_O L_O R} \tag{14.94}$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_Q \leq \sqrt{2kz_N} \tag{14.95}$$

The output voltage in DCM is

$$V_O = \left[4 + k^2(1-k)\frac{R}{2fL}\right] V_I \quad \text{with} \quad \sqrt{k}\sqrt{\frac{2R}{fL}} \geq \frac{4}{1-k} \tag{14.96}$$
FIGURE 14.38   N/O Luo-converter quadruple-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

Summary for all N/O Luo-converters:

$$M = \frac{V_O}{V_I} = \frac{I_I}{I_O}; \quad z_N = \frac{R}{fL}; \quad R = \frac{V_O}{I_O}$$

To write common formulas for all circuits parameters, we define that subscript $j = 0$ for the elementary circuit, $j = 1$ for the self-lift circuit, $j = 2$ for the re-lift circuit, $j = 3$ for the triple-lift circuit, $j = 4$ for the quadruple-lift circuit, and so on. The voltage transfer gain is

$$M_j = \frac{k^{h(j)}[j + h(j)]}{1 - k} \tag{14.97}$$

The variation ratio of the output voltage is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{128} \frac{1}{f^3 C C_O L_O R} \tag{14.98}$$

The condition for discontinuous conduction mode is

$$\frac{k^{[1+h(j)]}}{M_j^2} \frac{j + h(j)}{2} z_N \geq 1 \tag{14.99}$$

The output voltage in discontinuous conduction mode is

$$V_{O-j} = \left\{ j + k^{[2-h(j)]} \frac{1 - k}{2} z_N \right\} V_I \tag{14.100}$$

where

$$h(j) = \begin{cases} 0 & if \quad j \geq 1 \\ 1 & if \quad j = 0 \end{cases}$$

is the **Hong** function.

14.4 Double Output Luo-converters

Double output (D/O) Luo-converters perform the voltage conversion from positive to positive and negative voltages simultaneously using the voltage-lift technique. They work in the first- and third-quadrants with high voltage transfer gain. There are five circuits introduced in this section:

- D/O Luo-converter elementary circuit;
- D/O Luo-converter self-lift circuit;
- D/O Luo-converter re-lift circuit;
- D/O Luo-converter triple-lift circuit;
- D/O Luo-converter quadruple-lift circuit.

Further lift circuits can be derived from above circuits. In all D/O Luo-converters, each circuit has two conversion paths – positive conversion path and negative conversion path. The positive path likes P/O Luo-converters, and the negative path likes N/O Luo-converters. We define normalized impedance $z_{N+} = R/fL$ for positive path, and normalized impedance $z_{N-} = R_1/fL_{11}$. We usually purposely select $R = R_1$ and $L = L_{11}$, so that we have $z_N = z_{N+} = z_{N-}$.

D/O Luo-converter elementary circuit is shown in Fig. 14.7. Its output voltages and currents (absolute values) are

$$V_{O+} = |V_{O-}| = \frac{k}{1 - k} V_I$$

$$I_{O+} = \frac{1 - k}{k} I_{I+}$$

and

$$I_{O-} = \frac{1 - k}{k} I_{I-}$$

When k is greater than 0.5, the output voltage can be higher than the input voltage.

The voltage transfer gain in CCM is

$$M_E = \frac{V_{O+}}{V_I} = \frac{|V_{O-}|}{V_I} = \frac{k}{1 - k} \tag{14.101}$$

The variation ratio of the output voltage v_{O+} in CCM is

$$\varepsilon_+ = \frac{\Delta v_{O+}/2}{V_{O+}} = \frac{k}{16 M_E} \frac{1}{f^2 C_O L_2} \tag{14.102}$$

The variation ratio of the output voltage v_{O-} in CCM is

$$\varepsilon_- = \frac{\Delta v_{O-}/2}{V_{O-}} = \frac{k}{128} \frac{1}{f^3 C_{11} C_{10} L_{12} R_1} \tag{14.103}$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_E \leq k\sqrt{\frac{z_N}{2}} \tag{14.104}$$

The output voltages in DCM are

$$V_O = V_{O+} = |V_{O-}| = k(1 - k)\frac{z_N}{2} V_I \quad with \quad \sqrt{\frac{z_N}{2}} \geq \frac{1}{1 - k} \tag{14.105}$$
FIGURE 14.39 Double output Luo-converter self-lift circuit.

D/O Luo-converter self-lift circuit is shown in Fig. 14.39. Its output voltages and currents (absolute values) are

$$V_{O+} = |V_{O-}| = \frac{1}{1-k} V_I$$

$$I_{O+} = (1-k)I_{I+}$$

and

$$I_{O-} = (1-k)I_{I-}$$

The voltage transfer gain in CCM is

$$M_S = \frac{V_{O+}}{V_I} = \frac{|V_{O-}|}{V_I} = \frac{1}{1-k} \tag{14.106}$$

The variation ratio of the output voltage v_{O+} in CCM is

$$\varepsilon_+ = \frac{\Delta v_{O+}/2}{V_{O+}} = \frac{k}{128} \frac{1}{f^3 L_2 C_O C_2 R} \tag{14.107}$$

The variation ratio of the output voltage v_{O-} in CCM is

$$\varepsilon_- = \frac{\Delta v_{O-}/2}{V_{O-}} = \frac{k}{128} \frac{1}{f^3 C_{11} C_{10} L_{12} R_1} \tag{14.108}$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_S \leq \sqrt{k} \sqrt{\frac{z_N}{2}} \tag{14.109}$$

The output voltages in DCM are

$$V_O = V_{O+} = |V_{O-}| = \left[1 + k^2(1-k)\frac{z_N}{2}\right] V_I$$

$$\text{with} \quad \sqrt{\frac{kz_N}{2}} \geq \frac{1}{1-k} \tag{14.110}$$

D/O Luo-converter re-lift circuit is shown in Fig. 14.40. Its output voltages and currents (absolute values) are

$$V_{O+} = |V_{O-}| = \frac{2}{1-k} V_I$$

$$I_{O+} = \frac{1-k}{2} I_{I+}$$

and

$$I_{O-} = \frac{1-k}{2} I_{I-}$$

The voltage transfer gain in CCM is

$$M_R = \frac{V_{O+}}{V_I} = \frac{|V_{O-}|}{V_I} = \frac{2}{1-k} \tag{14.111}$$

The variation ratio of the output voltage v_{O+} in CCM is

$$\varepsilon_+ = \frac{\Delta v_{O+}/2}{V_{O+}} = \frac{k}{128} \frac{1}{f^3 L_2 C_O C_2 R} \tag{14.112}$$

The variation ratio of the output voltage v_{O-} in CCM is

$$\varepsilon_- = \frac{\Delta v_{O-}/2}{V_{O-}} = \frac{k}{128} \frac{1}{f^3 C_{11} C_{10} L_{12} R_1} \tag{14.113}$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small,
FIGURE 14.40   D/O Luo-converter re-lift circuit.

inductance L is small, and load current is high. The condition for DCM is

$$M_R \leq \sqrt{k z_N} \qquad (14.114)$$

The output voltages in DCM are

$$V_O = V_{O+} = |V_{O-}| = \left[2 + k^2(1-k)\frac{z_N}{2}\right]V_I$$

with $\sqrt{k z_N} \geq \dfrac{2}{1-k}$ (14.115)

D/O Luo-converter triple-lift circuit is shown in Fig. 14.41. Its output voltages and currents (absolute values) are

$$V_{O+} = |V_{O-}| = \frac{3}{1-k}V_I$$

$$I_{O+} = \frac{1-k}{3}I_{I+}$$

and

$$I_{O-} = \frac{1-k}{3}I_{I-}$$
FIGURE 14.41   D/O Luo-converter triple-lift circuit.
FIGURE 14.42 D/O Luo-converter quadruple-lift circuit.

The voltage transfer gain in CCM is

$$M_T = \frac{V_{O+}}{V_I} = \frac{|V_{O-}|}{V_I} = \frac{3}{1-k} \qquad (14.116)$$

The variation ratio of the output voltage v_{O+} in CCM is

$$\varepsilon_+ = \frac{\Delta v_{O+}/2}{V_{O+}} = \frac{k}{128} \frac{1}{f^3 L_2 C_O C_2 R} \qquad (14.117)$$

The variation ratio of the output voltage v_{O-} in CCM is

$$\varepsilon_- = \frac{\Delta v_{O-}/2}{V_{O-}} = \frac{k}{128} \frac{1}{f^3 C_{11} C_{10} L_{12} R_1} \qquad (14.118)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small, inductance L is small, and load current is high. The condition for DCM is

$$M_T \leq \sqrt{\frac{3kz_N}{2}} \qquad (14.119)$$

The output voltages in DCM are

$$V_O = V_{O+} = |V_{O-}| = \left[3 + k^2(1-k)\frac{z_N}{2}\right] V_I$$

with $\quad \sqrt{\dfrac{3kz_N}{2}} \geq \dfrac{3}{1-k} \qquad (14.120)$

D/O Luo-converter quadruple-lift circuit is shown in Fig. 14.42. Its output voltages (absolute values) are

$$V_{O+} = |V_{O-}| = \frac{4}{1-k} V_I$$

$$I_{O+} = \frac{1-k}{4} I_{I+}$$

and

$$I_{O-} = \frac{1-k}{4} I_{I-}$$

The voltage transfer gain in CCM is

$$M_Q = \frac{V_{O+}}{V_I} = \frac{|V_{O-}|}{V_I} = \frac{4}{1-k} \qquad (14.121)$$

The variation ratio of the output voltage v_{O+} in CCM is

$$\varepsilon_+ = \frac{\Delta v_{O+}/2}{V_{O+}} = \frac{k}{128} \frac{1}{f^3 L_2 C_O C_2 R} \qquad (14.122)$$

The variation ratio of the output voltage v_{O-} in CCM is

$$\varepsilon_- = \frac{\Delta v_{O-}/2}{V_{O-}} = \frac{k}{128} \frac{1}{f^3 C_{11} C_{10} L_{12} R_1} \qquad (14.123)$$

This converter may work in discontinuous conduction mode if the frequency f is small, conduction duty k is small,

inductance L is small, and load current is high. The condition for DCM is

$$M_Q \leq \sqrt{2kz_N} \qquad (14.124)$$

The output voltages in DCM are

$$V_O = V_{O+} = |V_{O-}| = \left[4 + k^2(1 - k)\frac{z_N}{2}\right] V_I$$

$$\text{with} \quad \sqrt{2kz_N} \geq \frac{4}{1 - k} \qquad (14.125)$$

Summary for all D/O Luo-converters:

$$M = \frac{V_{O+}}{V_I} = \frac{|V_{O-}|}{V_I}; \quad L = \frac{L_1 L_2}{L_1 + L_2}; \quad L = L_{11}; \quad R = R_1;$$

$$z_{N+} = \frac{R}{fL}; \quad z_{N-} = \frac{R_1}{fL_{11}}$$

so that

$$z_N = z_{N+} = z_{N-}$$

To write common formulas for all circuits parameters, we define that subscript $j = 0$ for the elementary circuit, $j = 1$ for the self-lift circuit, $j = 2$ for the re-lift circuit, $j = 3$ for the triple-lift circuit, $j = 4$ for the quadruple-lift circuit, and so on. The voltage transfer gain is

$$M_j = \frac{k^{h(j)}[j + h(j)]}{1 - k} \qquad (14.126)$$

The variation ratio of the output voltage v_{O+} in CCM is

$$\varepsilon_{+j} = \frac{\Delta v_{O+}/2}{V_{O+}} = \frac{k}{128} \frac{1}{f^3 L_2 C_O C_2 R} \qquad (14.127)$$

The variation ratio of the output voltage v_{O-} in CCM is

$$\varepsilon_{-j} = \frac{\Delta v_{O-}/2}{V_{O-}} = \frac{k}{128} \frac{1}{f^3 C_{11} C_{10} L_{12} R_1} \qquad (14.128)$$

The condition for DCM is

$$\frac{k^{[1+h(j)]}}{M_j^2} \frac{j + h(j)}{2} z_N \geq 1 \qquad (14.129)$$

The output voltage in DCM is

$$V_{O-j} = \left\{j + k^{[2-h(j)]}\frac{1 - k}{2} z_N\right\} V_I \qquad (14.130)$$

where

$$h(j) = \begin{cases} 0 & if \quad j \geq 1 \\ 1 & if \quad j = 0 \end{cases}$$

is the **Hong** function.

14.5 Super-lift Luo-converters

Voltage-lift (VL) technique has been successfully applied in DC/DC converter's design. However, the output voltage of all VL converters increases in arithmetic progression stage-by-stage. Super-lift (SL) technique is more powerful than VL technique. The output voltage of all SL converters increases in geometric progression stage-by-stage. All super-lift converters are outstanding contributions in DC/DC conversion technology, and invented by Professor Luo and Dr. Ye in 2000–2003. There are four series SL Converters introduced in this section:

1. Positive output (P/O) super-lift Luo-converters;
2. Negative output (N/O) super-lift Luo-converters;
3. Positive output (P/O) cascade boost-converter;
4. Negative output (N/O) cascade boost-converter;

14.5.1 P/O Super-lift Luo-converters

There are several sub-series of P/O super-lift Luo-converters:

- Main series;
- Additional series;
- Enhanced series;
- Re-enhanced series;
- Multi-enhanced series.

We only introduce three circuits of main series and additional series.

P/O SL Luo-converter elementary circuit is shown in Fig. 14.43a. The equivalent circuits during switch on and switch off are shown in Figs. 14.43b and c. Its output voltage and current are

$$V_O = \frac{2 - k}{1 - k} V_I$$

and

$$I_O = \frac{1 - k}{2 - k} I_I$$

The voltage transfer gain is

$$M_E = \frac{V_O}{V_I} = \frac{2 - k}{1 - k} \qquad (14.131)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_2} \qquad (14.132)$$

P/O SL Luo-converter re-lift circuit is shown in Fig. 14.44a. The equivalent circuits during switch on and switch off are

**FIGURE 14.43** P/O SL Luo-converter elementary circuit: (a) circuit diagram; (b) switch on; and (c) switch off.
FIGURE 14.44 P/O SL Luo-converter re-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

shown in Figs. 14.44b and c. Its output voltage and current are

$$V_O = \left(\frac{2-k}{1-k}\right)^2 V_I$$

and

$$I_O = \left(\frac{1-k}{2-k}\right)^2 I_I$$

The voltage transfer gain is

$$M_R = \frac{V_O}{V_I} = \left(\frac{2-k}{1-k}\right)^2 \tag{14.133}$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_4} \tag{14.134}$$
FIGURE 14.45 P/O SL Luo-converter triple-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

P/O SL Luo-converter triple-lift circuit is shown in Fig. 14.45a. The equivalent circuits during switch on and switch off are shown in Figs. 14.45b and c. Its output voltage and current are

$$V_O = \left(\frac{2-k}{1-k}\right)^3 V_I$$

and

$$I_O = \left(\frac{1-k}{2-k}\right)^3 I_I$$

The voltage transfer gain is

$$M_T = \frac{V_O}{V_I} = \left(\frac{2-k}{1-k}\right)^3 \qquad (14.135)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_6} \qquad (14.136)$$

P/O SL Luo-converter additional circuit is shown in Fig. 14.46a. The equivalent circuits during switch on and switch off are shown in Figs. 14.46b and c. Its output voltage and current are

$$V_O = \frac{3-k}{1-k} V_I$$

and

$$I_O = \frac{1-k}{3-k} I_I$$

The voltage transfer gain is

$$M_A = \frac{V_O}{V_I} = \frac{3-k}{1-k} \qquad (14.137)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \qquad (14.138)$$

P/O SL Luo-converter additional re-lift circuit is shown in Fig. 14.47a. The equivalent circuits during switch on and switch off are shown in Figs. 14.47b and c. Its output voltage and current are

$$V_O = \frac{2-k}{1-k}\frac{3-k}{1-k} V_I$$

and

$$I_O = \frac{1-k}{2-k}\frac{1-k}{3-k} I_I$$

The voltage transfer gain is

$$M_{AR} = \frac{V_O}{V_I} = \frac{2-k}{1-k}\frac{3-k}{1-k} \qquad (14.139)$$
FIGURE 14.46 P/O SL Luo-converter additional circuit: (a) circuit diagram; (b) switch on; and (c) switch off.
FIGURE 14.47 P/O SL Luo-converter additional re-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \quad (14.140)$$

P/O SL Luo-converter additional triple-lift circuit is shown in Fig. 14.48a. The equivalent circuits during switch on and switch off are shown in Figs. 14.48b and c. Its output voltage

and current are

$$V_O = \left(\frac{2-k}{1-k}\right)^2 \frac{3-k}{1-k} V_I$$

and

$$I_O = \left(\frac{1-k}{2-k}\right)^2 \frac{1-k}{3-k} I_I$$
FIGURE 14.48 P/O SL Luo-converter additional triple-lift circuit: (a) circuit diagram; (b) switch on; and (c) switch off.

The voltage transfer gain is

$$M_{AT} = \frac{V_O}{V_I} = \left(\frac{2-k}{1-k}\right)^2 \frac{3-k}{1-k} \qquad (14.141)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \qquad (14.142)$$

14.5.2 N/O Super-lift Luo-converters

There are several subseries of N/O Super-lift Luo-converters:

- Main series;
- Additional series;
- Enhanced series;
- Re-enhanced series;
- Multi-enhanced series.

We only introduce three circuits of main series and additional series.

N/O SL Luo-converter elementary circuit is shown in Fig. 14.49. Its output voltage and current are

$$V_O = \left[\frac{2-k}{1-k} - 1\right] = \frac{1}{1-k} V_I$$
FIGURE 14.49 N/O SL Luo-converter elementary circuit.

and

$$I_O = (1 - k)I_I$$

The voltage transfer gain is

$$M_E = \frac{V_O}{V_I} = \frac{1}{1 - k} \qquad (14.143)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_2} \qquad (14.144)$$

N/O SL Luo-converter re-lift circuit is shown in Fig. 14.50. Its output voltage and current are

$$V_O = \left[\left(\frac{2-k}{1-k} \right)^2 - 1 \right] V_I$$

and

$$I_O = \frac{I_I}{\left((2-k)/(1-k) \right)^2 - 1}$$

The voltage transfer gain is

$$M_R = \frac{V_O}{V_I} = \left(\frac{2-k}{1-k} \right)^2 - 1 \qquad (14.145)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_4} \qquad (14.146)$$

N/O SL Luo-converter triple-lift circuit is shown in Fig. 14.51. Its output voltage and current are

$$V_O = \left[\left(\frac{2-k}{1-k} \right)^3 - 1 \right] V_I$$

and

$$I_O = \frac{I_I}{\left((2-k)/(1-k) \right)^3 - 1}$$

FIGURE 14.51   N/O SL Luo-converter triple-lift circuit.

The voltage transfer gain is

$$M_T = \frac{V_O}{V_I} = \left(\frac{2-k}{1-k} \right)^3 - 1 \qquad (14.147)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_6} \qquad (14.148)$$

N/O SL Luo-converter additional circuit is shown in Fig. 14.52. Its output voltage and current are

$$V_O = \left[\frac{3-k}{1-k} - 1 \right] V_I = \frac{2}{1-k} V_I$$

and

$$I_O = \frac{1-k}{2} I_I$$

The voltage transfer gain is

$$M_A = \frac{V_O}{V_I} = \frac{3-k}{1-k} - 1 = \frac{2}{1-k} \qquad (14.149)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \qquad (14.150)$$

FIGURE 14.50   N/O SL Luo-converter re-lift circuit.
FIGURE 14.52   N/O SL Luo-converter additional circuit.
FIGURE 14.53   N/O SL Luo-converter additional re-lift circuit.

NO SL Luo-converter additional re-lift circuit is shown in Fig. 14.53. Its output voltage and current are

$$V_O = \left[\frac{2-k}{1-k} \frac{3-k}{1-k} - 1 \right] V_I$$

and

$$I_O = \frac{I_I}{((2-k)/(1-k))\left((3-k)/(1-k)\right) - 1}$$

The voltage transfer gain is

$$M_{AR} = \frac{V_O}{V_I} = \frac{2-k}{1-k} \frac{3-k}{1-k} - 1 \qquad (14.151)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \qquad (14.152)$$

N/O SL Luo-converter additional triple-lift circuit is shown in Fig. 14.54. Its output voltage and current are

$$V_O = \left[\left(\frac{2-k}{1-k}\right)^2 \frac{3-k}{1-k} - 1 \right] V_I$$

and

$$I_O = \frac{I_I}{\left((2-k)/(1-k)\right)^2 \left((3-k)/(2-k)\right) - 1}$$

The voltage transfer gain is

$$M_{AT} = \frac{V_O}{V_I} = \left(\frac{2-k}{1-k}\right)^2 \frac{3-k}{1-k} - 1 \qquad (14.153)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \qquad (14.154)$$

14.5.3 P/O Cascade Boost-converters

There are several subseries of P/O cascade boost-converters (CBC):

- Main series;
- Additional series;
- Double series;
- Triple series;
- Multiple series.

We only introduce three circuits of main series and additional series.
FIGURE 14.54   N/O SL Luo-converter additional triple-lift circuit.

FIGURE 14.58   P/O CBC additional circuit.

The voltage transfer gain is

$$M_3 = \frac{V_O}{V_I} = \left(\frac{1}{1-k}\right)^3 \qquad (14.159)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_3} \qquad (14.160)$$

P/O CBC additional circuit is shown in Fig. 14.58. Its output voltage and current are

$$V_O = \frac{2}{1-k}V_I$$

and

$$I_O = \frac{1-k}{2}I_I$$

The voltage transfer gain is

$$M_A = \frac{V_O}{V_I} = \frac{2}{1-k} \qquad (14.161)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \qquad (14.162)$$

P/O CBC additional two-stage circuit is shown in Fig. 14.59. Its output voltage and current are

$$V_O = 2\left(\frac{1}{1-k}\right)^2 V_I$$

and

$$I_O = \frac{(1-k)^2}{2}I_I$$

The voltage transfer gain is

$$M_{A2} = \frac{V_O}{V_I} = 2\left(\frac{1}{1-k}\right)^2 \qquad (14.163)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \qquad (14.164)$$

P/O CBC additional three-stage circuit is shown in Fig. 14.60. Its output voltage and current are

$$V_O = 2\left(\frac{1}{1-k}\right)^3 V_I$$

and

$$I_O = \frac{(1-k)^3}{2}I_I$$

The voltage transfer gain is

$$M_{A3} = \frac{V_O}{V_I} = 2\left(\frac{1}{1-k}\right)^3 \qquad (14.165)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \qquad (14.166)$$

N/O CBC two-stage circuit is shown in Fig. 14.62. Its output voltage and current are

$$V_O = \left[\left(\frac{1}{1-k} \right)^2 - 1 \right] V_I$$

and

$$I_O = \frac{I_I}{\left(1/(1-k) \right)^2 - 1}$$

The voltage transfer gain is

$$M_2 = \frac{V_O}{V_I} = \left(\frac{1}{1-k} \right)^2 - 1 \qquad (14.169)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_2} \qquad (14.170)$$

N/O CBC three-stage circuit is shown in Fig. 14.63. Its output voltage and current are

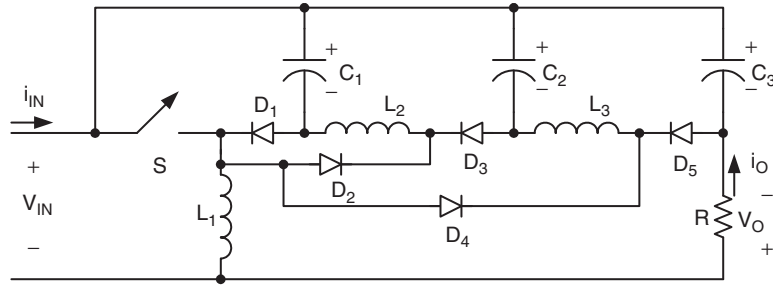
$$V_O = \left[\left(\frac{1}{1-k} \right)^3 - 1 \right] V_I$$


FIGURE 14.63 N/O CBC three-stage circuit.

and

$$I_O = \frac{I_I}{\left(1/(1-k)\right)^3 - 1}$$

The voltage transfer gain is

$$M_3 = \frac{V_O}{V_I} = \left(\frac{1}{1-k}\right)^3 - 1 \qquad (14.171)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_3} \qquad (14.172)$$

N/O CBC additional circuit is shown in Fig. 14.64. Its output voltage and current are

$$V_O = \left[\frac{2}{1-k} - 1\right] V_I = \frac{1+k}{1-k} V_I$$

and

$$I_O = \frac{1-k}{1+k} I_I$$
FIGURE 14.64 N/O CBC additional circuit.

The voltage transfer gain is

$$M_A = \frac{V_O}{V_I} = \frac{1+k}{1-k} \qquad (14.173)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \qquad (14.174)$$

N/O CBC additional two-stage circuit is shown in Fig. 14.65. Its output voltage and current are

$$V_O = \left[2\left(\frac{1}{1-k}\right)^2 - 1\right] V_I$$

and

$$I_O = \frac{I_I}{2\left(1/(1-k)\right)^2 - 1}$$

The voltage transfer gain is

$$M_{A2} = \frac{V_O}{V_I} = 2\left(\frac{1}{1-k}\right)^2 - 1 \qquad (14.175)$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \qquad (14.176)$$

N/O CBC additional three-stage circuit is shown in Fig. 14.66. Its output voltage and current are

$$V_O = \left[2\left(\frac{1}{1-k}\right)^3 - 1\right] V_I$$

and

$$I_O = \frac{I_I}{2\left(1/(1-k)\right)^3 - 1}$$
FIGURE 14.65   N/O CBC additional two-stage circuit.

The voltage transfer gain is

$$M_{A3} = \frac{V_O}{V_I} = 2\left(\frac{1}{1-k}\right)^3 - 1 \tag{14.177}$$

The variation ratio of the output voltage v_O is

$$\varepsilon = \frac{\Delta v_O/2}{V_O} = \frac{k}{2RfC_{12}} \tag{14.178}$$

14.6 Ultra-lift Luo-converters

Ultra-lift (UL) Luo-converter performs very high voltage transfer gain conversion. Its voltage transfer gain is the product of those of VL Luo-converter and SL Luo-converter.

We know that the gain of P/O VL Luo-converters (as in Eq. (14.52)) is

$$M = \frac{V_O}{V_I} = \frac{k^{h(n)}[n + h(n)]}{1-k}$$

where n is the stage number, $h(n)$ (as in Eq. (14.56)) is the Hong function.

$$h(n) = \begin{cases} 1 & n = 0 \\ 0 & n > 0 \end{cases}$$

(from Eq. (14.32)) $n = 0$ for the elementary circuit with the

voltage transfer gain

$$M_E = \frac{V_O}{V_I} = \frac{k}{1-k}$$

The voltage transfer gain of P/O SL Luo-converters is

$$M = \frac{V_O}{V_I} = \left(\frac{j+2-k}{1-k}\right)^n \tag{14.179}$$

where n is the stage number, j is the multiple-enhanced number. $n = 1$ and $j = 0$ for the elementary circuit with gain (as in Eq. (14.131))

$$M_E = \frac{V_O}{V_I} = \frac{2-k}{1-k}$$

The circuit diagram of UL Luo-converter is shown in Fig. 14.67a, which consists of one switch S, two inductors L_1 and L_2, two capacitors C_1 and C_2, three diodes, and the load R. Its switch-on equivalent circuit is shown in Fig. 14.67b. Its switch-off equivalent circuit for the continuous conduction mode is shown in Fig. 14.67c and switch-off equivalent circuit for the discontinuous conduction mode is shown in Fig. 14.67d.

14.6.1 Continuous Conduction Mode

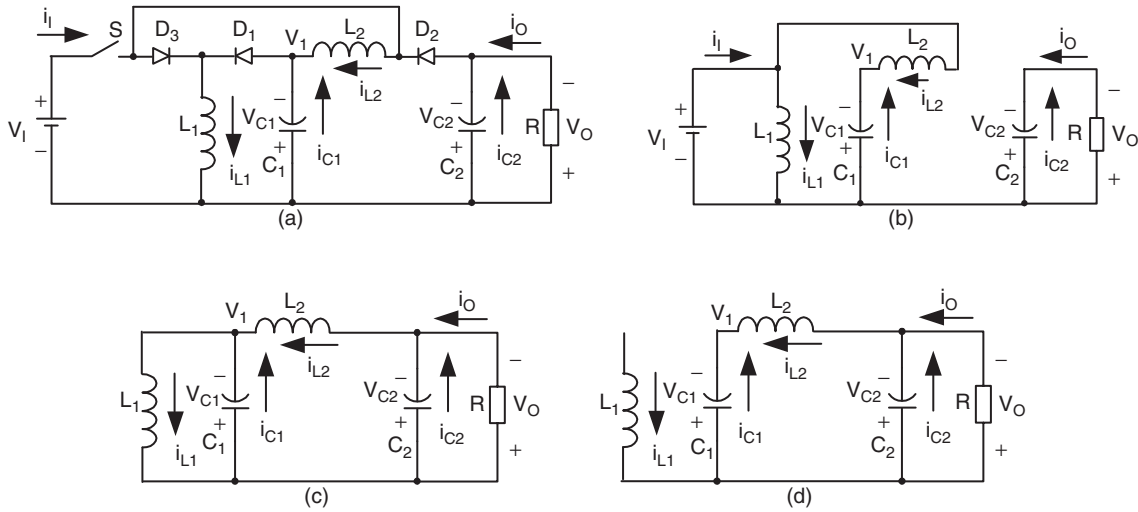
Referring to Figs. 14.67b and c, we have got the current i_{L1} increases with the slope $+V_I/L_1$ during switch on, and


FIGURE 14.67 Ultra-lift (UL) Luo-converter: (a) circuit diagram; (b) switch on; (c) switch off in CCM; and (d) switch off in DCM.

decreases with the slope $-V_1/L_1$ during switch off. In the steady state, the current increment is equal to the decrement in a whole period T. The relation below is obtained

$$kT\frac{V_I}{L_1} = (1-k)T\frac{V_1}{L_1} \tag{14.180}$$

Thus,

$$V_{C1} = V_1 = \frac{k}{1-k}V_I \tag{14.181}$$

The current i_{L2} increases with the slope $+(V_I - V_1)/L_2$ during switch on, and decreases with the slope $-(V_1 - V_O)/L_2$ during switch off. In the steady state, the current increment is equal to the decrement in a whole period T. We obtain the relation below

$$kT\frac{V_I + V_1}{L_2} = (1-k)T\frac{V_O - V_1}{L_2} \tag{14.182}$$

$$V_O = V_{C2} = \frac{2-k}{1-k}V_1 = \frac{k}{1-k}\frac{2-k}{1-k}V_I = \frac{k(2-k)}{(1-k)^2}V_I \tag{14.183}$$

$$I_O = \frac{(1-k)^2}{k(2-k)}I_I \tag{14.184}$$

The voltage transfer gain is

$$M = \frac{V_O}{V_I} = \frac{k(2-k)}{(1-k)^2} = \frac{k}{1-k}\frac{2-k}{1-k} = M_{E-VL} \times M_{E-SL} \tag{14.185}$$

From Eq. (14.185) we can see that the voltage transfer gain of UL Luo-converter is very high which is the product of those

TABLE 14.3 Comparison of various converters gains

k	0.2	0.33	0.5	0.67	0.8	0.9
Buck	0.2	0.33	0.5	0.67	0.8	0.9
Boost	1.25	1.5	2	3	5	10
Buck–Boost	0.25	0.5	1	2	4	9
VL Luo-converter	0.25	0.5	1	2	4	9
SL Luo-converter	2.25	2.5	3	4	6	11
UL Luo-converter	0.56	1.25	3	8	24	99

of VL Luo-converter and SL Luo-converter. We list the transfer gains of various converters in Table 14.3 for reference.

The variation of inductor current i_{L1} is

$$\Delta i_{L1} = kT\frac{V_I}{L_1} \tag{14.186}$$

and its variation ratio is

$$\xi_1 = \frac{\Delta i_{L1}/2}{I_{L1}} = \frac{k(1-k)^2 TV_I}{2L_1 I_2} = \frac{k(1-k)^2 TR}{2L_1 M} = \frac{(1-k)^4 TR}{2(2-k)fL_1} \tag{14.187}$$

The variation of inductor current i_{L2} is

$$\Delta i_{L2} = \frac{kTV_I}{(1-k)L_2} \tag{14.188}$$

and its variation ratio is

$$\xi_2 = \frac{\Delta i_{L2}/2}{I_{L2}} = \frac{kTV_I}{2L_2 I_2} = \frac{kTR}{2L_2 M} = \frac{(1-k)^2 TR}{2(2-k)fL_2} \tag{14.189}$$

The variation of capacitor voltage v_{C1} is

$$\Delta v_{C1} = \frac{\Delta Q_{C1}}{C_1} = \frac{kTI_{L2}}{C_1} = \frac{kTI_O}{(1-k)C_1} \qquad (14.190)$$

and its variation ratio is

$$\sigma_1 = \frac{\Delta v_{C1}/2}{V_{C1}} = \frac{kTI_O}{2(1-k)V_1 C_1} = \frac{k(2-k)}{2(1-k)^2 fC_1 R} \quad (14.191)$$

The variation of capacitor voltage v_{C2} is

$$\Delta v_{C2} = \frac{\Delta Q_{C2}}{C_2} = \frac{kTI_O}{C_2} \qquad (14.192)$$

and its variation ratio is

$$\varepsilon = \sigma_2 = \frac{\Delta v_{C2}/2}{V_{C2}} = \frac{kTI_O}{2V_O C_2} = \frac{k}{2fC_2 R} \qquad (14.193)$$

From the analysis and calculations, we can see that all variations are very small. A design example is that $V_I = 10\,\text{V}$, $L_1 = L_2 = 1\,\text{mH}$, $C_1 = C_2 = 1\,\mu\text{F}$, $R = 3000\,\Omega$, $f = 50\,\text{kHz}$, and conduction duty cycle k varies from 0.1 to 0.9. We then obtain the output voltage variation ratio ε, which is less than 0.003. The output voltage is very smooth DC voltage nearly no ripple.

14.6.2 Discontinuous Conduction Mode

Referring to Fig. 14.67d, we have got the current i_{L1} decreases to zero before $t = T$, i.e. the current becomes zero before next time the switch turns on. The DCM operation condition is defined as

$$\xi \geq 1$$

or

$$\xi_1 = \frac{k(1-k)^2 TR}{2L_1 M} = \frac{(1-k)^4 TR}{2(2-k)fL_1} \geq 1 \qquad (14.194)$$

The normalized impedance Z_N is,

$$Z_N = \frac{R}{fL_1} \qquad (14.195)$$

We define the filling factor m to describe the current exists time. For DCM operation, $0 < m \leq 1$,

$$m = \frac{1}{\xi_1} = \frac{2L_1 G}{k(1-k)^2 TR} = \frac{2(2-k)}{(1-k)^4 Z_N} \qquad (14.196)$$

$$kT\frac{V_I}{L_1} = (1-k)mT\frac{V_1}{L_1}$$

Thus,

$$V_{C1} = V_1 = \frac{k}{(1-k)m}V_I \qquad (14.197)$$

We finally obtain the relation below

$$kT\frac{V_I + V_1}{L_2} = (1-k)T\frac{V_O - V_1}{L_2} \qquad (14.198)$$

$$V_O = V_{C2} = \frac{2-k}{1-k}V_1 = \frac{k(2-k)}{m(1-k)^2}V_I \qquad (14.199)$$

The voltage transfer gain in DCM is higher than that in CCM.

$$M_{DCM} = \frac{V_O}{V_I} = \frac{k(2-k)}{m(1-k)^2} = \frac{M_{CCM}}{m} \quad \text{with } m < 1 \qquad (14.200)$$

14.7 Multiple-quadrant Operating Luo-converters

Multiple-quadrant operating converters are the second-generation converters. These converters usually perform between two voltage sources: V_1 and V_2. Voltage source V_1 is proposed positive voltage and voltage V_2 is the load voltage. In the investigation both voltages are proposed constant voltage. Since V_1 and V_2 are constant values, voltage transfer gain is constant. Our interesting research will concentrate the working current, minimum conduction duty k_{min}, and the power transfer efficiency η.

Multiple-quadrant operating Luo-converters are the second-generation converters and they have three modes:

- Two-quadrant DC/DC Luo-converter in forward operation;
- Two-quadrant DC/DC Luo-converter in reverse operation;
- Four-quadrant DC/DC Luo-converter.

The two-quadrant DC/DC Luo-converter in forward operation has been derived from the positive output Luo-converter. It performs in the first-quadrant Q_I and the second-quadrant Q_{II} corresponding to the DC motor forward operation in motoring and regenerative braking states.

The two-quadrant DC/DC Luo-converter in reverse operation has been derived from the N/O Luo-converter. It performs in the third-quadrant Q_{III} and the fourth-quadrant Q_{IV} corresponding to the DC motor reverse operation in motoring and regenerative braking states.

The four-quadrant DC/DC Luo-converter has been derived from the double output Luo-converter. It performs four-quadrant operation corresponding to the DC motor forward

and reverse operation in motoring and regenerative braking states.

In the following analysis the input source and output load are usually constant voltages as shown, V_1 and V_2. Switches S_1 and S_2 in this diagram are power metal oxide semiconductor field effect transistor (MOSFET) devices, and they are driven by a PWM switching signal with repeating frequency f and conduction duty k. In this paper the switch repeating period is $T = 1/f$, so that the switch-on period is kT and switch-off period is $(1 - k)T$. The equivalent resistance is R for each inductor. During switch-on the voltage drop across the switches and diodes are V_S and V_D respectively.

14.7.1 Forward Two-quadrant DC/DC Luo-converter

Forward Two-quadrant (F 2Q) Luo-converter is shown in Fig. 14.68. The source voltage (V_1) and load voltage (V_2) are usually considered as constant voltages. The load can be a battery or motor back electromotive force (EMF). For example, the source voltage is 42 V and load voltage is +14 V. There are two modes of operation:

1. Mode A (Quadrant I): electrical energy is transferred from source side V_1 to load side V_2;
2. Mode B (Quadrant II): electrical energy is transferred from load side V_2 to source side V_1.

Mode A: The equivalent circuits during switch-on and -off periods are shown in Figs. 14.69a and b. The typical output voltage and current waveforms are shown in Fig. 14.69c. We have the output current I_2 as

$$I_2 = \frac{1 - k}{k} I_1 \qquad (14.201)$$

and

$$I_2 = \frac{V_1 - V_S - V_D - V_2((1 - k)/k)}{R\left((k/(1 - k)) + ((1 - k)/k)\right)} \qquad (14.202)$$
FIGURE 14.68   Forward two-quadrant operating Luo-converter.

The minimum conduction duty k corresponding to $I_2 = 0$ is

$$k_{min} = \frac{V_2}{V_1 + V_2 - V_S - V_D} \qquad (14.203)$$

The power transfer efficiency is

$$\eta_A = \frac{P_O}{P_I} = \frac{V_2 I_2}{V_1 I_1}$$

$$= \frac{1}{1 + ((V_S + V_D)/V_2)(k/(1 - k)) + (RI_2/V_2)\left[1 + ((1 - k)/k)^2\right]} \qquad (14.204)$$

The variation ratio of capacitor voltage v_C is

$$\rho = \frac{\Delta v_C/2}{V_C} = \frac{(1 - k)I_2}{2fC(V_1 - RI_2(1/(1 - k)))} \qquad (14.205)$$

The variation ratio of inductor current i_{L1} is

$$\xi_1 = \frac{\Delta i_{L1}/2}{I_{L1}} = k\frac{V_1 - V_S - RI_1}{2fL_1 I_1} \qquad (14.206)$$

The variation ratio of inductor current i_{L2} is

$$\xi_2 = \frac{\Delta i_{L2}/2}{I_{L2}} = k\frac{V_1 - V_S - RI_1}{2fL_2 I_2} \qquad (14.207)$$

The variation ratio of diode current i_{D2} is

$$\zeta_{D2} = \frac{\Delta i_{D2}/2}{I_{L1} + I_{L2}} = k\frac{V_1 - V_S - RI_1}{2fL(I_1 + I_2)} = k^2\frac{V_1 - V_S - RI_1}{2fLI_1} \qquad (14.208)$$

If the diode current becomes zero before S_1 switch on again, the converter works in discontinuous region. The condition is

$$\zeta_{D2} = 1, \quad \text{i.e.} \quad k^2 = \frac{2fLI_1}{V_1 - V_S - RI_1} \qquad (14.209)$$

Mode B: The equivalent circuits during switch-on and -off periods are shown in Figs. 14.70a and b. The typical output voltage and current waveforms are shown in Fig. 14.70c. We have the output current I_1 as

$$I_1 = \frac{1 - k}{k} I_2 \qquad (14.210)$$

and

$$I_1 = \frac{V_2 - (V_1 + V_S + V_D)((1 - k)/k)}{R\left((k/(1 - k)) + ((1 - k)/k)\right)} \qquad (14.211)$$

The minimum conduction duty k corresponding to $I_1 = 0$ is

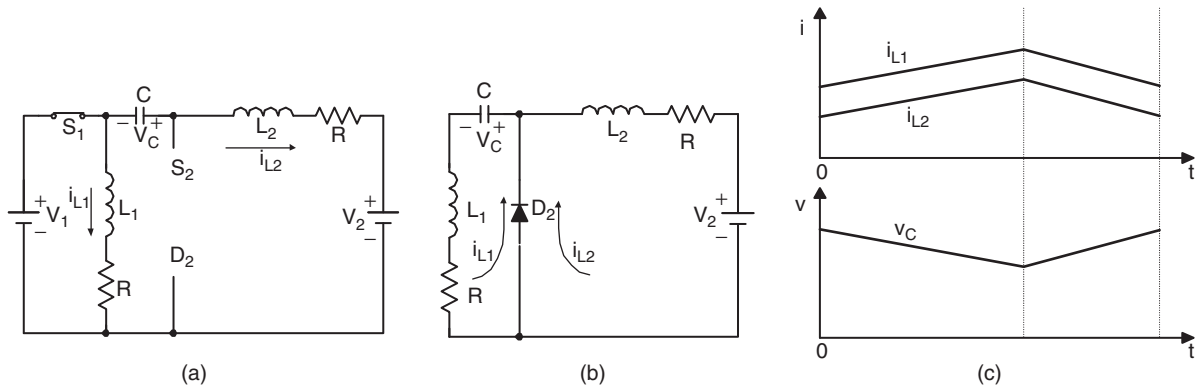
$$k_{min} = \frac{V_1 + V_S + V_D}{V_1 + V_2 + V_S + V_D} \qquad (14.212)$$


FIGURE 14.69 Mode A: (a) switch on; (b) switch off; and (c) waveforms.
FIGURE 14.70 Mode B: (a) switch on; (b) switch off; and (c) waveforms.

The power transfer efficiency

$$\eta_B = \frac{P_O}{P_I} = \frac{V_1 I_1}{V_2 I_2}$$

$$= \frac{1}{1 + ((V_S + V_D)/V_1) + (RI_1/V_1)[1 + ((1-k)/k)^2]}$$
(14.213)

The variation ratio of capacitor voltage v_C is

$$\rho = \frac{\Delta v_C/2}{V_C} = \frac{kI_1}{2fC[(V_2/(1-k)) - V_1 - RI_1(k/(1-k)^2)]}$$
(14.214)

The variation ratio of inductor current i_{L1} is

$$\xi_1 = \frac{\Delta i_{L1}/2}{I_{L1}} = k\frac{V_2 - V_S - RI_2}{2fL_1 I_1}$$
(14.215)

The variation ratio of inductor current i_{L2} is

$$\xi_2 = \frac{\Delta i_{L2}/2}{I_{L2}} = k\frac{V_2 - V_S - RI_2}{2fL_2 I_2}$$
(14.216)

The variation ratio of diode current i_{D1} is

$$\zeta_{D1} = \frac{\Delta i_{D2}/2}{I_{L1} + I_{L2}} = k\frac{V_2 - V_S - RI_2}{2fL(I_1 + I_2)} = k^2\frac{V_2 - V_S - RI_2}{2fLI_2}$$
(14.217)

If the diode current becomes zero before S_2 switch on again, the converter works in discontinuous region. The condition is

$$\zeta_{D1} = 1, \quad \text{i.e.} \quad k^2 = \frac{2fLI_2}{V_2 - V_S - RI_2}$$
(14.218)

14.7.2 Two-quadrant DC/DC Luo-converter in Reverse Operation

Reverse two-quadrant operating (R 2Q) Luo-converter is shown in Fig. 14.71, and it consists of two switches with two passive diodes, two inductors and one capacitor. The source voltage (V_1) and load voltage (V_2) are usually considered as constant voltages. The load can be a battery or motor back EMF. For example, the source voltage is 42 V and load voltage
FIGURE 14.71   Reverse two-quadrant operating Luo-converter.

is $-14\,V$. There are two modes of operation:

1. Mode C (Quadrant III): electrical energy is transferred from source side V_1 to load side $-V_2$;
2. Mode D (Quadrant IV): electrical energy is transferred from load side $-V_2$ to source side V_1.

Mode C: The equivalent circuits during switch-on and -off periods are shown in Figs. 14.72a and b. The typical output voltage and current waveforms are shown in Fig. 14.72c. We have the output current I_2 as

$$I_2 = \frac{1-k}{k} I_1 \tag{14.219}$$

and

$$I_2 = \frac{V_1 - V_S - V_D - V_2((1-k)/k)}{R\left[(1/(k(1-k))) + ((1-k)/k)\right]} \tag{14.220}$$

The minimum conduction duty k corresponding to $I_2 = 0$ is

$$k_{min} = \frac{V_2}{V_1 + V_2 - V_S - V_D} \tag{14.221}$$

The power transfer efficiency is

$$\eta_C = \frac{P_O}{P_I} = \frac{V_2 I_2}{V_1 I_1}$$

$$= \frac{1}{1 + ((V_S + V_D)/V_2)(k/(1-k)) + (RI_2/V_2)[1 + (1/(1-k))^2]} \tag{14.222}$$

The variation ratio of capacitor voltage v_C is

$$\rho = \frac{\Delta v_C/2}{V_C} = \frac{kI_2}{2fC\left[(k/(1-k))V_1 - ((RI_2)/(1-k)^2)\right]} \tag{14.223}$$

The variation ratio of inductor current i_{L1} is

$$\xi_1 = \frac{\Delta i_{L1}/2}{I_{L1}} = k\frac{V_1 - V_S - RI_1}{2fL_1 I_1} \tag{14.224}$$

The variation ratio of inductor current i_{D2} is

$$\zeta_{D2} = \xi_1 = \frac{\Delta i_{D2}/2}{I_{L1}} = k\frac{V_1 - V_S - RI_1}{2fL_1 I_1} \tag{14.225}$$

The variation ratio of inductor current i_{L2} is

$$\xi_2 = \frac{\Delta i_{L2}/2}{I_2} = \frac{k}{16f^2 CL_2} \tag{14.226}$$

If the diode current becomes zero before S_1 switch on again, the converter works in discontinuous region. The condition is

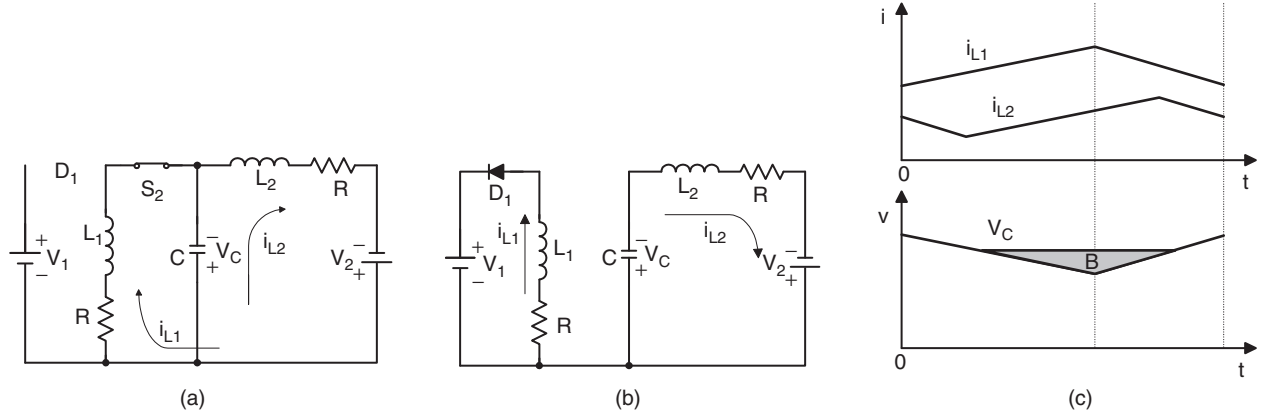
$$\zeta_{D2} = 1, \quad \text{i.e.} \quad k = \frac{2fL_1 I_1}{V_1 - V_S - RI_1} \tag{14.227}$$
FIGURE 14.72   Mode C: (a) switch on; (b) switch off; and (c) waveforms.


FIGURE 14.73   Mode D: (a) switch on; (b) switch off; and (c) waveforms.

Mode D: The equivalent circuits during switch-on and -off periods are shown in Figs. 14.73a and b. The typical output voltage and current waveforms are shown in Fig. 14.73c. We have the output current I_1 as

$$I_1 = \frac{1-k}{k} I_2 \qquad (14.228)$$

and

$$I_1 = \frac{V_2 - (V_1 + V_S + V_D)((1-k)/k)}{R[(1/(k(1-k))) + (k/(1-k))]} \qquad (14.229)$$

The minimum conduction duty k corresponding to $I_1 = 0$ is

$$k_{min} = \frac{V_1 + V_S + V_D}{V_1 + V_2 + V_S + V_D} \qquad (14.230)$$

The power transfer efficiency is

$$\eta_D = \frac{P_O}{P_I} = \frac{V_1 I_1}{V_2 I_2}$$

$$= \frac{1}{1 + ((V_S + V_D)/V_1) + (RI_1/V_1)[(1/(1-k)^2) + (k/(1-k))^2]} \qquad (14.231)$$

The variation ratio of capacitor voltage v_C is

$$\rho = \frac{\Delta v_C/2}{V_C} = \frac{kI_1}{2fC\left[((1-k)/k)V_1 + ((RI_1)/(k(1-k)))\right]} \qquad (14.232)$$

The variation ratio of inductor current i_{L1} is

$$\xi_1 = \frac{\Delta i_{L1}/2}{I_{L1}} = (1-k)\frac{V_2 - V_S - RI_2}{2fL_1 I_1} \qquad (14.233)$$

And the variation ratio of inductor current i_{D1} is

$$\zeta_{D1} = \xi_1 = \frac{\Delta i_{D1}/2}{I_{L1}} = k\frac{V_2 - V_S - RI_2}{2fL_1 I_2} \qquad (14.234)$$

The variation ratio of inductor current i_{L2} is

$$\xi_2 = \frac{\Delta i_{L2}/2}{I_2} = \frac{1-k}{16f^2 CL_2} \qquad (14.235)$$

If the diode current becomes zero before S_2 switch on again, the converter works in discontinuous region. The condition is

$$\zeta_{D1} = 1, \quad \text{i.e.} \quad k = \frac{2fL_1 I_2}{V_2 - V_S - RI_2} \qquad (14.236)$$

14.7.3 Four-quadrant DC/DC Luo-converter

Four-quadrant DC/DC Luo-converter is shown in Fig. 14.74, which consists of two switches with two passive diodes, two inductors, and one capacitor. The source voltage (V_1) and load voltage (V_2) are usually considered as constant voltages. The load can be a battery or motor back EMF. For example, the source voltage is 42 V and load voltage is ±14 V. There are four modes of operation:

1. Mode A (Quadrant I): electrical energy is transferred from source side V_1 to load side V_2;
2. Mode B (Quadrant II): electrical energy is transferred from load side V_2 to source side V_1;
3. Mode C (Quadrant III): electrical energy is transferred from source side V_1 to load side $-V_2$;
4. Mode D (Quadrant IV): electrical energy is transferred from load side $-V_2$ to source side V_1.

Each mode has two states: "on" and "off." Usually, each state is operating in different conduction duty k. The switches
FIGURE 14.74   Four-quadrant operating Luo-converter: (a) circuit 1 and (b) circuit 2.

are the power MOSFET devices. The circuit 1 in Fig. 14.74 implements Modes A and B, and the circuit 2 in Fig. 14.74 implements Modes C and D. Circuits 1 and 2 can changeover by auxiliary switches (not in the figure).

Mode A: During state-**on** switch S_1 is closed, switch S_2 and diodes D_1 and D_2 are not conducted. In this case inductor currents i_{L1} and i_{L2} increase, and $i_1 = i_{L1} + i_{L2}$. During state-**off** switches S_1, S_2, and diode D_1 are off and diode D_2 is conducted. In this case current i_{L1} flows via diode D_2 to charge capacitor C, in the meantime current i_{L2} is kept to flow through load battery V_2. The free-wheeling diode current $i_{D2} = i_{L1} + i_{L2}$. Mode A implements the characteristics of the buck–boost conversion.

Mode B: During state-**on** switches S_2 is closed, switch S_1 and diodes D_1 and D_2 are not conducted. In this case inductor current i_{L2} increases by biased V_2, inductor current i_{L1} increases by biased V_C. Therefore capacitor voltage V_C reduces. During state-**off** switches S_1, S_2, and diode D_2 are not on, and only diode D_1 is on. In this case source current $i_1 = i_{L1} + i_{L2}$ which is a negative value to perform the regenerative operation. Inductor current i_{L2} flows through capacitor C, it is charged by current i_{L2}. After capacitor C, i_{L2} then flows through the source V_1. Inductor current i_{L1} flows through the source V_1 as well via diode D_1. Mode B implements the characteristics of the boost conversion.

Mode C: During state-**on** switch S_1 is closed, switch S_2 and diodes D_1 and D_2 are not conducted. In this case inductor

currents i_{L1} and i_{L2} increase, and $i_1 = i_{L1}$. During state-**off** switches S_1, S_2, and diode D_1 are off and diode D_2 is conducted. In this case current i_{L1} flows via diode D_2 to charge capacitor C and the load battery V_2 via inductor L_2. The free-wheeling diode current $i_{D2} = i_{L1} = i_C + i_2$. Mode C implements the characteristics of the buck–boost conversion.

Mode D: During state-**on** switches S_2 is closed, switch S_1 and diodes D_1 and D_2 are not conducted. In this case inductor current i_{L1} increases by biased V_2, inductor current i_{L2} decreases by biased $(V_2 - V_C)$. Therefore capacitor voltage V_C reduces. Current $i_{L1} = i_{C-on} + i_2$. During state-**off** switches S_1, S_2, and diode D_2 are not on, and only diode D_1 is on. In this case source current $i_1 = i_{L1}$ which is a negative value to perform the regenerative operation. Inductor current i_2 flows through capacitor C that is charged by current i_2, i.e. $i_{C-off} = i_2$. Mode D implements the characteristics of the boost conversion.

Summary: The switch status is shown in Table 14.4. The operation of all modes A, B, C, and D is same to the description in Sections 14.7.1 and 14.7.2.

14.8 Switched-capacitor Multi-quadrant Luo-converters

Switched-component converters are the third-generation converters. These converters are made of only inductor

or capacitors. They usually perform in the systems between two voltage sources: V_1 and V_2. Voltage source V_1 is proposed positive voltage and voltage V_2 is the load voltage that can be positive or negative. In the investigation both voltages are proposed constant voltage. Since V_1 and V_2 are constant values, so that voltage transfer gain is constant. Our interesting research will concentrate on the working current and the power transfer efficiency η. The resistance R of the capacitors and inductor has to be considered for the power transfer efficiency η calculation.

Reviewing the papers in the literature, we can find that almost of the papers investigating the switched-component converters are working in single-quadrant operation. Professor Luo and colleagues have developed this technique into multi-quadrant operation. We describe these in this and next sections.

Switched-capacitor multi-quadrant Luo-converters are the third-generation converters, and they are made of only capacitors. Because these converters implement voltage-lift and current-amplification techniques, they have the advantages of high power density, high power transfer efficiency, and low EMI. They have two modes:

- Two-quadrant switched-capacitor DC/DC Luo-converter;
- Four-quadrant switched-capacitor DC/DC Luo-converter.

The two-quadrant switched-capacitor DC/DC Luo-converter in forward operation has been derived for the energy transmission of a dual-voltage system in two-quadrant operation. The both, source and load voltages are positive polarity. It performs in the first-quadrant Q_I and the second-quadrant Q_{II} corresponding to the DC motor forward operation in motoring and regenerative braking states.

The four-quadrant switched-capacitor DC/DC Luo-converter has been derived for the energy transmission of a dual-voltage system in four-quadrant operation. The source voltage is positive and load voltage can be positive or negative

polarity. It performs four-quadrant operation corresponding to the DC motor forward and reverse operation in motoring and regenerative braking states.

From the analysis and calculation, the conduction duty k does not affect the power transfer efficiency. It affects the input and output power in a small region. The maximum output power corresponds at $k = 0.5$.

14.8.1 Two-quadrant Switched-capacitor DC/DC Luo-converter

This converter is shown in Fig. 14.75. It consists of nine switches, seven diodes, and three capacitors. The high source voltage V_H and low load voltage V_L are usually considered as constant voltages, e.g. the source voltage is 48 V and load voltage is 14 V. There are two modes of operation:

- Mode A (Quadrant I): electrical energy is transferred from V_H side to V_L side;
- Mode B (Quadrant II): electrical energy is transferred from V_L side to V_H side.

Each mode has two states: "on" and "off." Usually, each state is operating in different conduction duty k. The switching period is T where $T = 1/f$, where f is the switching frequency. The switches are the power MOSFET devices. The parasitic resistance of all switches is r_S. The equivalent resistance of all capacitors is r_C and the equivalent voltage drop of all diodes is V_D. Usually we select the three capacitors having same capacitance $C = C_1 = C_2 = C_3$. Some reference data are useful: $r_S = 0.03\,\Omega$, $r_C = 0.02\,\Omega$, and $V_D = 0.5\,V$, $f = 5\,kHz$, and $C = 5000\,\mu F$. The switch's status is shown in Table 14.5.

For Mode A, state-**on** is shown in Fig. 14.76a: switches S_1 and S_{10} are closed and diodes D_5 and D_5 are conducted. Other switches and diodes are open. In this case capacitors C_1, C_2, and C_3 are charged via the circuit V_H–S_1–C_1–D_5–C_2–D_6–C_3–S_{10}, and the voltage across capacitors

TABLE 14.5 Switch's status (the blank status means OFF)

Switch or diode	Mode A		Mode B	
	State-on	State-off	State-on	State-off
S_1	ON			
D_1				ON
S_2,S_3,S_4		ON		
D_2,D_3,D_4			ON	
S_5,S_6,S_7				ON
D_5,D_6	ON			
S_8,S_9			ON	
S_{10}	ON		ON	
D_8,D_9,D_{10}		ON		

C_1, C_2, and C_3 is increasing. The equivalent circuit resistance is $R_{AN} = (2r_S + 3r_C) = 0.12\,\Omega$, and the voltage deduction is $2V_D = 1\,\text{V}$. State-**off** is shown in Fig. 14.76b: switches S_2, S_3, and S_4 are closed and diodes D_8, D_9, and D_{10} are conducted. Other switches and diodes are open. In this case capacitor $C_1(C_2$ and $C_3)$ is discharged via the circuit $S_2(S_3$ and $S_4)$–V_L–$D_8(D_9$ and $D_{10})$–$C_1(C_2$ and $C_3)$, and the voltage across capacitor $C_1(C_2$ and $C_3)$ is decreasing. Mode A implements the **current-amplification technique**. The voltage and current waveforms are shown in Fig. 14.76c. All three capacitors are charged in series during state-on. The input current flows through three capacitors and the charges accumulated on the three capacitors should be the same. These three capacitors are discharged in parallel during state-off. Therefore, the output current is amplified by three times.

The variation of the voltage across capacitor C_1 is:

$$\Delta v_{C1} = \frac{k(V_H - 3V_{C1} - 2V_D)}{fCR_{AN}}$$

$$= \frac{2.4k(1-k)(V_H - 3V_L - 5V_D)}{(2.4 + 0.6k)fCR_{AN}} \quad (14.237)$$

After calculation,

$$V_{C1} = \frac{k(V_H - 2V_D) + 2.4(1-k)(V_L + V_D)}{2.4 + 0.6k} \quad (14.238)$$

The average output current is

$$I_L = \frac{3}{T}\int_{kT}^{T} i_{C1}(t)dt \approx 3(1-k)\frac{V_{C1} - V_L - V_D}{R_{AF}} \quad (14.239)$$

The average input current is

$$I_H = \frac{1}{T}\int_{0}^{kT} i_{C1}(t)dt \approx k\frac{V_H - 3V_{C1} - 2V_D}{R_{AN}} \quad (14.240)$$

Therefore, we have $3I_H = I_L$.
Output power is

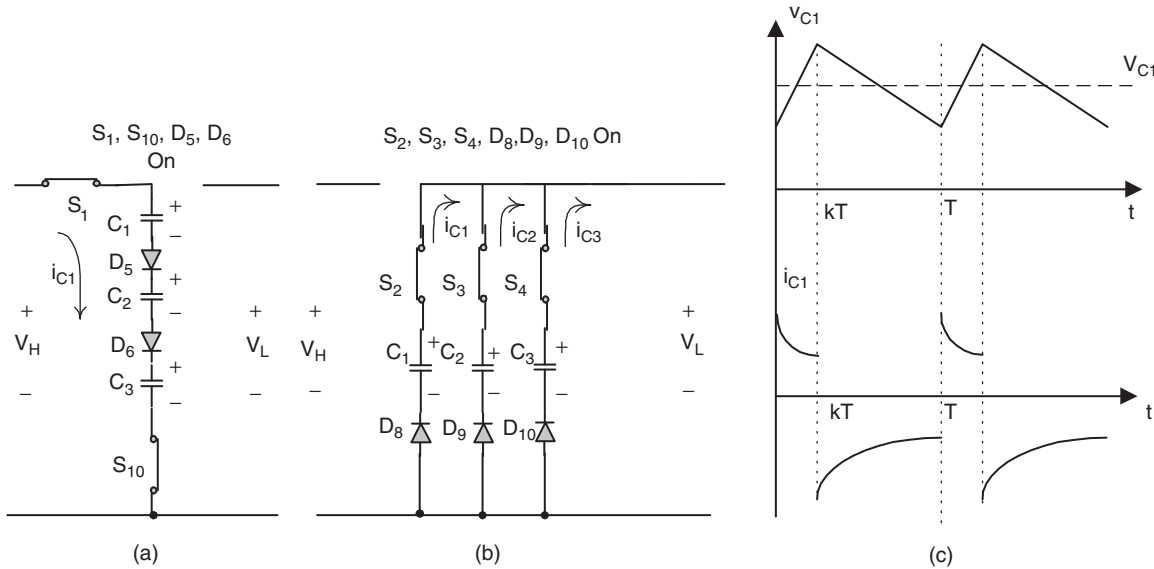
$$P_O = V_L I_L = 3(1-k)V_L \frac{V_{C1} - V_L - V_D}{R_{AF}} \quad (14.241)$$


FIGURE 14.76 Mode A operation: (a) state-on; (b) state-off; and (c) voltage and current waveforms.

Input power

$$P_I = V_H I_H = k V_H \frac{V_H - 3V_{C1} - V_D}{R_{AN}} \qquad (14.242)$$

The transfer efficiency is

$$\eta_A = \frac{P_O}{P_I} = \frac{1-k}{k} \frac{3V_L}{V_H} \frac{V_{C1} - V_L - V_D}{V_H - 3V_{C1} - V_D} \frac{R_{AN}}{R_{AF}} = \frac{3V_L}{V_H} \qquad (14.243)$$

For Mode B, state-**on** is shown in Fig. 14.77a: switches S_8, S_9, and S_{10} are closed and diodes D_2, D_3, and D_4 are conducted. Other switches and diodes are off. In this case all three capacitors are charged via each circuit V_L–D_2(and D_3, D_4)–C_1(and C_2, C_3)–S_8(and S_9, S_{10}), and the voltage across three capacitors are increasing. The equivalent circuit resistance is $R_{BN} = r_S + r_C$ and the voltage deduction is V_D in each circuit. State-**off** is shown in Fig. 14.77b: switches S_5, S_6, and S_7 are closed and diode D_1 is on. Other switches and diodes are open. In this case all capacitors is discharged via the circuit V_L–S_7–C_3–S_6–C_2–S_5–C_1–D_1–V_H, and the voltage across all capacitors is decreasing. Mode B implements the **voltage-lift technique**. The voltage and current waveforms are shown in Fig. 14.77c. All three capacitors are charged in parallel during state-on. The input voltage is applied to the three capacitors symmetrically, so that the voltages across these three capacitors should be same. They are discharged in series during state-off. Therefore, the output voltage is lifted by three times.

The variation of the voltage across capacitor C is:

$$\Delta v_{C1} = \frac{k(1-k)[4(V_L - V_D) - V_H]}{f C R_{BN}} \qquad (14.244)$$

After calculation

$$V_{C1} = k(V_L - V_D) + \frac{1-k}{3}(V_H - V_L + V_D) \qquad (14.245)$$

The average input current is

$$I_L = \frac{1}{T}\left[3\int_0^{kT} i_{C1}(t)\,dt + \int_{kT}^{T} i_{C1}(t)\,dt \right]$$

$$\approx 3k\frac{V_L - V_{C1} - V_D}{R_{BN}} + (1-k)\frac{3V_{C1} + V_L - V_H - V_D}{R_{BF}} \qquad (14.246)$$

The average output current is

$$I_H = \frac{1}{T}\int_{kT}^{T} i_{C1}(t)\,dt \approx (1-k)\frac{3V_{C1} + V_L - V_H - V_D}{R_{BF}} \qquad (14.247)$$

From this formula, we have $4I_H = I_L$.
Input power is

$$P_I = V_L I_L$$

$$= V_L\left[3k\frac{V_L - V_C - V_D}{R_{BN}} + (1-k)\frac{3V_C + V_L - V_H - V_D}{R_{BF}} \right] \qquad (14.248)$$

Output power is

$$P_O = V_H I_H = V_H(1-k)\frac{3V_C + V_L - V_H - V_D}{R_{BF}} \qquad (14.249)$$
FIGURE 14.77 Mode B operation: (a) state-on; (b) state-off; and (c) voltage and current waveforms.

The efficiency is

$$\eta_B = \frac{P_O}{P_I} = \frac{V_H}{4V_L} \quad (14.250)$$

14.8.2 Four-quadrant Switched-capacitor DC/DC Luo-converter

Four-quadrant switched-capacitor DC/DC Luo-converter is shown in Fig. 14.78. Since it performs the *voltage-lift technique,* it has a simple structure with four-quadrant operation. This converter consists of eight switches and two capacitors. The source voltage V_1 and load voltage V_2 (e.g. a battery or DC motor back EMF) are usually constant voltages. In this paper they are supposed to be ± 21 V and ± 14 V. Capacitors C_1 and C_2 are same and $C_1 = C_2 = 2000\,\mu$F. The circuit equivalent resistance $R = 50\,$mΩ. Therefore, there are four modes of operation for this converter:

1. Mode A: energy is converted from source to positive voltage load; the first-quadrant operation, Q_I;
2. Mode B: energy is converted from positive voltage load to source; the second-quadrant operation, Q_{II};
3. Mode C: energy is converted from source to negative voltage load; the third-quadrant operation, Q_{III};
4. Mode D: energy is converted from negative voltage load to source; the fourth-quadrant operation, Q_{IV}.

The first-quadrant (Mode A) is so called the forward motoring (Forw. Mot.) operation. V_1 and V_2 are positive, and I_1 and I_2 are positive as well. The second-quadrant (Mode B) is so called the forward regenerative (Forw. Reg.) braking operation. V_1 and V_2 are positive, and I_1 and I_2 are negative. The third-quadrant (Mode C) is so-called the reverse motoring (Rev. Mot.) operation. V_1 and I_1 are positive, and V_2 and I_2 are negative. The fourth-quadrant (Mode D) is so-called the reverse regenerative (Rev. Reg.) braking operation. V_1 and I_2 are positive, and I_1 and V_2 are negative.

Each mode has two conditions: $V_1 > V_2$ and $V_1 < V_2$ (or $|V_2|$ for Q_{III} and Q_{IV}). Each condition has two states: "on" and

TABLE 14.6 Switch's status (mentioned switches are not open)

Quadrant No. and mode	Condition	State		Source side	Load side
		ON	OFF		
QI, Mode A	$V_1 > V_2$	$S_{1,4,6,8}$	$S_{2,4,6,8}$	V_1+	V_2+
Forw. Mot.	$V_1 < V_2$	$S_{1,4,6,8}$	$S_{2,4,7}$	I_1+	I_2+
QII, Mode B	$V_1 > V_2$	$S_{2,4,6,8}$	$S_{1,4,7}$	V_1+	V_2+
Forw. Reg.	$V_1 < V_2$	$S_{2,4,6,8}$	$S_{1,4,6,8}$	I_1-	I_2-
QIII, Mode C	$V_1 > |V_2|$	$S_{1,4,6,8}$	$S_{3,5,6,8}$	V_1+	V_2-
Rev. Mot.	$V_1 < |V_2|$	$S_{1,4,6,8}$	$S_{3,5,7}$	I_1+	I_2-
QIV Mode D	$V_1 > |V_2|$	$S_{3,5,6,8}$	$S_{1,4,7}$	V_1+	V_2-
Rev. Reg.	$V_1 < |V_2|$	$S_{3,5,6,8}$	$S_{1,4,6,8}$	I_1-	I_2+

"off." Usually, each state is operating in various conduction duty k for different currents. As usual, the efficiency of all SC DC/DC converters is independent from the conduction duty cycle k. The switching period is T where $T = 1/f$. The switch status is shown in Table 14.6.

As usual, the transfer efficiency only relies on the ratio of the source and load voltages, and it is independent on R, C, f, and k. We select $k = 0.5$ for our description. Other values for the reference are $f = 5$ kHz, $V_1 = 21$ V, $V_2 = 14$ V, and total $C = 4000\,\mu$F, $R = 50\,$mΩ.

For **Mode A1**, condition $V_1 > V_2$ is shown in Fig. 14.78a. Since $V_1 > V_2$, two capacitors C_1 and C_2 are connected in parallel. During switch-**on** state, switches S_1, S_4, S_6, and S_8 are closed and other switches are open. In this case, capacitors $C_1 \| C_2$ are charged via the circuit V_1–S_1–$C_1 \| C_2$–S_4, and the voltage across capacitors C_1 and C_2 is increasing. During switch-**off** state, switch S_2, S_4, S_6, and S_8 are closed and other switches are open. In this case capacitors $C_1 \| C_2$ are discharged via the circuit S_2–V_2–S_4–$C_1 \| C_2$, and the voltage across capacitors C_1 and C_2 is decreasing. Capacitors C_1 and C_2 transfer the energy from the source to the load.

The average capacitor voltage

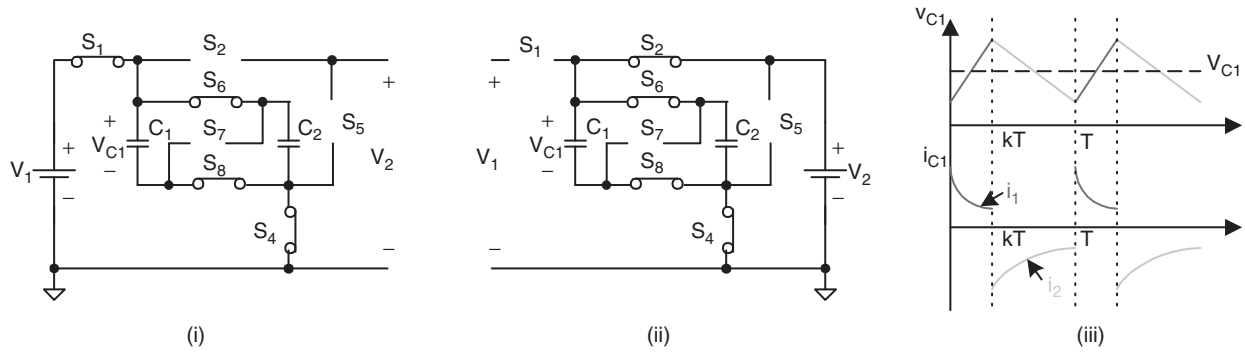
$$V_C = kV_1 + (1 - k)V_2 \quad (14.251)$$
FIGURE 14.78 Four-quadrant sc DC/DC Luo-converter.


FIGURE 14.78a Mode A1 (QI): forward motoring with $V_1 > V_2$: (i) switch on: S_1, S_4, S_6, and S_8 on; (ii) switch off: S_2, S_4, S_6, and S_8, on; and (iii) waveforms.

The average current is

$$I_2 = \frac{1}{T}\int_{kT}^{T} i_C(t)\,dt \approx (1-k)\frac{V_C - V_2}{R} \qquad (14.252)$$

and

$$I_1 = \frac{1}{T}\int_{0}^{kT} i_C(t)\,dt \approx k\frac{V_1 - V_C}{R} \qquad (14.253)$$

The transfer efficiency is

$$\eta_{A1} = \frac{P_O}{P_I} = \frac{1-k}{k}\frac{V_2}{V_1}\frac{V_C - V_2}{V_1 - V_C} = \frac{V_2}{V_1} \qquad (14.254)$$

For **Mode A2**, condition $V_1 < V_2$ is shown in Fig. 14.78b. Since $V_1 < V_2$, two capacitors C_1 and C_2 are connected in parallel during switch on and in series during switch off. This is so-called the *voltage-lift technique*. During switch-**on** state, switches S_1, S_4, S_6, and S_8 are closed and other switches are open. In this case, capacitors $C_1/\!/C_2$ are charged via the circuit

V_1–S_1–$C_1/\!/C_2$–S_4, and the voltage across capacitors C_1 and C_2 is increasing. During switch-**off** state, switches S_2, S_4, and S_7 are closed and other switches are open. In this case, capacitors C_1 and C_2 are discharged via the circuit S_2–V_2–S_4–C_1–S_7–C_2, and the voltage across capacitor C_1 and C_2 is decreasing. Capacitors C_1 and C_2 transfer the energy from the source to the load.

The average capacitor voltage is

$$V_C = \frac{0.5V_1 + V_2}{2.5} = 11.2 \qquad (14.255)$$

The average current is

$$I_2 = \frac{1}{T}\int_{kT}^{T} i_C(t)\,dt \approx (1-k)\frac{2V_C - V_2}{R} \qquad (14.256)$$

and

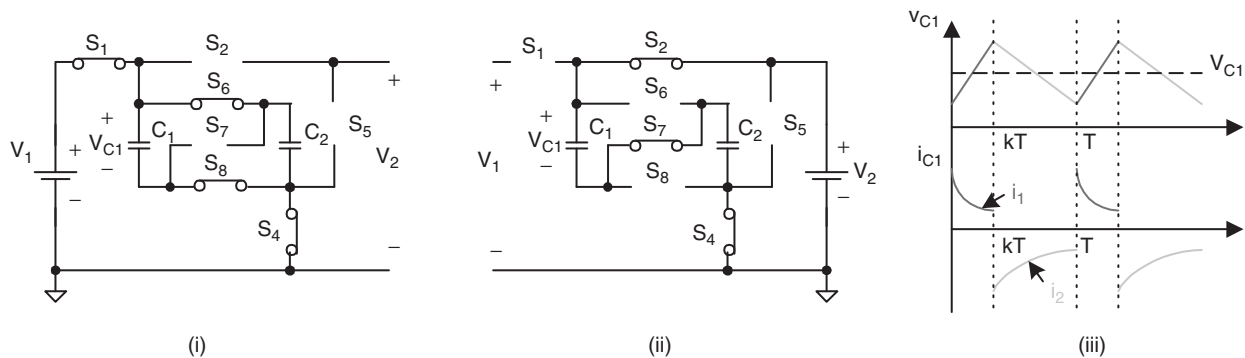
$$I_1 = \frac{1}{T}\int_{0}^{kT} i_C(t)\,dt \approx k\frac{V_1 - V_C}{R} \qquad (14.257)$$


FIGURE 14.78b Mode A2 (QI): forward motoring with $V_1 < V_2$: (i) switch on: S_1, S_4, S_6, and S_8, on; (ii) switch off: S_2, S_4, and S_7, on; and (iii) waveforms.
FIGURE 14.78c Mode B1 (QII): forward regenerative braking with $V_1 > V_2$: (i) switch on: S_2, S_4, S_6, and S_8, on; (ii) switch off; S_1, $S_4(S_5)$, and S_7 on; and (iii) waveforms.

The transfer efficiency is

$$\eta_{A2} = \frac{P_O}{P_I} = \frac{1-k}{k} \frac{V_2}{V_1} \frac{2V_C - V_2}{V_1 - V_C} = \frac{V_2}{2V_1} \qquad (14.258)$$

For **Mode B1**, condition $V_1 > V_2$ is shown in Fig. 14.78c. Since $V_1 > V_2$, two capacitors C_1 and C_2 are connected in parallel during switch on and in series during switch off. The *voltage-lift technique* is applied. During switch-**on** state, switches S_2, S_4, S_6, and S_8 are closed. In this case, capacitors $C_1 /\!/ C_2$ are charged via the circuit V_2–S_2–$C_1 /\!/ C_2$–S_4, and the voltage across capacitors C_1 and C_2 is increasing. During switch-**off** state, switches S_1, S_4, and S_7 are closed. In this case, capacitors C_1 and C_2 are discharged via the circuit S_1–V_1–S_4–C_2–S_7–C_1, and the voltage across capacitor C_1 and C_2 is decreasing. Capacitors C_1 and C_2 transfer the energy from the load to the source. Therefore, we have $I_2 = 2I_1$.

The average capacitor voltage is

$$V_C = \frac{0.5V_2 + V_1}{2.5} = 11.2 \qquad (14.259)$$

The average current is

$$I_1 = \frac{1}{T} \int_{kT}^{T} i_C(t)\,dt \approx (1-k)\frac{2V_C - V_1}{R} \qquad (14.260)$$

and

$$I_2 = \frac{1}{T} \int_0^{kT} i_C(t)\,dt \approx k\frac{V_2 - V_C}{R} \qquad (14.261)$$

The transfer efficiency is

$$\eta_{B1} = \frac{P_O}{P_I} = \frac{1-k}{k} \frac{V_1}{V_2} \frac{2V_C - V_1}{V_2 - V_C} = \frac{V_1}{2V_2} \qquad (14.262)$$

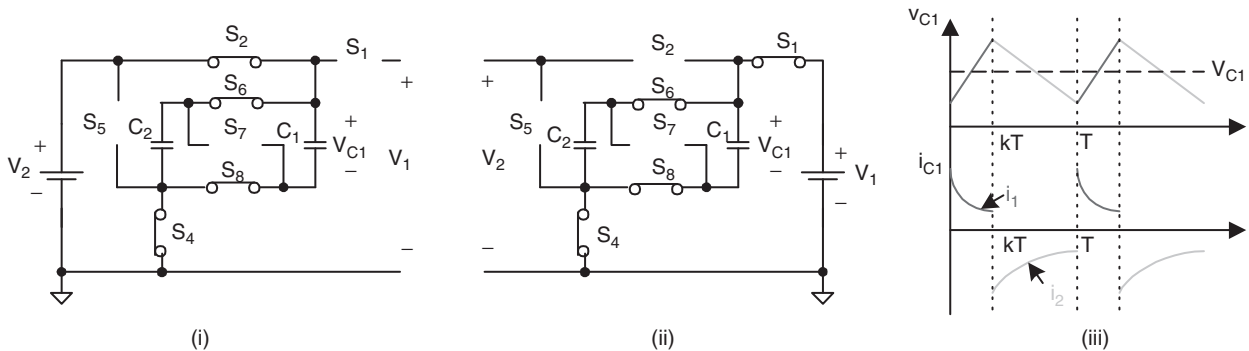
For **Mode B2**, condition $V_1 < V_2$ is shown in Fig. 14.78d. Since $V_1 < V_2$, two capacitors C_1 and C_2 are connected in parallel. During switch-**on** state, switches S_2, S_4, S_6, and S_8 are closed. In this case, capacitors $C_1 /\!/ C_2$ are charged via the circuit V_2–S_2–$C_1 /\!/ C_2$–S_4, and the voltage across capacitors C_1 and C_2


FIGURE 14.78d Mode B2 (QII): forward regenerative braking with $V_1 < V_2$: (i) switch on: S_2, S_4, S_6, and S_8, on; (ii) switch off: S_1, $S_4(S_5)$, S_6, and S_8 on; and (iii) waveforms.

is increasing. During switch-**off** state, switches S_1, S_4, S_6, and S_8 are closed. In this case capacitors $C_1 /\!/ C_2$ is discharged via the circuit $S_1 - V_1 - S_4 - C_1 /\!/ C_2$, and the voltage across capacitors C_1 and C_2 is decreasing. Capacitors C_1 and C_2 transfer the energy from the load to the source. Therefore, we have $I_2 = I_1$.

The average capacitor voltage is

$$V_C = kV_2 + (1 - k)V_1 \tag{14.263}$$

The average current is

$$I_1 = \frac{1}{T} \int_{kT}^{T} i_C(t)dt \approx (1 - k)\frac{V_C - V_1}{R} \tag{14.264}$$

and

$$I_2 = \frac{1}{T} \int_{0}^{kT} i_C(t)dt \approx k\frac{V_2 - V_C}{R} \tag{14.265}$$

The transfer efficiency is

$$\eta_{B2} = \frac{P_O}{P_I} = \frac{1 - k}{k} \frac{V_1}{V_2} \frac{V_C - V_1}{V_2 - V_C} = \frac{V_1}{V_2} \tag{14.266}$$

For **Mode C1**, condition $V_1 > |V_2|$ is shown in Fig. 14.78e. Since $V_1 > |V_2|$, two capacitors C_1 and C_2 are connected in parallel. During switch-**on** state, switches S_1, S_4, S_6, and S_8 are closed. In this case, capacitors $C_1 /\!/ C_2$ are charged via the circuit $V_1 - S_1 - C_1 /\!/ C_2 - S_4$, and the voltage across capacitors C_1 and C_2 is increasing. During switch-**off** state, switches S_3, S_5, S_6, and S_8 are closed. Capacitors C_1 and C_2 are discharged via the circuit $S_3 - V_2 - S_5 - C_1 /\!/ C_2$, and the voltage across capacitors C_1 and C_2 is decreasing. Capacitors C_1 and C_2 transfer the energy from the source to the load. We have $I_1 = I_2$.

The average capacitor voltage is

$$V_C = kV_1 + (1 - k)|V_2| \tag{14.267}$$

The average current (absolute value) is

$$I_2 = \frac{1}{T} \int_{kT}^{T} i_C(t)dt \approx (1 - k)\frac{V_C - |V_2|}{R} \tag{14.268}$$

and the average input current is

$$I_1 = \frac{1}{T} \int_{0}^{kT} i_C(t)dt \approx k\frac{V_1 - V_C}{R} \tag{14.269}$$

The transfer efficiency is

$$\eta_{C1} = \frac{P_O}{P_I} = \frac{1 - k}{k} \frac{|V_2|}{V_1} \frac{V_C - |V_2|}{V_1 - V_C} = \frac{|V_2|}{V_1} \tag{14.270}$$

For **Mode C2**, condition $V_1 < |V_2|$ is shown in Fig. 14.78f. Since $V_1 < |V_2|$, two capacitors C_1 and C_2 are connected in parallel during switch on and in series during switch off, applying the *voltage-lift technique*. During switch-**on** state, switches S_1, S_4, S_6, and S_8, are closed. Capacitors C_1 and C_2 are charged via the circuit $V_1 - S_1 - C_1 /\!/ C_2 - S_4$, and the voltage across capacitors C_1 and C_2 is increasing. During switch-**off** state, switches S_3, S_5, and S_7 are closed. Capacitors C_1 and C_2 is discharged via the circuit $S_3 - V_2 - S_5 - C_1 - S_7 - C_2$, and the voltage across capacitor C_1 and C_2 is decreasing. Capacitors C_1 and C_2 transfer the energy from the source to the load. We have $I_1 = 2I_2$.

The average capacitor voltage is

$$V_C = \frac{0.5V_1 + |V_2|}{2.5} = 11.2 \tag{14.271}$$

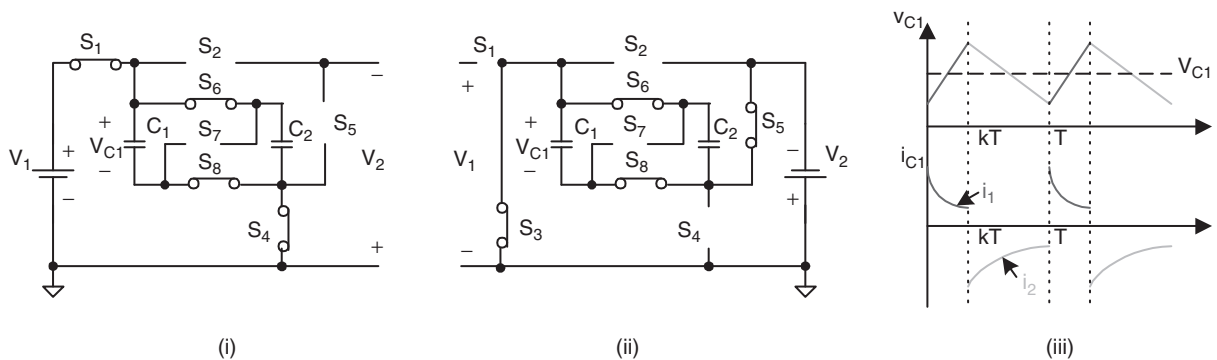
(i)   (ii)   (iii)


FIGURE 14.78e Mode C1 (QIII): reverse motoring with $V_1 > |V_2|$: (i) switch on: S_1, S_4, S_6, and S_8 on; (ii) switch off: S_3, S_5, S_6, and S_8 on; and (iii) waveforms.
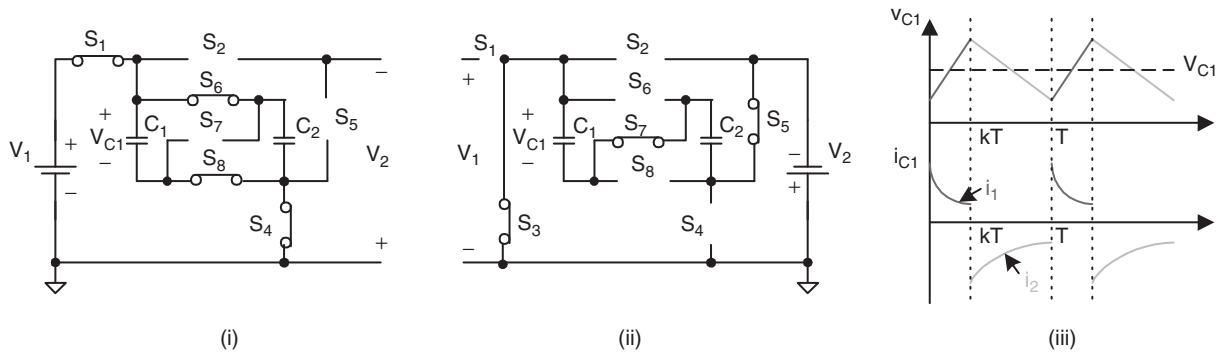

FIGURE 14.78f Mode C2 (QIII): reverse motoring with $V_1 < |V_2|$: (i) switch on: S_1, S_4, S_6, and S_8, on; (ii) switch off: S_3, S_5, and S_7, on; and (iii) waveforms.

The average currents are

$$I_2 = \frac{1}{T} \int_{kT}^{T} i_C(t)\,dt \approx (1-k)\frac{2V_C - |V_2|}{R} \qquad (14.272)$$

and

$$I_1 = \frac{1}{T} \int_{0}^{kT} i_C(t)\,dt \approx k\frac{V_1 - V_C}{R} \qquad (14.273)$$

The transfer efficiency is

$$\eta_{C2} = \frac{P_O}{P_I} = \frac{1-k}{k}\frac{|V_2|}{V_1}\frac{2V_C - |V_2|}{V_1 - V_C} = \frac{|V_2|}{2V_1} \qquad (14.274)$$

For **Mode D1**, condition $V_1 > |V_2|$ is shown in Fig. 14.78g. Since $V_1 > |V_2|$, two capacitors C_1 and C_2 are connected in parallel during switch on and in series during switch off, applying the *voltage-lift technique*. During switch-**on** state, switches

S_3, S_5, S_6, and S_8 are closed. In this case, capacitors $C_1/\!/C_2$ are charged via the circuit V_2–S_3–$C_1/\!/C_2$–S_5, and the voltage across capacitors C_1 and C_2 is increasing. During switch-**off** state, switches S_1, S_4, and S_7 are closed. Capacitors C_1 and C_2 are discharged via the circuit S_1–V_1–S_4–C_2–S_7–C_1, and the voltage across capacitor C_1 and C_2 is decreasing. Capacitors C_1 and C_2 transfer the energy from the load to the source. We have $I_2 = 2I_1$.

The average capacitor voltage is

$$V_C = \frac{0.5|V_2| + V_1}{2.5} = 11.2 \qquad (14.275)$$

The average currents are

$$I_1 = \frac{1}{T} \int_{kT}^{T} i_C(t)\,dt \approx (1-k)\frac{2V_C - V_1}{R} \qquad (14.276)$$

and

$$I_2 = \frac{1}{T} \int_{0}^{kT} i_C(t)\,dt \approx k\frac{|V_2| - V_C}{R} \qquad (14.277)$$
FIGURE 14.78g Mode D1 (QIV): reverse regenerative braking with $V_1 > |V_2|$: (i) switch on: S_3, S_4, S_6, and S_8, on; (ii) switch off: S_1, S_4, and S_7 on; and (iii) waveforms.
FIGURE 14.78h Mode D2 (QIV): reverse regenerative braking with $V_1 < |V_2|$: (i) switch on: S_3, S_5, S_6, and S_8, on; (ii) switch off: S_1, S_4, S_6, and S_8 on; and (iii) waveforms.

The transfer efficiency is

$$\eta_{D1} = \frac{P_O}{P_I} = \frac{1-k}{k} \frac{V_1}{|V_2|} \frac{2V_C - V_1}{|V_2| - V_C} = \frac{V_1}{2|V_2|} \quad (14.278)$$

For **Mode D2**, condition $V_1 < |V_2|$ is shown in Fig. 14.78h. Since $V_1 < |V_2|$, two capacitors C_1 and C_2 are connected in parallel. During switch-**on** state, switches S_3, S_5, S_6, and S_8 are closed. In this case, capacitors $C_1 /\!/ C_2$ are charged via the circuit V_2–S_3–$C_1 /\!/ C_2$–S_5, and the voltage across capacitors C_1 and C_2 is increasing. During switch-**off** state, switches S_1, S_4, S_6, and S_8 are closed. Capacitors C_1 and C_2 are discharged via the circuit S_1–V_1–S_4–$C_1 /\!/ C_2$, and the voltage across capacitors C_1 and C_2 is decreasing. Capacitors C_1 and C_2 transfer the energy from the load to the source. We have $I_2 = I_1$.

The average capacitor voltage is

$$V_C = k|V_2| + (1-k)V_1 \quad (14.279)$$

The average currents are

$$I_1 = \frac{1}{T} \int_{kT}^{T} i_C(t)\,dt \approx (1-k)\frac{V_C - V_1}{R} \quad (14.280)$$

and

$$I_2 = \frac{1}{T} \int_{0}^{kT} i_C(t)\,dt \approx k\frac{|V_2| - V_C}{R} \quad (14.281)$$

The transfer efficiency is

$$\eta_{D2} = \frac{P_O}{P_I} = \frac{1-k}{k} \frac{V_1}{|V_2|} \frac{V_C - V_1}{|V_2| - V_C} = \frac{V_1}{|V_2|} \quad (14.282)$$

14.9 Multiple-lift Push–Pull Switched-capacitor Luo-converters

Micro-power-consumption technique requires high power density DC/DC converters and power supply source. Voltage-lift (VL) technique is a popular method to apply in electronic circuit design. Since switched-capacitor can be integrated into power integrated circuit (IC) chip, its size is small. Combining switched-capacitor and VL techniques the DC/DC converters with small size, high power density, high voltage transfer gain, high power efficiency, and low EMI can be constructed. This section introduces a new series DC/DC converters – multiple-lift push–pull switched-capacitor DC/DC Luo-converters. There are two subseries:

- P/O multiple-lift (ML) push–pull (PP) switched-capacitor (SC) DC/DC Luo-converter;
- N/O multiple-lift push–pull switched-capacitor DC/DC Luo-converter.

14.9.1 P/O Multiple-lift Push–Pull Switched-capacitor DC/DC Luo-converter

P/O ML-PP SC DC/DC Luo-converters have several subseries:

- Main series;
- Additional series;
- Enhanced series;
- Re-enhanced series;
- Multiple-enhanced series.

We only introduce three circuits of main series and additional series in this section.

P/O ML-PP SC Luo-converter elementary circuit is shown in Fig. 14.79a. Its output voltage and current are

$$V_O = 2V_I$$
FIGURE 14.79 P/O ML-PP SC Luo-converter: (a) elemental; (b) re-lift; and (c) triple-lift circuits.

and

$$I_O = \frac{1}{2}I_I$$

The voltage transfer gain is

$$M_E = \frac{V_O}{V_I} = 2 \qquad (14.283)$$

P/O ML-PP SC Luo-converter re-lift circuit is shown in Fig. 14.79b. Its output voltage and current are

$$V_O = 4V_I$$

and

$$I_O = \frac{1}{4}I_I$$

The voltage transfer gain is

$$M_R = 4 \qquad (14.284)$$

P/O ML-PP SC Luo-converter triple-lift circuit is shown in Fig. 14.79c. Its output voltage and current are

$$V_O = 8V_I$$

and

$$I_O = \frac{1}{8}I_I$$

The voltage transfer gain is

$$M_T = 8 \qquad (14.285)$$

P/O ML-PP SC Luo-converter additional circuit is shown in Fig. 14.80a. Its output voltage and current are

$$V_O = 3V_I$$

and

$$I_O = \frac{1}{3}I_I$$

The voltage transfer gain is

$$M_A = \frac{V_O}{V_I} = 3 \qquad (14.286)$$

P/O ML-PP SC Luo-converter additional re-lift circuit is shown in Fig. 14.80b. Its output voltage and current are

$$V_O = 6V_I$$

and

$$I_O = \frac{1}{6}I_I$$

The voltage transfer gain is

$$M_{AR} = \frac{V_O}{V_I} = 6 \qquad (14.287)$$
FIGURE 14.80 P/O ML-PP SC Luo-converter re-lift circuit: (a) additional; (b) re-lift; and (c) triple-lift circuits.

P/O ML-PP SC Luo-converter additional triple-lift circuit is shown in Fig. 14.80c. Its output voltage and current are

$$V_O = 12V_I$$

and

$$I_O = \frac{1}{12}I_I$$

The voltage transfer gain is

$$M_{AT} = \frac{V_O}{V_I} = 12 \tag{14.288}$$

14.9.2 N/O Multiple-lift Push–Pull Switched-capacitor DC/DC Luo-converter

N/O ML-PP SC DC/DC Luo-converters have several subseries:

- Main series;
- Additional series;
- Enhanced series;
- Re-enhanced series;
- Multiple-enhanced series.

We only introduce three circuits of main series and additional series in this section.

N/O ML-PP SC Luo-converter elementary circuit is shown in Fig. 14.81a. Its output voltage and current are

$$V_O = V_I$$

and

$$I_O = I_I$$

The voltage transfer gain is

$$M_E = \frac{V_O}{V_I} = 1 \tag{14.289}$$

N/O ML-PP SC Luo-converter re-lift circuit is shown in Fig. 14.81b. Its output voltage and current are

$$V_O = 3V_I$$

and

$$I_O = \frac{1}{3}I_I$$

The voltage transfer gain is

$$M_R = 3 \tag{14.290}$$

N/O ML-PP SC Luo-converter triple-lift circuit is shown in Fig. 14.81c. Its output voltage and current are

$$V_O = 7V_I$$

and

$$I_O = \frac{1}{7}I_I$$
FIGURE 14.81 N/O ML-PP SC Luo-converter: (a) elemental; (b) re-lift; and (c) triple-lift circuits.

The voltage transfer gain is

$$M_T = 7 \qquad (14.291)$$

N/O ML-PP SC Luo-converter additional circuit is shown in Fig. 14.82a. Its output voltage and current are

$$V_O = 2V_I$$

and

$$I_O = \frac{1}{2}I_I$$

The voltage transfer gain is

$$M_A = \frac{V_O}{V_I} = 2 \qquad (14.292)$$

N/O ML-PP SC Luo-converter additional re-lift circuit is shown in Fig. 14.82b. Its output voltage and current are

$$V_O = 5V_I$$

and

$$I_O = \frac{1}{5}I_I$$

The voltage transfer gain is

$$M_{AR} = \frac{V_O}{V_I} = 5 \qquad (14.293)$$

N/O ML-PP SC Luo-converter additional triple-lift circuit is shown in Fig. 14.82c. Its output voltage and current are

$$V_O = 11V_I$$

and

$$I_O = \frac{1}{11}I_I$$

The voltage transfer gain is

$$M_{AT} = \frac{V_O}{V_I} = 11 \qquad (14.294)$$

14.10 Switched-inductor Multi-quadrant Operation Luo-converters

Switched-capacitor converters usually have many switches and capacitors, especially for the system with high ratio between
FIGURE 14.82 N/O ML-PP SC Luo-converter re-lift circuit: (a) additional; (b) re-lift; and (c) triple-lift circuits.

source and load voltages. Switched-inductor converter usually has only one inductor even if it works in single-, two-, and/or four-quadrant operation. Simplicity is the main advantage of all switched inductor converters.

Switched-inductor multi-quadrant Luo-converters are the third-generation converters, and they are made of only inductor. These converters have been derived from chopper circuits. They have three modes:

- Two-quadrant switched-inductor DC/DC Luo-converter in forward operation;
- Two-quadrant switched-inductor DC/DC Luo-converter in reverse operation;
- Four-quadrant switched-inductor DC/DC Luo-converter.

The two-quadrant switched-inductor DC/DC Luo-converter in forward operation has been derived for the energy transmission of a dual-voltage system. The both, source and load voltages are positive polarity. It performs in the first-quadrant Q_I and the second-quadrant Q_{II} corresponding to the DC motor forward operation in motoring and regenerative braking states.

The two-quadrant switched-inductor DC/DC Luo-converter in reverse operation has been derived for the energy transmission of a dual-voltage system. The source voltage is positive and load voltage is negative polarity. It performs

in the third-quadrant Q_{III} and the fourth-quadrant Q_{IV} corresponding to the DC motor reverse operation in motoring and regenerative braking states.

The four-quadrant switched-inductor DC/DC Luo-converter has been derived for the energy transmission of a dual-voltage system. The source voltage is positive and load voltage can be positive or negative polarity. It performs four-quadrant operation corresponding to the DC motor forward and reverse operation in motoring and regenerative braking states.

14.10.1 Two-quadrant Switched-inductor DC/DC Luo-converter in Forward Operation

Forward operation (F) 2Q SI Luo-converter is shown in Fig. 14.83, and it consists of two switches with two passive diodes, two inductors, and one capacitor. The source voltage (V_1) and load voltage (V_2) are usually considered as constant voltages. The load can be a battery or motor back EMF. For example, the source voltage is 42 V and load voltage is $+14$ V. There are two modes of operation:

1. Mode A (QI): electrical energy is transferred from source side V_1 to load side V_2;
FIGURE 14.83 Switched-inductor QI and II DC/DC Luo-converter.

The power transfer efficiency is

$$\eta_A = \frac{P_O}{P_I} = \frac{V_2}{kV_1} \qquad (14.297)$$

The boundary between continuous and discontinuous regions is defined as

$$\zeta \geq 1 \quad \text{i.e.}$$

$$\frac{k(1-k)V_1}{kV_1 - V_2}\frac{R}{2fL} \geq 1 \quad \text{or} \quad k \leq \frac{V_2}{V_1} + k(1-k)\frac{R}{2fL} \quad (14.298)$$

Average inductor current I_L in discontinuous region is

$$I_L = \frac{V_1}{V_2 + RI_L}\frac{V_1 - V_2 - RI_L}{2fL}k^2 \qquad (14.299)$$

2. Mode B (QII): electrical energy is transferred from load side V_2 to source side V_1.

Mode A: The equivalent circuits during switch-on and -off periods are shown in Figs. 14.84a and b. The typical output voltage and current waveforms are shown in Fig. 14.84c.

We have the average inductor current I_L as

$$I_L = \frac{kV_1 - V_2}{R} \qquad (14.295)$$

The variation ratio of the inductor current i_L is

$$\zeta = \frac{\Delta i_L/2}{I_L} = \frac{k(1-k)V_1}{kV_1 - V_2}\frac{R}{2fL} \qquad (14.296)$$

The power transfer efficiency is

$$\eta_{A-dis} = \frac{P_O}{P_I} = \frac{V_2}{V_2 + RI_L} \quad \text{with} \quad k \leq \frac{V_2}{V_1} + k(1-k)\frac{R}{2fL} \qquad (14.300)$$

Mode B: The equivalent circuits during switch-on and -off periods are shown in Figs. 14.85a and b. The typical output voltage and current waveforms are shown in Fig. 14.85c.

The average inductor current I_L is

$$I_L = \frac{V_2 - (1-k)V_1}{R} \qquad (14.301)$$
FIGURE 14.84 Mode A of F 2Q SI Luo-converter: (a) state-on: S_1 on; (b) state-off: D_2 on, S_1, off; and (c) input and output current waveforms.
FIGURE 14.85 Mode B of F 2Q SI Luo-converter: (a) state-on: S_2 on; (b) state-off: D_1 on, S_2 off; and (c) input and output current waveforms.

The variation ratio of the inductor current i_L is

$$\zeta = \frac{\Delta i_L/2}{I_L} = \frac{k(1-k)V_1}{V_2 - (1-k)V_1} \frac{R}{2fL} \qquad (14.302)$$

The power transfer efficiency

$$\eta_B = \frac{P_O}{P_I} = \frac{(1-k)V_1}{V_2} \qquad (14.303)$$

The boundary between continuous and discontinuous regions is defined as

$$\zeta \geq 1, \quad \text{i.e.}$$

$$\frac{k(1-k)V_1}{V_2 - (1-k)V_1} \frac{R}{2fL} \geq 1 \quad \text{or} \quad k \leq \left(1 - \frac{V_2}{V_1}\right) + k(1-k)\frac{R}{2fL} \qquad (14.304)$$

Average inductor current I_L in discontinuous region is

$$I_L = \frac{V_1}{V_1 - V_2 + RI_L} \frac{V_2 - RI_L}{2fL} k^2 \qquad (14.305)$$

The power transfer efficiency is

$$\eta_{B-dis} = \frac{P_O}{P_I} = \frac{V_2 - RI_L}{V_2}$$

$$\text{with} \quad k \leq \left(1 - \frac{V_2}{V_1}\right) + k(1-k)\frac{R}{2fL} \qquad (14.306)$$

14.10.2 Two-quadrant Switched-inductor DC/DC Luo-converter in Reverse Operation

Reverse operation (R) 2Q SI Luo-converter is shown in Fig. 14.86, and it consists of two switches with two passive diodes, two inductors, and one capacitor. The source voltage (V_1) and load voltage (V_2) are usually considered as constant
FIGURE 14.86   Switched-inductor QIII and IV DC/DC Luo-converter.

voltages. The load can be a battery or motor back EMF. For example, the source voltage is 42 V and load voltage is −14 V. There are two modes of operation:

1. Mode C (QIII): electrical energy is transferred from source side V_1 to load side $-V_2$;
2. Mode D (QIV): electrical energy is transferred from load side $-V_2$ to source side V_1.

Mode C: The equivalent circuits during switch-on and -off periods are shown in Figs. 14.87a and b. The typical output voltage and current waveforms are shown in Fig. 14.87c.

We have the average inductor current I_L as

$$I_L = \frac{kV_1 - (1-k)V_2}{R} \qquad (14.307)$$

The variation ratio of the inductor current i_L is

$$\zeta = \frac{\Delta i_L/2}{I_L} = \frac{k(1-k)(V_1 + V_2)}{kV_1 - (1-k)V_2} \frac{R}{2fL} \qquad (14.308)$$

The power transfer efficiency is

$$\eta_C = \frac{P_O}{P_I} = \frac{(1-k)V_2}{kV_1} \qquad (14.309)$$
FIGURE 14.87   Mode C of F 2Q SI Luo-converter: (a) state-on; S$_1$ on; (b) state-off: D$_2$ on, S$_1$ off; and (c) input and output current waveforms.

The boundary between continuous and discontinuous regions is defined as

$$\zeta \geq 1, \quad \text{i.e.}$$

$$\frac{k(1-k)(V_1+V_2)}{kV_1-(1-k)V_2}\frac{R}{2fL}\geq 1 \quad \text{or} \quad k\leq\frac{V_2}{V_1+V_2}+k(1-k)\frac{R}{2fL}$$

$$(14.310)$$

Average inductor current I_L in discontinuous region is

$$I_L = \frac{V_1+V_2}{V_2+RI_L}\frac{V_1-RI_L}{2fL}k^2 \tag{14.311}$$

The power transfer efficiency is

$$\eta_{C-dis} = \frac{P_O}{P_I} = \frac{V_2}{V_1}\frac{V_1-RI_L}{V_2+RI_L}$$

$$\text{with} \quad k\leq\frac{V_2}{V_1+V_2}+k(1-k)\frac{R}{2fL} \tag{14.312}$$

Mode D: The equivalent circuits during switch-on and -off periods are shown in Figs. 14.88a and b. The typical output voltage and current waveforms are shown in Fig. 14.88c.

The average inductor current I_L is

$$I_L = \frac{kV_2-(1-k)V_1}{R} \tag{14.313}$$

The variation ratio of the inductor current i_L is

$$\zeta = \frac{\Delta i_L/2}{I_L} = \frac{k(1-k)(V_1+V_2)}{kV_2-(1-k)V_1}\frac{R}{2fL} \tag{14.314}$$

The power transfer efficiency is

$$\eta_D = \frac{P_O}{P_I} = \frac{(1-k)V_1}{kV_2} \tag{14.315}$$

The boundary between continuous and discontinuous regions is defined as

$$\zeta \geq 1, \quad \text{i.e.}$$

$$\frac{k(1-k)(V_1+V_2)}{kV_2-(1-k)V_1}\frac{R}{2fL}\geq 1 \quad \text{or} \quad k\leq\frac{V_1}{V_1+V_2}+k(1-k)\frac{R}{2fL}$$

$$(14.316)$$

Average inductor current I_L in discontinuous region is

$$I_L = \int_0^{t_4} = \frac{V_1+V_2}{V_1+RI_L}\frac{V_2-RI_L}{2fL}k^2 \tag{14.317}$$

The power transfer efficiency is

$$\eta_{D-dis} = \frac{P_O}{P_I} = \frac{V_1}{V_2}\frac{V_2-RI_L}{V_1+RI_L}$$

$$\text{with} \quad k\leq\frac{V_1}{V_1+V_2}+k(1-k)\frac{R}{2fL} \tag{14.318}$$

14.10.3 Four-quadrant Switched-inductor DC/DC Luo-converter

Switched-inductor DC/DC converters successfully overcome the disadvantage of switched-capacitor converters. Usually, only one inductor is required for each converter with one- or two- or four-quadrant operation, no matter how large the difference between the input and output voltage is. Therefore, switched-inductor converter has very simple topology and circuit. Consequently, it has high power density. This paper introduces a *switched-inductor four-quadrant DC/DC Luo-converter*.

This converter, shown in Fig. 14.89, consists of three switches, two diodes, and only one inductor L. The source voltage V_1 and load voltage V_2 (e.g. a battery or DC motor back EMF) are usually constant voltages. R is the equivalent resistance of the circuit, it is usually small. In this paper, $V_1 > |V_2|$,

(a)   (b)   (c)

FIGURE 14.88   Mode D of F 2Q SI Luo-converter: (a) state-on: S_2 on; (b) state-off: D_1 on, S_2 off; and (c) input and output waveforms.
FIGURE 14.89 Four-quadrant switched-inductor DC/DC Luo-converter.

they are supposed as $+42$ V and ± 14 V, respectively. Therefore, there are four-quadrants (modes) of operation:

1. Mode A: energy is transferred from source to positive voltage load; the first-quadrant operation, Q_I;
2. Mode B: energy is transferred from positive voltage load to source; the second-quadrant operation, Q_{II};
3. Mode C: energy is transferred from source to negative voltage load; the third-quadrant operation, Q_{III};
4. Mode C: energy is transferred from negative voltage load to source; the fourth-quadrant operation, Q_{IV}.

The first-quadrant is so-called the forward motoring (Forw. Mot.) operation. V_1 and V_2 are positive, and I_1 and I_2 are positive as well. The second-quadrant is so-called the forward regenerative (Forw. Reg.) braking operation. V_1 and V_2 are positive, and I_1 and I_2 are negative. The third-quadrant is so-called the reverse motoring (Rev. Mot.) operation. V_1 and I_1 are positive, and V_2 and I_2 are negative. The fourth-quadrant is so-called the reverse regenerative (Rev. Reg.) braking operation. V_1 and I_2 are positive, and I_1 and V_2 are negative. Each mode has two states: "on" and "off." Usually, each state is operating in different conduction duty k. The switching period is T, where $T = 1/f$. The switch status is shown in Table 14.7.

Mode A is shown in Fig. 14.84. During switch-**on** state, switch S_1 is closed. In this case the source voltage V_1 supplies the load V_2 and inductor L, inductor current i_L increases.

During switch-**off** state, diode D_2 is on. In this case current i_L flows through the load V_2 via the free-wheeling diode D_2, and it decreases.

Mode B is shown in Fig. 14.85. During switch-**on** state, switch S_2 is closed. In this case the load voltage V_2 supplies the inductor L, inductor current i_L increases. During switch-**off** state, diode D_1 is on, current i_L flows through the source V_1 and load V_2 via the diode D_1, and it decreases.

Mode C is shown in Fig. 14.87. During switch-**on** state, switch S_1 is closed. The source voltage V_1 supplies the inductor L, inductor current i_L increases. During switch-**off** state, diode D_2 is on. Current i_L flows through the load V_2 via the free-wheeling diode D_2, and it decreases.

Mode D is shown in Fig. 14.88. During switch-**on** state, switch S_2 is closed. The load voltage V_2 supplies the inductor L, inductor current i_L increases. During switch-**off** state, diode D_1 is on. Current i_L flows through the source V_1 via the diode D_1, and it decreases.

All description of the Modes A, B, C, and D is same as in Sections 14.10.1 and 14.10.2.

14.11 Multi-quadrant ZCS Quasi-resonant Luo-converters

Soft-switching converters are the fourth-generation converters. These converters are made of only inductor or capacitors. They usually perform in the systems between two voltage sources: V_1 and V_2. Voltage source V_1 is proposed positive voltage and voltage V_2 is the load voltage that can be positive or negative. In the investigation, both voltages are proposed constant voltage. Since V_1 and V_2 are constant value, the voltage transfer gain is constant. Our interesting research will concentrate on the working current and the power transfer efficiency η. The resistance R of the inductor has to be considered for the power transfer efficiency η calculation.

Reviewing the papers in the literature, we can find that most of the papers investigating the switched-component converters

are working in single-quadrant operation. Professor Luo and colleagues have developed this technique into multi-quadrant operation. We describe these in this section and the next sections.

Multi-quadrant ZCS quasi-resonant Luo-converters are the fourth-generation converters. Because these converters implement ZCS technique, they have the advantages of high power density, high power transfer efficiency, low EMI, and reasonable EMC. They have three modes:

- Two-quadrant ZCS quasi-resonant DC/DC Luo-converter in forward operation;
- Two-quadrant ZCS quasi-resonant DC/DC Luo-converter in reverse operation;
- Four-quadrant ZCS quasi-resonant DC/DC Luo-converter.

The two-quadrant ZCS quasi-resonant DC/DC Luo-converter in forward operation is derived for the energy transmission of a dual-voltage system. Both, the source and load voltages are positive polarity. It performs in the first-quadrant Q_I and the second-quadrant Q_{II} corresponding to the DC motor forward operation in motoring and regenerative braking states.

The two-quadrant ZCS quasi-resonant DC/DC Luo-converter in reverse operation is derived for the energy transmission of a dual-voltage system. The source voltage is positive and load voltage is negative polarity. It performs in the third-quadrant Q_{III} and the fourth-quadrant Q_{IV} corresponding to the DC motor reverse operation in motoring and regenerative braking states.

The four-quadrant ZCS quasi-resonant DC/DC Luo-converter is derived for the energy transmission of a dual-voltage system. The source voltage is positive, and load voltage can be positive or negative polarity. It performs four-quadrant operation corresponding to the DC motor forward and reverse operation in motoring and regenerative braking states.

14.11.1 Two-quadrant ZCS Quasi-resonant Luo-converter in Forward Operation

Since both voltages are low, this converter is designed as a ZCS quasi-resonant converter (ZCS-QRC). It is shown in Fig. 14.90. This converter consists of one main inductor L and

FIGURE 14.90 Two-quadrant (QI+QII) DC/DC ZCS quasi-resonant Luo-converter.

TABLE 14.8 Switch's status (the blank status means off)

Switch or diode	Mode A (QI)		Mode B (QII)

S_2			ON	
D_2		ON		

two switches with their auxiliary components. A switch S_a is used for two-quadrant operation. Assuming the main inductance is sufficiently large, the current i_L is constant. The source voltage V_1 and load voltage V_2 are usually constant, $V_1 = 42\,\text{V}$ and $V_2 = 14\,\text{V}$. There are two modes of operation:

1. Mode A (Quadrant I): electrical energy is transferred from V_1 side to V_2 side, switch S_a links to D_2;
2. Mode B (Quadrant II): electrical energy is transferred from V_2 side to V_1 side, switch S_a links to D_1.

Each mode has two states: "on" and "off." The switch status of each state is shown in Table 14.8.

Mode A is a ZCS buck converter. The equivalent circuit, current, and voltage waveforms are shown in Fig. 14.91. There are four time regions for the switching on and off period. The conduction duty cycle is $k = (t_1 + t_2)$ when the input current
FIGURE 14.91 Mode A operation: (a) equivalent circuit and (b) waveforms.

flows through the switch S_1 and inductor L. The whole period is $T = (t_1 + t_2 + t_3 + t_4)$. Some formulas are listed below

$$\omega_1 = \frac{1}{\sqrt{L_{r1}C_r}}; \quad Z_1 = \sqrt{\frac{L_{r1}}{C_r}}; \quad i_{1-peak} = I_L + \frac{V_1}{Z_1} \tag{14.319}$$

$$t_1 = \frac{I_L L_{r1}}{V_1}; \quad \alpha_1 = \sin^{-1}\left(\frac{I_L Z_1}{V_1}\right) \tag{14.320}$$

$$t_2 = \frac{1}{\omega_1}(\pi + \alpha_1); \quad v_{CO} = V_1(1 + \cos\alpha_1) \tag{14.321}$$

$$t_3 = \frac{v_{CO}C_r}{I_L}; \quad \frac{I_L V_2}{V_1} = \frac{t_1 + t_2}{T}\left(I_L + \frac{V_1}{Z_1}\frac{\cos\alpha_1}{\pi/2 + \alpha_1}\right) \tag{14.322}$$

$$t_4 = \frac{V_1(t_1 + t_2)}{V_2 I_L}\left(I_L + \frac{V_1}{Z_1}\frac{\cos\alpha_1}{\pi/2 + \alpha_1}\right) - (t_1 + t_2 + t_3); \tag{14.323}$$

$$k = \frac{t_1 + t_2}{t_1 + t_2 + t_3 + t_4}; \quad T = t_1 + t_2 + t_3 + t_4; \quad f = 1/T \tag{14.324}$$

Mode B is a ZCS boost converter. The equivalent circuit, current, and voltage waveforms are shown in Fig. 14.92. There

are four time regions for the switching on and off period. The conduction duty cycle is $k = (t_1 + t_2)$, but the output current only flows through the source V_1 in the period t_4. The whole period is $T = (t_1 + t_2 + t_3 + t_4)$. Some formulas are listed below

$$\omega_2 = \frac{1}{\sqrt{L_{r2}C_r}}; \quad Z_2 = \sqrt{\frac{L_{r2}}{C_r}}; \quad i_{2-peak} = I_L + \frac{V_1}{Z_2} \tag{14.325}$$

$$t_1 = \frac{I_L L_{r2}}{V_1}; \quad \alpha_2 = \sin^{-1}\left(\frac{I_L Z_2}{V_1}\right) \tag{14.326}$$

$$t_2 = \frac{1}{\omega_2}(\pi + \alpha_2); \quad v_{CO} = -V_1\cos\alpha_2 \tag{14.327}$$

$$t_3 = \frac{(V_1 - v_{CO})C_r}{I_L}; \quad \frac{I_L V_2}{V_1} = \frac{t_4}{T}I_L \tag{14.328}$$

$$\frac{V_2}{V_1} = \frac{t_4}{T} = \frac{t_4}{t_1 + t_2 + t_3 + t_4}; \quad t_4 = \frac{t_1 + t_2 + t_3}{(V_1/V_2) - 1} \tag{14.329}$$

$$k = \frac{t_1 + t_2}{t_1 + t_2 + t_3 + t_4}; \quad T = t_1 + t_2 + t_3 + t_4; \quad f = 1/T \tag{14.330}$$

14.11.2 Two-quadrant ZCS Quasi-resonant Luo-converter in Reverse Operation

Two-quadrant ZCS quasi-resonant Luo-converter in reverse operation is shown in Fig. 14.93. It is a new soft-switching technique with two-quadrant operation, which effectively reduces the power losses and largely increases the power transfer efficiency. It consists of one main inductor L and two switches with their auxiliary components. A switch S_a is used for two-quadrant operation. Assuming the main inductance L is sufficiently large, the current i_L is constant. The source voltage V_1 and load voltage V_2 are usually constant, e.g. $V_1 = 42\,\text{V}$ and $V_2 = -28\,\text{V}$. There are two modes of operation:

1. Mode C (Quadrant III): electrical energy is transferred from V_1 side to $-V_2$ side, switch S_a links to D_2;
2. Mode D (Quadrant IV): electrical energy is transferred from $-V_2$ side to V_1 side, switch S_a links to D_1.

FIGURE 14.92 Mode B operation: (a) equivalent circuit and (b) waveforms.
FIGURE 14.93 Two-quadrant (QIII+IV) DC/DC ZCS quasi-resonant Luo-converter.

Each mode has two states: "on" and "off." The switch status of each state is shown in Table 14.9.

Mode C is a ZCS buck–boost converter. The equivalent circuit, current, and voltage waveforms are shown in Fig. 14.94. There are four time regions for the switching on and off period. The conduction duty cycle is $kT = (t_1 + t_2)$ when the input current flows through the switch S_1 and the main inductor L. The whole period is $T = (t_1 + t_2 + t_3 + t_4)$. Some formulas are listed below

$$\omega_1 = \frac{1}{\sqrt{L_{r1}C_r}}; \quad Z_1 = \sqrt{\frac{L_{r1}}{C_r}}; \quad i_{1-peak} = I_L + \frac{V_1}{Z_1}$$

$$k = \frac{t_1 + t_2}{t_1 + t_2 + t_3 + t_4}; \quad T = t_1 + t_2 + t_3 + t_4; \quad f = 1/T$$

$$(14.342)$$

14.11.3 Four-quadrant ZCS Quasi-resonant Luo-converter

Four-quadrant ZCS quasi-resonant Luo-converter is shown in Fig. 14.96. Circuit 1 implements the operation in quadrants I and II, circuit 2 implements the operation in quadrants III and IV. Circuit 1 and 2 can be converted to each other by auxiliary switch. Each circuit consists of one main inductor L and two switches. A switch S_a is used for four-quadrant operation. Assuming that the main inductance L is sufficiently large, the
FIGURE 14.96 Four-quadrant DC/DC ZCS quasi-resonant Luo-converter.

current i_L remains constant. The source and load voltages are usually constant, e.g. $V_1 = 42$ V and $V_2 = \pm 28$ V [7–9]. There are four modes of operation:

1. Mode A (Quadrant I): electrical energy is transferred from V_1 side to V_2 side, switch S_a links to D_2;
2. Mode B (Quadrant II): electrical energy is transferred from V_2 side to V_1 side, switch S_a links to D_1;
3. Mode C (Quadrant III): electrical energy is transferred from V_1 side to $-V_2$ side, switch S_a links to D_2;
4. Mode D (Quadrant IV): electrical energy is transferred from $-V_2$ side to V_1 side, switch S_a links to D_1.

Each mode has two states: "on" and "off." The switch status of each state is shown in Table 14.10.

The operation of Mode A, B, C, and D is same as in the previous Sections 14.11.1 and 14.11.2.

14.12 Multi-quadrant ZVS Quasi-resonant Luo-converters

Multi-quadrant ZVS quasi-resonant Luo-converters are the fourth-generation converters. Because these converters implement ZCS technique, they have the advantages of high power density, high power transfer efficiency, low EMI, and reasonable EMC. They have three modes:

- Two-quadrant ZVS quasi-resonant DC/DC Luo-converter in forward operation;
- Two-quadrant ZVS quasi-resonant DC/DC Luo-converter in reverse operation;
- Four-quadrant ZVS quasi-resonant DC/DC Luo-converter.

The two-quadrant ZVS quasi-resonant DC/DC Luo-converter in forward operation is derived for the energy transmission of a dual-voltage system. Both, the source and load voltages are positive polarity. It performs in the first-quadrant Q_I and the second-quadrant Q_{II} corresponding to the DC motor forward operation in motoring and regenerative braking states.

The two-quadrant ZVS quasi-resonant DC/DC Luo-converter in reverse operation is derived for the energy transmission of a dual-voltage system. The source voltage is positive and load voltage is negative polarity. It performs in the third-quadrant Q_{III} and the fourth-quadrant Q_{IV} corresponding to the DC motor reverse operation in motoring and regenerative braking states.

The four-quadrant ZVS quasi-resonant DC/DC Luo-converter is derived for the energy transmission of a dual-voltage system. The source voltage is positive, and load voltage can be positive or negative polarity. It performs four-quadrant operation corresponding to the DC motor forward and reverse operation in motoring and regenerative braking states.

(b)

FIGURE 14.99 Mode B operation: (a) equivalent circuit and (b) waveforms.

$$t_2 = \frac{1}{\omega_2}(\pi + \alpha_2); \quad i_{rO2} = I_L(1 + \cos\alpha_2) \tag{14.351}$$

$$t_3 = \frac{i_{rO2} L_r}{V_1};$$

$$I_1 = \frac{I_L V_2}{V_1} = \frac{1}{T}\int_{t_1}^{t_3} i_r dt \approx \frac{1}{T}\left[I_L(t_2 + t_3)\right] = \frac{t_2 + t_3}{T}I_L;$$

or $\quad \dfrac{V_2}{V_1} = \dfrac{1}{T}(t_2 + t_3) = \dfrac{t_2 + t_3}{t_1 + t_2 + t_3 + t_4} \tag{14.352}$

$$t_4 = \left(\frac{V_1}{V_2} - 1\right)(t_2 + t_3) - t_1; \tag{14.353}$$

$$k = \frac{t_3 + t_4}{t_1 + t_2 + t_3 + t_4}; \quad T = t_1 + t_2 + t_3 + t_4; \quad f = 1/T$$

$$(14.354)$$

14.12.2 Two-quadrant ZVS Quasi-resonant DC/DC Luo-converter in Reverse Operation

Two-quadrant ZVS quasi-resonant Luo-converter in reverse operation is shown in Fig. 14.100. It consists of one main inductor L and two switches with their auxiliary components. Assuming the main inductance L is sufficiently large, the current i_L is constant. The source voltage V_1 and load voltage V_2 are usually constant, e.g. $V_1 = +42$ V and $V_2 = -28$ V. There are two modes of operation:

1. Mode C (Quadrant III): electrical energy is transferred from V_1 side to $-V_2$ side;
2. Mode D (Quadrant IV): electrical energy is transferred from $-V_2$ side to V_1 side.

Each mode has two states: "on" and "off." The switch status of each state is shown in Table 14.12.

Mode C is a ZVS buck–boost converter shown in Fig. 14.101. There are four time regions for the switching on and off period. The conduction duty cycle is $kT = (t_3 + t_4)$ when the input current flows through the switch S_1 and the main inductor L. The whole period is $T = (t_1 + t_2 + t_3 + t_4)$.

$$\frac{V_2}{V_1} = \frac{1}{T}(t_1 + t_2 + t_3) = \frac{t_1 + t_2 + t_3}{t_1 + t_2 + t_3 + t_4}$$
$$(14.364)$$

$$t_4 = \left(\frac{V_1}{V_2} - 1\right)(t_1 + t_2 + t_3) \quad (14.365)$$

$$k = \frac{t_3 + t_4}{t_1 + t_2 + t_3 + t_4}; \quad T = t_1 + t_2 + t_3 + t_4; \quad f = 1/T$$
$$(14.366)$$

14.12.3 Four-quadrant ZVS Quasi-resonant DC/DC Luo-converter

Four-quadrant ZVS quasi-resonant Luo-converter is shown in Fig. 14.103. Circuit 1 implements the operation in quadrants I and II, circuit 2 implements the operation in quadrants III and IV. Circuit 1 and 2 can be converted to each other by auxiliary switch. Each circuit consists of one main inductor L and two switches. Assuming that the main inductance L is sufficiently large, the current i_L is constant. The source and load voltages are usually constant, e.g. $V_1 = 42$ V and $V_2 = \pm28$ V. There are four modes of operation:
FIGURE 14.103 Four-quadrant DC/DC ZVS quasi-resonant Luo-converter.

- Mode A (Quadrant I): electrical energy is transferred from V_1 side to V_2 side;
- Mode B (Quadrant II): electrical energy is transferred from V_2 side to V_1 side;
- Mode C (Quadrant III): electrical energy is transferred from V_1 side to $-V_2$ side;
- Mode D (Quadrant IV): electrical energy is transferred from $-V_2$ side to V_1 side.

Each mode has two states: "on" and "off." The switch status of each state is shown in Table 14.13.

The description of Modes A, B, C, and D is same as in the previous Sections 14.12.1 and 14.12.2.

14.13 Synchronous-rectifier DC/DC Luo-converters

Synchronous-rectifier (SR) DC/DC converters are called the fifth-generation converters. The development of the microelectronics and computer science requires the power supplies with low output voltage and strong current. Traditional diode bridge rectifiers are not available for this requirement. Soft-switching technique can be applied in SR DC/DC converters. We have created few converters with very low voltage (5 V, 3.3 V, and $1.8 \sim 1.5$ V) and strong current (30 A, 60 A up to 200 A) and high power transfer efficiency (86%, 90% up to 93%). In this section, few new circuits, different from the ordinary SR DC/DC converters, are introduced:

- Flat transformer synchronous-rectifier DC/DC Luo-converter;
- Double current synchronous-rectifier DC/DC Luo-converter with active clamp circuit;
- Zero-current-switching synchronous-rectifier DC/DC Luo-converter;
- Zero-voltage-switching synchronous-rectifier DC/DC Luo-converter.

14.13.1 Flat Transformer Synchronous-rectifier DC/DC Luo-converter

Flat transformer **SR DC/DC Luo-converter** is shown in Fig. 14.104. The switches S_1, S_2, and S_3 are the low-resistance MOSFET devices with very low resistance R_S (7–8 mΩ). Since we use a flat transformer, the leakage inductance L_m and resistance R_L are small. Other parameters are $C = 1\,\mu$F, $L_m = 1$ nH, $R_L = 2$ mΩ, $L = 5\,\mu$H, $C_O = 10\,\mu$F. The input voltage is $V_1 = 30$ VDC and output voltage is V_2, the output current is I_O. The transformer term's ratio is $N = 12 : 1$. The repeating period is $T = 1/f$ and conduction duty is k. There are four working modes.

TABLE 14.13   Switch's status (the blank status means off)

Circuit//switch or diode	Mode A (QI)		Mode B (QII)		Mode C (QIII)		Mode D (QIV)	
	State-on	State-off	State-on	State-off	State-on	State-off	State-on	State-off
Circuit	Circuit 1				Circuit 2			
S_1	ON				ON			
D_1			ON					ON
S_2			ON		ON			
D_2		ON				ON		

FIGURE 14.104   Flat transformer SR Luo-converter.

The natural resonant frequency is

$$\omega = \frac{1}{\sqrt{L_m C}} \qquad (14.367)$$

The intervals are

$$t_1 = \frac{L_m}{V_1}\frac{I_O}{N}; \quad t_2 \approx kT; \qquad (14.368)$$

$$t_3 = \sqrt{L_m C}\left[\frac{\pi}{2} + \frac{V_1}{\sqrt{V_1^2 + \frac{L_m}{C}\left(\frac{I_O}{N}\right)^2}}\right]; \quad t_4 \approx (1-k)T$$

$$(14.369)$$

Average output voltage V_2 and input current I_1 are

$$V_2 = \frac{kV_1}{N} - \left(R_L + R_S + \frac{L_m}{TN^2}\right)I_O; \quad I_1 = k\frac{I_O}{N} \quad (14.370)$$

The power transfer efficiency is

$$\eta = \frac{V_2 I_O}{V_1 I_1} = 1 - \frac{R_L + R_S + (L_m/TN^2)}{kV_1/N}I_O \qquad (14.371)$$

When we set the frequency $f = 150$–200 kHz, we obtained the $V_2 = 1.8$ V, $N = 12$, $I_O = 0$–30 A, Volume $= 2.5$ in^3. The average power transfer efficiency is 92.3% and the maximum power density (PD) is 21.6 W/in^3.

14.13.2 Double Current SR DC/DC Luo-converter with Active Clamp Circuit

The converter in Fig. 14.104 resembles a half-wave rectifier. **Double current (DC) SR DC/DC Luo-converter** with active clamp circuit is shown in Fig. 14.105. The switches S_1–S_4 are the low-resistance MOSFET devices with very low resistance R_S (7–8 mΩ). Since S_3 and S_4 plus L_1 and L_2 form a double current circuit and S_2 plus C is the active clamp circuit, this converter resembles a full-wave rectifier and obtains strong output current. Other parameters are $C = 1\,\mu$F, $L_m = 1$ nH, $R_L = 2$ mΩ, $L = 5\,\mu$H, $C_O = 10\,\mu$F. The input voltage is $V_1 = 30$ VDC and output voltage is V_2, the output current is I_O. The transformer term's ratio is $N = 12 : 1$. The repeating period is $T = 1/f$ and conduction duty is k. There are four working modes.

The natural resonant frequency is

$$\omega = \frac{1}{\sqrt{L_m C}}; \quad V_C = \frac{k}{1-k}V_1 \qquad (14.372)$$

The interval of t_1 is

$$t_1 = \frac{L_m}{V_1}\frac{I_O}{N}; \quad t_2 \approx kT; \qquad (14.373)$$
FIGURE 14.105 Double current SR Luo-converter.

$$t_3 = \sqrt{L_m C}\left[\frac{\pi}{2} + \frac{V_1}{\sqrt{V_1^2 + \frac{L_m}{C}\left(\frac{I_O}{N}\right)^2}}\right]; \quad t_4 \approx (1-k)T$$

(14.374)

Average output voltage V_2 and input current I_1 are

$$V_2 = \frac{kV_1}{N} - \left(R_L + R_S + \frac{L_m}{TN^2}\right)I_O; \quad I_1 = k\frac{I_O}{N} \quad (14.375)$$

The power transfer efficiency

$$\eta = \frac{V_2 I_O}{V_1 I_1} = 1 - \frac{R_L + R_S + (L_m/TN^2)}{kV_1/N}I_O \qquad (14.376)$$

When we set the frequency $f = 200\text{–}250\,\text{kHz}$, we obtained the $V_2 = 1.8\,\text{V}$, $N = 12$, $I_O = 0\text{–}35\,\text{A}$, Volume $= 2.5\,\text{in}^3$. The average power transfer efficiency is 94% and the maximum power density (PD) is $25\,\text{W/in}^3$.

14.13.3 Zero-current-switching Synchronous-rectifier DC/DC Luo-converter

Since the power loss across the main switch S_1 is high in **DC SR DC/DC Luo-converter**, we designed **ZCS SR DC/DC Luo-converter** shown in Fig. 14.106. This converter is based on the **DC SR DC/DC Luo-converter** plus ZCS technique. It employs a double core flat transformer.

The ZCS resonant frequency is

$$\omega_r = \frac{1}{\sqrt{L_r C_r}} \qquad (14.377)$$

The normalized impedance is

$$Z_r = \sqrt{\frac{L_r}{C_r}} \quad \text{and} \quad \alpha = \sin^{-1}\left(\frac{I_1 Z_r}{V_1}\right) \qquad (14.378)$$

The intervals are

$$t_1 = \frac{I_1 L_r}{V_1}; \quad t_2 = \frac{1}{\omega_r}(\pi + \alpha); \qquad (14.379)$$

$$t_3 = \frac{V_1(1 + \cos\alpha)C_r}{I_1};$$

$$t_4 = \frac{V_1(t_1 + t_2)}{V_2 I_1}\left(I_L + \frac{V_1}{Z_r}\frac{\cos\alpha}{\pi/2 + \alpha}\right) - (t_1 + t_2 + t_3)$$

(14.380)

Average output voltage V_2 and input current I_1 are

$$V_2 = \frac{kV_1}{N} - \left(R_L + R_S + \frac{L_m}{TN^2}\right)I_O; \quad I_1 = k\frac{I_O}{N} \quad (14.381)$$

The power transfer efficiency

$$\eta = \frac{V_2 I_O}{V_1 I_1} = 1 - \frac{R_L + R_S + (L_m/TN^2)}{kV_1/N}I_O \qquad (14.382)$$

When we set the $V_1 = 60\,\text{V}$ and frequency $f = 200\text{–}250\,\text{kHz}$, we obtained the $V_2 = 1.8\,\text{V}$, $N = 12$, $I_O = 0\text{–}60\,\text{A}$, Volume $= 4\,\text{in}^3$. The average power transfer efficiency is 94.5% and the maximum power density (PD) is $27\,\text{W/in}^3$.

14.13.4 Zero-voltage-switching Synchronous-rectifier DC/DC Luo-converter

ZVS SR DC/DC Luo-converter is shown in Fig. 14.107. This converter is based on the **DC SR DC/DC Luo-converter** plus ZVS technique. It employs a double core flat transformer.

The ZVS resonant frequency is

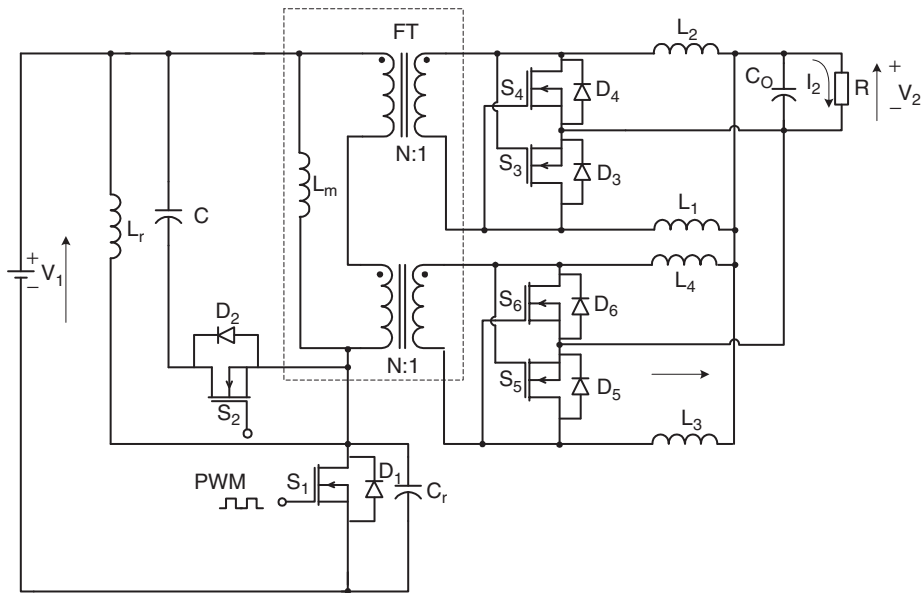
$$\omega_r = \frac{1}{\sqrt{L_r C_r}} \qquad (14.383)$$
FIGURE 14.106 ZCS DC SR Luo-converter.


FIGURE 14.107 ZVS DC SR Luo-converter.

The normalized impedance is

$$Z_r = \sqrt{\frac{L_r}{C_r}}; \quad \alpha = \sin^{-1}\left(\frac{V_1}{Z_r I_1}\right) \quad (14.384)$$

The intervals are

$$t_1 = \frac{V_1 C_r}{I_1}; \quad t_2 = \frac{1}{\omega_r}(\pi + \alpha); \quad (14.385)$$

$$t_3 = \frac{I_1(1 + \cos\alpha)L_r}{V_1}; \quad t_4 = \frac{t_1 + t_2 + t_3}{(V_1/V_2) - 1} \quad (14.386)$$

Average output voltage V_2 and input current I_1 are

$$V_2 = \frac{kV_1}{N} - \left(R_L + R_S + \frac{L_m}{TN^2}\right)I_O; \quad I_1 = k\frac{I_O}{N} \quad (14.387)$$

The power transfer efficiency

$$\eta = \frac{V_2 I_O}{V_1 I_1} = 1 - \frac{R_L + R_S + (L_m/TN^2)}{kV_1/N}I_O \quad (14.388)$$

When we set the $V_1 = 60\,V$ and frequency $f = 200$–$250\,kHz$, we obtained the $V_2 = 1.8\,V$, $N = 12$, $I_O = 0$–$60\,A$, Volume $= 4\,in^3$. The average power transfer efficiency is 94.5% and the maximum power density (PD) is $27\,W/in^3$.

14.14   Multiple-element Resonant Power Converters

Multiple energy-storage elements resonant power converters (x-Element RPC) are the sixth-generation converters. According to the transferring, power becomes higher and higher, traditional methods are hardly satisfied to deliver large power from source to final actuators with high efficiency. In order to reduce the power losses during the conversion process the sixth-generation converters – multiple energy-storage elements resonant power converters (x-Element RPC) – are created. They can be sorted into two main groups:

- DC/DC resonant converters;
- DC/AC resonant inverters.

Both groups converters consist of multiple energy-storage elements: two elements, three elements, or four elements. These energy-storage elements are passive parts: inductors and capacitors. They can be connected in series or parallel in various methods. In full statistics, the circuits of the multiple energy-storage elements converters are:

- 8 topologies of 2-element RPC;
- 38 topologies of 3-element RPC;
- 98 topologies of 4-element (2L-2C) RPC.

How to investigate the large quantity converters is a vital task. This problem was addressed in the last decade of last century. Unfortunately, much attention was not paid to it. This generation converters were not well discussed, only limited number of papers was published in the literature.

14.14.1   Two Energy-storage Elements Resonant Power Converters

The 8 topologies of 2-element RPC are shown in Fig. 14.108. These topologies have simple circuit structure and least components. Consequently, they can transfer the power from source to end-users with higher power efficiency and lower power losses.

Usually, the 2-Element RPC has very narrow response frequency bands, which is defined as the frequency width between the two half-power points. The working point must be selected in the vicinity of the natural resonant frequency $\omega_0 = 1/\sqrt{LC}$. Another drawback is that the transferred waveform is usually not a perfect sinusoidal, i.e. the output waveform THD is not zero.

Since total power losses are mainly contributed by the power losses across the main switches. As resonant conversion technique, the 2-Element RPC has high power transferring efficiency.
FIGURE 14.108   8 topologies of 2-element RPC.

14.14.2 Three Energy-storage Elements Resonant Power Converters

The 38 topologies of 3-element RPC are shown in Fig. 14.109. These topologies have one more component when compared to the 2-element RPC topologies. Consequently, they can transfer the power from source to end-users with higher lower power and lower power transfer efficiency.

Usually, the 3-element RPC has a much wider response frequency bands, which is defined as the frequency width between the two half-power points. If the circuit is a low-pass filter, the frequency bands can cover the frequency range from 0 to the natural resonant frequency $\omega_0 = 1/\sqrt{LC}$. The working point can be selected from a much wider frequency width which is lower than the natural resonant frequency $\omega_0 = 1/\sqrt{LC}$.

Another advantage, better than the 2-element RPC topologies, is that the transferred waveform can usually be a perfect sinusoidal, i.e. the output waveform THD is nearly zero. As well-known, mono-frequency waveform transferring operation has very low EMI.

14.14.3 Four Energy-storage Elements Resonant Power Converters

The 98 topologies of 4-element (2L-2C) RPC are shown in Fig. 14.110. If no restriction such as 2*L*-2*C* for 4-element RPC,
FIGURE 14.109   38 topologies of 3-element RPC.
FIGURE 14.110   98 topologies of 4-element RPC.

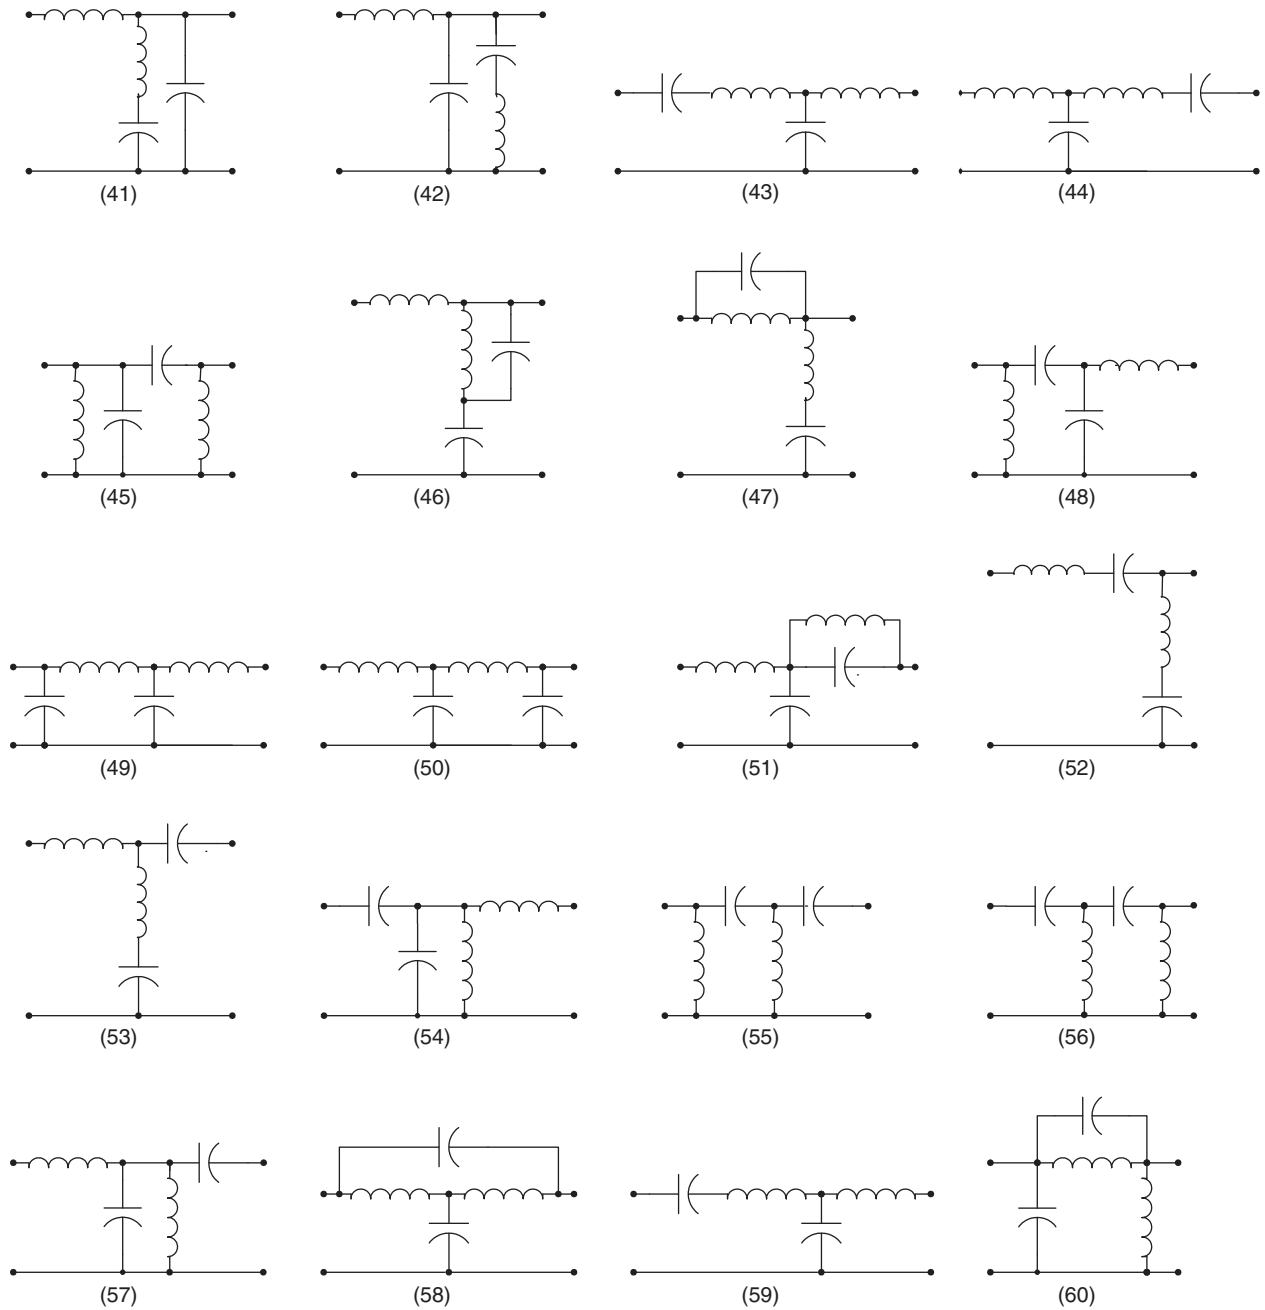
FIGURE 14.110   *continued.*


FIGURE 14.110 *continued.*

the number of the topologies of 4-element RPC can be much larger. Although these topologies have comparably complex circuit structure, they can still transfer the power from source to end-users with higher power efficiency and lower power losses.

Usually, the 4-element RPC has a wide response frequency bands, which is defined as the frequency width between the two half-power points. If the circuit is a low-pass filter, the frequency bands can cover the frequency range from 0 to the high half-power point which is definitely higher that the natural resonant frequency $\omega_0 = 1/\sqrt{LC}$. The working point can be selected from a wide area across (lower and higher than) the natural resonant frequency $\omega_0 = 1/\sqrt{LC}$. Another advantage is that the transferred waveform is usually a perfect sinusoidal, i.e. the output waveform THD is very close to zero. As well-known, mono-frequency-waveform
FIGURE 14.110 *continued.*
FIGURE 14.110 *continued.*

transferring operation has very low EMI and reasonable EMS and EMC.

14.14.4 Bipolar Current and Voltage Sources

Depending on different applications, resonant network can be low-pass filter, high-pass filter, or band-pass filter. For large power transferring, low-pass filter is usually employed. In this case, inductors are arranged in series arms and capacitors are arranged in shunt arms. If the first component is inductor, only voltage source can be applied since inductor current is continuous. Vice versa, if the first component is capacitor, only current source can be applied since capacitor voltage is continuous.

14.14.4.1 Bipolar Voltage Source

A bipolar voltage source using single voltage source is shown in Fig. 14.111. Since only voltage source is applied, there are four switches applied alternatively switching on or off to supply positive and negative voltage to the network. In the figure, the load is a resistance *R*.

The circuit of this voltage source is likely a four-quadrant operational chopper. The conduction duty cycle for each switch is 50%. For safety reason, the particular circuitry design has to consider some small gap between the turn-over (commutation) operation to avoid the short-circuit incidence.

The repeating frequency is theoretically not restricted. For industrial applications, the operating frequency is usually arranged in the range between 10 kHz and 5 MHz, depending on the application conditions.

14.14.4.2 Bipolar Current Source

A bipolar current voltage source using single voltage sources is shown in Fig. 14.112. To obtain stable current, the voltage source is connected in series by a large inductor. There are four switches applied alternatively switching on or off to supply positive and negative current to the network. In the figure, the load is a resistance *R*.

The circuit of this current source is likely a two-quadrant operational chopper. The conduction duty cycle for each
FIGURE 14.111 A bipolar voltage source using single voltage source.
FIGURE 14.112 A bipolar current voltage source using single voltage source.

switch is 50%. For safety reason, the particular circuitry design has to consider some small gap between the turnover (commutation) operation to avoid the short-circuit incidence.

The repeating frequency is theoretically not restricted. For industrial applications, the operating frequency is usually arranged in the range between 10 kHz and 5 MHz, depending on the application conditions.

14.15 Gate Control Luo-resonator

Luo-resonator is shown in Fig. 14.113. It generates the PWM pulse train to drive the static switch S. Luo-resonator is a high efficiency and simple structure circuit with easily adjusting frequency f and conduction duty k. It consists of three operational amplifiers (**OA**) named OA1-3 and auxiliary. These three 741-type OA's are integrated in a chip TL074 (which contains four OA's). Two potentiometers are applied to adjust the frequency f and conduction duty k. The voltage waveforms are shown in Fig. 14.114.

Type-741 OA can work at the power supply $\pm 3 - \pm 18$ V that are marked $V+$, G, and $V-$ with $|V-| = V+$. OA2 in Fig. 14.113 acts as the integration operation, its output V_C is a triangle waveform with regulated frequency $f = 1/T$ controlled by potentiometer R_4. OA1 acts as a resonant operation, its output V_B is a square-waveform with the frequency f. OA3 acts as a comparator, its output V_D is a square-waveform pulse train with regulated conduction duty k controlled by R_7.

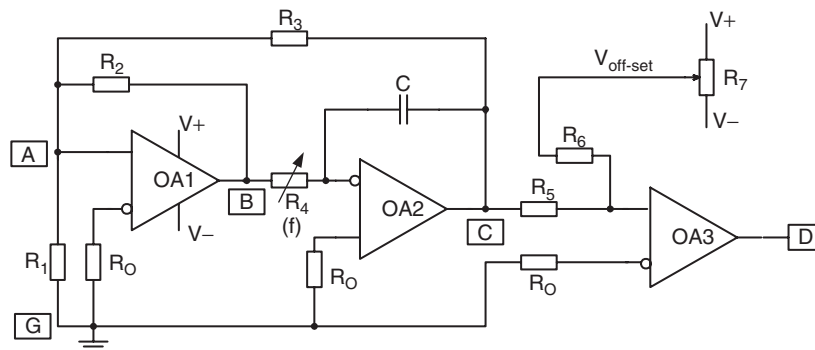
Firstly, assuming the voltage $V_B = V+$ at $t = 0$ and feeds positively back to OA1 via R_2. This causes the OA1's output voltage maintained at $V_B = V+$. In the meantime, V_B inputs to OA2 via R_4, the output voltage V_C of OA2, therefore, decreases towards $V-$ with the slope $1/R_4C$. Voltage V_C feeds negatively back to OA1 via R_3. Voltage V_A at point A changes from $(mV+)$ to 0 in the period of $2mR_4C$. Usually, R_3 is set slightly smaller than R_2, the ratio is defined as $m = R_3/R_2$. Thus, voltage V_A intends towards negative. It causes the OA1's output voltage $V_B = V-$ at $t = 2mR_4C$ and voltage V_A jumps to $mV-$. Vice versa, the voltage $V_B = V-$ at $t = 2mR_4C$ and feeds positively back to OA1 via R_2. This causes the OA1's output voltage maintained at $V_B = V-$. In the meantime, V_B inputs to OA2 via R_4, the output voltage V_C of OA2, therefore, increases towards $V+$ with the slope $1/R_4C$. Voltage V_C feeds negatively back to OA1 via R_3. Voltage V_A at point A changes from $(mV-)$ to 0 in the period of $2mR_4C$. Thus, voltage V_A intends towards positive. It causes the OA1's output voltage $V_B = V+$ at $t = 4mR_4C$ and voltage V_A jumps to $mV+$.


FIGURE 14.113 Luo-resonator.
FIGURE 14.114   Voltage waveforms of Luo-resonator.

Then V_C inputs to OA3 and compares with shift signal $V_{off\text{-}set}$ regulated by the potentiometer R_7 via R_6. When $V_{off\text{-}set} = 0$, OA3 yields its output voltage V_D as a pulse train with conduction duty $k = 0.5$. Positive $V_{off\text{-}set}$ shifts the zero-cross point of voltage V_C downwards, hence, OA3 yields its output voltage V_D as a pulse train with conduction duty $k > 0.5$. Vice versa, negative $V_{off\text{-}set}$ shifts the zero-cross point of voltage V_C upwards, hence, OA3 yields its output voltage V_D as a pulse train with conduction duty $k < 0.5$ as shown in Fig. 14.114. Conduction duty k is controlled by $V_{off\text{-}set}$ via the potentiometer R_7.

The calculation formulas are

$$m = \frac{R_3}{R_2} \tag{14.389}$$

$$f = \frac{1}{4mR_4C} \tag{14.390}$$

$$k = 0.5 + \frac{R_5 V_{off\text{-}set}}{2R_6 V+} \tag{14.391}$$

This PWM pulse train V_D is applied to the DC/DC converter switch such as a transistor, MOSFET, or IGBT via a coupling circuit.

A design example: A Luo-resonator was designed as shown in Fig. 14.113 with the component values of $R_0 = 10\,\text{k}\Omega$; $R_1 = R_2 = R_5 = 100\,\text{k}\Omega$, $R_3 = R_6 = 95\,\text{k}\Omega$; $R_4 = 510\,\Omega$–$5.1\,\text{k}\Omega$ $R_7 = 20\,\text{k}\Omega$; and $C = 5.1\,\text{nF}$. The results are $m = 0.95$, frequency $f = 10$–$100\,\text{kHz}$ and conduction duty $k = 0$–1.0.

14.16 Applications

The DC/DC conversion technique has been rapidly developed and has been widely applied in industrial applications and computer peripheral equipment. Three examples are listed below:

- 5000 V insulation test bench;
- MIT 42/14 V DC/DC converter;
- IBM 1.8 V/200 A power supply.

14.16.1 5000 V Insulation Test Bench

Insulation test bench is the necessary equipment for semiconductor manufacturing organizations. An adjustable DC voltage power supply is the heart of this equipment. Traditional method to obtain the adjustable high DC voltage is a diode rectifier via a setting up transformer. It is costly and larger in size with poor efficiency.

Using a positive output super-lift Luo-converter triple-lift circuit, which is shown in Fig. 14.115. This circuit is small, effective, and low cost. The output voltage can be determined by

$$V_O = \left(\frac{2-k}{1-k}\right)^3 V_{in} \tag{14.392}$$

The conduction duty cycle k is only adjusted in the range 0–0.8 to carry out the output voltage in the range of 192–5184 V.

The experimental results are listed in Table 14.14. The measured data verified the advantages of this power supply.

14.16.2 MIT 42/14 V–3 KW DC/DC Converter

MIT 42/14 V–3 KW DC/DC converter was requested to transfer 3 kW energy between two battery sources with 42 and 14 V. The circuit diagram is shown in Fig. 14.116. This is a two-quadrant zero-voltage-switching (ZVS) quasi-resonant-converter (QRC). The current in low voltage side can be up to 250 A. This is a typical low voltage strong current converter. It is easier to carry out by ZVS-QRC.

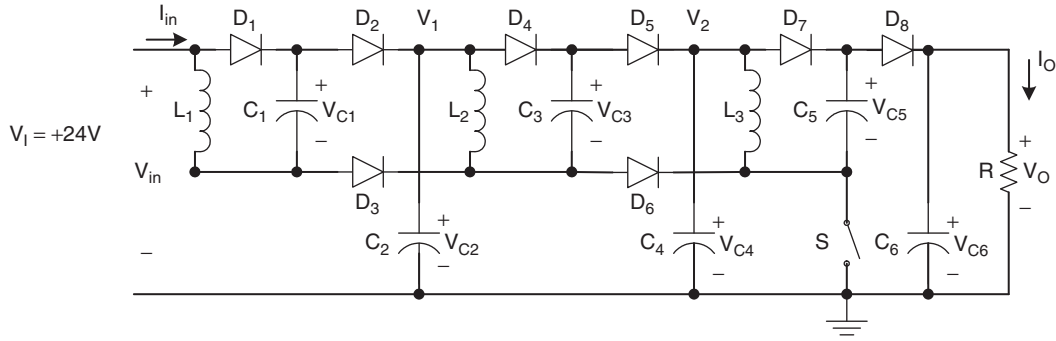
This converter consists of two sources V_1 and V_2, one main inductor L, two main switches S_1 and S_2, two reverse-paralleled


FIGURE 14.115 5000 V Insulation test bench.

TABLE 14.14 The experimental results of the 5000 V test bench

Conduction duty, k	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.82
Output voltage V_O (V)		192	226	273	244	455	648	1029	1953	5184	6760
FIGURE 14.116 MIT 42/14 V-3 kW DC/DC converter.

diodes D_1 and D_2, one resonant inductor L_r and two resonant capacitors C_{r1} and C_{r2}. The working condition is selected

$$V_1 = 42 \text{ V}; \quad V_2 = 14 \text{ V}$$

$$L = 470 \,\mu\text{H}; \quad C_{r1} = C_{r2} = C_r = 1 \,\mu\text{F}$$

$$L_r = \begin{cases} 1 \,\mu\text{H} & \text{normal operation} \\ 9 \,\mu\text{H} & \text{low current operation} \end{cases}$$

Therefore,

$$\omega_O = \frac{1}{\sqrt{L_r C_r}} = 10^6 \text{ rad/s} \qquad (14.393)$$

$$Z_O = \sqrt{\frac{L_r}{C_r}} = 1 \,\Omega \text{ (normal operation)} \qquad (14.394)$$

$$\alpha = \sin^{-1} \frac{V_1}{Z_O I_2} \qquad (14.395)$$

It is easy to keep the quasi-resonance when the working current $I_2 > 50$ A. If the working current is too low, the resonant inductor will take large value to guarantee the quasi-resonance state. This converter performs two-quadrant operation:

- Mode A (Quadrant I): energy transferred from V_1 side to V_2 side;
- Mode B (Quadrant II): energy transferred from V_2 side to V_1 side.

Assuming the working current is $I_2 = 100$ A and the converter works in Mode A, following calculations are obtained

$$\omega_O = \frac{1}{\sqrt{L_r C_r}} = 10^6 \text{ rad/s}$$

$$Z_O = \sqrt{\frac{L_r}{C_r}} = 1 \,\Omega$$

$$\alpha = \sin^{-1} \frac{V_1}{Z_O I_2} = 24.83° \qquad (14.396)$$

$$t_1 = \frac{V_1 C_r}{I_2} = 0.42 \,\mu\text{s} \qquad (14.397)$$

$$t_2 = \frac{\pi + \alpha}{\omega_O} = 3.58 \,\mu\text{s} \qquad (14.398)$$

$$t_3 = \frac{1 + \cos \alpha}{V_1} I_2 L_r = \frac{1 + 0.908}{42} 100 \times 10^{-6} = 4.54 \,\mu\text{s} \qquad (14.399)$$

$$t_4 = \frac{t_1 + t_2 + t_3}{V_1/V_2 - 1} = \frac{0.42 + 3.58 + 4.54}{2} = 4.27 \,\mu\text{s} \quad (14.400)$$

Mode	f(kHz)	I_1 (A)	I_2 (A)	I_L (A)	P_1 (W)	P_2 (W)	η (%)	PD (W/in^3)
A	78	77.1	220	220	3239	3080	95.1	23.40
A	80	78.3	220	220	3287	3080	93.7	23.58
A	82	81	220	220	3403	3080	90.5	24.01

B	70	220	68.3	220	3080	2871	93.2	22.04
B	72	220	66.6	220	3080	2797	90.8	21.77

$$T = t_1 + t_2 + t_3 + t_4 = 0.42 + 3.58 + 4.54 + 4.27 = 12.81\,\mu\text{s} \tag{14.401}$$

$$f = \frac{1}{T} = \frac{1}{12.81} = 78.06\,\text{kHz} \tag{14.402}$$

$$k = \frac{t_3 + t_4}{T} = \frac{4.54 + 4.27}{12.81} = 0.688 \tag{14.403}$$

The volume of this converter is $270\,\text{in}^3$. The experimental test results in full power $3\,\text{kW}$ are listed in Table 14.15. From the tested data, a high power density $22.85\,\text{W/in}^3$ and a high efficiency 93% are obtained. Because of soft-switching operation, the EMI is low and EMS and EMC are reasonable.

14.16.3 IBM 1.8 V/200 A Power Supply

This equipment is suitable for IBM new generation computer with power supply 1.8 V/200 A. This is a ZCS SR DC/DC Luo-converter, and is shown in Fig. 14.117. This converter is based on the double-current synchronous-rectifier DC/DC converter plus ZCS technique. It employs a hixaploid-core flat-transformer with the turns ratio $N = 1/12$. It has six-unit ZCS synchronous-rectifier double-current DC/DC converter. The six primary coils are connected in series, and six secondary circuits are connected in parallel. Each unit has particular input voltage V_{in} to be about 33 V, and can offer 1.8 V/35 A individually. Total output current is 210 A. The equivalent primary full current is $I_1 = 14.5\,\text{A}$ and equivalent primary load voltage is $V_2 = 200\,\text{V}$. The ZCS natural resonant frequency is

$$\omega_O = \frac{1}{\sqrt{L_r C_r}} \tag{14.404}$$

$$Z_O = \sqrt{\frac{L_r}{C_r}} \tag{14.405}$$

$$\alpha = \sin^{-1} \frac{Z_O I_1}{V_1} \tag{14.406}$$

The main power supply is from public utility board (PUB) via a diode rectifier. Therefore V_1 is nearly 200 V, and the each

unit input voltage V_{in} is about 33 V. Other calculation formulas are

$$t_1 = \frac{I_1 L_r}{V_1} \tag{14.407}$$

$$t_2 = \frac{\pi + \alpha}{\omega_O} \tag{14.408}$$

$$t_3 = \frac{1 + \cos\alpha}{I_1} V_1 C_r \tag{14.409}$$

$$t_4 = \frac{V_1(t_1 + t_2)}{I_1 V_2}\left(I_1 + \frac{V}{Z_O}\frac{\cos\alpha}{\pi/2 + \alpha}\right) - (t_1 + t_2 + t_3) \tag{14.410}$$

$$T = t_1 + t_2 + t_3 + t_4 \tag{14.411}$$

$$f = \frac{1}{T} \tag{14.412}$$

$$k = \frac{t_1 + t_2}{T} \tag{14.413}$$

Real output voltage and input current are

$$V_O = kNV_1 - \left(R_L + R_S + \frac{L_m}{T}N^2\right)I_O \tag{14.414}$$

$$I_{in} = kNI_O \tag{14.415}$$

The efficiency is

$$\eta = \frac{V_O I_O}{V_{in}I_{in}} = 1 - \frac{R_L + R_S + (L_m/T)N^2}{kNV_{in}}I_O \tag{14.416}$$

The commercial unit of this power supply works in voltage closed loop control with inner current closed loop to keep the output voltage constant. Applying frequency is arranged in the band of 200–250 kHz. Whole volume of the power supply is $14\,\text{in}^3$. The transfer efficiency is about 88–92% and power density is about $25.7\,\text{W/in}^3$.

14.17 Energy Factor and Mathematical Modeling for Power DC/DC Converters

We have well discussed the various DC/DC converters operating in steady state in previous sections. We will investigate the transient process of DC/DC converters. Furthermore, we define a series of new parameters such as energy factor (*EF*) and so on to establish the mathematical modeling of all power DC/DC converters.

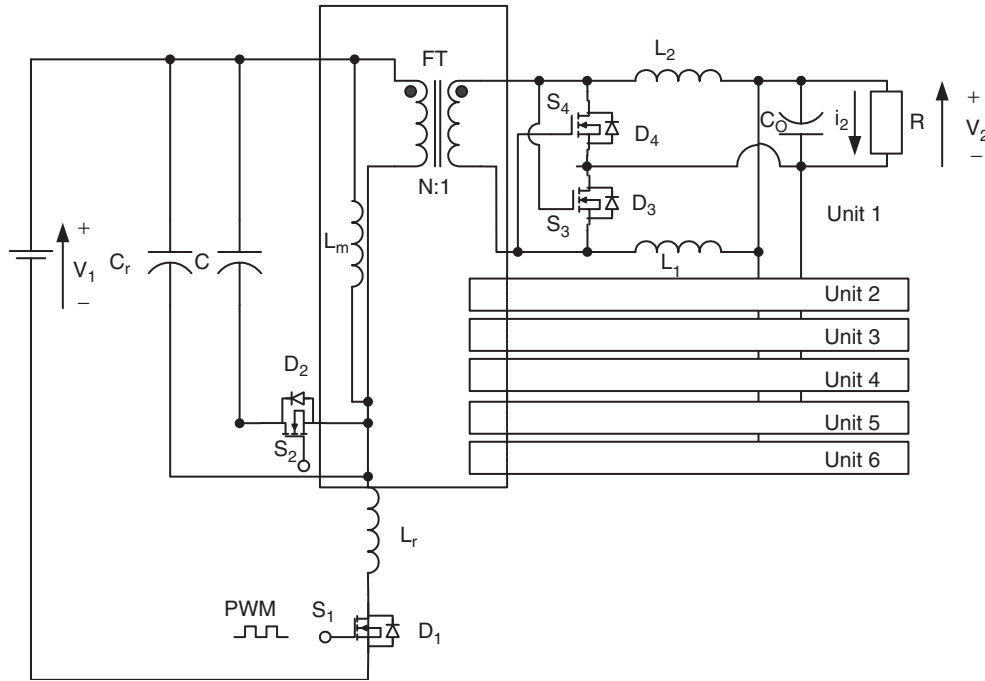
Energy storage in power DC/DC converters has been paid attention long time ago. Unfortunately, there is no clear


FIGURE 14.117   IBM 1.8 V/200 A power supply.

concept to describe the phenomena and reveal the relationship between the stored energy and the characteristics of power DC/DC converters. We have theoretically defined a new concept – energy factor (*EF*) and researched the relations between *EF* and the mathematical modeling of power DC/DC converters. Energy factor is a new concept in power electronics and conversion technology, which thoroughly differs from the traditional concepts such as power factor (*PF*), power transfer efficiency (η), total harmonic distortion (*THD*), and ripple factor (*RF*). Energy factor and the other sub-sequential parameters can illustrate the system stability, reference response, and interference recovery. This investigation is very helpful for system design and DC/DC converters characteristics foreseeing.

14.17.1 Pumping Energy (*PE*)

All power DC/DC converters have pumping circuit to transfer the energy from the source to some energy storage passive elements, e.g. inductors and capacitors. The *PE* is used to count the input energy in a switching period *T*. Its calculation formula is

$$PE = \int_0^T P_{in}(t)\,dt = \int_0^T V_1 i_1(t)\,dt = V_1 I_1 T \qquad (14.417)$$

where

$$I_1 = \int_0^T i_1(t)\,dt$$

is the average value of the input current if the input voltage V_1 is constant. Usually the input average current I_1 depends on the conduction duty cycle.

14.17.2 Stored Energy (*SE*)

The stored energy in an inductor is

$$W_L = \frac{1}{2} L I_L^2 \qquad (14.418)$$

The stored energy across a capacitor is

$$W_C = \frac{1}{2} C V_C^2 \qquad (14.419)$$

Therefore, if there are n_L inductors and n_C capacitors the total stored energy in a DC/DC converter is

$$SE = \sum_{j=1}^{n_L} W_{Lj} + \sum_{j=1}^{n_C} W_{Cj} \qquad (14.420)$$

Capacitor–inductor stored energy ratio (*CIR*) – Most power DC/DC converters consist of inductors and capacitors.

Therefore, we can define the capacitor–inductor stored energy ratio (**CIR**).

$$CIR = \frac{\sum_{j=1}^{n_C} W_{Cj}}{\sum_{j=1}^{n_L} W_{Lj}} \qquad (14.421)$$

Energy losses (**EL**) – Usually, most analysis applied in DC/DC converters is assuming no power losses, i.e. the input power is equal to the output power, $P_{in} = P_O$ or $V_1 I_1 = V_2 I_2$, so that pumping energy is equal to output energy in a period, T.

Particularly, power losses always exist during the conversion process. They are caused by the resistance of the connection cables, resistance of the inductor and capacitor wire, and power losses across the semiconductor devices (diode, IGBT, MOSFET, and so on). We can sort them as the resistance power losses P_r, passive element power losses P_e, and device power losses P_d. The total power losses are P_{loss}.

$$P_{loss} = P_r + P_e + P_d$$

and

$$P_{in} = P_O + P_{loss} = P_O + P_e + P_e + P_d = V_2 I_2 + P_e + P_e + P_d$$

Therefore,

$$EL = P_{loss} \times T = (P_r + P_e + P_d)T$$

The energy losses (**EL**) is in a period T,

$$EL = \int_0^T P_{loss}\, dt = P_{loss}\, T \qquad (14.422)$$

14.17.3 Energy Factor (*EF*)

As described in previous section the input energy in a period T is the pumping energy $PE = P_{in} \times T = V_{in}I_{in} \times T$. We now define the **EF**, that is the ratio of the *SE* over the pumping energy

$$EF = \frac{SE}{PE} = \frac{SE}{V_1 I_1 T} = \frac{\sum_{j=1}^{m} W_{Lj} + \sum_{j=1}^{n} W_{Cj}}{V_1 I_1 T} \qquad (14.423)$$

Energy factor is a very important factor of a power DC/DC converter. It is usually independent from the conduction duty cycle k, and proportional to the switching frequency f (inversely proportional to the period T) since the pumping energy PE is proportional to the switching period T.

14.17.4 Time Constant τ and Damping Time Constant τ_d

The **time constant τ** of a power DC/DC converter is a new concept to describe the transient process of a DC/DC converter. If no power losses in the converter, it is defined

$$\tau = \frac{2T \times EF}{1 + CIR}\left(1 + CIR\frac{1 - \eta}{\eta}\right) \qquad (14.424)$$

The **damping time constant τ_d** of a power DC/DC converter is new concept to describe the transient process of a DC/DC converter. If no power losses, it is defined

$$\tau_d = \frac{2T \times EF}{1 + CIR}\frac{CIR}{\eta + CIR(1 - \eta)} \qquad (14.425)$$

The **time constants ratio ξ** of a power DC/DC converter is new concept to describe the transient process of a DC/DC converter. If no power losses, it is defined

$$\xi = \frac{\tau_d}{\tau} = \frac{CIR}{\eta\left(1 + CIR\frac{1-\eta}{\eta}\right)^2} \qquad (14.426)$$

14.17.5 Mathematical Modeling for Power DC/DC Converters

The mathematical modeling for all power DC/DC converters is

$$G(s) = \frac{M}{1 + s\tau + s^2\tau\tau_d} \qquad (14.427)$$

where M is the voltage transfer gain: $M = V_O/V_{in}$, τ is the time constant in Eq. (14.424), τ_d the damping time constant in Eq. (14.425), $\tau_d = \xi\tau$. Using this mathematical model of power DC/DC converters, it is significantly easy to describe the characteristics of power DC/DC converters. In order to verify this theory, few converters are investigated to demonstrate the characteristics of power DC/DC converters and applications of the theory.

14.17.6 Buck Converter with Small Energy Losses (r_L = 1.5 Ω)

A buck converter shown in Fig. 14.118 has the components values: $V_1 = 40$ V, $L = 250\,\mu$H with resistance $r_L = 1.5\,\Omega$, $C = 60\,\mu$F, $R = 10\,\Omega$, the switching frequency $f = 20$ kHz ($T = 1/f = 50\,\mu$s) and conduction duty cycle $k = 0.4$. This converter is stable and works in CCM.

Therefore, we have got the voltage transfer gain $M = 0.35$, i.e. $V_2 = V_C = MV_1 = 0.35 \times 40 = 14$ V. $I_L = I_2 = 1.4$ A, $P_{loss} = I_L^2 \times r_L = 1.4^2 \times 1.5 = 2.94$ W, and $I_1 = 0.564$ A. The parameter *EF* and others are listed below

$$PE = V_1 I_1 T = 40 \times 0.564 \times 50\,\mu = 1.128 \text{ mJ};$$
FIGURE 14.118 A buck converter.

$$W_L = \frac{1}{2}LI_L^2 = 0.5 \times 250\,\mu \times 1.4^2 = 0.245 \text{ mJ}$$

$$W_C = \frac{1}{2}CV_C^2 = 0.5 \times 60\,\mu \times 14^2 = 5.88 \text{ mJ};$$

$$SE = W_L + W_C = 0.245 + 5.88 = 6.125 \text{ mJ}$$

$$EF = \frac{SE}{PE} = \frac{6.125}{1.128} = 5.43; \quad CIR = \frac{W_C}{W_L} = \frac{5.88}{0.245} = 24$$

$$EL = P_{loss} \times T = 2.94 \times 50 = 0.147 \text{ mJ};$$

$$\eta = \frac{P_O}{P_O + P_{loss}} = 0.87$$

$$\tau = \frac{2T \times EF}{1 + CIR}\left(1 + CIR\frac{1-\eta}{\eta}\right) = 99.6 \text{ μs};$$

$$\tau_d = \frac{2T \times EF}{1 + CIR}\frac{CIR}{\eta + CIR(1-\eta)} = 130.6 \text{ μs};$$

$$\xi = \frac{\tau_d}{\tau} = \frac{CIR}{\eta\left(1 + CIR\frac{1-\eta}{\eta}\right)^2} = 1.31 \gg 0.25$$

By cybernetic theory, since the damping time constant τ_d is larger than the time constant τ, the corresponding ratio ξ is $1.31 \gg 0.25$. The output voltage has heavy oscillation with high overshot. The corresponding transfer function is

$$G(s) = \frac{M}{1 + s\tau + s^2\tau\tau_d} = \frac{M/\tau\tau_d}{(s + s_1)(s + s_2)} \quad (14.428)$$

where

$$s_1 = \sigma + j\omega \quad \text{and} \quad s_2 = \sigma - j\omega$$

with

$$\sigma = \frac{1}{2\tau_d} = \frac{1}{261.2\,\mu s} = 3833 \text{ Hz}$$

and

$$\omega = \frac{\sqrt{4\tau\tau_d - \tau^2}}{2\tau\tau_d} = \frac{\sqrt{52,031 - 9920}}{26,015.5} = \frac{205.2}{26,015.5\,\mu} = 7888 \text{ rad/s}$$
FIGURE 14.119 Buck converter unit-step response.

The unit-step function response is

$$v_2(t) = 14\left[1 - e^{-(t/0.000261)}(\cos 7888t - 0.486\sin 7888t)\right] \text{ V}$$
$$(14.429)$$

The unit-step function response (transient process) has oscillation progress with damping factor σ and frequency ω. The simulation result is shown in Fig. 14.119.

The impulse interference response is

$$\Delta v_2(t) = 0.975\,U e^{-(t/0.000261)}\sin 7888t$$

where U is the interference signal. The impulse response (interference recovery process) has oscillation progress with damping factor σ and frequency ω. The simulation result is shown in Fig. 14.120.

In order to verify the analysis, calculation and simulation results, we constructed a test rig with same conditions. The corresponding experimental results are shown in Figs. 14.121 and 14.122.
FIGURE 14.120 Buck converter impulse response.
FIGURE 14.121   Unit-step response (test).
FIGURE 14.122   Impulse response (test).

14.17.7 A Super-lift Luo-converter in CCM

Figure 14.123 shows a super-lift Luo-converter with the conduction duty $k = 0.5$. The components values are $V_1 = 20$ V, $f = 50$ kHz ($T = 20\,\mu$s), $L = 100\,\mu$H with resistance $r_L = 0.12\,\Omega$, $C_1 = 2500\,\mu$F, $C_2 = 800\,\mu$F, and $R = 10\,\Omega$. This converter is stable and works in CCM.

Therefore, we have got the voltage transfer gain $M = 2.863$, i.e. the output voltage $V_2 = V_{C2} = 57.25$ V. $V_{C1} = V_1 = 20$ V, $I_1 = 14.145$ A, $I_2 = 5.725$ A, $I_L = 11.45$ A, and $P_{loss} = I_L^2 \times r_L = 11.45^2 \times 0.12 = 15.73$ W. The parameter EF and others are listed below

$$PE = V_1 I_1 T = 20 \times 17.175 \times 20\,\mu = 6.87 \text{ mJ};$$

$$W_L = \frac{1}{2}LI_L^2 = 0.5 \times 100\,\mu \times 11.45^2 = 6.555 \text{ mJ};$$

$$W_{C1} = \frac{1}{2}C_1 V_{C1}^2 = 0.5 \times 2500\,\mu \times 20^2 = 500 \text{ mJ};$$

$$W_{C2} = \frac{1}{2}C_2 V_{C2}^2 = 0.5 \times 800\,\mu \times 57.25^2 = 1311 \text{ mJ}$$

$$SE = W_L + W_{C1} + W_{C2} = 6.555 + 500 + 1311 = 1817.6 \text{ mJ};$$

$$EF = \frac{SE}{PE} = \frac{1817.6}{6.87} = 264.6;$$

$$CIR = \frac{W_{C1} + W_{C2}}{W_L} = \frac{1811}{6.555} = 276.3$$

$$EL = P_{loss}T = 15.73 \times 20 = 0.3146 \text{ mJ};$$

$$\eta = \frac{P_O}{P_O + P_{loss}} = \frac{327.76}{343.49} = 0.9542$$

$$\tau = \frac{2T \times EF}{1 + CIR}\left(1 + CIR\frac{1 - \eta}{\eta}\right)$$

$$= \frac{40\,\mu \times 264.6 \times 13.26}{277.3} = 506\,\mu\text{s}$$

$$\tau_d = \frac{2T \times EF}{1 + CIR}\frac{CIR}{\eta + CIR(1 - \eta)}$$

$$= \frac{40 \times 264.6 \times 20.3}{277.3} = 775\,\mu\text{s}$$

By cybernetic theory, since the damping time constant τ_d is much larger than the time constant τ, the corresponding ratio $\xi = 775/506 = 1.53 \gg 0.25$. The output voltage has heavy oscillation with high overshot. The transfer function of this converter has two poles ($-s_1$ and $-s_2$) that are located in the left-hand half plane (LHHP).

$$G(s) = \frac{M}{1 + s\tau + s^2\tau\tau_d} = \frac{M/\tau\tau_d}{(s + s_1)(s + s_2)} \qquad (14.430)$$

where

$$s_1 = \sigma + j\omega \quad \text{and} \quad s_2 = \sigma - j\omega$$

with

$$\sigma = \frac{1}{2\tau_d} = \frac{1}{1.55 \text{ ms}} = 645 \text{ Hz}$$

$$\omega = \frac{\sqrt{4\tau\tau_d - \tau^2}}{2\tau\tau_d} = \frac{\sqrt{16,86,400 - 2,95,936}}{8,43,200}$$

$$= \frac{1197.2}{8,43,200\,\mu} = 1398 \text{ rad/s}$$

FIGURE 14.123   A super-lift Luo-converter.
FIGURE 14.124   SL Luo-converter unit-step response.

The unit-step function response is

$$v_2(t) = 57.25\Big[1 - e^{-(t/0.00155)}(\cos 1398t - 0.461\sin 1398t)\Big]\,\text{V}$$

The unit-step function response (transient process) has oscillation progress with damping factor σ and frequency ω. The simulation is shown in Fig. 14.124.

The impulse interference response is

$$\Delta v_2(t) = 0.923\,U e^{-(t/0.00155)}\sin 1398t$$

where U is the interference signal. The impulse response (interference recovery process) has oscillation progress with damping factor σ and frequency ω, and is shown in Fig. 14.125.

In order to verify the analysis, calculation and simulation results, we constructed a test rig with same conditions. The corresponding test results are shown in Figs. 14.126 and 14.127.

15.1 Introduction

The main objective of static power converters is to produce an ac output waveform from a dc power supply. These are the types of waveforms required in adjustable speed drives (ASDs), uninterruptible power supplies (UPSs), static var compensators, active filters, flexible ac transmission systems (FACTSs), and voltage compensators, which are only a few applications. For sinusoidal ac outputs, the magnitude, frequency, and phase should be controllable. According to the type of ac output waveform, these topologies can be considered as voltage-source inverters (VSIs), where the independently controlled ac output is a voltage waveform. These structures are the most widely used because they naturally behave as voltage sources as required by many industrial applications, such as ASDs, which are the most popular application of inverters (Fig. 15.1a). Similarly, these topologies can be found as current-source inverters (CSIs), where the independently controlled ac output is a current waveform. These structures are still widely used in medium-voltage industrial applications, where high-quality voltage waveforms are required.

Static power converters, specifically inverters, are constructed from power switches and the ac output waveforms are therefore made up of discrete values. This leads to the generation of waveforms that feature fast transitions rather than smooth ones. For instance, the ac output voltage produced by the VSI of a three-level ASD is a, Pulse Width Modulation (PWM) type of waveform (Fig. 15.1c). Although this waveform is not sinusoidal as expected (Fig. 15.1b), its fundamental component behaves as such. This behavior should be ensured by a modulating technique that controls
FIGURE 15.1 A three-level adjustable speed drive scheme and associated waveforms: (a) the electrical power conversion topology; (b) the ideal input (ac mains) and output (load) waveforms; and (c) the actual input (ac mains) and output (load) waveforms.

the amount of time and the sequence used to switch the power valves on and off. The modulating techniques most used are the carrier-based technique (e.g. sinusoidal pulsewidth modulation, SPWM), the space-vector (SV) technique, and the selective-harmonic-elimination (SHE) technique.

The discrete shape of the ac output waveforms generated by these topologies imposes basic restrictions on the applications of inverters. The VSI generates an ac output voltage waveform composed of discrete values (high dv/dt); therefore, the load should be inductive at the harmonic frequencies in order to produce a smooth current waveform. A capacitive load in the VSIs will generate large current spikes. If this is the case, an inductive filter between the VSI ac side and the load should be used. On the other hand, the CSI generates an ac output current waveform composed of discrete values (high di/dt); therefore, the load should be capacitive at the harmonic frequencies in order to produce a smooth voltage waveform. An inductive load in CSIs will generate large voltage spikes. If this is the case, a capacitive filter between the CSI ac side and the load should be used.

A three-level voltage waveform is not recommended for medium-voltage ASDs due to the high dv/dt that would apply to the motor terminals. Several negative side effects of this approach have been reported (bearing and isolation problems). As alternatives, to improve the ac output waveforms in VSIs are the multistage topologies (multilevel and multicell). The basic principle is to construct the required ac output waveform from various voltage levels, which achieves medium-voltage waveforms at reduced dv/dt. Although these topologies are well developed in ASDs, they are also suitable for static var compensators, active filters, and voltage compensators. Specialized modulating techniques have been developed to switch the higher number of power valves involved in these topologies. Among others, the carrier-based (SPWM) and SV-based techniques have been naturally extended to these applications.

In many applications, it is required to take energy from the ac side of the inverter and send it back into the dc side. For instance, whenever ASDs need to either brake or slow down the motor speed, the kinetic energy is sent into the voltage dc link (Fig. 15.1a). This is known as the regenerative operating mode and, in contrast to the motoring mode, the dc link current direction is reversed due to the fact that the dc link voltage is fixed. If a capacitor is used to maintain the dc link voltage (as in standard ASDs) the energy must either be dissipated or fed back into the distribution system, otherwise, the dc link voltage gradually increases. The first approach requires the dc link capacitor be connected in parallel with a resistor, which must be properly switched only when the energy flows from the motor into the dc link. A better alternative is to feed back such energy into the distribution system. However, this alternative requires a reversible-current topology connected between the distribution system and the dc link capacitor. A modern approach to such a requirement is to use the active front-end rectifier technologies, where the regeneration mode is a natural operating mode of the system.

In this chapter, single- and three-phase inverters in their voltage and current source alternatives will be reviewed. The dc link will be assumed to be a perfect dc, either voltage or current source that could be fixed as the dc link voltage in standard ASDs, or variable as the dc link current in some medium-voltage current source drives. Specifically, the topologies, modulating techniques and control aspects oriented to standard applications, are analyzed. In order to simplify the analysis, the inverters are considered lossless topologies, which are composed of ideal power valves. Nevertheless, some practical non-ideal conditions are also considered.

15.2 Single-phase Voltage Source Inverters

Single-phase VSI can be found as half-bridge and full-bridge topologies. Although, the power range they cover is the low one, they are widely used in power supplies, single-phase UPSs, and currently to form high-power static power topologies, such as the multicell configurations that are reviewed in Section 15.7. The main features of both approaches are reviewed and presented in the following.

15.2.1 Half-bridge VSI

Figure 15.2 shows the power topology of a half-bridge VSI, where two large capacitors are required to provide a neutral point N, such that each capacitor maintains a constant voltage $v_i/2$. Because the current harmonics injected by the operation of the inverter are low-order harmonics, a set of large capacitors (C_+ and C_-) is required. It is clear that both switches S_+ and S_- cannot be on simultaneously because a short circuit across the dc link voltage source v_i would be produced. There are two defined (states 1 and 2) and one undefined (state 3) switch state as shown in Table 15.1. In order to avoid the short circuit across the dc bus and the undefined ac output-voltage condition, the modulating technique should always ensure that at any instant either the top or the bottom switch of the inverter leg is on.
FIGURE 15.2 Single-phase half-bridge VSI.

TABLE 15.1 Switch states for a half-bridge single-phase VSI

State	State #	v_o	Components conducting	
S_+ is on and S_- is off	1	$v_i/2$	S_+	if $i_o > 0$
			D_+	if $i_o < 0$
S_- is on and S_+ is off	2	$-v_i/2$	D_-	if $i_o > 0$
			S_-	if $i_o < 0$
S_+ and S_- are all off	3	$-v_i/2$	D_-	if $i_o > 0$
		$v_i/2$	D_+	if $i_o < 0$

Figure 15.3 shows the ideal waveforms associated with the half-bridge inverter shown in Fig. 15.2. The states for the switches S_+ and S_- are defined by the modulating technique, which in this case is a carrier-based PWM.

A. The Carrier-based Pulse Width Modulation (PWM) Technique

As mentioned earlier, it is desired that the ac output voltage, $v_o = v_{aN}$, follow a given waveform (e.g. sinusoidal) on a continuous basis by properly switching the power valves. The carrier-based PWM technique fulfills such a requirement as it defines the on- and off-states of the switches of one leg of a VSI by comparing a modulating signal v_c (desired ac output voltage) and a triangular waveform v_Δ (carrier signal). In practice, when $v_c > v_\Delta$ the switch S_+ is on and the switch S_- is off; similarly, when $v_c < v_\Delta$ the switch S_+ is off and the switch S_- is on.

A special case is when the modulating signal v_c is a sinusoidal at frequency f_c and amplitude $\hat{v}_c$, and the triangular signal v_Δ is at frequency f_Δ and amplitude $\hat{v}_\Delta$. This is the sinusoidal PWM (SPWM) scheme. In this case, the modulation index m_a (also known as the amplitude-modulation ratio) is defined as

$$m_a = \frac{\hat{v}_c}{\hat{v}_\Delta} \qquad (15.1)$$

and the normalized carrier frequency m_f (also known as the frequency-modulation ratio) is

$$m_f = \frac{f_\Delta}{f_c} \qquad (15.2)$$

Figure 15.3e clearly shows that the ac output voltage $v_o = v_{aN}$ is basically a sinusoidal waveform plus harmonics, which features: (a) the amplitude of the fundamental component of the ac output voltage $\hat{v}_{o1}$ satisfying the following expression:

$$\hat{v}_{o1} = \hat{v}_{aN1} = \frac{v_i}{2} m_a \qquad (15.3)$$

for $m_a \leq 1$, which is called the linear region of the modulating technique (higher values of m_a leads to overmodulation that
FIGURE 15.3 The half-bridge VSI. Ideal waveforms for the SPWM ($m_a = 0.8$, $m_f = 9$): (a) carrier and modulating signals; (b) switch S_+ state; (c) switch S_- state; (d) ac output voltage; (e) ac output voltage spectrum; (f) ac output current; (g) dc current; (h) dc current spectrum; (i) switch S_+ current; and (j) diode D_+ current.

will be discussed later); (b) for odd values of the normalized carrier frequency m_f the harmonics in the ac output voltage appear at normalized frequencies f_h centered around m_f and its multiples, specifically,

$$h = l\, m_f \pm k \quad l = 1, 2, 3, \ldots \qquad (15.4)$$

where $k = 2, 4, 6, \ldots$ for $l = 1, 3, 5, \ldots$; and $k = 1, 3, 5, \ldots$ for $l = 2, 4, 6, \ldots$; (c) the amplitude of the ac output voltage harmonics is a function of the modulation index m_a and is independent of the normalized carrier frequency m_f for $m_f > 9$; (d) the harmonics in the dc link current (due to

the modulation) appear at normalized frequencies f_p centered around the normalized carrier frequency m_f and its multiples, specifically,

$$p = l\, m_f \pm k \pm 1 \quad l = 1, 2, \ldots \qquad (15.5)$$

where $k = 2, 4, 6, \ldots$ for $l = 1, 3, 5, \ldots$; and $k = 1, 3, 5, \ldots$ for $l = 2, 4, 6, \ldots$. Additional important issues are: (a) for small values of m_f ($m_f < 21$), the carrier signal v_Δ and the signal v_c should be synchronized to each other (m_f integer), which is required to hold the previous features; if this is not the case, subharmonics will be present in the ac output voltage;

(b) for large values of m_f ($m_f > 21$), the subharmonics are negligible if an asynchronous PWM technique is used, however, due to potential very low-order subharmonics, its use should be avoided; finally (c) in the overmodulation region ($m_a > 1$) some intersections between the carrier and the modulating signal are missed, which leads to the generation of low-order harmonics but a higher fundamental ac output voltage is obtained; unfortunately, the linearity between m_a and $\hat{v}_{o1}$ achieved in the linear region does not hold in the overmodulation region, moreover, a saturation effect can be observed (Fig. 15.4).

The PWM technique allows an ac output voltage to be generated that tracks a given modulating signal. A special case is the SPWM technique (the modulating signal is a sinusoidal) that provides, in the linear region, an ac output voltage that varies linearly as a function of the modulation index, and the harmonics are at well-defined frequencies and amplitudes. These features simplify the design of filtering components. Unfortunately, the maximum amplitude of the fundamental ac voltage is $v_i/2$ in this operating mode. Higher voltages are obtained by using the overmodulation region ($m_a > 1$); however, low-order harmonics appear in the ac output voltage. Very large values of the modulation index ($m_a > 3.24$) lead to a totally square ac output voltage that is considered as the square-wave modulating technique.

B. Square-wave Modulating Technique

Both switches S_+ and S_- are on for one half-cycle of the ac output period. This is equivalent to the SPWM technique with an infinite modulation index m_a. Figure 15.5 shows the following: (a) the normalized ac output voltage harmonics are

FIGURE 15.4 Normalized fundamental ac component of the output voltage in a half-bridge VSI SPWM modulated.
FIGURE 15.5 The half-bridge VSI. Ideal waveforms for the square-wave modulating technique: (a) ac output voltage and (b) ac output voltage spectrum.

at frequencies $h = 3, 5, 7, 9, \ldots$, and for a given dc link voltage; (b) the fundamental ac output voltage features an amplitude given by

$$\hat{v}_{o1} = \hat{v}_{aN1} = \frac{4}{\pi} \frac{v_i}{2} \qquad (15.6)$$

and the harmonics feature an amplitude given by

$$\hat{v}_{oh} = \frac{\hat{v}_{o1}}{h} \qquad (15.7)$$

It can be seen that the ac output voltage cannot be changed by the inverter. However, it could be changed by controlling the dc link voltage v_i. Other modulating techniques that are applicable to half-bridge configurations (e.g., selective harmonic elimination) are reviewed here as they can easily be extended to modulate other topologies.

C. Selective Harmonic Elimination

The main objective is to obtain a sinusoidal ac output voltage waveform where the fundamental component can be adjusted arbitrarily within a range and the intrinsic harmonics selectively eliminated. This is achieved by mathematically generating the exact instant of the turn-on and turn-off of the power valves. The ac output voltage features odd half- and quarter-wave symmetry; therefore, even harmonics are not present ($v_{oh} = 0$, $h = 2, 4, 6, \ldots$). Moreover, the phase voltage waveform ($v_o = v_{aN}$ in Fig. 15.2), should be chopped N times per half-cycle in order to adjust the fundamental and eliminate $N - 1$ harmonics in the ac output voltage waveform. For instance, to eliminate the third and fifth harmonics

and to perform fundamental magnitude control ($N = 3$), the equations to be solved are the following:

$$\cos(1\alpha_1) - \cos(1\alpha_2) + \cos(1\alpha_3) = (2 + \pi \hat{v}_{o1}/v_i)/4$$

$$\cos(3\alpha_1) - \cos(3\alpha_2) + \cos(3\alpha_3) = 1/2 \qquad (15.8)$$

$$\cos(5\alpha_1) - \cos(5\alpha_2) + \cos(5\alpha_3) = 1/2$$

where the angles α_1, α_2 and α_3 are defined as shown in Fig. 15.6a. The angles are found by means of iterative algorithms as no analytical solutions can be derived. The angles α_1, α_2, and α_3 are plotted for different values of $\hat{v}_{o1}/v_i$ in Fig. 15.7a. The general expressions to eliminate an even $N - 1$

$(N - 1 = 2, 4, 6, \ldots)$ number of harmonics are

$$-\sum_{k=1}^{N} (-1)^k \cos(\alpha_k) = \frac{(2 + \pi \hat{v}_{o1})/v_i}{4}$$

$$-\sum_{k=1}^{N} (-1)^k \cos(n\alpha_k) = \frac{1}{2} \quad \text{for } n = 3, 5, \ldots, 2N - 1$$

(15.9)

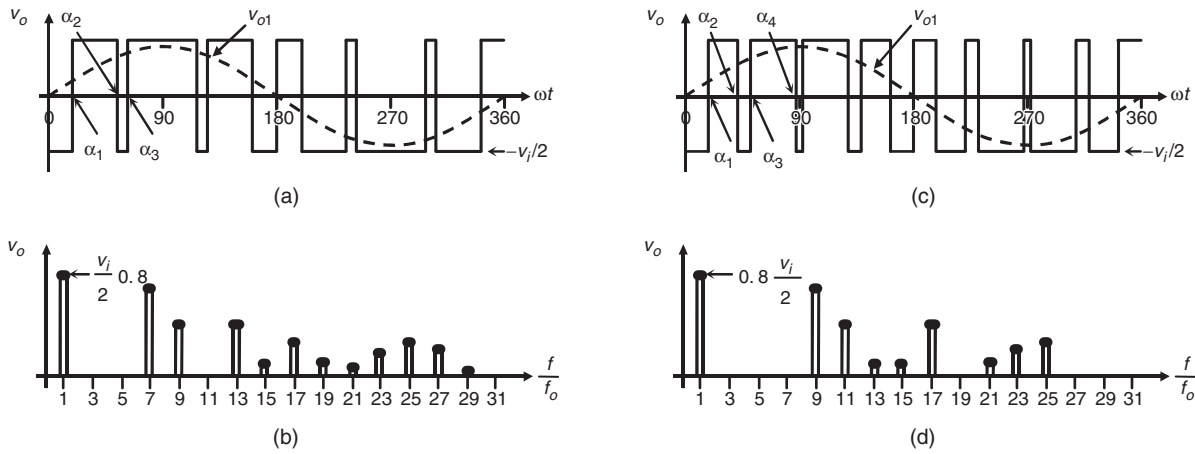
where α_1, $\alpha_2,\ldots$, α_N should satisfy $\alpha_1 < \alpha_2 < \cdots < \alpha_N < \pi/2$. Similarly, to eliminate an odd number of harmonics, for instance the third, fifth, and seventh, and to perform the


FIGURE 15.6 The half-bridge VSI. Ideal waveforms for the SHE technique: (a) ac output voltage for third and fifth harmonic elimination; (b) spectrum of (a); (c) ac output voltage for third, fifth, and seventh harmonic elimination; and (d) spectrum of (c).
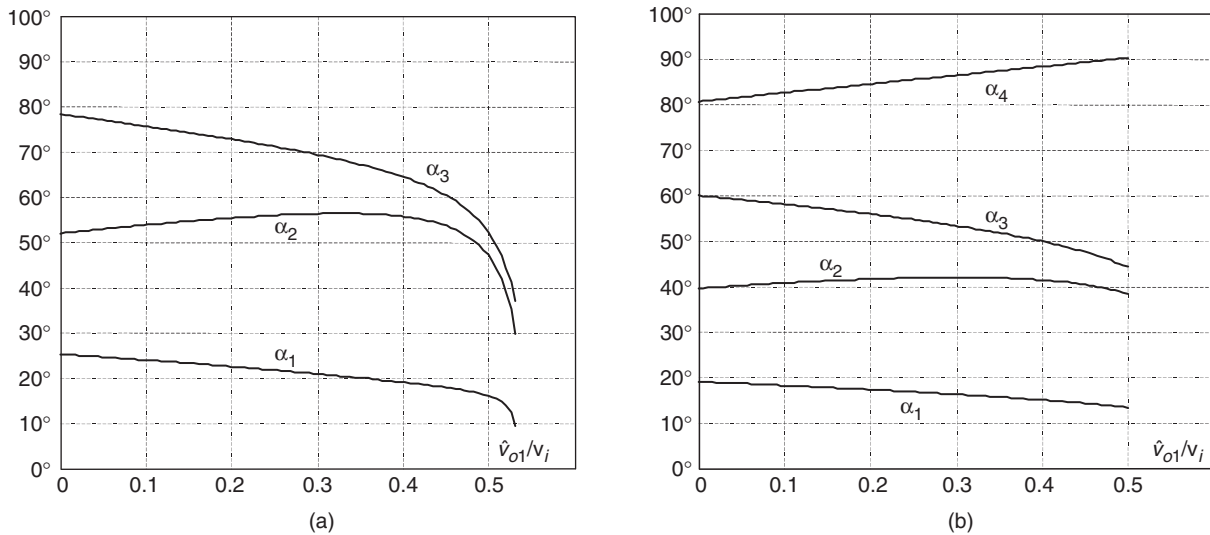

FIGURE 15.7 Chopping angles for SHE and fundamental voltage control in half-bridge VSIs: (a) third and fifth harmonic elimination and (b) third, fifth, and seventh harmonic elimination.

fundamental magnitude control ($N - 1 = 3$), the equations to be solved are:

$$\cos(1\alpha_1) - \cos(1\alpha_2) + \cos(1\alpha_3) - \cos(1\alpha_4) = (2 - \pi\hat{v}_{o1}/v_i)/4$$

$$\cos(3\alpha_1) - \cos(3\alpha_2) + \cos(3\alpha_3) - \cos(3\alpha_4) = 1/2$$

$$\cos(5\alpha_1) - \cos(5\alpha_2) + \cos(5\alpha_3) - \cos(5\alpha_4) = 1/2$$

$$\cos(7\alpha_1) - \cos(7\alpha_2) + \cos(7\alpha_3) - \cos(7\alpha_4) = 1/2$$

$$(15.10)$$

where the angles α_1, α_2, α_3, and α_4 are defined as shown in Fig. 15.6b. The angles α_1, α_2, and α_3 are plotted for different values of $\hat{v}_{o1}/v_i$ in Fig. 15.7b. The general expressions to eliminate an odd $N - 1$ ($N - 1 = 3, 5, 7, \ldots$) number of harmonics are given by

$$-\sum_{k=1}^{N} (-1)^k \cos(n\alpha_k) = \frac{(2 - \pi\hat{v}_{o1})/v_i}{4}$$

$$-\sum_{k=1}^{N} (-1)^k \cos(n\alpha_k) = \frac{1}{2} \quad \text{for } n = 3, 5, \ldots, 2N - 1$$

$$(15.11)$$

where $\alpha_1, \alpha_2, \ldots, \alpha_N$ should satisfy $\alpha_1 < \alpha_2 < \cdots < \alpha_N < \pi/2$.

To implement the SHE modulating technique, the modulator should generate the gating pattern according to the angles as shown in Fig. 15.7. This task is usually performed by digital systems that normally store the angles in look-up tables.

D. DC Link Current

The split capacitors are considered a part of the inverter and therefore an instantaneous power balance cannot be considered due to the storage energy components (C_+ and C_-). However, if a lossless inverter is assumed, the average power absorbed in one period by the load must be equal to the average power supplied by the dc source. Thus, we can write

$$\int_0^T v_i(t) \cdot i_i(t) \cdot dt = \int_0^T v_o(t) \cdot i_o(t) \cdot dt \qquad (15.12)$$

where T is the period of the ac output voltage. For an inductive load and a relatively high switching frequency, the load current i_o is nearly sinusoidal and therefore, only the fundamental component of the ac output voltage provides power to the load. On the other hand, if the dc link voltage remains constant

$v_i(t) = V_i$, Eq. (15.12) can be simplified to

$$\int_0^T i_i(t) \cdot dt = \frac{1}{V_i} \int_0^T \sqrt{2} V_{o1} \sin(\omega t) \cdot \sqrt{2} I_o \sin(\omega t - \phi) \cdot dt = I_i$$

$$(15.13)$$

where V_{o1} is the fundamental rms ac output voltage, I_o is the rms load current, ϕ is an arbitrary inductive load power factor, and I_i is the dc link current that can be further simplified to

$$I_i = \frac{V_{o1}}{V_i} I_o \cos(\phi) \qquad (15.14)$$

15.2.2 Full-bridge VSI

Figure 15.8 shows the power topology of a full-bridge VSI. This inverter is similar to the half-bridge inverter; however, a second leg provides the neutral point to the load. As expected, both switches S_{1+} and S_{1-} (or S_{2+} and S_{2-}) cannot be on simultaneously because a short circuit across the dc link voltage source v_i would be produced. There are four defined (states 1, 2, 3, and 4) and one undefined (state 5) switch state as shown in Table 15.2.

The undefined condition should be avoided so as to be always capable of defining the ac output voltage always. In order to avoid the short circuit across the dc bus and the undefined ac output voltage condition, the modulating technique should ensure that either the top or the bottom switch of each leg is on at any instant. It can be observed that the ac output voltage can take values up to the dc link value v_i, which is twice that obtained with half-bridge VSI topologies.

Several modulating techniques have been developed that are applicable to full-bridge VSIs. Among them are the PWM (bipolar and unipolar) techniques.

A. Bipolar PWM Technique

States 1 and 2 (Table 15.2) are used to generate the ac output voltage in this approach. Thus, the ac output voltage waveform features only two values, which are v_i and $-v_i$. To generate the
FIGURE 15.8 Single-phase full-bridge VSI.

states, a carrier-based technique can be used as in half-bridge configurations (Fig. 15.3), where only one sinusoidal modulating signal has been used. It should be noted that the on-state in switch S_+ in the half-bridge corresponds to both switches S_{1+} and S_{2-} being in the on-state in the full-bridge configuration. Similarly, S_- in the on-state in the half-bridge corresponds to both switches S_{1-} and S_{2+} being in the on-state in the full-bridge configuration. This is called bipolar carrier-based SPWM. The ac output voltage waveform in a full-bridge VSI is basically a sinusoidal waveform that features a fundamental component of amplitude $\hat{v}_{o1}$ that satisfies the expression

$$\hat{v}_{o1} = \hat{v}_{ab1} = v_i m_a \qquad (15.15)$$

in the linear region of the modulating technique ($m_a \leq 1$), which is twice that obtained in the half-bridge VSI. Identical conclusions can be drawn for the frequencies and the amplitudes of the harmonics in the ac output voltage and dc link current, and for operations at smaller and larger values of odd m_f (including the overmodulation region ($m_a > 1$)), than in half-bridge VSIs, but considering that the maximum ac output voltage is the dc link voltage v_i. Thus, in the overmodulation region the fundamental component of amplitude $\hat{v}_{o1}$ satisfies the expression

$$v_i < \hat{v}_{o1} = \hat{v}_{ab1} < \frac{4}{\pi} v_i \qquad (15.16)$$

B. Unipolar PWM Technique

In contrast to the bipolar approach, the unipolar PWM technique uses the states 1, 2, 3, and 4 (Table 15.2) to generate the ac output voltage. Thus, the ac output voltage waveform can instantaneously take one of the three values, namely v_i, $-v_i$, and 0. To generate the states, a carrier-based technique can be used as shown in Fig. 15.9, where two sinusoidal modulating signals (v_c and $-v_c$) are used. The signal v_c is used to generate v_{aN}, and $-v_c$ is used to generate v_{bN}; thus $v_{bN1} = -v_{aN1}$. On the other hand, $v_{o1} = v_{aN1} - v_{bN1}, = 2 \cdot v_{aN1}$; thus $\hat{v}_{o1} = 2 \cdot \hat{v}_{aN1} = m_a \cdot v_i$ This is called unipolar carrier-based SPWM.

Identical conclusions can be drawn for the amplitude of the fundamental component and harmonics in the ac output voltage and dc link current, and for operations at smaller and larger values of m_f (including the overmodulation region ($m_a > 1$)) than in full-bridge VSIs modulated by the bipolar SPWM. However, because the phase voltages (v_{aN} and v_{bN}) are identical but 180° out of phase, the output voltage ($v_o = v_{ab} = v_{aN} - v_{bN}$) will not contain even harmonics. Thus, if m_f is taken even, the harmonics in the ac output voltage appear at normalized odd frequencies f_h centered around twice the normalized carrier frequency m_f and its multiples. Specifically,

$$h = l\, m_f \pm k \quad l = 2, 4, \ldots \qquad (15.17)$$

where $k = 1, 3, 5, \ldots$ and the harmonics in the dc link current appear at normalized frequencies f_p centered around twice the normalized carrier frequency m_f and its multiples. Specifically,

$$p = l\, m_f \pm k \pm 1 \quad l = 2, 4, \ldots \qquad (15.18)$$

where $k = 1, 3, 5, \ldots$ This feature is considered to be an advantage because it allows the use of smaller filtering components to obtain high-quality voltage and current waveforms while using the same switching frequency as in VSIs modulated by the bipolar approach.

C. Selective Harmonic Elimination

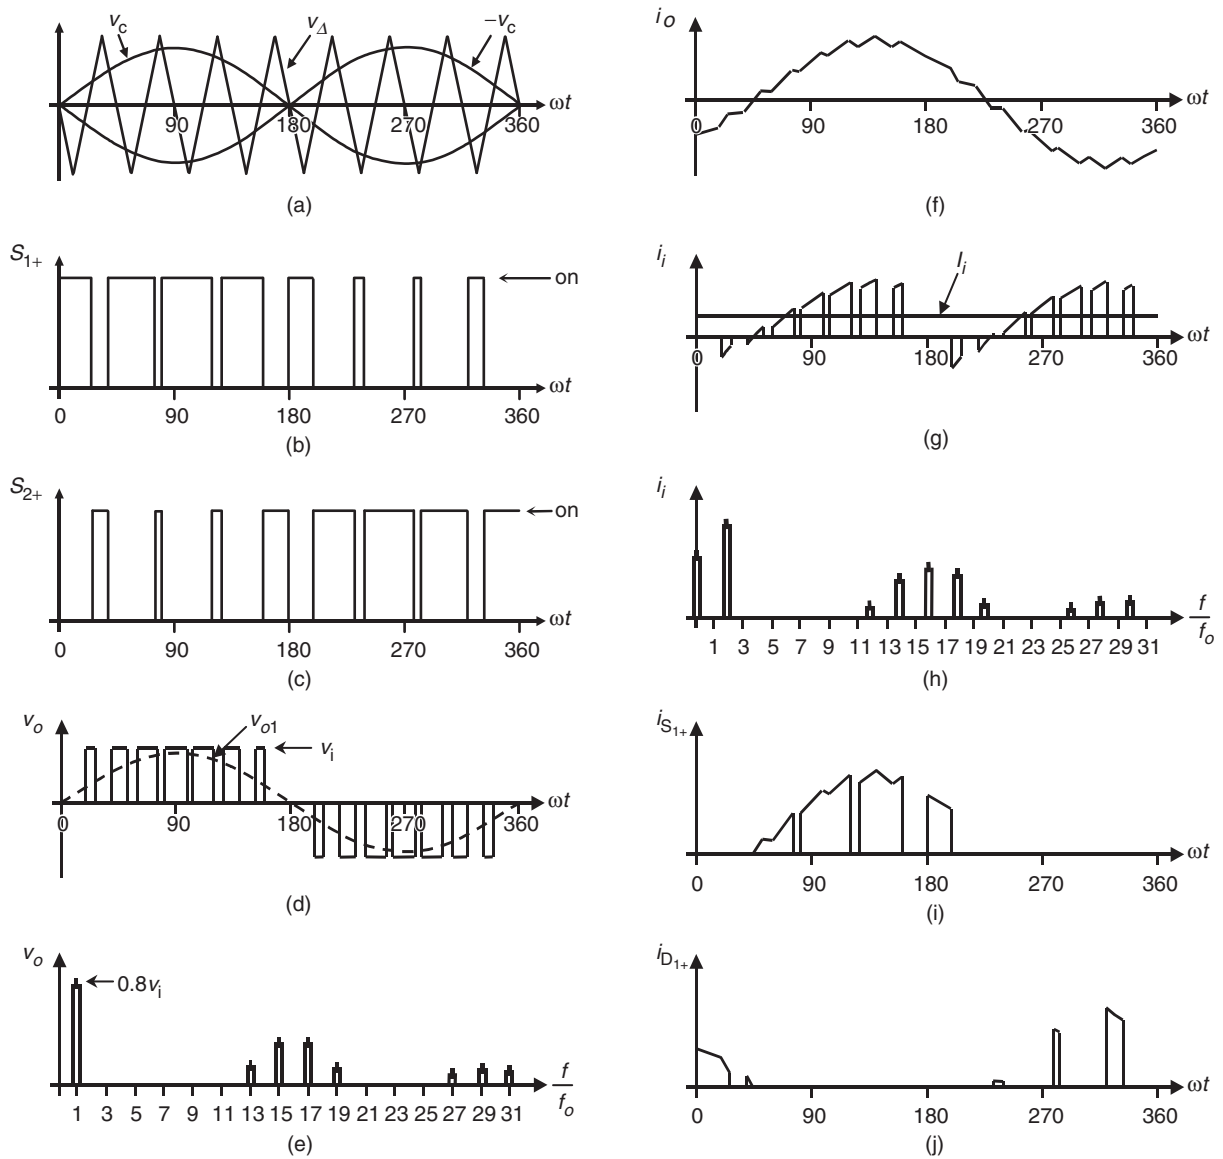
In contrast to half-bridge VSIs, this approach is applied in a per-line fashion for full-bridge VSIs. The ac output voltage features odd half- and quarter-wave symmetry; therefore, even harmonics are not present ($\hat{v}_{oh} = 0$, $h = 2, 4, 6, \ldots$). Moreover, the ac output voltage waveform ($v_o = v_{ab}$ in Fig. 15.8), should feature N pulses per half-cycle in order to adjust the fundamental component and eliminate $N - 1$ harmonics. For instance, to eliminate the third, fifth, and the seventh harmonics and to perform fundamental component magnitude control


FIGURE 15.9   The full-bridge VSI. Ideal waveforms for the unipolar SPWM ($m_a = 0.8$, $m_f = 8$): (a) carrier and modulating signals; (b) switch S_{1+} state; (c) switch S_{2+} state; (d) ac output voltage; (e) ac output voltage spectrum; (f) ac output current; (g) dc current; (h) dc current spectrum; (i) switch S_{1+} current; and (j) diode D_{1+} current.

($N = 4$), the equations to be solved are:

$$\cos(1\alpha_1) - \cos(1\alpha_2) + \cos(1\alpha_3) - \cos(1\alpha_4) = \pi\hat{v}_{o1}/(v_i 4)$$

$$\cos(3\alpha_1) - \cos(3\alpha_2) + \cos(3\alpha_3) - \cos(3\alpha_4) = 0$$

$$\cos(5\alpha_1) - \cos(5\alpha_2) + \cos(5\alpha_3) - \cos(5\alpha_4) = 0$$

$$\cos(7\alpha_1) - \cos(7\alpha_2) + \cos(7\alpha_3) - \cos(7\alpha_4) = 0$$

(15.19)

where the angles α_1, α_2, α_3, and α_4 are defined as shown in Fig. 15.10a. The angles α_1, α_2, α_3, and α_4 are plotted for

different values of $\hat{v}_{o1}/v_i$ in Fig. 15.11a. The general expressions to eliminate an arbitrary $N - 1$ ($N - 1 = 3, 5, 7, \ldots$) number of harmonics are given by

$$-\sum_{k=1}^{N} (-1)^k \cos(n\alpha_k) = \frac{\pi}{4}\left(\frac{\hat{v}_{o1}}{v_i}\right)$$

$$-\sum_{k=1}^{N} (-1)^k \cos(n\alpha_k) = 0 \quad \text{for } n = 3, 5, \ldots, 2N - 1$$

(15.20)

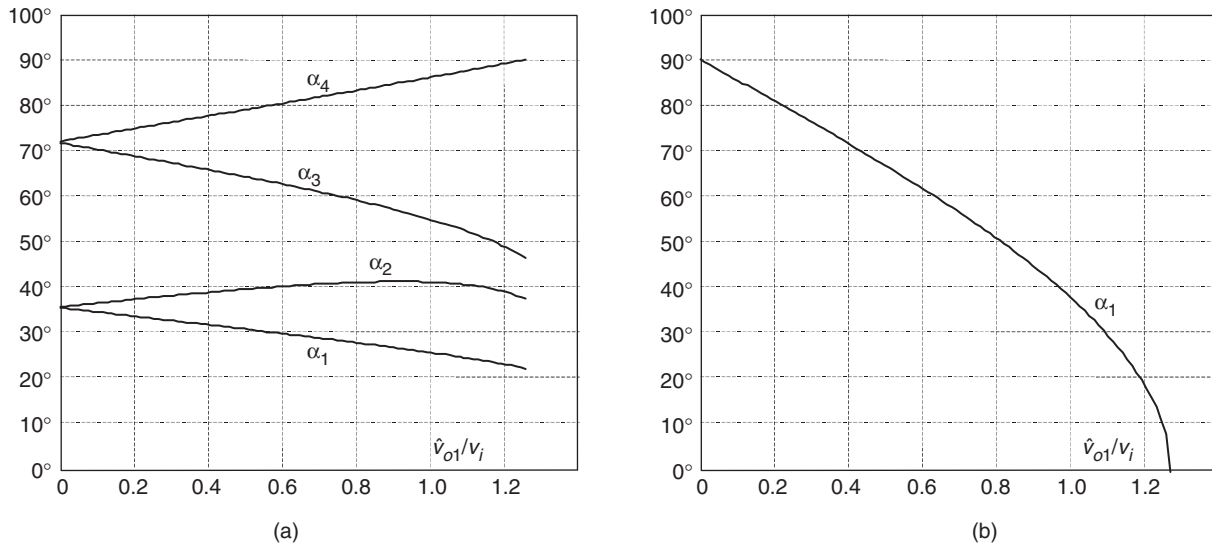
where $\alpha_1, \alpha_2, \ldots, \alpha_N$ should satisfy $\alpha_1 < \alpha_2 < \cdots < \alpha_N < \pi/2$.
FIGURE 15.10   The half-bridge VSI. Ideal waveforms for the SHE technique: (a) ac output voltage for third, fifth, and seventh harmonic elimination; (b) spectrum of (a); (c) ac output voltage for fundamental control; and (d) spectrum of (c).


FIGURE 15.11   Chopping angles for SHE and fundamental voltage control in half-bridge VSIs: (a) fundamental control and third, fifth, and seventh harmonic elimination and (b) fundamental control.

Figure 15.10c shows a special case where only the fundamental ac output voltage is controlled. This is known as output control by voltage cancellation, which derives from the fact that its implementation is easily attainable by using two phase-shifted square-wave switching signals as shown in Fig. 15.12. The phase-shift angle becomes $2 \cdot \alpha_1$ (Fig. 15.11b). Thus, the amplitude of the fundamental component and harmonics in the ac output voltage are given by

$$\hat{v}_{oh} = \frac{4}{\pi} v_i \frac{(-1)^{(h-1)/2}}{h} \cos(h\alpha_1) \quad h = 1, 3, 5, \dots \quad (15.21)$$

It can also be observed in Fig. 15.12c that for $\alpha_1 = 0$ square-wave operation is achieved. In this case, the fundamental

ac output voltage is given by

$$\hat{v}_{o1} = \frac{4}{\pi} v_i \quad (15.22)$$

where the fundamental load voltage can be controlled by the manipulation of the dc link voltage.

D. DC Link Current

Due to the fact that the inverter is assumed lossless and constructed without storage energy components, the instantaneous power balance indicates that,

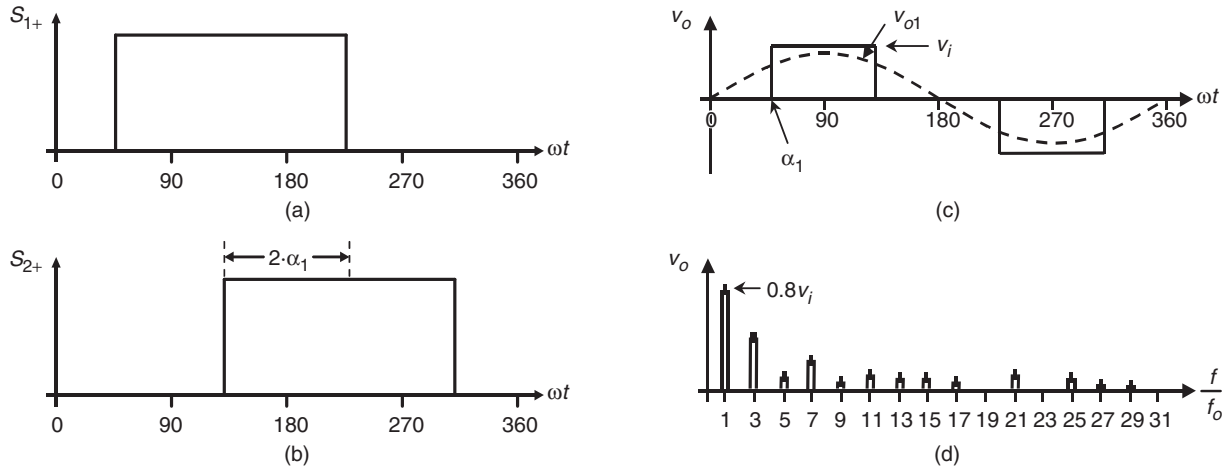
$$v_i(t) \cdot i_i(t) = v_o(t) \cdot i_o(t) \quad (15.23)$$


FIGURE 15.12 The full-bridge VSI. Ideal waveforms for the output control by voltage cancellation: (a) switch S_{1+} state; (b) switch S_{2+} state; (c) ac output voltage; and (d) ac output voltage spectrum.

For inductive load and relatively high switching frequencies, the load current i_o is nearly sinusoidal. As a first approximation, the ac output voltage can also be considered sinusoidal. On the other hand, if the dc link voltage remains constant $v_i(t) = V_i$, Eq. (15.23) can be simplified to

$$i_i(t) = \frac{1}{V_i}\sqrt{2}V_{o1}\sin(\omega t) \cdot \sqrt{2}I_o\sin(\omega t - \phi) \qquad (15.24)$$

where V_{o1} is the fundamental rms ac output voltage, I_o is the rms load current, and ϕ is an arbitrary inductive load power factor. Thus, the dc link current can be further simplified to

$$i_i(t) = \frac{V_{o1}}{V_i}I_o\cos(\phi) - \frac{V_{o1}}{V_i}I_o\cos(2\omega t - \phi) \qquad (15.25)$$

The preceding expression reveals an important issue, that is, the presence of a large second-order harmonic in the dc link current (its amplitude is similar to the dc link current). This second harmonic is injected back into the dc voltage source, thus its design should consider it in order to guarantee a nearly constant dc link voltage. In practical terms, the dc voltage source is required to feature large amounts of capacitance, which is costly and demands space, both undesired features, especially in medium- to high-power supplies.

15.3 Three-phase Voltage Source Inverters

Single-phase VSIs cover low-range power applications and three-phase VSIs cover medium- to high-power applications. The main purpose of these topologies is to provide a three-phase voltage source, where the amplitude, phase, and frequency of the voltages should always be controllable. Although most of the applications require sinusoidal voltage waveforms (e.g. ASDs, UPSs, FACTS, var compensators), arbitrary voltages are also required in some emerging applications (e.g. active filters, voltage compensators).

The standard three-phase VSI topology is shown in Fig. 15.13 and the eight valid switch states are given in Table 15.3. As in single-phase VSIs, the switches of any leg
FIGURE 15.13 Three-phase VSI topology.

TABLE 15.3 Valid switch states for a three-phase VSI

State	State #	v_{ab}	v_{bc}	v_{ca}	Space vector

S_4, S_5, and S_3 are on and S_1, S_2, and S_6 are off	4	$-v_i$	0	v_i	$\vec{v}_4 = -1 - j0.577$
S_5, S_6, and S_4 are on and S_2, S_3, and S_1 are off	5	0	$-v_i$	v_i	$\vec{v}_5 = -j1.155$
S_6, S_1, and S_5 are on and S_3, S_4, and S_2 are off	6	v_i	$-v_i$	0	$\vec{v}_6 = 1 - j0.577$
S_1, S_3, and S_5 are on and S_4, S_6, and S_2 are off	7	0	0	0	$\vec{v}_7 = 0$
S_4, S_6, and S_2 are on and S_1, S_3, and S_5 are off	8	0	0	0	$\vec{v}_8 = 0$

of the inverter (S_1 and S_4, S_3 and S_6, or S_5 and S_2) cannot be switched on simultaneously because this would result in a short circuit across the dc link voltage supply. Similarly, in order to avoid undefined states in the VSI, and thus undefined ac output line voltages, the switches of any leg of the inverter cannot be switched off simultaneously as this will result in voltages that will depend upon the respective line current polarity.

Of the eight valid states, two of them (7 and 8 in Table 15.3) produce zero ac line voltages. In this case, the ac line currents freewheel through either the upper or lower components. The remaining states (1 to 6 in Table 15.3) produce non-zero ac output voltages. In order to generate a given voltage waveform, the inverter moves from one state to another. Thus the resulting ac output line voltages consist of discrete values of voltages that are v_i, 0, and $-v_i$ for the topology shown in Fig. 15.13. The selection of the states in order to generate the given waveform is done by the modulating technique that should ensure the use of only the valid states.

15.3.1 Sinusoidal PWM

This is an extension of the one introduced for single-phase VSIs. In this case and in order to produce 120° out-of-phase load voltages, three modulating signals that are 120° out-of-phase are used. Figure 15.14 shows the ideal waveforms of three-phase VSI SPWM. In order to use a single carrier signal and preserve the features of the PWM technique, the normalized carrier frequency m_f should be an odd multiple of 3. Thus, all phase voltages (v_{aN}, v_{bN}, and v_{cN}) are identical, but 120° out-of-phase without even harmonics; moreover, harmonics at frequencies, a multiple of 3, are identical in amplitude and phase in all phases. For instance, if the ninth harmonic in phase aN is

$$v_{aN9}(t) = \hat{v}_9 \sin(9\omega t) \qquad (15.26)$$

the ninth harmonic in phase bN will be

$$v_{bN9}(t) = \hat{v}_9 \sin\left[9(\omega t - 120°)\right]$$
$$= \hat{v}_9 \sin(9\omega t - 1080°) = \hat{v}_9 \sin(9\omega t) \qquad (15.27)$$

Thus, the ac output line voltage $v_{ab} = v_{aN} - v_{bN}$ will not contain the ninth harmonic. Therefore, for odd multiple of 3 values of the normalized carrier frequency m_f, the harmonics in the ac output voltage appear at normalized frequencies f_h centered around m_f and its multiples, specifically, at

$$h = l\, m_f \pm k \quad l = 1, 2, \ldots \qquad (15.28)$$

where $l = 1, 3, 5, \ldots$ for $k = 2, 4, 6, \ldots$ and $l = 2, 4, \ldots$ for $k = 1, 5, 7, \ldots$ such that h is not a multiple of 3. Therefore, the harmonics will be at $m_f \pm 2$, $m_f \pm 4, \ldots, 2m_f \pm 1$, $2m_f \pm 5, \ldots, 3m_f \pm 2$, $3m_f \pm 4, \ldots, 4m_f \pm 1$, $4m_f \pm 5, \ldots$. For nearly sinusoidal ac load current, the harmonics in the dc link current are at frequencies given by

$$h = l\, m_f \pm k \pm 1 \quad l = 1, 2, \ldots \qquad (15.29)$$

where $l = 0, 2, 4, \ldots$ for $k = 1, 5, 7, \ldots$ and $l = 1, 3, 5, \ldots$ for $k = 2, 4, 6, \ldots$ such that $h = l \cdot m_f \pm k$ is positive and not a multiple of 3. For instance, Fig. 15.14h shows the sixth harmonic ($h = 6$), which is due to $h = 1 \cdot 9 - 2 - 1 = 6$.

The identical conclusions can be drawn for the operation at small and large values of m_f as for the single-phase configurations. However, because the maximum amplitude of the fundamental phase voltage in the linear region ($m_a \leq 1$) is $v_i/2$, the maximum amplitude of the fundamental ac output line voltage is $\sqrt{3}v_i/2$. Therefore, one can write

$$\hat{v}_{ab1} = m_a \sqrt{3}\frac{v_i}{2} \quad 0 < m_a \leq 1 \qquad (15.30)$$

To further increase the amplitude of the load voltage, the amplitude of the modulating signal $\hat{v}_c$ can be made higher than the amplitude of the carrier signal $\hat{v}_\Delta$, which leads to overmodulation. The relationship between the amplitude of the fundamental ac output line voltage and the dc link voltage becomes non-linear as in single-phase VSIs. Thus, in the overmodulation region, the line voltages range is

$$\sqrt{3}\frac{v_i}{2} < \hat{v}_{ab1} = \hat{v}_{bc1} = \hat{v}_{ca1} < \frac{4}{\pi}\sqrt{3}\frac{v_i}{2} \qquad (15.31)$$

15.3.2 Square-wave Operation of Three-phase VSIs

Large values of m_a in the SPWM technique lead to full overmodulation. This is known as square-wave operation as illustrated in Fig. 15.15, where the power valves are on for 180°.
FIGURE 15.14   The three-phase VSI. Ideal waveforms for the SPWM ($m_a = 0.8$, $m_f = 9$): (a) carrier and modulating signals; (b) switch S_1 state; (c) switch S_3 state; (d) ac output voltage; (e) ac output voltage spectrum; (f) ac output current; (g) dc current; (h) dc current spectrum; (i) switch S_1 current; and (j) diode D_1 current.

In this operation mode, the VSI cannot control the load voltage except by means of the dc link voltage v_i. This is based on the fundamental ac line-voltage expression

$$\hat{v}_{ab\,1} = \frac{4}{\pi}\sqrt{3}\frac{v_i}{2} \tag{15.32}$$

The ac line output voltage contains the harmonics f_h, where $h = 6 \cdot k \pm 1$ ($k = 1, 2, 3, \ldots$) and they feature amplitudes that are inversely proportional to their harmonic order

(Fig. 15.15d). Their amplitudes are

$$\hat{v}_{ab\,h} = \frac{1}{h}\frac{4}{\pi}\sqrt{3}\frac{v_i}{2} \tag{15.33}$$

15.3.3 Sinusoidal PWM with Zero Sequence Signal Injection

The restriction for m_a ($m_a \leq 1$) can be relaxed if a zero sequence signal is added to the modulating signals before they are compared to the carrier signal. Figure 15.16 shows the block diagram of the technique. Clearly, the addition of
FIGURE 15.15 The three-phase VSI. Square-wave operation: (a) switch S_1 state; (b) switch S_3 state; (c) ac output voltage; and (d) ac output voltage spectrum.
FIGURE 15.16 Zero sequence signal generator ($m_a = 1.0$, $m_f = 9$): (a) block diagram; (b) modulating signals; and (c) zero sequence and modulating signals with zero sequence injection.

the zero sequence reduces the peak amplitude of the resulting modulating signals (u_{ca}, u_{cb}, u_{cc}), while the fundamental components remain unchanged. This approach expands the range of the linear region as it allows the use of modulation indexes m_a up to $2/\sqrt{3}$ without getting into the overmodulating region.

The maximum amplitude of the fundamental phase voltage in the linear region $(m_a \leq 2/\sqrt{3})$ is $v_i/2$, thus, the maximum amplitude of the fundamental ac output line voltage is v_i. Therefore, one can write

$$\hat{v}_{ab1} = m_a\sqrt{3}\frac{v_i}{2} \quad \left(0 < m_a \leq 2/\sqrt{3}\right) \tag{15.34}$$

Figure 15.17 shows the ideal waveforms of a three-phase VSI SPWM with zero injection for $m_a = 0.8$.
FIGURE 15.17 The three-phase VSI. Ideal waveforms for the SPWM ($m_a = 0.8$, $m_f = 9$) with zero sequence signal injection: (a) modulating signals; (b) carrier and modulating signals with zero sequence signal injection; (c) switch S_1 state; (d) ac output voltage; (e) ac output voltage spectrum; (f) ac output current; (g) dc current; (h) dc current spectrum; (i) switch S_1 current; and (j) diode D_1 current.

15.3.4 Selective Harmonic Elimination in Three-phase VSIs

As in single-phase VSIs, the SHE technique can be applied to three-phase VSIs. In this case, the power valves of each leg of the inverter are switched so as to eliminate a given number of harmonics and to control the fundamental phase-voltage amplitude. Considering that in many applications, the required line output voltages should be balanced and 120° out of phase, the harmonics multiples of 3 ($h = 3, 9, 15, \ldots$), which

could be present in the phase voltages (v_{aN}, v_{bN}, and v_{cN}), will not be present in the load voltages (v_{ab}, v_{bc}, and v_{ca}). Therefore, these harmonics are not required to be eliminated, thus the chopping angles are used to eliminate only the harmonics at frequencies $h = 5, 7, 11, 13, \ldots$ as required.

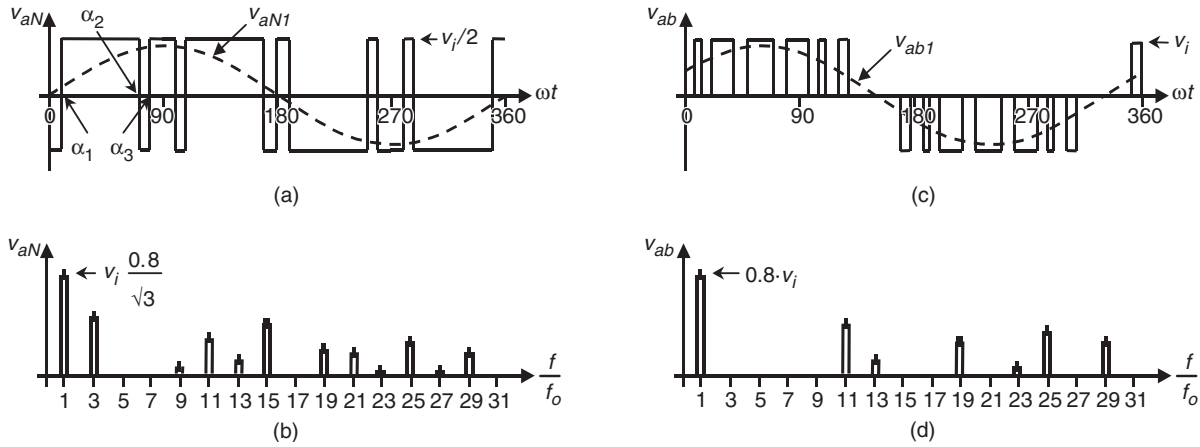
The expressions to eliminate a given number of harmonics are the same as those used in single-phase inverters. For instance, to eliminate the fifth and seventh harmonics and perform fundamental magnitude control ($N = 3$), the equations


FIGURE 15.18 The three-phase VSI. Ideal waveforms for the SHE technique: (a) phase voltage v_{aN} for fifth and seventh harmonic elimination; (b) spectrum of (a); (c) line voltage v_{ab} for fifth and seventh harmonic elimination; and (d) spectrum of (c).

to be solved are:

$$\cos(1\alpha_1) - \cos(1\alpha_2) + \cos(1\alpha_3) = (2 + \pi\hat{v}_{aN1}/v_i)/4$$

$$\cos(5\alpha_1) - \cos(5\alpha_2) + \cos(5\alpha_3) = 1/2$$

$$\cos(7\alpha_1) - \cos(7\alpha_2) + \cos(7\alpha_3) = 1/2$$

$$(15.35)$$

where the angles α_1, α_2, and α_3 are defined as shown in Fig. 15.18a and plotted in Fig. 15.19. Figure 15.18b shows that the third, ninth, fifteenth, ... harmonics are all present in the phase voltages; however, they are not in the line voltages (Fig. 15.18d).
FIGURE 15.19 Chopping angles for SHE and fundamental voltage control in three-phase VSIs: fifth and seventh harmonic elimination.

15.3.5 Space-vector (SV)-based Modulating Techniques

At present, the control strategies are implemented in digital systems, and therefore digital modulating techniques are also available. The SV-based modulating technique is a digital technique in which the objective is to generate PWM load line voltages that are on average equal to given load line voltages. This is done in each sampling period by properly selecting the switch states from the valid ones of the VSI (Table 15.3) and by proper calculation of the period of times they are used. The selection and calculation times are based upon the SV transformation.

A. Space-vector Transformation

Any three-phase set of variables that add up to zero in the stationary *abc* frame can be represented in a complex plane by a complex vector that contains a real (α) and an imaginary (β) component. For instance, the vector of three-phase line-modulating signals $\mathbf{v_c^{abc}} = [v_{ca} v_{cb} v_{cc}]^T$ can be represented by the complex vector $\vec{v}_c = \mathbf{v_c^{\alpha\beta}} = [v_{c\alpha} v_{c\beta}]^T$ by means of the following transformation:

$$v_{c\alpha} = \frac{2}{3}\left[v_{ca} - 0.5\left(v_{cb} + v_{cc}\right)\right] \qquad (15.36)$$

$$v_{c\beta} = \frac{\sqrt{3}}{3}\left(v_{cb} - v_{cc}\right) \qquad (15.37)$$

If the line-modulating signals $\mathbf{v_c^{abc}}$ are three balanced sinusoidal waveforms that feature an amplitude $\hat{v}_c$ and an angular frequency ω, the resulting modulating signals in the $\alpha\beta$ stationary frame become a vector $\vec{v}_c = \mathbf{v_c^{\alpha\beta}}$ of fixed module $\hat{v}_c$, which rotates at frequency ω (Fig. 15.20). Similarly, the SV transformation is applied to the line voltages of the eight states of the

modulating vector $\vec{v}_c = \mathbf{v}_c{}^{\alpha\beta}$

sector number

state

$\vec{v}_2 = \vec{v}_{i+1}$

$\vec{v}_1 = \vec{v}_i$

$\vec{v}_4$

$\vec{v}_6$

$\vec{v}_5$
FIGURE 15.20 The space-vector representation.

VSI normalized with respect to v_i (Table 15.3), which generates the eight space vectors ($\vec{v}_i$, $i = 1, 2, \ldots, 8$) in Fig. 15.20. As expected, $\vec{v}_1$ to $\vec{v}_6$ are non-null line-voltage vectors and $\vec{v}_7$ and $\vec{v}_8$ are null line-voltage vectors.

The objective of the SV technique is to approximate the line-modulating signal space vector $\vec{v}_c$ with the eight space vectors ($\vec{v}_i$, $i = 1, 2, \ldots, 8$) available in VSIs. However, if the modulating signal $\vec{v}_c$ is laying between the arbitrary vectors $\vec{v}_i$ and $\vec{v}_{i+1}$, only the nearest two non-zero vectors ($\vec{v}_i$ and $\vec{v}_{i+1}$) and one zero SV ($\vec{v}_z = \vec{v}_7$ or $\vec{v}_8$) should be used. Thus, the maximum load line voltage is maximized and the switching frequency is minimized. To ensure that the generated voltage in one sampling period T_s (made up of the voltages provided by the vectors $\vec{v}_i$, $\vec{v}_{i+1}$, and $\vec{v}_z$ used during times T_i, T_{i+1}, and T_z) is on average equal to the vector $\vec{v}_c$ the following expression should hold:

$$\vec{v}_c \cdot T_s = \vec{v}_i \cdot T_s + \vec{v}_{i+1} \cdot T_{i+1} + \vec{v}_z \cdot T_z \qquad (15.38)$$

The solution of the real and imaginary parts of Eq. (15.37) for a line-load voltage that features an amplitude restricted to $0 \le \hat{v}_c \le 1$ gives

$$T_i = T_s \cdot \hat{v}_c \cdot \sin(\pi/3 - \theta) \qquad (15.39)$$

$$T_{i+1} = T_s \cdot \hat{v}_c \cdot \sin(\theta) \qquad (15.40)$$

$$T_z = T_s - T_i - T_{i+1} \qquad (15.41)$$

The preceding expressions indicate that the maximum fundamental line-voltage amplitude is unity as $0 \le \theta \le \pi/3$. This is an advantage over the SPWM technique which achieves a $\sqrt{3}/2$ maximum fundamental line-voltage amplitude in the linear operating region. Although, the space vector

modulation (SVM) technique selects the vectors to be used and their respective on-times, the sequence in which they are used, the selection of the zero space vector, and the normalized sampled frequency remain undetermined.

For instance, if the modulating line-voltage vector is in sector 1 (Fig. 15.20), the vectors $\vec{v}_1$, $\vec{v}_2$, and $\vec{v}_z$ should be used within a sampling period by intervals given by T_1, T_2, and T_z, respectively. The question that remains is whether the sequence (i) $\vec{v}_1 - \vec{v}_2 - \vec{v}_z$, (ii) $\vec{v}_z - \vec{v}_1 - \vec{v}_2 - \vec{v}_z$, (iii) $\vec{v}_z - \vec{v}_1 - \vec{v}_2 - \vec{v}_1 - \vec{v}_z$, (iv) $\vec{v}_z - \vec{v}_1 - \vec{v}_2 - \vec{v}_z - \vec{v}_2 - \vec{v}_1 - \vec{v}_z$, or any other sequence should actually be used. Finally, the technique does not indicate whether $\vec{v}_z$ should be $\vec{v}_7$, $\vec{v}_8$, or a combination of both.

B. Space-vector Sequences and Zero Space-vector Selection
The sequence to be used should ensure load line-voltages that feature quarter-wave symmetry in order to reduce unwanted harmonics in their spectra (even harmonics). Additionally, the zero SV selection should be done in order to reduce the switching frequency. Although there is not a systematic approach to generate a SV sequence, a graphical representation shows that the sequence $\vec{v}_i$, $\vec{v}_{i+1}$, $\vec{v}_z$ (where $\vec{v}_z$ is alternately chosen among $\vec{v}_7$ and $\vec{v}_8$) provides high performance in terms of minimizing unwanted harmonics and reducing the switching frequency.

C. The Normalized Sampling Frequency
The normalized carrier frequency m_f in three-phase carrier-based PWM techniques is chosen to be an odd integer number multiple of 3 ($m_f = 3 \cdot n$, $n = 1, 3, 5, \ldots$). Thus, it is possible to minimize parasitic or non-intrinsic harmonics in the PWM waveforms. A similar approach can be used in the SVM technique to minimize uncharacteristic harmonics. Hence, it is found that the normalized sampling frequency f_{sn} should be an integer multiple of 6. This is due to the fact that in order to produce symmetrical line voltages, all the sectors (a total of 6) should be used equally in one period. As an example, Fig. 15.21 shows the relevant waveforms of a VSI SVM for $f_{sn} = 18$ and $\hat{v}_c = 0.8$. Figure 15.21 confirms that the first set of relevant harmonics in the load line voltage are at f_{sn} which is also the switching frequency.

15.3.6 DC Link Current in Three-phase VSIs

Due to the fact that the inverter is assumed to be lossless and constructed without storage energy components, the instantaneous power balance indicates that

$$v_i(t) \cdot i_i(t) = v_{ab}(t) \cdot i_a(t) + v_{bc}(t) \cdot i_b(t) + v_{ca}(t) \cdot i_c(t) \qquad (15.42)$$

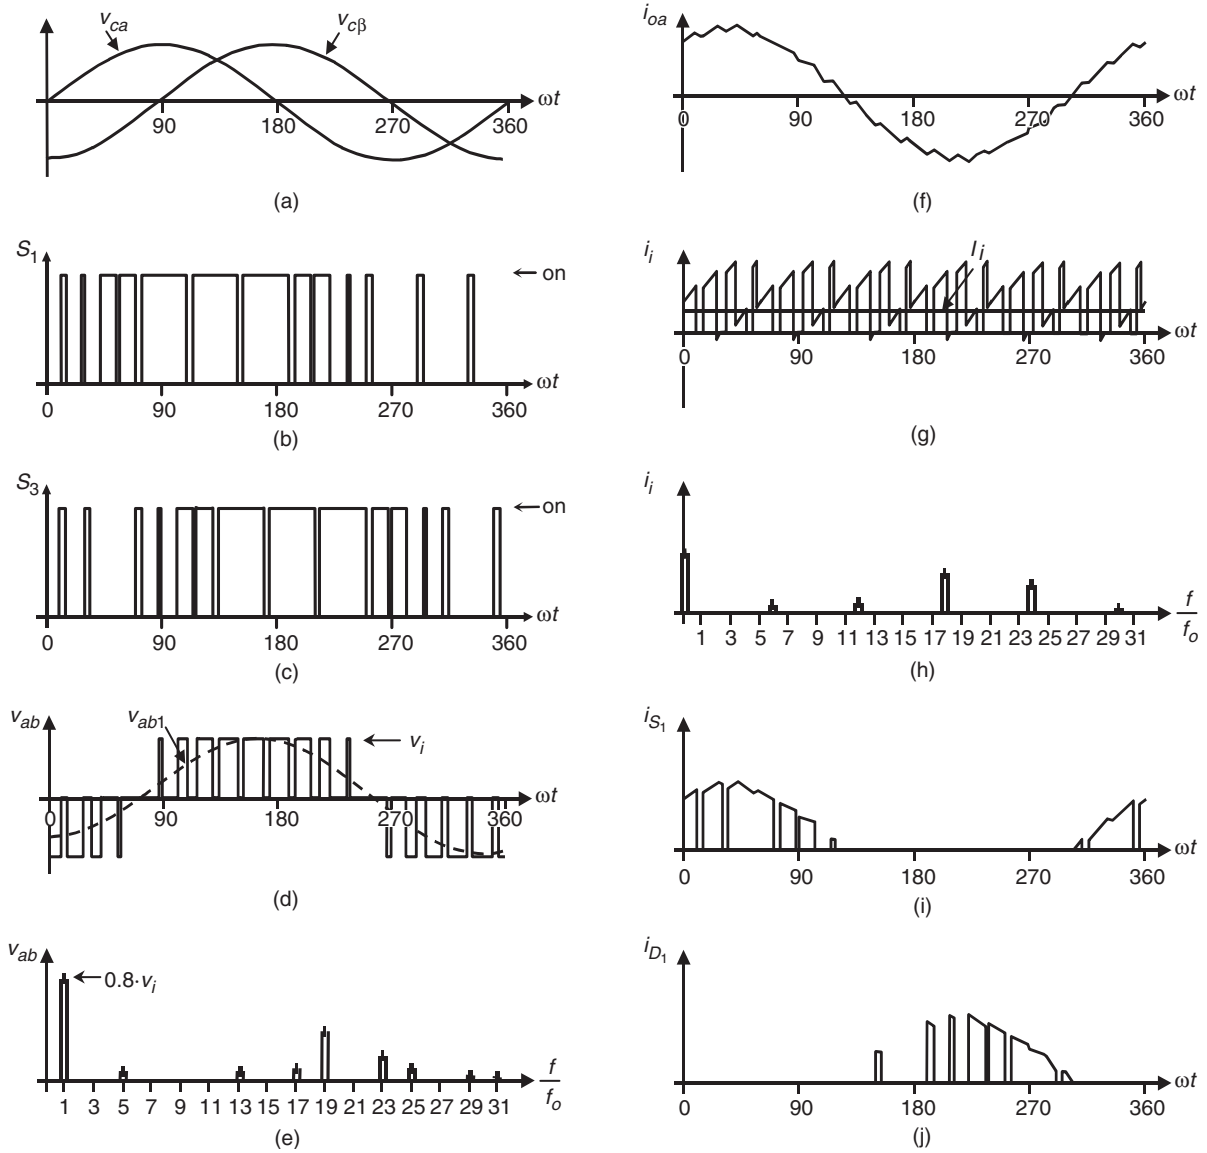
where $i_a(t)$, $i_b(t)$, and $i_c(t)$ are the phase-load currents as shown in Fig. 15.22. If the load is balanced and inductive, and a relatively high switching frequency is used, the load currents become nearly sinusoidal balanced waveforms. On the other


FIGURE 15.21 The three-phase VSI. Ideal waveforms for space-vector modulation ($\hat{v}_c = 0.8$, $f_{sn} = 18$): (a) modulating signals; (b) switch S_1 state; (c) switch S_3 state; (d) ac output voltage; (e) ac output voltage spectrum; (f) ac output current; (g) dc current; (h) dc current spectrum; (i) switch S_1 current; and (j) diode D_1 current.

hand, if the ac output voltages are considered sinusoidal and the dc link voltage is assumed constant $v_i(t) = V_i$, Eq. (15.42) can be simplified to

$$i_i(t) = \frac{1}{V_i} \left\{ \begin{array}{l} \sqrt{2}V_{o1}\sin(\omega t) \cdot \sqrt{2}I_o\sin(\omega t - \phi) \\ +\sqrt{2}V_{o1}\sin(\omega t - 120°) \cdot \sqrt{2}I_o\sin(\omega t - 120° - \phi) \\ +\sqrt{2}V_{o1}\sin(\omega t - 240°) \cdot \sqrt{2}I_o\sin(\omega t - 240° - \phi) \end{array} \right\}$$

$$(15.43)$$

where V_{o1} is the fundamental rms ac output line voltage, I_o is the rms load-phase current, and ϕ is an arbitrary inductive

load power factor. Hence, the dc link current expression can be further simplified to

$$i_i(t) = 3\frac{V_{o1}}{V_i}I_o\cos(\phi) = \sqrt{3}\frac{V_{o1}}{V_i}I_l\cos(\phi) \qquad (15.44)$$

where $I_l = \sqrt{3}I_o$ is the rms load line current. The resulting dc link current expression indicates that under harmonic-free load voltages, only a clean dc current should be expected in the dc bus and, compared to single-phase VSIs, there is no presence of second harmonic. However, as the ac load line voltages contain harmonics around the normalized sampling
FIGURE 15.22 Phase-load currents definition in a delta-connected load.

frequency f_{sn}, the dc link current will contain harmonics but around f_{sn} as shown in Fig. 15.21h.

15.3.7 Load-phase Voltages in Three-phase VSIs

The load is sometimes wye-connected and the phase-load voltages v_{an}, v_{bn}, and v_{cn} may be required (Fig. 15.23). To obtain them, it should be considered that the line-voltage vector is

$$\begin{bmatrix} v_{ab} \\ v_{bc} \\ v_{ca} \end{bmatrix} = \begin{bmatrix} v_{an} - v_{bn} \\ v_{bn} - v_{cn} \\ v_{cn} - v_{an} \end{bmatrix} \tag{15.45}$$

which can be written as a function of the phase-voltage vector $[v_{an} v_{bn} v_{cn}]^T$ as

$$\begin{bmatrix} v_{ab} \\ v_{bc} \\ v_{ca} \end{bmatrix} = \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \\ -1 & 0 & 1 \end{bmatrix} \begin{bmatrix} v_{an} \\ v_{bn} \\ v_{cn} \end{bmatrix} \tag{15.46}$$

Expression (15.46) represents a linear system where the unknown quantity is the vector $[v_{an} v_{bn} v_{cn}]^T$. Unfortunately,
FIGURE 15.23 Phase-load voltages definition in a wye-connected load.

the system is singular as the rows add up to zero (line voltages add up to zero), therefore, the phase-load voltages cannot be obtained by matrix inversion. However, if the phase-load voltages add up to zero, Eq. (15.46) can be rewritten as

$$\begin{bmatrix} v_{ab} \\ v_{bc} \\ 0 \end{bmatrix} = \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \\ 1 & 1 & 1 \end{bmatrix} \begin{bmatrix} v_{an} \\ v_{bn} \\ v_{cn} \end{bmatrix} \tag{15.47}$$

which is not singular and hence,

$$\begin{bmatrix} v_{an} \\ v_{bn} \\ v_{cn} \end{bmatrix} = \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \\ 1 & 1 & 1 \end{bmatrix}^{-1} \begin{bmatrix} v_{ab} \\ v_{bc} \\ 0 \end{bmatrix} = \frac{1}{3} \begin{bmatrix} 2 & 1 & 1 \\ -1 & 1 & 1 \\ -1 & -2 & 1 \end{bmatrix} \begin{bmatrix} v_{ab} \\ v_{bc} \\ 0 \end{bmatrix} \tag{15.48}$$

that can be further simplified to

$$\begin{bmatrix} v_{an} \\ v_{bn} \\ v_{cn} \end{bmatrix} = \frac{1}{3} \begin{bmatrix} 2 & 1 \\ -1 & 1 \\ -1 & -2 \end{bmatrix} \begin{bmatrix} v_{ab} \\ v_{bc} \end{bmatrix} \tag{15.49}$$

The final expression for the phase-load voltages is only a function of v_{ab} and v_{bc}, which is due to fact that the last row in Eq. (15.46) is chosen to be only ones. Figure 15.24 shows the line- and phase-voltages obtained using Eq. (15.49).

15.4 Current Source Inverters

The main objective of these static power converters is to produce an ac output current waveforms from a dc current power supply. For sinusoidal ac outputs, its magnitude, frequency, and phase should be controllable. Due to the fact that the ac line currents i_{oa}, i_{ob}, and i_{oc} (Fig. 15.25) feature high di/dt, a capacitive filter should be connected at the ac terminals in inductive load applications (such as ASDs). Thus, nearly sinusoidal load voltages are generated that justifies the use of these topologies in medium-voltage industrial applications, where high-quality voltage waveforms are required. Although single-phase CSIs can in the same way as three-phase CSIs topologies, be developed under similar principles, only three-phase applications are of practical use and are analyzed below.

(a)

(b)
FIGURE 15.24 The three-phase VSI. Line- and phase-load voltages: (a) line-load voltage v_{ab}; and (b) phase-load voltage v_{an}.
FIGURE 15.25   Three-phase CSI topology.

In order to properly gate the power switches of a three-phase CSI, two main constraints must always be met: (a) the ac side is mainly capacitive, thus, it must not be short-circuited; this implies that, at most one top switch (1, 3, or 5 (Fig. 15.25)) and one bottom switch (4, 6, or 2 (Fig. 15.25)) should be closed at any time; and (b) the dc bus is of the current-source type and thus it cannot be opened; therefore, there must be at least one top switch (1, 3, or 5) and one bottom switch (4, 6, or 2) closed at all times. Note that both constraints can be summarized by stating that at any time, only one top switch and one bottom switch must be closed.

There are nine valid states in three-phase CSIs. The states 7, 8, and 9 (Table 15.4) produce zero ac line currents. In this case, the dc link current freewheels through either the switches S_1 and S_4, switches S_3 and S_6, or switches S_5 and S_2. The remaining states (1 to 6 in Table 15.4) produce non-zero ac output line currents. In order to generate a given set of ac line current waveforms, the inverter must move from one state to another. Thus, the resulting line currents consist of discrete values of

current, which are i_i, 0, and $-i_i$. The selection of the states in order to generate the given waveforms is done by the modulating technique that should ensure the use of only the valid states.

There are several modulating techniques that deal with the special requirements of CSIs and can be implemented online. These techniques are classified into three categories: (a) the carrier-based; (b) the SHE-based; and (c) the SV-based techniques. Although they are different, they generate gating signals that satisfy the special requirements of CSIs. To simplify the analysis, a constant dc link-current source is considered ($i_i = I_i$).

15.4.1 Carrier-based PWM Techniques in CSIs

It has been shown that the carrier-based PWM techniques that were initially developed for three-phase VSIs can be extended to three-phase CSIs. The circuit shown in Fig. 15.26 obtains the gating pattern for a CSI from the gating pattern developed for a VSI. As a result, the line current appears to be identical to the line voltage in a VSI for similar carrier and modulating signals.

It is composed of a *switching pulse generator*, a *shorting pulse generator*, a *shorting pulse distributor*, and a *switching and shorting pulse combinator*. The circuit basically produces the gating signals ($\mathbf{s} = [s_1 \dots s_6]^T$) according to a carrier i_Δ and three modulating signals $\mathbf{i}_\mathbf{c}^{abc} = [i_{ca}\ i_{cb}\ i_{ca}]^T$. Therefore, any set of modulating signals which when combined result in a sinusoidal line-to-line set of signals, will satisfy the requirement for a sinusoidal line current pattern. Examples of such a modulating signals are the standard sinusoidal, sinusoidal with third harmonic injection, trapezoidal, and deadband waveforms.

The first component of this stage (Fig. 15.26) is the *switching pulse generator*, where the signals $\mathbf{s}_\mathbf{a}^{123}$ are generated according to:

TABLE 15.4   Valid switch states for a three-phase CSI

State	State #	i_{oa}	i_{ob}	i_{oc}	Space vector
S_1 and S_2 are on and S_3, S_4, S_5, and S_6 are off	1	i_i	0	$-i_i$	$\vec{\mathbf{i}}_1 = 1 + j0.577$
S_2 and S_3 are on and S_4, S_5, S_6, and S_1 are off	2	0	i_i	$-i_i$	$\vec{\mathbf{i}}_2 = j1.155$
S_3 and S_4 are on and S_5, S_6, S_1, and S_2 are off	3	$-i_i$	i_i	0	$\vec{\mathbf{i}}_3 = -1 + j0.577$
S_4 and S_5 are on and S_6, S_1, S_2, and S_3 are off	4	$-i_i$	0	i_i	$\vec{\mathbf{i}}_4 = -1 - j0.577$
S_5 and S_6 are on and S_1, S_2, S_3, and S_4 are off	5	0	$-i_i$	i_i	$\vec{\mathbf{i}}_5 = -j1.155$
S_6 and S_1 are on and S_2, S_3, S_4, and S_5 are off	6	i_i	$-i_i$	0	$\vec{\mathbf{i}}_6 = 1 - j0.577$
S_1 and S_4 are on and S_2, S_3, S_5, and S_6 are off	7	0	0	0	$\vec{\mathbf{i}}_7 = 0$
S_3 and S_6 are on and S_1, S_2, S_4, and S_5 are off	8	0	0	0	$\vec{\mathbf{i}}_8 = 0$
S_5 and S_2 are on and S_6, S_1, S_3, and S_4 are off	9	0	0	0	$\vec{\mathbf{i}}_9 = 0$

$$\mathbf{s}_\mathbf{a}^{123} = \begin{cases} \text{HIGH} = 1 \ \ if \ \ \ \mathbf{i}_\mathbf{c}^{abc} > v_c \\ \text{LOW} = 0 \ \ \ \ otherwise \end{cases} \tag{15.50}$$
FIGURE 15.26   The three-phase CSI. Gating pattern generator for analog on-line carrier-based PWM.

The outputs of the *switching pulse generator* are the signals $\mathbf{s_c}$, which are basically the gating signals of the CSI without the shorting pulses. These are necessary to freewheel the dc link current i_i when zero ac output currents are required. Table 15.5 shows the truth table of $\mathbf{s_c}$ for all combinations of their inputs $\mathbf{s_a^{123}}$. It can be clearly seen that at most one top switch and one bottom switch is on, which satisfies the first constraint of the gating signals as stated before.

In order to satisfy the second constraint, the shorting pulse ($s_d = 1$) ($s_d = 1$) is generated (*shorting pulse generator* (Fig. 15.26)) the top switches ($s_{c1} = s_{c3} = s_{c5} = 0$) or none of the bottom switches ($s_{c4} = s_{c6} = s_{c2} = 0$) are gated. Then, this pulse is added (using OR gates) to only one leg of the CSI (either to the switches 1 and 4, 3 and 6, or 5 and 2) by means of the *switching and shorting pulse combinator* (Fig. 15.26). The signals generated by the *shorting pulse generator* $\mathbf{s_e^{123}}$ ensure that: (a) only one leg of the CSI is shorted, as only one of the signals is HIGH at any time; and (b) there is an even distribution of the shorting pulse, as $\mathbf{s_e^{123}}$ is high for 120° in each period. This ensures that the rms currents are equal in all legs.

Figure 15.27 shows the relevant waveforms if a triangular carrier i_Δ and sinusoidal modulating signals $\mathbf{i_c^{abc}}$ are used in combination with the gating pattern generator circuit (Fig. 15.26); this is SPWM in CSIs. It can be observed that some of the waveforms (Fig. 15.27) are identical to those
FIGURE 15.27 The three-phase CSI. Ideal waveforms for the SPWM ($m_a = 0.8$, $m_f = 9$): (a) carrier and modulating signals; (b) switch S_1 state; (c) switch S_3 state; (d) ac output current; (e) ac output current spectrum; (f) ac output voltage; (g) dc voltage; (h) dc voltage spectrum; (i) switch S_1 current; and (j) switch S_1 voltage.

obtained in three-phase VSIs, where a SPWM technique is used (Fig. 15.15). Specifically: (i) the load line voltage (Fig. 15.15d) in the VSI is identical to the load line current (Fig. 15.27d) in the CSI; and (ii) the dc link current (Fig. 15.15g) in the VSI is identical to the dc link voltage (Fig. 15.27g) in the CSI.

This brings up the duality issue between both the topologies when similar modulation approaches are used. Therefore, for odd multiples of 3 values of the normalized carrier frequency m_f, the harmonics in the ac output current appear at normalized frequencies f_h centered around m_f and its

multiples, specifically, at

$$h = l\, m_f \pm k \quad l = 1, 2, \ldots \tag{15.51}$$

where $l = 1, 3, 5, \ldots$ for $k = 2, 4, 6, \ldots$ and $l = 2, 4, \ldots$ for $k = 1, 5, 7, \ldots$ such that h is not a multiple of 3. Therefore, the harmonics will be at $m_f \pm 2$, $m_f \pm 4, \ldots$, $2m_f \pm 1$, $2m_f \pm 5, \ldots$, $3m_f \pm 2$, $3m_f \pm 4, \ldots$, $4m_f \pm 1$, $4m_f \pm 5, \ldots$. For nearly sinusoidal ac load voltages, the harmonics in the dc link voltage are at frequencies given by

$$h = l\, m_f \pm k \pm 1 \quad l = 1, 2, \ldots \tag{15.52}$$

where $l = 0, 2, 4, \ldots$ for $k = 1, 5, 7, \ldots$ and $l = 1, 3, 5, \ldots$ for $k = 2, 4, 6, \ldots$ such that $h = l \cdot m_f \pm k$ is positive and not a multiple of 3. For instance, Fig. 15.27h shows the sixth harmonic ($h = 6$), which is due to $h = 1 \cdot 9 - 2 - 1 = 6$. Identical conclusions can be drawn for the small and large values of m_f in the same way as for three-phase VSI configurations. Thus, the maximum amplitude of the fundamental ac output line current is $\hat{i}_{oa1} = \sqrt{3}\, i_i / 2$ and therefore one can write

$$\hat{i}_{oa1} = m_a \frac{\sqrt{3}}{2} i_i \quad 0 < m_a \leq 1 \tag{15.53}$$

To further increase the amplitude of the load current, the overmodulation approach can be used. In this region, the fundamental line currents range in

$$\frac{\sqrt{3}}{2} i_i < \hat{i}_{oa1} = \hat{i}_{ob1} = \hat{i}_{oc1} < \frac{4}{\pi} \frac{\sqrt{3}}{2} i_i \tag{15.54}$$

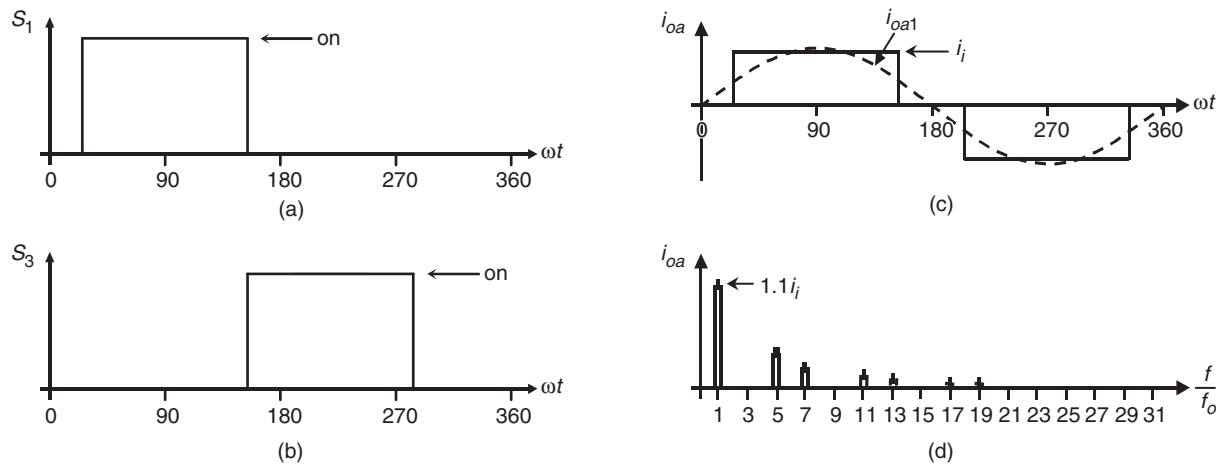
To further test the gating signal generator circuit (Fig. 15.26), a sinusoidal set with third and ninth harmonic injection modulating signals are used. Figure 15.28 shows the relevant waveforms.
FIGURE 15.28 Gating pattern generator. Waveforms for third and ninth harmonic injection PWM ($m_a = 0.8$, $m_f = 15$): signals as described in Fig. 15.26.


FIGURE 15.29 The three-phase CSI. Square-wave operation: (a) switch S_1 state; (b) switch S_3 state; (c) ac output current; and (d) ac output current spectrum.

15.4.2 Square-wave Operation of Three-phase CSIs

As in VSIs, large values of m_a in the SPWM technique lead to full overmodulation. This is known as square-wave operation. Figure 15.29 depicts this operating mode in a three-phase CSI, where the power valves are on for 120°. As presumed, the CSI cannot control the load current except by means of the dc link current i_i. This is due to the fact that the fundamental ac line current expression is

$$\hat{i}_{oa1} = \frac{4}{\pi} \frac{\sqrt{3}}{2} i_i \tag{15.55}$$

The ac line current contains the harmonics f_h, where $h = 6 \cdot k \pm 1$ ($k = 1, 2, 3, \ldots$), and they feature amplitudes that is inversely proportional to their harmonic order (Fig. 15.29d). Thus,

$$\hat{i}_{oah} = \frac{1}{h} \frac{4}{\pi} \frac{\sqrt{3}}{2} i_i \tag{15.56}$$

The duality issue among both the three-phase VSI and CSI should be noted especially in terms of the line-load waveforms. The line-load voltage produced by a VSI is identical to the load line current produced by the CSI when both are modulated using identical techniques. The next section will show that this also holds for SHE-based techniques.

15.4.3 Selective Harmonic Elimination in Three-phase CSIs

The SHE-based modulating techniques in VSIs define the gating signals such that a given number of harmonics are eliminated and the fundamental phase-voltage amplitude is

controlled. If the required line output voltages are balanced and 120° out-of-phase, the chopping angles are used to eliminate only the harmonics at frequencies $h = 5, 7, 11, 13, \ldots$ as required.

The circuit shown in Fig. 15.30 uses the gating signals $\mathbf{s}_a^{123}$ developed for a VSI and a set of synchronizing signals $\mathbf{i}_c^{abc}$ to obtain the gating signals $\mathbf{s}$ for a CSI. The synchronizing signals $\mathbf{i}_c^{abc}$ are sinusoidal balanced waveforms that are synchronized with the signals $\mathbf{s}_a^{123}$ in order to symmetrically distribute the shorting pulse and thus generate symmetrical gating patterns. The circuit ensures line current waveforms as the line voltages in a VSI. Therefore, any arbitrary number of harmonics can be eliminated and the fundamental line current can be controlled in CSIs. Moreover, the same chopping angles obtained for VSIs can be used in CSIs.

For instance, to eliminate the fifth and seventh harmonics, the chopping angles are shown in Fig. 15.31, which are identical to that obtained for a VSI using Eq. (15.9). Figure 15.32 shows that the line current does not contain the fifth and the seventh harmonics as expected. Hence, any number of harmonics can be eliminated in three-phase CSIs by means of the circuit (Fig. 15.30) without the hassle of how to satisfy the gating signal constrains.

15.4.4 Space-vector-based Modulating Techniques in CSIs

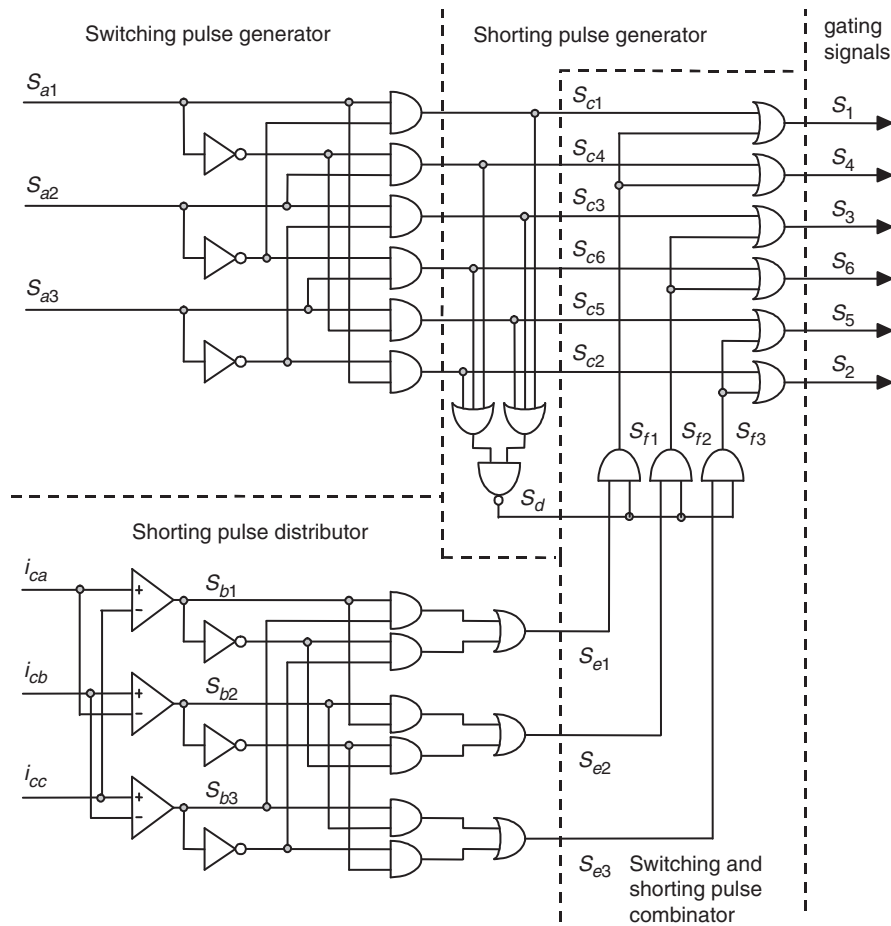
The objective of the SV-based modulating technique is to generate PWM load line currents that are on average equal to given load line currents. This is done digitally in each sampling period by properly selecting the switch states from the valid ones of the CSI (Table 15.4) and the proper calculation of the period of times they are used. As in VSIs, the selection and time calculations are based upon the space-vector transformation.


FIGURE 15.30 The three-phase CSI. Gating pattern generator for SHE PWM techniques.
FIGURE 15.31 Chopping angles for SHE and fundamental current control in three-phase CSIs: fifth and seventh harmonic elimination.

A. Space-vector Transformation in CSIs

Similarly to VSIs, the vector of three-phase line-modulating signals $\mathbf{i_c^{abc}} = [i_{ca}\ i_{cb}\ i_{cc}]^T$ can be represented by the complex vector $\vec{\mathbf{i}}_\mathbf{c} = \mathbf{i_c^{\alpha\beta}} = [i_{c\alpha}\ i_{c\beta}]^T$ by means of Eqs. (15.36) and (15.37). For three-phase balanced sinusoidal modulating waveforms, which feature an amplitude $\hat{i}_c$ and an angular frequency ω, the resulting modulating signals complex vector $\vec{\mathbf{i}}_\mathbf{c} = \mathbf{i_c^{\alpha\beta}}$ becomes a vector of fixed module $\hat{i}_c$, which rotates at frequency ω (Fig. 15.33). Similarly, the SV transformation is applied to the line currents of the nine states of the CSI normalized with respect to i_i, which generates nine space vectors ($\vec{\mathbf{i}}_\mathbf{i}$, $i = 1, 2, \ldots, 9$ in Fig. 15.33). As expected, $\vec{\mathbf{i}}_1$ to $\vec{\mathbf{i}}_6$ are non-null line current vectors and $\vec{\mathbf{i}}_7$, $\vec{\mathbf{i}}_8$, and $\vec{\mathbf{i}}_9$ are null line current vectors.

The SV technique approximates the line-modulating signal space vector $\vec{\mathbf{i}}_\mathbf{c}$ by using the nine space vectors ($\vec{\mathbf{i}}_\mathbf{i}$, $i = 1, 2, \ldots, 9$) available in CSIs. If the modulating signal vector $\vec{\mathbf{i}}_\mathbf{c}$ is between the arbitrary vectors $\vec{\mathbf{i}}_i$ and $\vec{\mathbf{i}}_{i+1}$, then $\vec{\mathbf{i}}_i$ and $\vec{\mathbf{i}}_{i+1}$ combined with one zero SV ($\vec{\mathbf{i}}_z = \vec{\mathbf{i}}_7$ or $\vec{\mathbf{i}}_8$ or $\vec{\mathbf{i}}_9$) should be used to generate $\vec{\mathbf{i}}_\mathbf{c}$. To ensure that the generated current in

FIGURE 15.33 The space-vector representation in CSIs.

one sampling period T_s (made up of the currents provided by the vectors $\vec{i}_i$, $\vec{i}_{i+1}$, and $\vec{i}_z$ used during times T_i, T_{i+1}, and T_z) is on average equal to the vector $\vec{i}_c$, the following expressions should hold:

$$T_i = T_s \cdot \hat{i}_c \cdot \sin(\pi/3 - \theta) \tag{15.57}$$

$$T_{i+1} = T_s \cdot \hat{i}_c \cdot \sin(\theta) \tag{15.58}$$

$$T_z = T_s - T_i - T_{i+1} \tag{15.59}$$

where $0 \leq \hat{i}_c \leq 1$. Although, the SVM technique selects the vectors to be used and their respective on-times, the sequence in which they are used, the selection of the zero space vector, and the normalized sampled frequency remain undetermined.

B. Space-vector Sequences and Zero Space-vector Selection

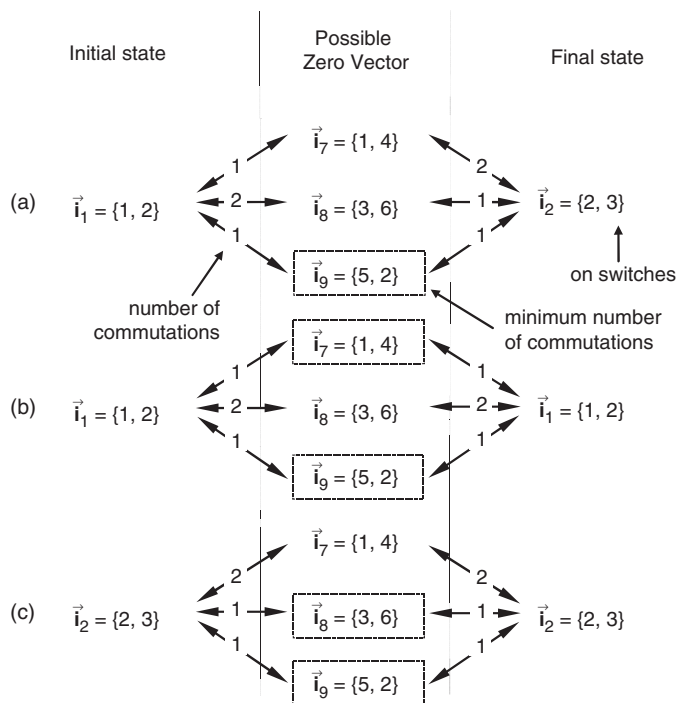
Although there is no systematic approach to generate a SV sequence, a graphical representation shows that the sequence $\vec{i}_i$, $\vec{i}_{i+1}$, $\vec{i}_z$ (where the chosen $\vec{i}_z$ depends upon the sector) provides high performance in terms of minimizing unwanted harmonics and reducing the switching frequency. To obtain the zero SV that minimizes the switching frequency, it is assumed that $\mathbf{I_c}$ is in Sector ②. Then Fig. 15.34 shows all


FIGURE 15.34 Possible state transitions in Sector ② involving a zero SV: (a) transition: $\vec{i}_1 \Leftrightarrow \vec{i}_z \Leftrightarrow \vec{i}_2$ or $\vec{i}_2 \Leftrightarrow \vec{i}_z \Leftrightarrow \vec{i}_1$; (b) transition: $\vec{i}_1 \Leftrightarrow \vec{i}_z \Leftrightarrow \vec{i}_1$; and (c) transition: $\vec{i}_2 \Leftrightarrow \vec{i}_z \Leftrightarrow \vec{i}_2$.

TABLE 15.6 Zero SV for minimum switching frequency in CSI and sequence $\vec{i}_i, \vec{i}_{i+1}, \vec{i}_z$

Sector	$\vec{i}_i$	$\vec{i}_{i+1}$	$\vec{i}_z$
①	$\vec{i}_6$	$\vec{i}_1$	$\vec{i}_7$
②	$\vec{i}_1$	$\vec{i}_2$	$\vec{i}_9$
③	$\vec{i}_2$	$\vec{i}_3$	$\vec{i}_8$
④	$\vec{i}_3$	$\vec{i}_4$	$\vec{i}_7$
⑤	$\vec{i}_4$	$\vec{i}_5$	$\vec{i}_9$
⑥	$\vec{i}_5$	$\vec{i}_6$	$\vec{i}_8$

the possible transitions that could be found in Sector ②. It can be seen that the zero vector $\vec{i}_9$ should be chosen to minimize the switching frequency. Table 15.6 gives a summary of the zero space vector to be used in each sector in order to minimize the switching frequency. However, should be noted that Table 15.6 is valid only for the sequence $\vec{i}_i$, $\vec{i}_{i+1}$, $\vec{i}_z$. Another sequence will require reformulating the zero space-vector selection algorithm.

C. The Normalized Sampling Frequency

As in VSIs modulated by a SV approach, the normalized sampling frequency f_{sn} should be an integer multiple of 6 to minimize uncharacteristic harmonics. As an example, Fig. 15.35 shows the relevant waveforms of a CSI SVM for $f_{sn} = 18$ and $\hat{i}_c = 0.8$. Figure 15.35 also shows that the first set of relevant harmonics load line current are at f_{sn}.

15.4.5 DC Link Voltage in Three-phase CSIs

An instantaneous power balance indicates that

$$v_i(t) \cdot i_i(t) = v_{an}(t) \cdot i_{oa}(t) + v_{bn}(t) \cdot i_{ob}(t) + v_{cn}(t) \cdot i_{oc}(t) \tag{15.60}$$

where $v_{an}(t)$, $v_{bn}(t)$, and $v_{cn}(t)$ are the phase filter voltages as shown in Fig. 15.36. If the filter is large enough and a relatively high switching frequency is used, the phase voltages become nearly sinusoidal balanced waveforms. On the other hand, if the ac output currents are considered sinusoidal and the dc link current is assumed constant $i_i(t) = I_i$, Eq. (15.60) can be simplified to

$$v_i(t) = \frac{1}{I_i} \left\{ \begin{array}{l} \sqrt{2}V_{on}\sin(\omega t)\cdot\sqrt{2}I_{o1}\sin(\omega t-\phi) \\ +\sqrt{2}V_{on}\sin(\omega t-120°)\cdot\sqrt{2}I_{o1}\sin(\omega t-120°-\phi) \\ +\sqrt{2}V_{on}\sin(\omega t-240°)\cdot\sqrt{2}I_{o1}\sin(\omega t-240°-\phi) \end{array} \right\} \tag{15.61}$$

where V_{on} is the rms ac output phase voltage, I_{o1} is the rms fundamental line current, and ϕ is an arbitrary filter-load angle. Hence, the dc link voltage expression can be further simplified to the following:

$$v_i(t) = 3\frac{I_{o1}}{I_i}V_{on}\cos(\phi) = \sqrt{3}\frac{I_{o1}}{I_i}V_o\cos(\phi) \tag{15.62}$$

where $V_o = \sqrt{3}V_{on}$ is the rms load line voltage. The resulting dc link voltage expression indicates that the first line-current harmonic I_{o1} generates a clean dc current. However, as the load line currents contain harmonics around the normalized sampling frequency f_{sn}, the dc link current will contain harmonics but around f_{sn} as shown in Fig. 15.35h. Similarly, in carrier-based PWM techniques, the dc link current will contain harmonics around the carrier frequency m_f (Fig. 15.27).

In practical implementations, a CSI requires a dc current source that should behave as a constant (as required by PWM CSIs) or variable (as square-wave CSIs) current source. Such current sources should be implemented as separate units and they are described earlier in this book.

15.5 Closed-loop Operation of Inverters

Inverters generate variable ac waveforms from a dc power supply to feed, for instance, ASDs. As the load conditions usually change, the ac waveforms should be adjusted to these new conditions. Also, as the dc power supplies are not ideal and the dc quantities are not fixed, the inverter should compensate for such variations. Such adjustments can be done automatically by means of a closed-loop approach. Inverters also provide an alternative to changing the load operating conditions (i.e. speed in an ASD).

There are two alternatives for closed-loop operation the feedback and the feedforward approaches. It is known that the feedback approach can compensate for both the perturbations (dc power variations) and the load variations (load torque changes). However, the feedforward strategy is more effective in mitigating perturbations as it prevents its negative effects at the load side. These cause-effect issues are analyzed in three-phase inverters in the following, although similar results are obtained for single-phase VSIs.

15.5.1 Feedforward Techniques in Voltage Source Inverters

The dc link bus voltage in VSIs is usually considered a constant voltage source v_i. Unfortunately, and due to the fact that most practical applications generate the dc bus voltage by means of a diode rectifier (Fig. 15.37), the dc bus voltage contains low-order harmonics such as the sixth, twelfth, ... (due to six-pulse
FIGURE 15.35 The three-phase CSI. Ideal waveforms for space-vector modulation ($\hat{i}_c = 0.8$, $f_{sn} = 18$): (a) modulating signals; (b) switch S_1 state; (c) switch S_3 state; (d) ac output current; (e) ac output current spectrum; (f) ac output voltage; (g) dc voltage; (h) dc voltage spectrum; (i) switch S_1 current; and (j) switch S_1 voltage.
FIGURE 15.36 Phase-voltage definition in a wye-connected filter.

diode rectifiers), and the second if the ac voltage supply features an unbalance, which is usually the case. Additionally, if the three-phase load is unbalanced, as in UPS applications, the dc input current in the inverter i_i also contains the second harmonic, which in turn contributes to the generation of a second voltage harmonic in the dc bus.

The basic principle of feedforward approaches is to sense the perturbation and then modify the input in order to compensate for its effect. In this case, the dc link voltage should be sensed and the modulating technique should accordingly be modified. The fundamental ab line voltage in a VSI SPWM
FIGURE 15.37 Three-phase VSI topology with a diode-based front-end rectifier.

can be written as

$$v_{ab1}(t) = \left\{ \frac{v_{ca1}(t)}{\hat{v}_\Delta} - \frac{v_{cb1}(t)}{\hat{v}_\Delta} \right\} \frac{\sqrt{3}}{2} v_i(t) \quad \hat{v}_\Delta > \hat{v}_{ca1}, \hat{v}_{cb1} \tag{15.63}$$

where $\hat{v}_\Delta$ is the carrier signal peak, $\hat{v}_{ca1}$ and $\hat{v}_{cb1}$ are the modulating signal peaks, and $v_{ca}(t)$ and $v_{ca}(t)$ are the modulating signals. If the dc bus voltage v_i varies around a nominal V_i value, then the fundamental line voltage varies proportionally; however, if the carrier signal peak $\hat{v}_\Delta$ is redefined as

$$\hat{v}_\Delta = \hat{v}_{\Delta m} \frac{v_i(t)}{V_i} \tag{15.64}$$

where $\hat{v}_{\Delta m}$ is the carrier signal peak (Fig. 15.38), then the resulting fundamental ab line voltage in a VSI SPWM is

$$v_{ab1}(t) = \left\{ \frac{v_{ca1}(t)}{\hat{v}_{\Delta m}} - \frac{v_{cb1}(t)}{\hat{v}_{\Delta m}} \right\} \frac{\sqrt{3}}{2} V_i \tag{15.65}$$

where, clearly, the result does not depend upon the variations of the dc bus voltage.

Figure 15.39 shows the waveforms generated by the SPWM under a severe dc bus voltage variation (a second harmonic has been added manually to a constant V_i). As a consequence, the ac line voltage generated by the VSI is distorted as it contains
FIGURE 15.39 The three-phase VSI. Waveforms for regular SPWM ($m_a = 0.8$, $m_f = 9$): (a) dc bus voltage; (b) carrier and modulating signals; (c) ac output voltage; and (d) ac output voltage spectrum.

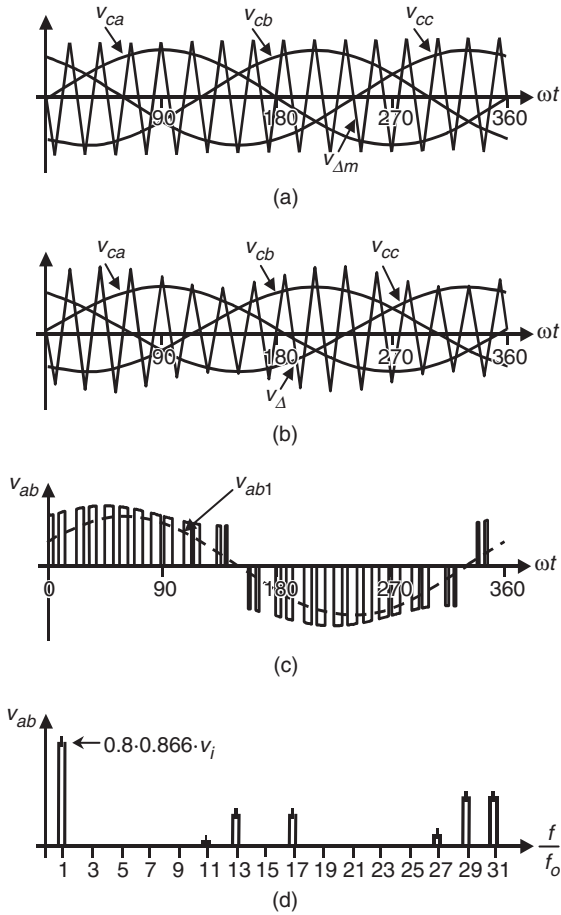
low-order harmonics (Fig. 15.39e). These operating conditions may not be acceptable in standard applications such as ASDs because the load will draw distorted three-phase currents as well. The feedforward loop performance is illustrated in Fig. 15.40. As expected, the carrier signal is modified so as to compensate for the dc bus voltage variation (Fig. 15.40b). This is probed by the spectrum of the ac line voltage that does not
FIGURE 15.38 The three-phase VSI. Feedforward control technique to reject dc bus voltage variations.


FIGURE 15.40 The three-phase VSI. Waveforms for SPWM including a feedforward loop ($m_a = 0.8$, $m_f = 9$): (a) carrier and modulating signals; (b) modified carrier and modulating signals; (c) ac output voltage; and (d) ac output voltage spectrum.

contain low-order harmonics (Fig. 15.40e). It should be noted that $\hat{v}_\Delta > \hat{v}_{ca1}, \hat{v}_{cb1}$; therefore, the compensation capabilities are limited by the required ac line voltage.

The performance of the feedforward approach depends upon the frequency of the harmonics present in the dc bus voltage and the carrier signal frequency. Fortunately, the relevant unwanted harmonics to be found in the dc bus voltage are the second, due to unbalanced supply voltages, and/or the sixth as the dc bus voltage is generated by means of a six-pulse diode rectifier. Therefore, a carrier signal featuring a 15-pu frequency is found to be sufficient to properly compensate for dc bus voltage variations.

Unbalanced loads generate a dc input current i_i that contains a second harmonic, which contributes to the dc bus voltage variation. The previous feedforward approach can compensate for such perturbation and maintain balanced ac load voltages.

Digital techniques can also be modified in order to compensate for dc bus voltage variations by means of a feedforward

approach. For instance, the SVM techniques indicate that the on-times of the vectors $\vec{v}_i$, $\vec{v}_{i+1}$, and $\vec{v}_z$ are

$$T_i = T_s \cdot \hat{v}_c \cdot \sin(\pi/3 - \theta) \qquad (15.66)$$

$$T_{i+1} = T_s \cdot \hat{v}_c \cdot \sin(\theta) \qquad (15.67)$$

$$T_z = T_s - T_i - T_{i+1} \qquad (15.68)$$

respectively, where $\hat{v}_c$ is the amplitude of the desired ac line voltage, as shown in Fig. 15.18. By redefining this quantity to

$$0 \leq \hat{v}_c = \hat{v}_{cm} \frac{V_i}{v_i(t)} \leq 1 \qquad (15.69)$$

where V_i is the nominal dc bus voltage and $v_i(t)$ is the actual dc bus voltage. Thus, the on-times become

$$T_i = T_s \cdot \hat{v}_{cm} \frac{V_i}{v_i(t)} \cdot \sin(\pi/3 - \theta) \qquad (15.70)$$

$$T_{i+1} = T_s \cdot \hat{v}_{cm} \frac{V_i}{v_i(t)} \cdot \sin(\theta) \qquad (15.71)$$

$$T_z = T_s - T_i - T_{i+1} \qquad (15.72)$$

where $\hat{v}_{cm}$ is the desired maximum ac line voltage. The previous expressions account for dc bus voltage variations and behave as a feedforward loop as it needs to sense the perturbation in order to be implemented. The previous expressions are valid for the linear region, thus $\hat{v}_c$ is restricted to $0 \leq \hat{v}_c \leq 1$, which indicates that the compensation is indeed limited.

15.5.2 Feedforward Techniques in Current Source Inverters

The duality principle between the voltage and the current source inverters indicates that, as described previously, the feedforward approach can be used for CSIs as well as for VSIs. Therefore, low-order harmonics present in the dc bus current can be compensated for before they appear at the load side. This can be done for both analog-based (e.g. carrier-based) and digital-based (e.g. space-vector) modulating techniques.

15.5.3 Feedback Techniques in Voltage Source Inverters

Unlike the feedforward approach, the feedback techniques correct the input to the system (gating signals) depending upon the deviation of the output to the system (e.g. ac load line currents in VSIs). Another important difference is that feedback techniques need to sense the controlled variables. In general, the controlled variables (output to the system) are chosen according to the control objectives. For instance, in ASDs, it is usually necessary to keep the motor line currents equal to

a given set of sinusoidal references. Therefore, the controlled variables become the ac line currents. There are several alternatives to implement feedback techniques in VSIs, and three of them are discussed in the following.

A. Hysteresis Current Control

The main purpose here is to force the ac line current to follow a given reference. The status of the power valves S_1 and S_4 are changed whenever the actual i_{oa} current goes beyond a given reference $i_{oa,ref} \pm \Delta i/2$. Figure 15.41 shows the hysteresis current controller for phase a. Identical controllers are used in phase b and c. The implementation of this controller is simple as it requires an operational amplifier (op-amp) operating in the hysteresis mode, thus the controller and modulator are combined in one unit.

Unfortunately, there are several drawbacks associated with the technique itself. First, the switching frequency cannot be predicted as in carrier-based modulators and therefore the harmonic content of the ac line voltages and currents becomes random (Fig. 15.42d). This could be a disadvantage when designing the filtering components. Second, as three-phase loads do not have the neutral connected as in ASDs, the load currents add up to zero. This means that only two ac line currents can be controlled independently at any given instant. Therefore, one of the hysteresis controllers is redundant at a

given time. This explains why the load current goes beyond the limits and introduces limit cycles (Fig. 15.42a). Finally, although the ac load currents add up to zero, the controllers cannot ensure that all load line currents feature a zero dc component in one load cycle.

B. Linear Control of VSIs

Proportional and proportional-integrative controllers can also be used in VSIs. The main purpose is to generate the modulating signals v_{ca}, v_{cb}, and v_{cc} in a closed-loop fashion as depicted in Fig. 15.43. The modulating signals can be used by a carrier-based technique such as the SPWM (as depicted in Fig. 15.43) or by space vector modulation. Because the load line currents add up to zero, the load line current references must add up to zero. Thus, the abc/αβγ transformation can be used to reduce to two controllers the overall implementation scheme as the γ component is always zero. This avoids limit cycles in the ac load currents.

The transformation of a set of variables in the stationary abc frame $\mathbf{x}^{abc}$ into a set of variables in the stationary αβ frame $\mathbf{x}^{\alpha\beta}$ is given by

$$\mathbf{x}^{\alpha\beta} = \frac{2}{3}\begin{bmatrix} 1 & -1/2 & -1/2 \\ 0 & \sqrt{3}/2 & -\sqrt{3}/2 \end{bmatrix}\mathbf{x}^{abc} \qquad (15.73)$$

The selection of the controller (P, PI,...) is done according to the control procedures such as steady-state error, settling time, overshoot, and so forth. Figure 15.44 shows the relevant waveforms of a VSI SPWM controlled by means of a PI controller as shown in Fig. 15.43.

Although it is difficult to prove that no limit cycles are generated, the ac line current appears very much sinusoidal. Moreover, the ac line voltage generated by the VSI preserves the characteristics of such waveforms generated by SPWM modulators. This is confirmed by the harmonic spectrum
FIGURE 15.41 The three-phase VSI. Hysteresis current control (phase a).
FIGURE 15.42 The three-phase VSI. Ideal waveforms for hysteresis current control: (a) actual ac load current and reference; (b) switch S_1 state; (c) ac output voltage; and (d) ac output voltage spectrum.
FIGURE 15.43   The three-phase VSI. Feedback control based on linear controllers.
FIGURE 15.44   The three-phase VSI. Ideal waveforms for a PI controller in a feedback loop ($m_a = 0.8$, $m_f = 15$): (a) actual ac load current and reference; (b) carrier and modulating signals; (c) ac output voltage; and (d) ac output voltage spectrum.

shown in Fig. 15.44d, where the first set of characteristic harmonics are around the normalized carrier frequency $m_f = 15$.

However, an error between the actual i_{oa} and the ac line current reference $i_{oa,ref}$ can be observed (Fig. 15.44a). This error is inherent to linear controllers and cannot be totally eliminated, but it can be minimized by increasing the gain of the controller. However, the noise in the circuit is also increased, which could deteriorate the overall performance of the control scheme. The inherent presence of the error in this type of controllers is due to the fact that the controller needs a sinusoidal error to generate sinusoidal modulating signals v_{ca}, v_{cb}, and v_{cc}, as required by the modulator. Therefore, an error must exist between the actual and the ac line current references.

Nevertheless, as current-controlled VSIs are actually the inner loops in many control strategies, their inherent errors are compensated by the outer loop. This is the case of ASDs, where the outer speed loop compensates the inner current loops. In general, if the outer loop is implemented with dc quantities (such as speed), it can compensate the ac inner loops (such as ac line currents). If it is mandatory that a zero steady-state error be achieved with the ac quantities, then a stationary

(abc frame) to rotating (dq frame) transformation is a valid alternative to use.

C. Linear Control of VSIs in a Rotating Frame

The rotating dq transformation allows ac three-phase circuits to be operated as if they were dc circuits. This is based upon a mathematical operation, that is the transformation of a set of variables in the stationary abc frame $\mathbf{x}^{abc}$ into a set of variables in the rotating dq0 frame $\mathbf{x}^{dq0}$. The transformation is given by

$$\mathbf{x}^{dq} = \frac{2}{3} \begin{bmatrix} \sin(\omega t) & \sin(\omega t - 2\pi/3) & \sin(\omega t - 4\pi/3) \\ \cos(\omega t) & \cos(\omega t - 2\pi/3) & \cos(\omega t - 4\pi/3) \\ 1/\sqrt{2} & 1/\sqrt{2} & 1/\sqrt{2} \end{bmatrix} \mathbf{x}^{abc}$$

$$(15.74)$$

where ω is the angular frequency of the ac quantities. For instance, the current vector given by

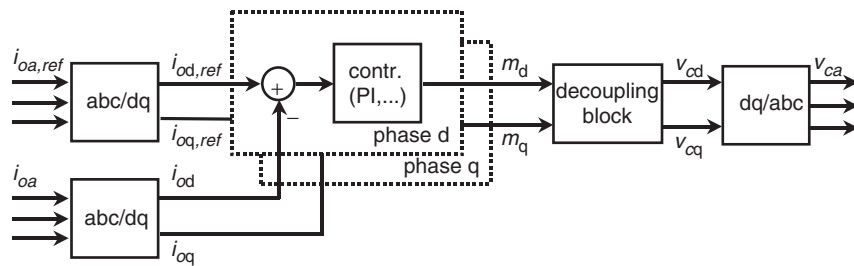
$$\mathbf{i}^{abc} = \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} = \begin{bmatrix} I\sin(\omega t - \varphi) \\ I\sin(\omega t - 2\pi/3 - \varphi) \\ I\sin(\omega t - 4\pi/3 - \varphi) \end{bmatrix} \qquad (15.75)$$


FIGURE 15.45 The three-phase VSI. Feedback control based on dq0 transformation.

becomes the vector

$$\mathbf{i}^{dq0} = \begin{bmatrix} i_d \\ i_q \\ i_0 \end{bmatrix} = \begin{bmatrix} I\cos(\varphi) \\ -I\sin(\varphi) \\ 0 \end{bmatrix} \quad (15.76)$$

where I and φ are the amplitude and phase of the line currents, respectively. It can be observed that: (a) the zero component i_0 is always zero as the three-phase quantities add up to zero; and (b) the d and q components i_d, i_q are dc quantities. Thus, linear controllers should help to achieve zero steady-state error. The control strategy shown in Fig. 15.45 is an alternative where the zero-component controller has been eliminated due to fact that the line currents at the load side add up to zero.

The controllers in Fig. 15.45 include an integrator that generates the appropriate dc outputs m_d and m_q even if the actual and the line current references are identical. This ensures that the zero steady-state error is achieved. The decoupling block in Fig. 15.45 is used to eliminate the cross-coupling effect generated by the dq0 transformation and to allow an easier design of the parameters of the controllers.

The dq0 transformation requires the intensive use of multiplications and trigonometric functions. These operations can readily be done by means of digital microprocessors. Also, analog implementations would indeed be involved.

15.5.4 Feedback Techniques in Current Source Inverters

Duality indicates that CSIs should be controlled as equally as VSIs except that the voltages become currents and the currents become voltages. Thus, hystersis, linear and dq linear-based control strategies are also applicable to CSIs; however, the controlled variables are the load voltages instead of the load line currents.

For instance, the linear control of a CSI based on a dq transformation is depicted in Fig. 15.46. In this case, a passive balanced load is considered. In order to show that zero steady-state error is achieved, the per phase equations of the converter

are written as

$$C\frac{d}{dt}\mathbf{v}_\mathbf{p}^{abc} = \mathbf{i}_\mathbf{o}^{abc} - \mathbf{i}_\mathbf{l}^{abc} \quad (15.77)$$

$$L\frac{d}{dt}\mathbf{i}_\mathbf{l}^{abc} = \mathbf{v}_\mathbf{p}^{abc} - R\mathbf{i}_\mathbf{l}^{abc} \quad (15.78)$$

the ac line currents are in fact imposed by the modulator and they satisfy

$$\mathbf{i}_\mathbf{o}^{abc} = i_i\mathbf{i}_\mathbf{c}^{abc} \quad (15.79)$$

Replacing Eq. (15.79) into the model of the converter Eqs. (15.77) and (15.78), using the dq0 transformation and assuming null zero component, the model of the converter becomes

$$\frac{d}{dt}\mathbf{v}_\mathbf{p}^{dq} = -\mathbf{W}\mathbf{v}_\mathbf{p}^{dq} + \frac{i_i}{C}\mathbf{i}_\mathbf{c}^{dq} - \frac{1}{C}\mathbf{i}_\mathbf{l}^{dq} \quad (15.80)$$

$$\frac{d}{dt}\mathbf{i}_\mathbf{l}^{dq} = -\mathbf{W}\mathbf{i}_\mathbf{l}^{dq} + \frac{1}{L}\mathbf{v}_\mathbf{p}^{dq} - \frac{R}{L}\mathbf{i}_\mathbf{l}^{dq} \quad (15.81)$$

where $\mathbf{W}$ is given by

$$\mathbf{W} = \begin{bmatrix} 0 & -\omega \\ \omega & 0 \end{bmatrix} \quad (15.82)$$

A first approximation is to assume that the decoupling block is not there; in other words, $\mathbf{i}_\mathbf{c}^{dq} = \mathbf{m}^{dq}$. On the other hand, the model of the controllers can be written as

$$\mathbf{m}^{dq} = k\left\{\mathbf{v}_{\mathbf{p},\mathbf{ref}}^{dq} - \mathbf{v}_\mathbf{p}^{dq}\right\} + \frac{1}{T}\int\limits_{-\infty}^{t}\left(\mathbf{v}_{\mathbf{p},\mathbf{ref}}^{dq} - \mathbf{v}_\mathbf{p}^{dq}\right)dt \quad (15.83)$$

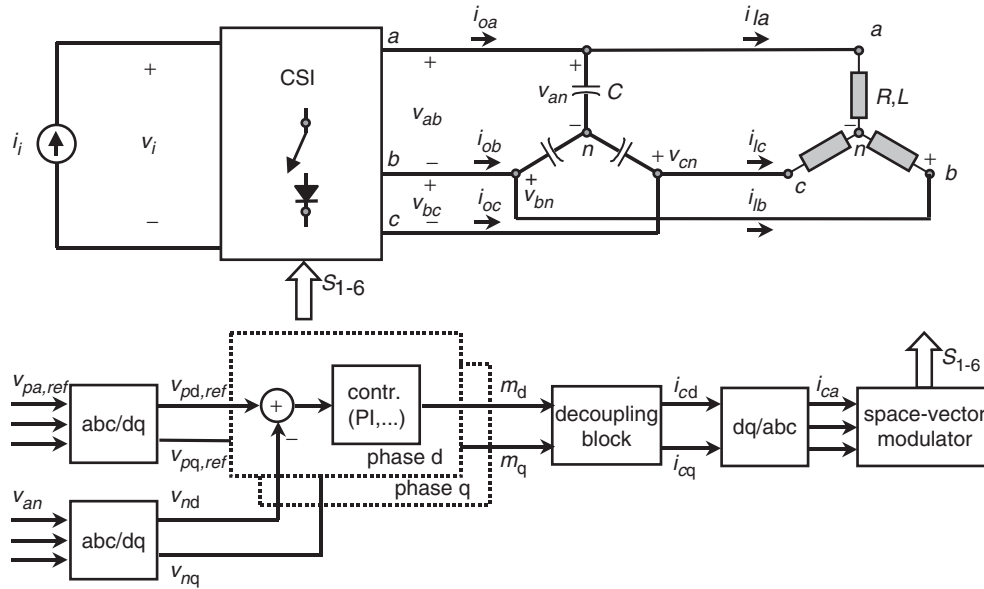
where k and T are the proportional and integrative gains of the PI controller that are chosen to achieve a desired dynamic response. Combining the model of the controllers and the model of the converter in dq coordinates and using


FIGURE 15.46   The three-phase CSI. Feedback control based on dq0 transformation.

the Laplace transform, the following relationship between the reference and actual load-phase voltages is found:

$$\mathbf{v}_\mathbf{p}^{dq} = \frac{i_i}{C} \left\{ sk + \frac{1}{T} \right\} \left\{ s\mathbf{I} + \mathbf{W} + \frac{R}{L}\mathbf{I} \right\} \times$$

$$\left[\left\{ s\mathbf{I} + \mathbf{W} + \frac{R}{L}\mathbf{I} \right\} \left\{ s^2\mathbf{I} + s\left(\mathbf{W} + \frac{i_i}{C}k\mathbf{I} \right) + \frac{i_i}{CT}\mathbf{I} \right\} \right.$$

$$\left. + \frac{s}{LC}\mathbf{I} \right]^{-1} \mathbf{v}_{\mathbf{p,ref}}^{dq} \qquad (15.84)$$

Finally, in order to prove that the zero steady-state error is achieved for step inputs in either the d or q component of the load-phase voltage reference, the previous expression is evaluated in $s = 0$. This results in the following:

$$\mathbf{v}_\mathbf{p}^{dq} = \frac{i_i}{C} \left\{ \frac{1}{T} \right\} \left\{ \mathbf{W} + \frac{R}{L}\mathbf{I} \right\} \left[\left\{ W + \frac{R}{L}\mathbf{I} \right\} \left\{ \frac{i_i}{CT}\mathbf{I} \right\} \right]^{-1} \mathbf{v}_{\mathbf{p,ref}}^{dq}$$

$$= \mathbf{v}_{\mathbf{p,ref}}^{dq} \qquad (15.85)$$

As expected, the actual and reference values are identical. Finally, the relationship in Eq. (15.84) is a matrix that is not diagonal. This means that both the actual and the reference load-phase voltages are coupled. In order to obtain a decoupled control, the decoupling block in Fig. 15.46 should be properly chosen.

15.6 Regeneration in Inverters

Industrial applications are usually characterized by a power flow that goes from the ac distribution system to the load. This is, for example, the case of an ASD operating in the motoring mode. In this instance, the active power flows from the dc side to the ac side of the inverter. However, there are an important number of applications in which the load may supply power to the system. Moreover, this could be an occasional condition as well as a normal operating condition. This is known as the regenerative operating mode. For example, when an ASD reduces the speed of an electrical machine this can be considered a transient condition. Downhill belt conveyors in mining applications can be considered as a normal operating condition. In order to simplify the notation, it could be said that an inverter operates in the motoring mode when the power flows from the dc to the ac side, and in the regenerative mode when the power flows from the ac to the dc side.

15.6.1 Motoring Operating Mode in Three-phase VSIs

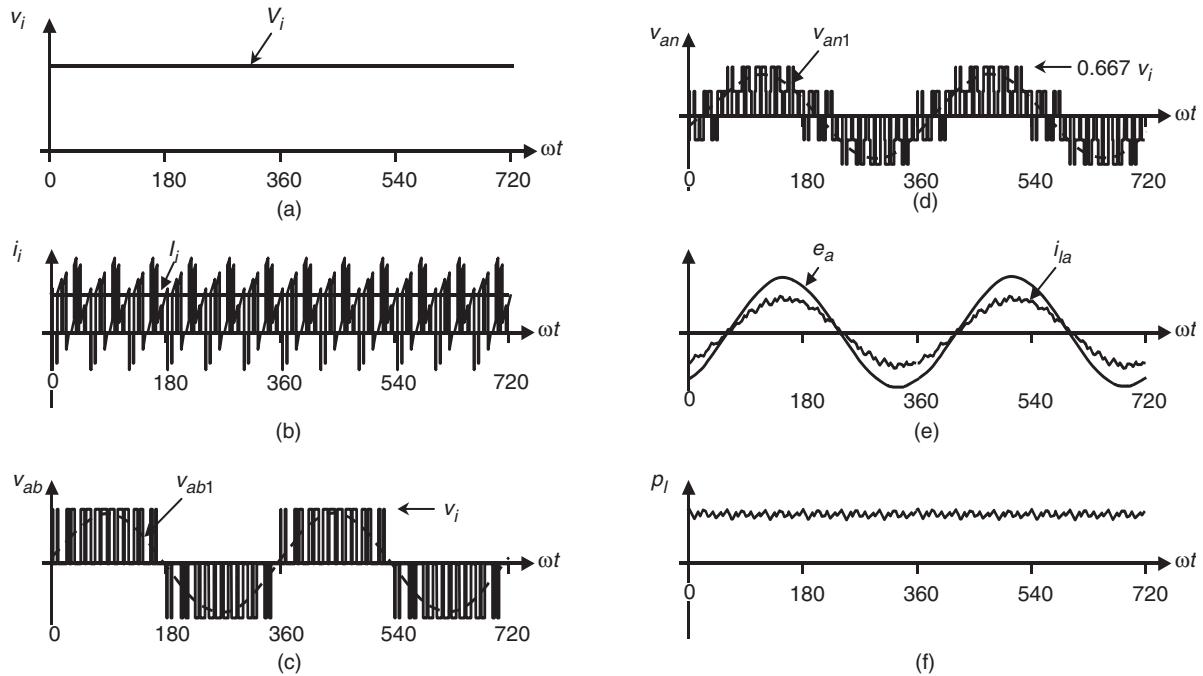
This is the case where the power flows from the dc side to the ac side of the inverter. Figure 15.47 shows a simplified scheme of an ASD where the motor has been modeled by three *RLe* branches, where the sources $\mathbf{e}^{abc}$ are the back-emf. Because the ac line voltages applied by the inverter are imposed by the pulsewidth modulation technique being used, they can be adjusted according to specific requirements. In particular, Fig. 15.48 shows the relevant waveforms in steady state for the
FIGURE 15.47   Three-phase VSI topology with a diode-based front-end rectifier.


FIGURE 15.48   The ASD based on a VSI. Motoring mode: (a) dc bus voltage; (b) dc bus current; (c) ac line-load voltage; (d) ac phase-load voltage; (e) motor line current and back-emf; and (f) shaft power.

motoring operating mode of the ASD. To simplify the analysis, a constant dc bus voltage $v_i = V_i$ has been considered.

It can be observed that: (i) the dc bus current i_i features a dc value I_i that is positive; and (ii) the motor line current is in phase with the back-emf. Both features confirm that the active power flows from the dc source to the motor. This is also confirmed by the shaft power plot (Fig. 15.48f), which is obtained as:

$$p_l(t) = e_a(t)i_{la}(t) + e_b(t)i_{lb}(t) + e_c(t)i_{lc}(t) \qquad (15.86)$$

15.6.2   Regenerative Operating Mode in Three-phase VSIs

The back-emf sources $\mathbf{e}^{abc}$ are functions of the machine speed and as such they ideally change just as the speed changes.

The regeneration operating mode can be achieved by properly modifying the ac line voltages applied to the machine. This is done by the speed outer loop that could be based on a scalar (e.g. V/f) or vectorial (e.g. field-oriented) control strategy. As indicated earlier, there are two cases of regenerative operating modes.

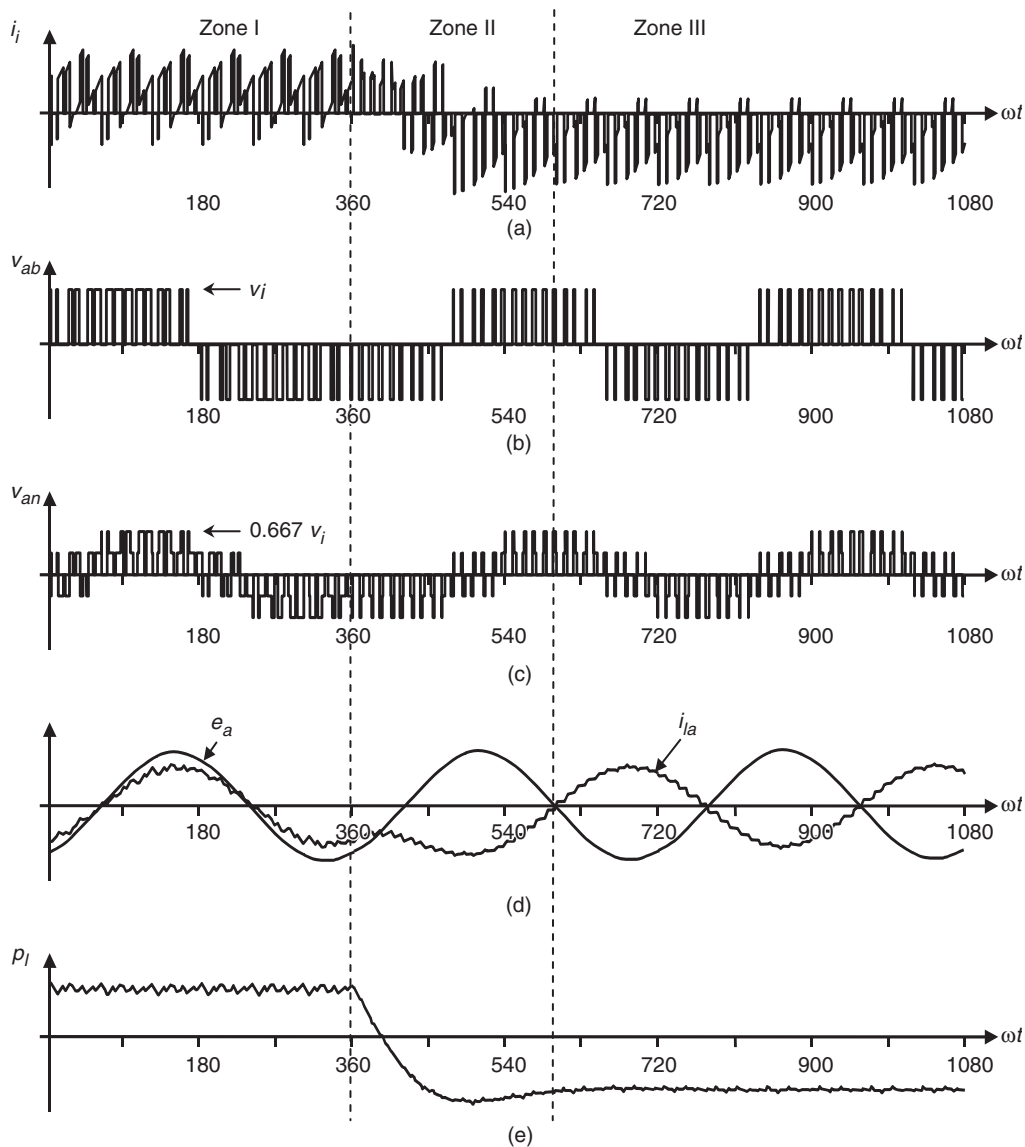
A. Occasional Regenerative Operating Mode
This mode is required during transient conditions such as in occasional braking of electrical machines (ASDs). Specifically, the speed needs to be reduced and the kinetic energy is taken into the dc bus. Because the motor line voltage is imposed by the VSI, the speed reduction should be done in such a way that the motor line currents do not exceed the maximum values. This boundary condition will limit the ramp-down speed to a minimum, but shorter braking times will require a mechanical braking system.


FIGURE 15.49   The ASD based on a VSI. Motoring to regenerative operating mode transition: (a) dc bus current; (b) ac line motor voltage; (c) ac phase motor voltage; (d) motor line current and back-emf; and (e) shaft power.

Figure 15.49 shows a transition from the motoring to regenerative operating mode for an ASD as shown in Fig. 15.47. Here, a stiff dc bus voltage has been used. Zone I in Fig. 15.49 is the motoring mode, Zone II is a transition condition, and Zone III is the regeneration mode. The line voltage is adjusted dynamically to obtain nominal motor line currents during regeneration (Fig. 15.49d). Zone III clearly shows that the shaft power gets reversed.

Occasional regeneration means that the drive rarely goes into this operating mode. Therefore, such energy can be: (a) left uncontrolled or (b) burned in resistors that are paralleled to the dc bus. The first option is used in low- to medium-power applications that use diode-based front-end rectifiers. Therefore, the dc bus current flows into the dc bus capacitor and the dc bus voltage rises accordingly to

$$\Delta v_i = \frac{1}{C} I_i \Delta t \qquad (15.87)$$

where Δv_i is the dc bus voltage variation, C is the dc bus voltage capacitor, I_i is the average dc bus current during regeneration, and Δt is the duration of the regeneration operating mode. Usually, the drives have the capacitor C designed to allow a 10% overvoltage in the dc bus.

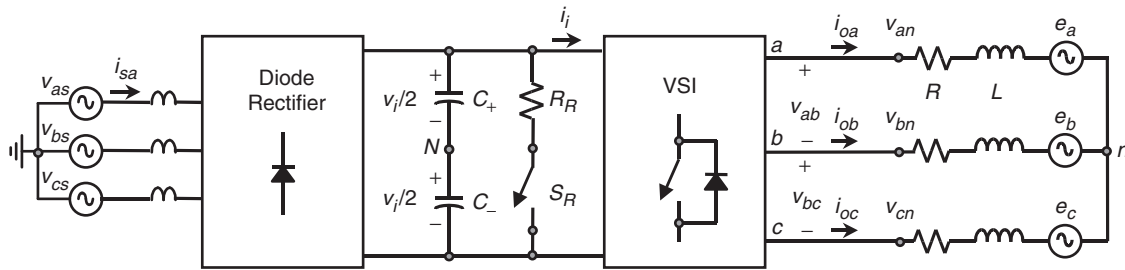
The second option uses burning resistors R_R that are paralleled in the dc bus as shown in Fig. 15.50 by means of the


FIGURE 15.50   The ASD based on a VSI. Burning resistor strategy.

switch S_R. A closed-loop strategy based on the actual dc bus voltage modifies the duty cycle of the turn-on/turn-off of the switch S_R in order to keep such voltage under a given reference. This alternative is used when the energy recovered by the VSI would result in an acceptable dc bus voltage variation if an uncontrolled alternative is used.

There are some special cases where the regeneration operating mode is frequently used. For instance, electrical shovels in mining companies have repetitive working cycles and ≈15% of the energy is sent back into the dc bus. In this case, a valid alternative is to send back the energy into the ac distribution system.

The schematic shown in Fig. 15.51 is capable of taking the kinetic energy and sending it into the ac grid. As reviewed earlier, the regeneration operating mode reverses the polarity of the dc current i_i, and because the diode-based front-end converter cannot take negative currents, a thyristor-based front-end converter is added. Similarly to the burning-resistor approach, a closed-loop strategy based on the actual dc bus voltage v_i modifies the commutation angle α of the thyristor rectifier in order to keep such voltage under a given reference.

B. Regenerative Operating Mode as Normal operating Mode
Fewer industrial applications are capable of returning energy into the ac distribution system on a continuous basis. For instance, mining companies usually transport their product downhill for a few kilometers before processing it. In such cases, the drive maintains the transportation belt conveyor at constant speed and takes the kinetic energy. Due to the large amount of energy and the continuous operating mode, the drive should be capable of taking the kinetic energy, transforming it into electrical energy, and sending it into the ac distribution system. This would make the drive a generator that would compensate for the active power required by other loads connected to the electrical grid.

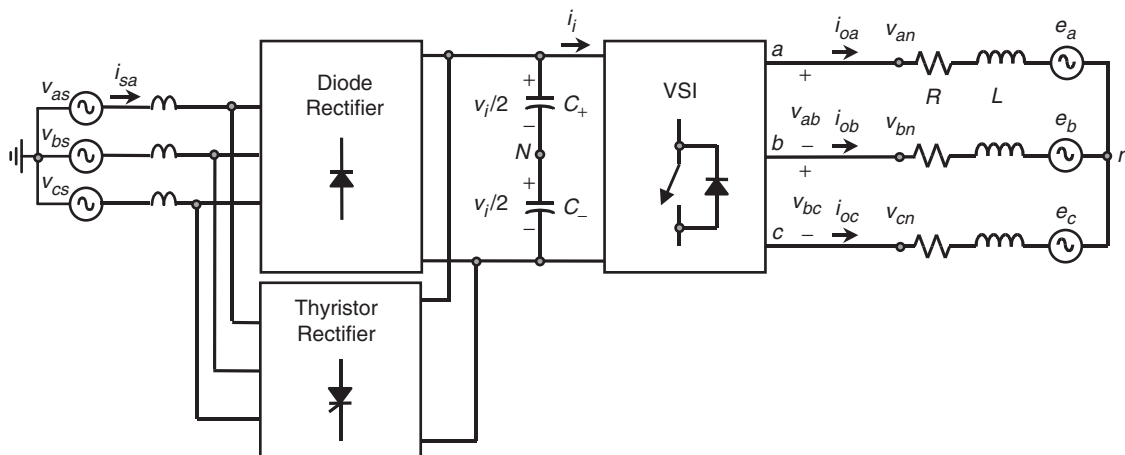
The schematic shown in Fig. 15.52 is a modern alternative for adding regeneration capabilities to the VSI-based drive on a continuous basis. In contrast to the previous alternatives, this scheme uses a VSI topology as an active front-end converter, which is generally called voltage-source rectifier (VSR). The VSR operates in two quadrants, that is, positive dc voltages and positive/negative dc currents as reviewed earlier. This feature makes it a perfect match for ASDs based on a VSI. Some of the advantages of using a VSR topology are: (i) the ac supply


FIGURE 15.51   The ASD based on a VSI. Diode-thyristor-based front-end rectifier with regeneration capabilities.
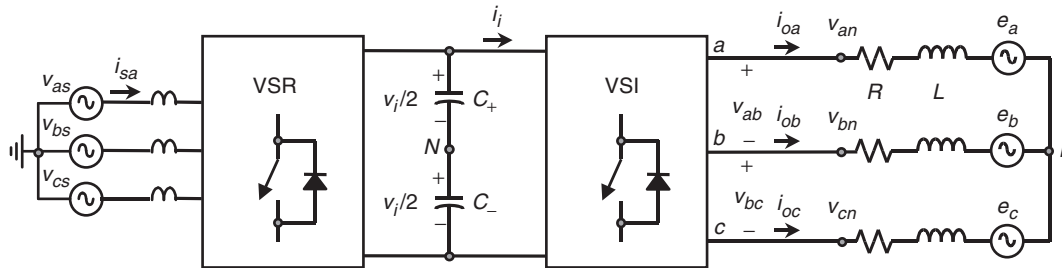

FIGURE 15.52 The ASD based on a VSI. Active front-end rectifier with regeneration capabilities.

current can be as sinusoidal as required (by increasing the switching frequency of the VSR or the ac line inductance); (ii) the operation can be done at a unity displacement power factor in both motoring and regenerative operating modes; and (iii) the control of the VSR is done in both motoring and regenerative operating modes by a single dc bus voltage loop.

15.6.3 Regenerative Operating Mode in Three-phase CSIs

There are drives where the motor side converter is a CSI. This is usually the case where near sinusoidal motor voltages are needed instead of the PWM type of waveform generated by VSIs. This is normally the case for medium-voltage applications. Such inverters require a dc current source that is constructed by means of a controlled rectifier.

Figure 15.53 shows a CSI-based ASD where the dc current source is generated by means of a thyristor-based rectifier in combination with a dc link inductor L_{dc}. In order to maintain a constant dc link current $i_i = I_i$, the thyristor-based rectifier adjusts the commutation angle α by means of a closed-loop control strategy. Assuming a constant dc link current, the regenerating operating mode is achieved when the dc link voltage v_i reverses its polarity. This can be done by modifying the PWM pattern applied to the CSI as in the VSI-based drive. To maintain the dc link current constant, the thyristor-based rectifier also reverses its dc link voltage v_r. Fortunately, the thyristor rectifier operates in two quadrant, that is, positive dc link currents and positive/ negative dc link voltages.

Thus, no additional equipment is required to include regeneration capabilities in CSI-based drives.

Similarly, an active front-end rectifier could be used to improve the overall performance of the thyristor-based rectifier. A PWM current-source rectifier (CSR) could replace the thyristor-based rectifier with the following added advantages: (i) the ac supply current can be as sinusoidal as required (e.g. by increasing the switching frequency of the CSR); (ii) the operation can be done at a unity displacement power factor in both motoring and regenerative operating modes; and (iii) the control of the CSR is done in both motoring and regenerative operating modes by a single dc bus current loop.

15.7 Multistage Inverters

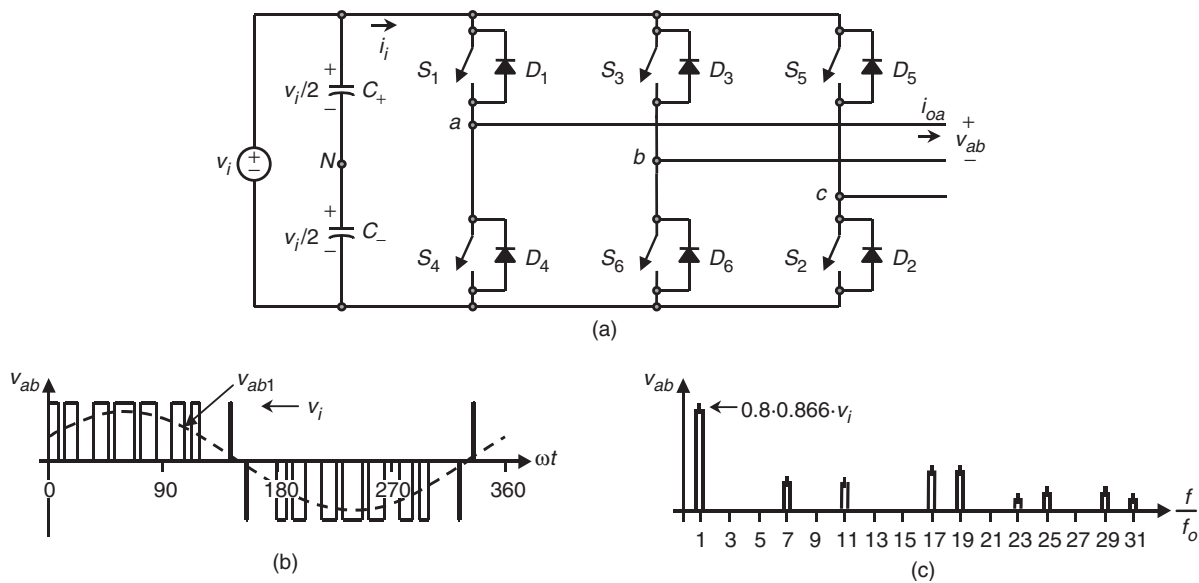
The most popular three-phase voltage source inverter (VSI) consists of a six-switch topology (Fig. 15.54a). The topology can generate a three-phase set of ac line voltages such that each line voltage v_{ab} (Fig. 15.54b) features a fundamental ac line voltage v_{ab1} and unwanted harmonics Fig. 15.54c. The fundamental ac line voltage is usually required as a sinusoidal waveform at variable amplitude and frequency, and the unwanted harmonics are located at high frequencies. These requirements are met by means of a modulating technique as shown earlier. Among the applications in low-voltage ranges of six-switch VSIs are the adjustable speed drives (ASDs). The range is in low voltages due to: (a) the high dv/dt present in the PWM ac line voltages (Fig. 15.54b), which will be unacceptable
FIGURE 15.53 The ASD based on a CSI. Thyristor-based rectifier.


FIGURE 15.54 Six-switch voltage source inverter ($m_f = 9$, $m_a = 0.8$): (a) power topology; (b) ac output voltage; and (c) ac output voltage spectrum.

in the medium- to high-voltage ranges and (b) the load power would be shared only among six switches. This may require paralleling and series-connected power valves, an option usually avoided as symmetrical sharing of the power is not natural in these arrangements.

Two solutions are available to generate near-sinusoidal voltage waveforms while using six-switch topologies. The first is a topology based on a CSI in combination with a capacitive filter. The second solution is a topology based on a VSI including an inductive or inductive/capacitive filter at the load terminals. Although both alternatives generate near-sinusoidal voltage waveforms, both continue sharing the load power only among six power valves.

Solutions based on multistage voltage source topologies have been proposed. They provide medium voltages at the ac terminals while keeping low dv/dts and a large number of power valves that symmetrically share the total load power. The multistage VSIs can be classified in multicell and multilevel topologies.

15.7.1 Multicell Topologies

The goal is to develop a new structure with improved performance based on standard structures that are known as cells. For instance, Fig. 15.55a shows a cell featuring a three-phase input and a single-phase output. The front-end converter is a six-diode-based rectifier, and a single-phase VSI generates a single-phase ac voltage v_o. Figure 15.55b and c shows characteristic waveforms where a sinusoidal unipolar PWM ($m_f = 6$, $m_a = 0.8$) has been used to modulate the inverter.

Standard cells are meant to be used at low voltages, thus they can use standard components that are less expensive

and widely available. The new structure should generate near-sinusoidal ac load voltages, draw near-sinusoidal ac line currents, and more importantly the load voltages should feature moderate dv/dts.

Figure 15.56 shows a multicell converter that generates a three-phase output voltage out of a three-phase ac distribution system. The structure uses three standard cells (as shown in Fig. 15.55) connected in series to form one phase; thus the phase-load voltages are the sum of the single-phase voltages generated by each cell. For instance, the phase voltage a is given by

$$v_{an} = v_{o11} + v_{o21} + v_{o31} \qquad (15.88)$$

In order to maximize the load-phase voltages, the ac voltages generated by the cells should feature identical fundamental components. On the other hand, each cell generates a PWM voltage waveform at the ac side, which contains unwanted voltage harmonics. If a carrier-based modulating technique is used, the harmonics generated by each cell are at well-defined frequencies (Fig. 15.55c). Some of these harmonics are not present in the phase-load voltage if the carrier signals of each cell are properly phase shifted.

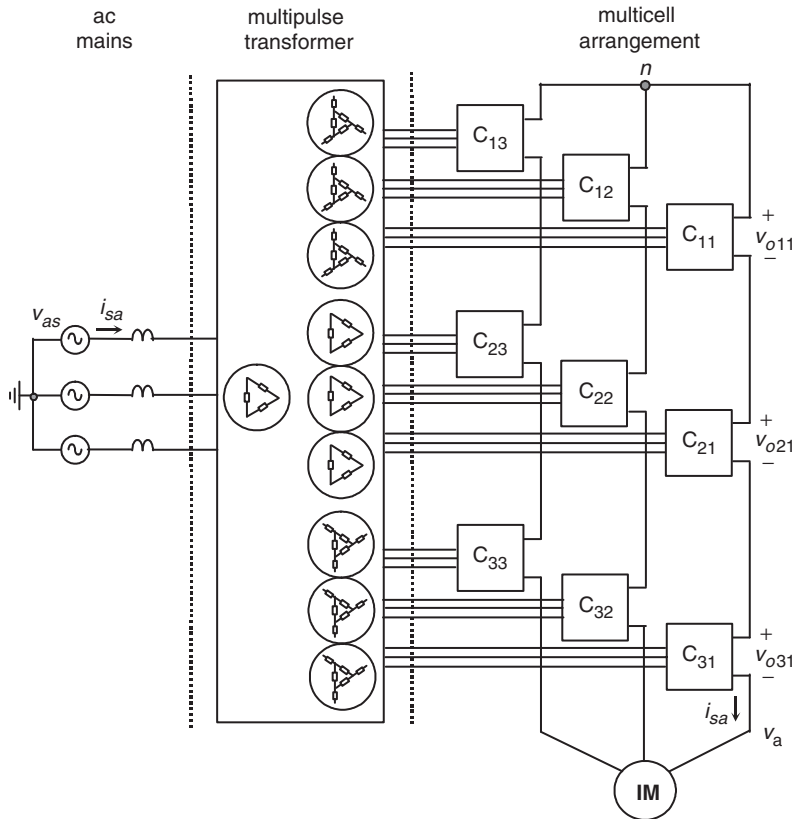
In fact, Fig. 15.57 shows the voltages generated by cells c_{11}, c_{21}, and c_{31}, which are v_{o11}, v_{o21}, and v_{o31}, respectively, and form the load-phase voltage a. They are generated using the unipolar SPWM approach, that is, one modulating signal v_{ca} and three carrier signals $v_{\Delta1}$, $v_{\Delta2}$, and $v_{\Delta3}$ that are used by cells c_{11}, c_{21}, and c_{31}, respectively (Fig. 15.57a). The carrier signals have a normalized frequency m_f, which ensures an m_f switching frequency in each power valve and the lowest unwanted set of harmonics $\approx 2 \cdot m_f$ (m_f even) in the ac cell
FIGURE 15.55   Three-phase-input single-phase output cell: (a) power topology; (b) ac input current, phase a; and (c) ac output voltage ($m_f = 6$, $m_a = 0.8$).


FIGURE 15.56   Multistage converter based on a multicell arrangement.
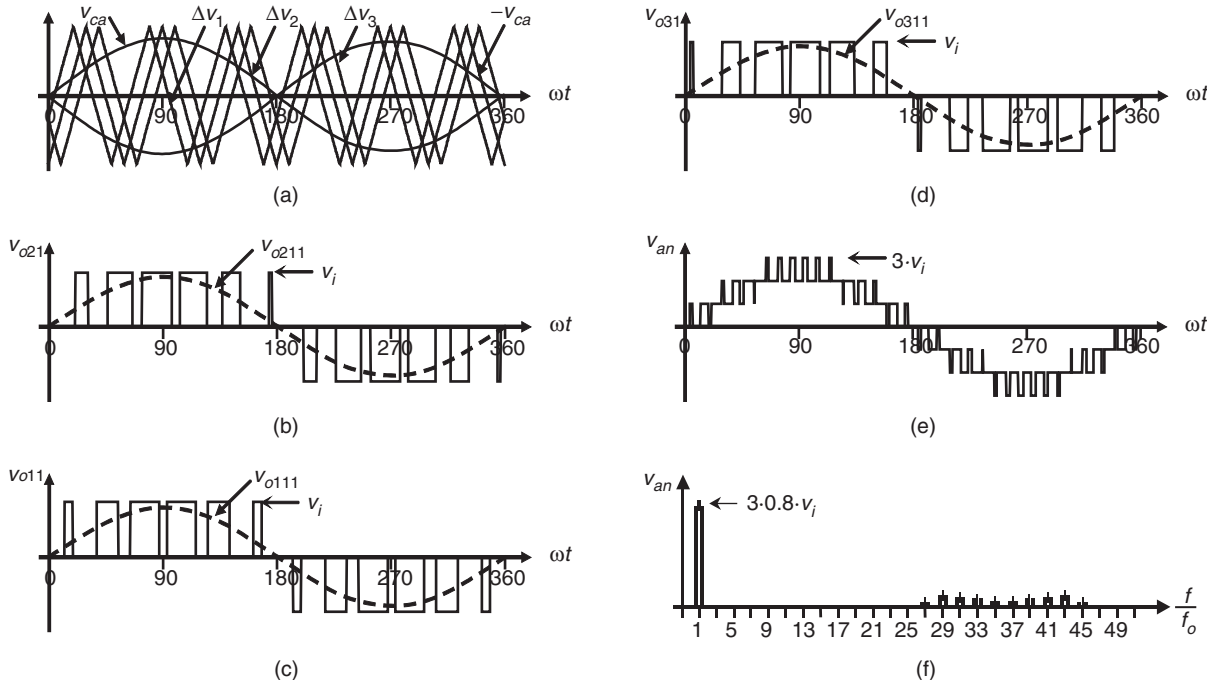

FIGURE 15.57   Multicell topology. Cell voltages in phase *a* using a unipolar SPWM ($m_f = 6$, $m_a = 0.8$): (a) modulating and carrier signals; (b) cell c_{11} ac output voltage; (c) cell c_{21} ac output voltage; (d) cell c_{31} ac output voltage; (e) phase *a* load voltage; and (f) phase *a* load-voltage spectrum.

voltages v_{o11}, v_{o21}, and v_{o31}. More importantly, the carrier signals are $\psi = 60°$ out-of-phase, which ensures the lowest unwanted set of voltage harmonics $\approx 6 \cdot m_f$ in the load-phase voltage v_{an}, that is, the lowest set of harmonics in Fig. 15.57f is $6 \cdot m_f = 6 \cdot 6 = 36$.

This can be explained as follows. The voltage harmonics present in the PWM voltage of each cell are at $l \cdot m_f \pm k$, $l = 2, 4, \ldots$ (where $k = 1, 3, 5, \ldots$); for instance, for $m_f = 6$, the first set of harmonics is at 12 ± 1, 12 ± 3, … in all cells. Because the cells in one phase use carrier signals that are 60° out-of-phase, all the voltage harmonics $\approx l \cdot m_f$ in all cells are $l \cdot 60°$ out-of-phase. Therefore, for $l = 2$, the cell c_{11} generates the harmonics $l \cdot m_f \pm k = 2 \cdot m_f \pm k$ at a given phase φ, the cell c_{21} generates the harmonics $2 \cdot m_f \pm k$ at a phase $\varphi + l \cdot 60° = \varphi + 2 \cdot 60° = \varphi + 120° = \varphi - 240°$, and the cell c_{21} generates the harmonics $2 \cdot m_f \pm k$ at a phase $\varphi - l \cdot 60° = \varphi - 2 \cdot 60° = \varphi - 120° = \varphi + 240°$; thus, if the voltages have identical amplitudes, the harmonics $\approx 2 \cdot m_f$ add up to zero. Similarly, for $l = 4$, the cell c_{11} generates the harmonics $l \cdot m_f \pm k = 4 \cdot m_f \pm k$ at a given phase φ, the cell c_{21} generates the harmonics $4 \cdot m_f \pm k$ at a phase $\varphi + l \cdot 60° = \varphi + 4 \cdot 60° = \varphi + 240° = \varphi - 120°$, and the cell c_{21} generates the harmonics $4 \cdot m_f \pm k$ at a phase $\varphi - l \cdot 60° = \varphi - 4 \cdot 60° = \varphi - 240° = \varphi + 120°$; thus, if the voltages have identical amplitudes, the harmonics $\approx 4 \cdot m_f$ add up to zero. However, for $l = 6$, the cell c_{11} generates the harmonics $l \cdot m_f \pm k = 6 \cdot m_f \pm k$ at a given phase φ,

the cell c_{21} generates the harmonics $6 \cdot m_f \pm k$ at a phase $\varphi + l \cdot 60° = \varphi + 6 \cdot 60° = \varphi + 360° = \varphi$, and the cell c_{21} generates the harmonics $6 \cdot m_f \pm k$ at a phase $\varphi - l \cdot 60° = \varphi - 6 \cdot 60° = \varphi - 360° = \varphi$; thus, if the voltages have identical amplitudes, the harmonics $\approx 6 \cdot m_f$ become triplicated rather than cancelled out.

In general, due to the fact that $n_c = 3$, cells are connected in series in each phase, n_c carriers are required, which should be $\psi = 180°/n_c$ out-of-phase. The number of cells per phase n_c depends on the required phase voltage. For instance, a 600 V dc cell generates an ac voltage of $\approx 600/\sqrt{2} = 424$ V. Then three cells connected in series generate a phase voltage of $3 \cdot 424 = 1.27$ kV, which in turn generates a $1.27 \cdot \sqrt{3} = 2.2$ kV line-to-line voltage.

Phases *b* and *c* are generated similarly to phase *a*. However, the modulating signals v_{cb} and v_{cc} should be 120° out-of-phase. In order to use identical carrier signals in phases *b* and *c*, the carrier-normalized frequency m_f should be a multiple of 3. Thus, three modulating signals and n_c carrier signals are required to generate three phase voltages by means of a multicell approach, where n_c depends upon the required load line voltage and the dc bus voltage of each cell.

The ac supply current of each cell is a six-pulse type of current as shown in Fig. 15.58, which feature harmonics at $6 \cdot k \pm 1$ ($k = 1, 2, \ldots$). Similarly to the load side, the ac supply currents of each cell are combined so as to achieve high-performance overall supply currents. Because the front-end converter of
FIGURE 15.58   Multicell topology. Ac input current, phase *a*: (a) cell c_{11}; (b) cell c_{21}; (c) cell c_{31}; (d) overall supply current; (e) supply phase voltage; and (f) overall supply current spectrum.

each cell is a six-pulse diode rectifier, a multipulse approach is used. This is based on the natural harmonic cancellation when, for instance, a wye to delta/wye transformer is used to form an $N = 12$-pulse configuration from two six-pulse diode rectifiers. In this case, the fifth and seventh harmonics are cancelled out because the supply voltages applied to each six-pulse rectifier become 30° out-of-phase. In general, to form an $N = 6 \cdot n_s$ pulse configuration, n_s set of supply voltages that should be $60°/n_s$ out-of-phase is required. This would ensure the first set of unwanted current harmonics at $6 \cdot n_s \pm 1$.

The configuration depicted in Fig. 15.56 contains $n_c = 9$ cells, and a transformer capable of providing $n_s = 9$ sets of three-phase voltages that should be $60°/n_s = 60°/9$ out-of-phase to form an $N = 6 \cdot n_s = 6 \cdot 9 = 54$-pulse configuration is required. Although this alternative would provide a near-sinusoidal overall supply current, a fewer number of pulses are also acceptable that would reduce the transformer complexity. An $N = 18$-pulse configuration usually satisfies all the requirements. In the example, this configuration can be achieved by means of a transformer with $n_c = 9$ isolated secondaries; however, only $n_s = 3$ set of three-phase voltages that are $60°/n_s = 60°/3 = 20°$ out-of-phase are generated (Fig. 15.56). The configuration of the transformer restricts the connection of the cells in groups of three as shown in Fig. 15.56. In this case, the fifth, seventh, eleventh, and thirteenth harmonics are cancelled out and thus the first set of harmonics in the supply currents are the seventeenth and the nineteenth. Figure 15.58d

shows the resulting supply current that is near-sinusoidal and Fig. 15.58f shows the corresponding spectrum. The fifth, seventh, eleventh, and thirteenth harmonics are still there, which is due to the fact that the ac input currents in each cell are not exactly the six-pulse type of waveforms as seen in Fig. 15.58a, b, and c. This is mainly because: (i) the dc link in the cells contains a small inductor L, which does not smooth out sufficiently the dc bus current (Fig. 15.55a) and (ii) the transformer leakage inductance (or added line inductance) smoothes out the edges of the current, which also contributes to the reactive power required by the cells. This last effect is not shown in Fig. 15.58a, b, and c.

15.7.2 Voltage Source-based Multilevel Topologies

The six-switch VSI is usually called a two-level VSI due to the fact that the inverter phase voltages v_{aN}, v_{bN}, and v_{cN} (Fig. 15.54a) are instantaneously either $v_i/2$ or $-v_i/2$. In other words, the phase voltages can take one of the two voltage levels. Multilevel topologies provide an alternative to these voltages to take one value out of N levels. For instance, Fig. 15.59 shows an $N = 3$-level topology, where the values of the inverter phase voltage are either $v_i/2$, 0, or $-v_i/2$ (Fig. 15.60d). An interesting problem is how to obtain the gating pattern for the 12 switches required in an $N = 3$-level topology. There are several modulating techniques to overcome this problem, which
FIGURE 15.59 Three-phase three-level VSI topology.

can be classified as analog (e.g. carrier-based) and digital (SV-based). Both approaches have to deal with the valid switch states of the inverter.

A. Valid Switch States in a Three-level VSI

The easiest way of obtaining the valid switch states is to analyze each phase separately. Phase a contains the switches S_{1a}, S_{1b}, S_{4a}, and S_{4b}, which cannot be on simultaneously because a short circuit across the dc bus would be produced, and cannot be off simultaneously because an undefined phase voltage v_{aN} would be produced. A summary of the valid switch combinations is given in Table 15.7. It is important to note that all valid switch combinations satisfy the condition that switch S_{1a} state is always the opposite to switch S_{4a} state, and that switch S_{1b} state is always the opposite to switch S_{4b} state. Any other switch-state combination would result in an undefined inverter phase a voltage because it will depend upon the load-phase current i_{oa} polarity. The switch states for phases b and c are identical to that of phase a; moreover,

because they are paralleled, they can operate in an independent manner.

B. The SPWM Technique in Three-level VSIs

The main objective is to generate the appropriate 12 gating signals so as to obtain fundamental inverter phase voltages equal to a given set of modulating signals. Specifically, the SPWM in three-level inverters uses a sinusoidal set of modulating signals (v_{ca}, v_{cb}, and v_{cc} for phases a, b, and c, respectively) and $N - 1 = 2$ triangular type of carrier signals ($v_{\triangle 1}$ and $v_{\triangle 2}$) as illustrated in Fig. 15.60a. The best results are obtained if the carrier signals are in-phase and feature an odd normalized frequency (e.g. $m_f = 15$). According to Fig. 15.60a, switch S_{1a} is either turned on if $v_{ca} > v_{\triangle 1}$ or off if $v_{ca} < v_{\triangle 1}$, and switch S_{1b} is either turned on if $v_{ca} > v_{\triangle 2}$ or off if $v_{ca} < v_{\triangle 2}$. Additionally, the switch S_{4a} status is obtained as the opposite to switch S_{1a}, and the switch S_{4b} status is obtained as the opposite to switch S_{1b}. In order to use the same set of carrier signals to generate the gating signals for phases b and c, the normalized frequency of the carrier signal m_f should be a multiple of 3. Thus, the possible values are $m_f = 3, 9, 15, 21, \ldots$.

Figure 15.60 shows the relevant waveforms for a three-level inverter modulated by means of a SPWM technique ($m_f = 15$, $m_a = 0.8$). Specifically, Fig. 15.60d shows the inverter phase voltage, which is clearly a three-level type of voltage, and Fig. 15.60f shows the load line voltage, which shows that the step voltages are at most $v_i/2$. More importantly, the inverter phase voltage (Fig. 15.60e) contains harmonics at $l \cdot m_f \pm k$ with $l = 1, 3, \ldots$ and $k = 0, 2, 4, \ldots$ and at $l \cdot m_f \pm k$ with $l = 2, 4, \ldots$ and $k = 1, 3, \ldots$ For instance, the first set of harmonics ($l = 1$, $m_f = 15$) are at 15, 15 ± 2, $15 \pm 4, \ldots$

(d)

(e)

(f)

(g)

(h)
FIGURE 15.60   Three-level VSI topology. Relevant waveforms using a SPWM ($m_f = 15$, $m_a = 0.8$): (a) modulating and carrier signals; (b) switch S_{1a} status; (c) switch S_{4b} status; (d) inverter phase a voltage; (e) inverter phase a voltage spectrum; (f) load line voltage; (g) load line voltage spectrum; and (h) load phase a voltage.

The inverter line voltage (Fig. 15.60g) contains harmonics at $l \cdot m_f \pm k$ with $l = 1, 3, \ldots$ and $k = 2, 4, \ldots$ and at $l \cdot m_f \pm k$ with $l = 2, 4, \ldots$ and $k = 1, 3, \ldots$. For instance, the first set of harmonics in the line voltages ($l = 1$, $m_f = 15$) are at 15 ± 2, $15 \pm 4, \ldots$.

   All the other features of carrier-based PWM techniques also apply in multilevel inverters. For instance, (I) the fundamental component of the inverter phase voltages satisfies

$$\hat{v}_{aN1} = \hat{v}_{bN1} = \hat{v}_{cN1} = m_a \frac{v_i}{2} \quad 0 < m_a \leq 1 \qquad (15.89)$$

and thus the line voltages satisfy

$$\hat{v}_{ab1} = \hat{v}_{bc1} = \hat{v}_{ca1} = m_a \sqrt{3} \frac{v_i}{2} \quad 0 < m_a \leq 1 \qquad (15.90)$$

where $0 < m_a \leq 1$ the linear operating region. To further increase the amplitude of the load voltages, the overmodulation operating region can be used by further increasing

the modulating signal amplitudes ($m_a > 1$), where the line voltages range in

$$\sqrt{3} \frac{v_i}{2} < \hat{v}_{ab1} = \hat{v}_{bc1} = \hat{v}_{ca1} < \frac{4}{\pi} \sqrt{3} \frac{v_i}{2} \qquad (15.91)$$

   Also, (II) the modulating signals could be improved by adding a third harmonic (zero sequence), which will increase the linear region up to $m_a = 1.15$. This results in a maximum fundamental line-voltage component equal to v_i; (III) a nonsinusoidal set of modulating signals could also be used by the modulating technique. This is the case where nonsinusoidal line voltages are required as in active filter applications; and (IV) because of the two quadrants operation of VSIs, the multilevel inverter could equally be used in applications where the active power flow goes from the dc to the ac side or from the ac to the dc side.

In general, for an N-level inverter modulated by means of a carrier-based technique, the following conclusions can be drawn:

(a) three modulating signals 120° out of phase and $N-1$ carrier signals are required;

(b) the phase voltages in the inverters have a peak value of $v_i/(N-1)$;

(c) the phase voltages in the inverters are discrete waveforms constructed from the values

$$\frac{v_i}{2}, \frac{v_i}{2} - \frac{v_i}{N-1}, \frac{v_i}{2} - \frac{2 \cdot v_i}{N-1}, \cdots, -\frac{v_i}{2} \quad (15.92)$$

(d) the maximum voltage step in the line voltages is

$$\frac{v_i}{N-1} \quad (15.93)$$

for instance, an $N = 5$-level inverter requires four carrier signals, the discrete values of the phase voltages are: $v_i/2$, $v_i/4$, 0, $-v_i/4$, and $-v_i/2$, and the maximum step voltage at the load side is $v_i/4$. Key waveforms are shown in Fig. 15.61.

One of the drawbacks of the multilevel inverter is that the dc link capacitors should be equal. Unfortunately, this is not a natural operating condition mainly due to the fact that the currents required by the inverter in the dc bus are not symmetrical and therefore the capacitors will not equally share the total dc supply voltage v_i. To overcome this problem, two alternatives are developed later on.

C. The Space-vector Modulation in Three-level VSIs

Digital techniques are naturally extended to multilevel inverters. In fact, the SV modulating technique can be applied using the same principles used in two-level inverters. However, the higher number of voltage levels increases the complexity of the practical implementation of the technique. For instance, in $N = 3$-level inverters, each leg allows $N = 3$ different switch combinations as indicated in Table 15.7. Therefore, there are $N^3 = 27$ total valid switch combinations, which generate $N^3 = 27$ load line voltages that are represented by $N^3 = 27$ space vectors ($\vec{v}_1, \vec{v}_2, \ldots, \vec{v}_{27}$) in Fig. 15.62. For instance, $\vec{v}_2 = 0.5 + j0.866$ is due to the line voltages $v_{ab} = 0.5$, $v_{bc} = 0.5$, $v_{ca} = -1.0$ in pu. Thus, although the principle of operation is the same, the SV digital algorithm will have to deal with a higher number of states N^3. Moreover, because some space vectors (e.g. $\vec{v}_{13}$ and $\vec{v}_{14}$ in Fig. 15.62) produce the same load-voltage terminals, the algorithm will have to decide between the two based on additional criteria and that of the basic SV-approach. Clearly, as the number of level increases, the algorithm becomes more and more elaborate. However, the benefits are not evident as the number of level increases. The maximum number of levels used in practical applications is five. This is based on a compromise between the complexity of the implementation and the benefits of the resulting waveforms.

D. DC Link Voltage Balancing Issues

Figure 15.59 shows a three-level inverter and the ideal waveforms are shown in Fig. 15.60, which assume an even distribution of the voltage across the dc link capacitors. This even distribution is not naturally achieved and could be overcome by supplying both capacitors from independent supplies or properly gating the power valves of the inverter in order to minimize the unbalance.

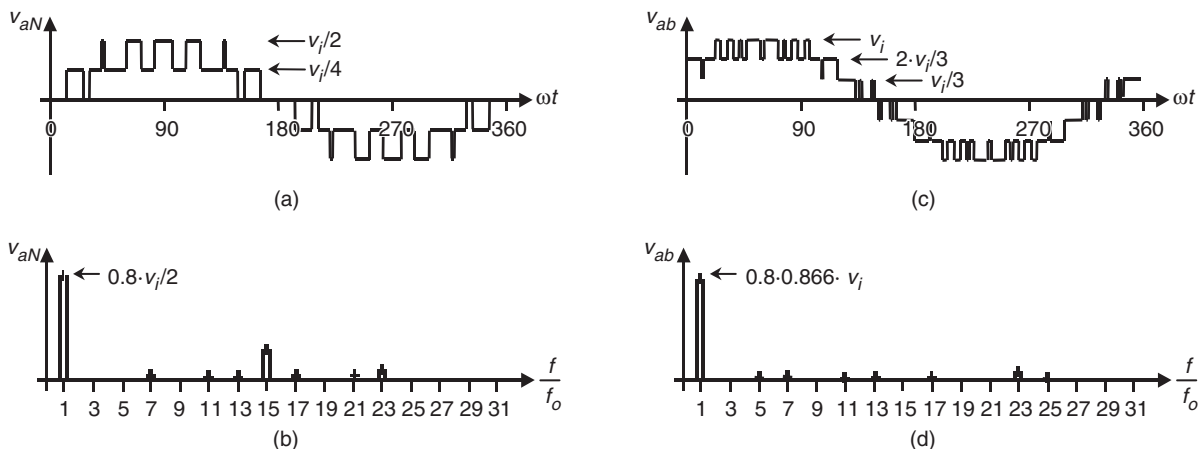
Figure 15.63 shows an ASD based on a three-level VSI, where the dc link capacitors are feed from two different sources. This approach is being commercially used as it ensures a robust balanced dc link voltage distribution and operates with a high-performance type of ac mains current.


FIGURE 15.61 Five-level VSI topology. Relevant waveforms using a SPWM ($m_f = 15$, $m_a = 0.8$): (a) inverter phase a voltage; (b) inverter phase a voltage spectrum; (c) load line voltage; and (d) load line voltage spectrum.
FIGURE 15.62 The space-vector representation in a three-level VSI.

Indeed, for a N level inverter, $N-1$ independent dc voltage supplies are required that could be provided by $N-1$ six-pulse rectifiers feed from an $N-1$ -pulse transformer. Therefore, the ac main currents is a $N-1$ level type of waveform.

This approach cannot be used when the inverter does not feature dc link voltage supplies. This is the case of static power reactive power compensators and static power active filters. In this case, the proper gating of the power valves becomes the only choice to keep and balance the dc link voltages. Figure 15.64a shows this case where the current added by the inverter i_o^{abc} provides the reactive power and current harmonics such that the ac mains current i_s^{abc} features a given power factor.

The SPWM modulating technique could be used as in Fig. 15.60; however, the zero level of the carriers δ is left as a manipulable variable Fig. 15.64b. In fact, it is used to control the difference of the upper and lower capacitor voltages

$\Delta v_i = v_{i1} - v_{i2}$. A closed loop alternative is depicted in Fig. 15.64c to manipulate δ. The modulating signals $\mathbf{v_c^{abc}}$ are left to control the reactive power and current harmonics injected into the ac mains by regulating the currents $\mathbf{i_o^{abc}}$ and keep the total dc link voltage $v_i = v_{i1} + v_{i2}$ equal to a reference. Both loops are not included in Fig. 15.64c.

15.7.3 Current Source-based Multilevel Topologies

Duality is found in many aspects related to voltage and current source inverters. Perhaps, the most evident is the duality in terms of modulating techniques. Thus, current source based multilevel topologies are available as well. As expected, all the benefits and all the drawbacks found in voltage source topologies should be found in current source topologies.

Figure 15.65 shows a three-level $N = 3$ current source topology, which is formed by paralleling two standard six-switches topologies. The main goal is to share evenly the ac current $\mathbf{i_o^{abc}}$ among the two topologies ($\mathbf{i_o^{abc}}/2 = \mathbf{i_{o1}^{abc}} = \mathbf{i_{o2}^{abc}}$). This should be ensured by having equal dc link currents ($i_{i1} = i_{i2}$). Similarly to voltages source based mutlilevel topologies, this could be achieved by using either two independent dc link currents or by properly gating the power valves. Both alternatives are reviewed later on.

A. The SPWM Technique in Three-level CSIs

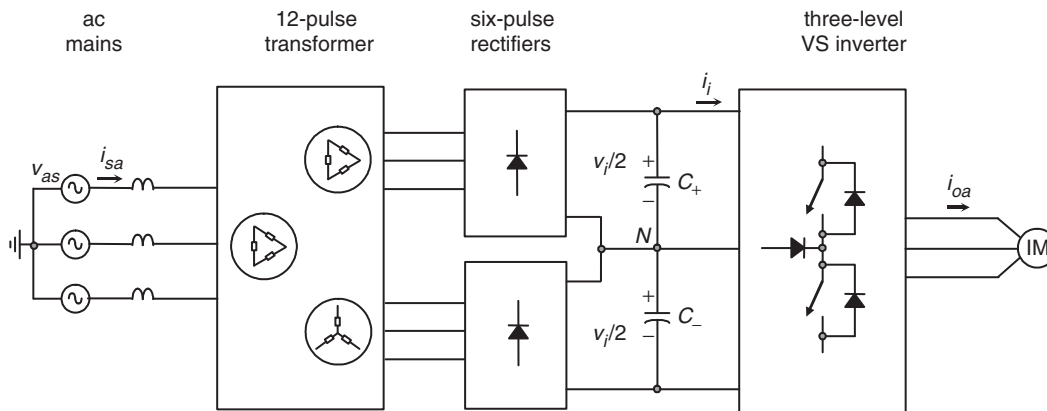
As in three-level VSIs, the main objective is to generate the appropriate 12 gating signals so as to obtain fundamental inverter line currents equal to a given set of modulating signals. Specifically, the SPWM in three-level inverters uses a sinusoidal set of modulating signals (i_{ca}, i_{cb}, and i_{cc} for phases a, b, and c, respectively) and $N - 1 = 2$ triangular type of carrier signals ($i_{\Delta 1}$ and $i_{\Delta 2}$) as illustrated in Fig. 15.66a and 15.66e. The best results are obtained if the carrier signals are 180° out of phase


FIGURE 15.63 ASD based on a three-phase three-level VSI topology.
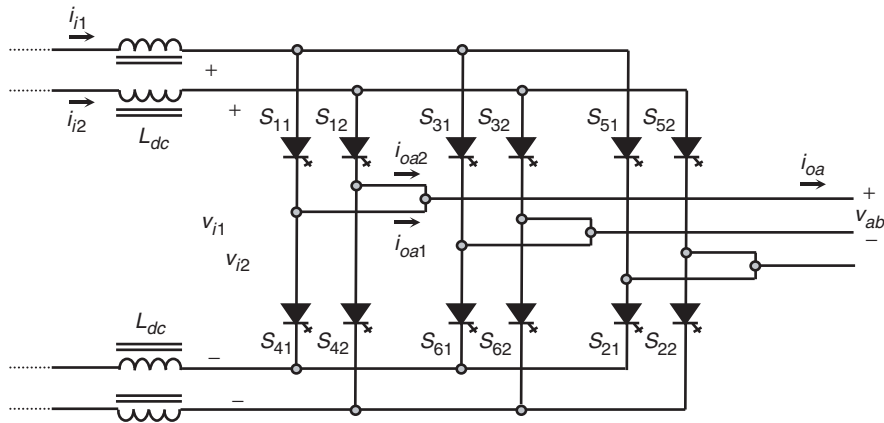
FIGURE 15.64   Reactive power and current harmonics compensator based on a three-phase three-level VSI topology: (a) power topology; (b) carrier and modulating signals; and (c) δ closed loop scheme.


FIGURE 15.65   Three-phase three-level CSI topology.

and feature an odd normalized frequency (e.g. $m_f = 15$). In order to use the same set of carrier signals to generate the gating signals for phases b and c, the normalized frequency of the carrier signal m_f should be a multiple of 3. Thus, the possible values are $m_f = 3, 9, 15, 21, \ldots$.

Figure 15.66 shows the relevant waveforms for a three-level inverter modulated by means of a SPWM technique ($m_f = 15$, $m_a = 0.8$). Specifically, Fig. 15.66b and 15.66f show the gating signals obtained as described earlier in this chapter. The inverter line currents shown in 15.66c and 15.66g feature spectra shown in 15.66d and 15.66h, respectively. As expected, the inverter line currents contain harmonics at $l \cdot m_f \pm k$ with $l = 1, 3, \ldots$ and $k = 2, 4, \ldots$ and at $l \cdot m_f \pm k$ with $l = 2, 4, \ldots$ and $k = 1, 3, \ldots$. For instance, the first set of harmonics in the line currents ($l = 1$, $m_f = 15$) are at $15 \pm 2, 15 \pm 4, \ldots$.

The total inverter line current is shown in Fig. 15.67a, and features the first set of unwanted harmonics around $2m_f$ Fig. 15.67b. This becomes the first advantage of using a multilevel topology as the filtering component requirements become

more relaxed. All the other features of carrier-based PWM techniques also apply in current source multilevel inverters. For instance: (I) the fundamental component of the line currents satisfy

$$\hat{i}_{oa1} = \hat{i}_{ob1} = \hat{i}_{oc1} = m_a \frac{\sqrt{3}}{2}(i_{i1} + i_{i2}) \quad 0 < m_a \le 1 \quad (15.94)$$

where $0 < m_a \le 1$ is the linear operating region. Also: (II) to further increase the amplitude of the load currents, a zero sequence signal could be injected to the modulating signals, in this case

$$\hat{i}_{oa1} = \hat{i}_{ob1} = \hat{i}_{oc1} = m_a \frac{\sqrt{3}}{2}(i_{i1} + i_{i2}) \quad 0 < m_a \le 2/\sqrt{3}$$

$$(15.95)$$

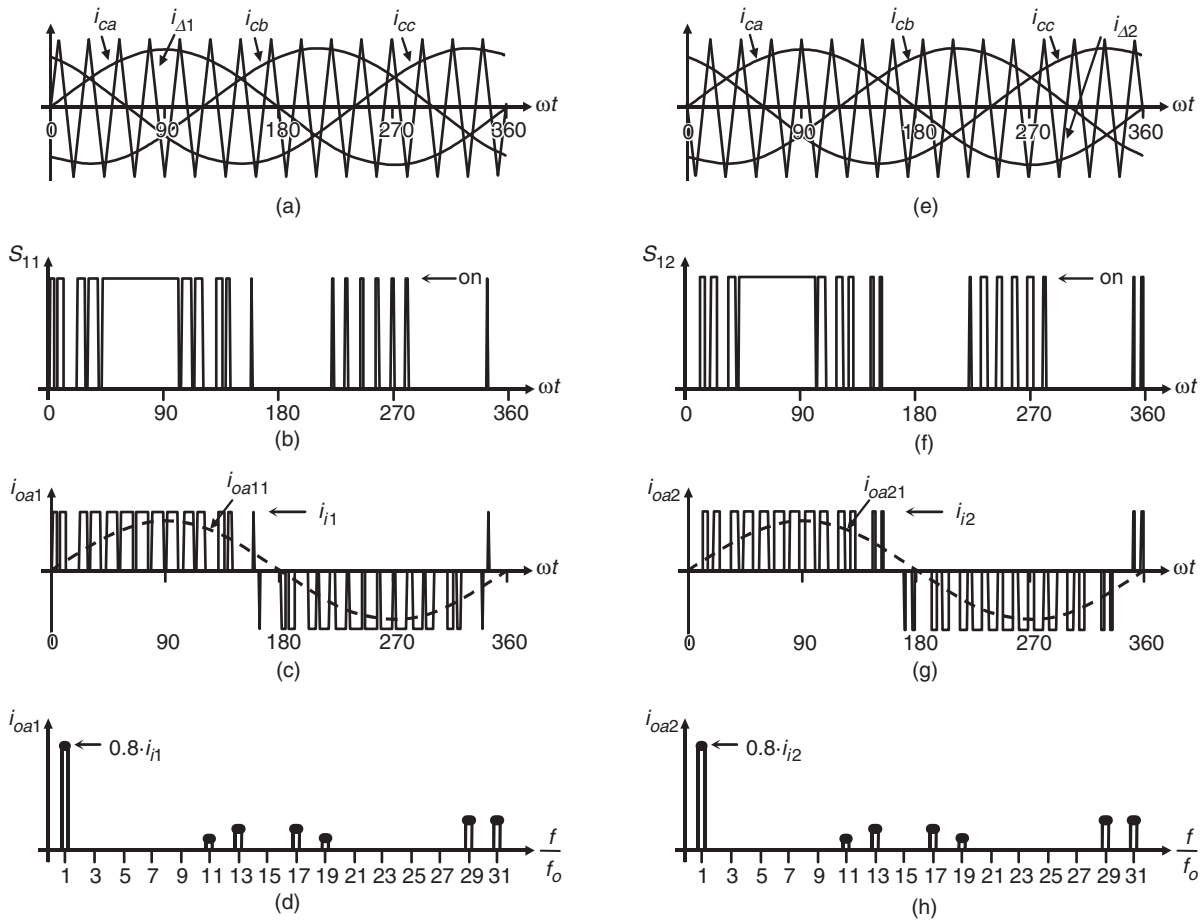
the overmodulation operating region can be used by further increasing the modulating signal amplitudes ($m_a > 2/\sqrt{3}$),


FIGURE 15.66 Three-level CSI topology. Relevant waveforms using a SPWM ($m_f = 15$, $m_a = 0.8$): (a) modulating signals and carrier signal 1; (b) switch S_{11} status; (c) inverter 1 linea current; (d) inverter 1 linea current spectrum; (e) modulating signals and carrier signal 2; (f) switch S_{12} status; (g) inverter 2 linea current; and (h) inverter 2 linea current spectrum.
FIGURE 15.67 Three-level CSI topology. Relevant waveforms using a SPWM ($m_f = 15$, $m_a = 0.8$): (a) total inverter line current and (b) total inverter line current spectrum.

where the line currents range in

$$(i_{i1} + i_{i2}) < \hat{i}_{oa1} = \hat{i}_{ob1} = \hat{i}_{oc1} < \frac{4}{\pi}(i_{i1} + i_{i2}) \qquad (15.96)$$

Also: (III) a nonsinusoidal set of modulating signals could also be used by the modulating technique. This is the case where nonsinusoidal line currents are required as in active filter applications; and (IV) because of the two quadrants operation of CSIs, the multilevel inverter could equally be used in applications where the active power flow goes from the dc to the ac side or from the ac to the dc side. In general, for an N-level inverter modulated by means of a carrier-based technique, three modulating signals 120° out-of-phase and $N - 1$ carrier signals are required and the line currents in the inverters have a peak value of $i_i/(N - 1)$.

One of the drawbacks of the multilevel inverter is that the dc link capacitors cannot be supplied by a single dc voltage source. This is due to the fact that the currents required by the inverter in the dc bus are not symmetrical and therefore the capacitors will not equally share the dc supply voltage v_i. To overcome this problem, two alternatives are developed later on.

B. DC Link Voltage Balancing Issues

Figure 15.65 shows a three-level inverter and the ideal waveforms are shown in Fig. 15.66 and Fig. 15.67, which assume equal dc link currents, $i_{i1} = i_{i2}$. This even distribution is not naturally achieved and could be overcome by supplying the dc link inductors from independent supplies or properly gating the power valves of the inverter in order to minimize the unbalance.

Figure 15.68 shows an ASD based on a three-level current source inverter, where the dc link inductors are feed from two different sources. Unlike the VS topology, the scheme needs a closed loop control strategy to keep constant the dc link

currents and equal to a given reference. This is achieved in commercial units by using either phase-controlled rectifiers or PWM rectifiers. Nevertheless, the multipulse transformer required to provide isolated dc link currents improves the ac mains current as in the VS multilevel topology.

This approach cannot be used when the inverter is not feed from an external power supply. This is the case of static series voltage compensators. In this case, the proper gating of the power valves becomes the only choice to keep and balance the dc link currents. Figure 15.64a shows this case where the voltage added by the inverter $n\mathbf{v_o^{abc}}$ compensates the sags and/or swells present in the ac mains in order to provide a constant voltage to the load.

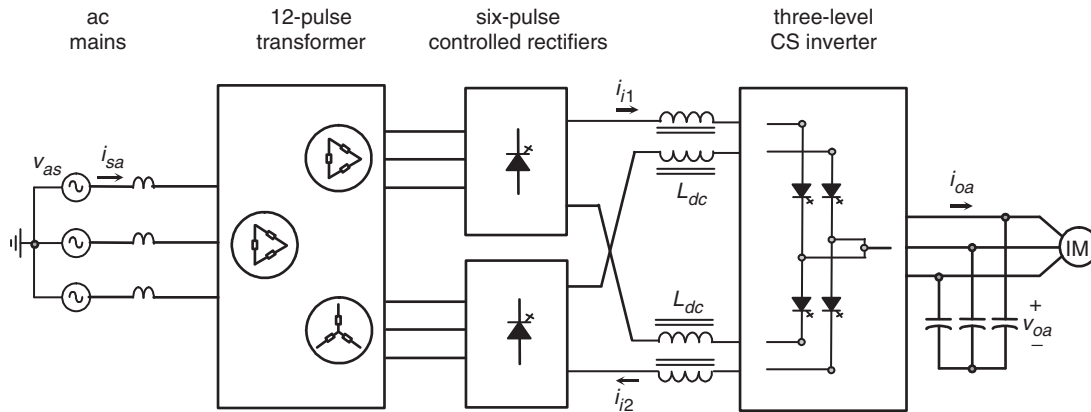
The SPWM modulating technique could be used as in Fig. 15.66 and Fig. 15.67; however, the peak amplitude of one triangular is amplified in the factor $1 + \delta$ and the peak amplitude of other triangular is amplified in the factor $1 - \delta$, where δ is left as a manipulable variable Fig. 15.69b. In fact, δ is used to control the difference of the dc link currents $\Delta i_i = i_{i1} - i_{i2}$.


FIGURE 15.68 ASD based on a three-phase three-level CSI topology.
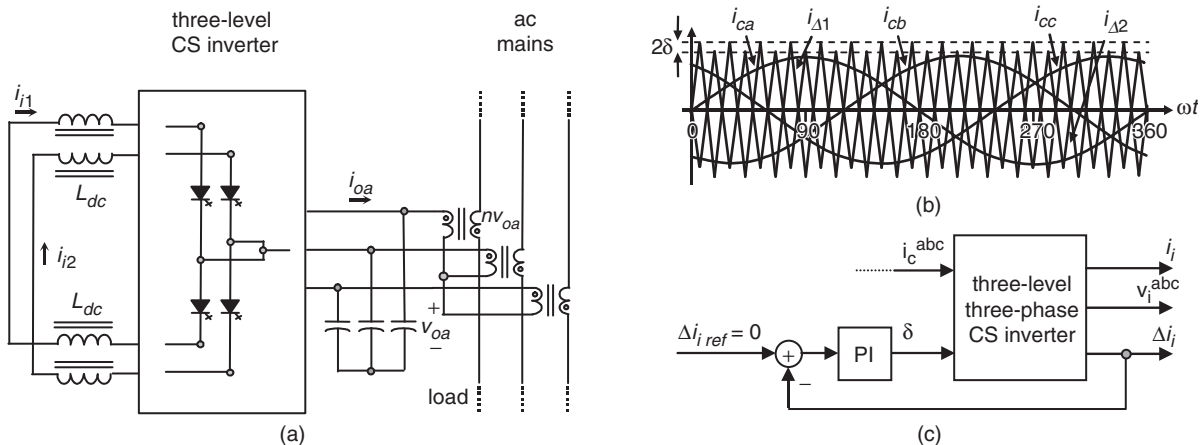

FIGURE 15.69 Reactive power and current harmonics compensator based on a three-phase three-level VSI topology: (a) power topology; (b) carrier and modulating signals; and (c) δ closed loop scheme.

A closed loop alternative is depicted in Fig. 15.69c to manipulate δ. The modulating signals $\mathbf{i_c^{abc}}$ are left to control the series injected voltage into the ac mains by regulating the voltages $\mathbf{v_o^{abc}}$ and keep the total dc link current $i_i = i_{i1} + i_{i2}$ equal to a reference. Both loops are not included in Fig. 15.69c.

16.1 Introduction

Advances in power electronics in the last few decades have led to not just improvements in power devices, but also new concepts in converter topologies and control. In the 1970s, conventional pulse width modulated (PWM) power converters were operated in a switched mode operation. Power switches have to cut off the load current within the turn-on and turn-off times under the hard switching conditions. Hard switching refers to the stressful switching behavior of the power electronic devices. The switching trajectory of a hard-switched power device is shown in Fig. 16.1. During the turn-on and turn-off processes, the power device has to withstand high voltage and current simultaneously, resulting in
FIGURE 16.1   Typical switching trajectories of power switches.

high switching losses and stress. Dissipative passive snubbers are usually added to the power circuits so that the *dv/dt* and *di/dt* of the power devices could be reduced, and the switching loss and stress be diverted to the passive snubber circuits. However, the switching loss is proportional to the switching frequency, thus limiting the maximum switching frequency of the power converters. Typical converter switching frequency was limited to a few tens of kilo-Hertz (typically 20–50 kHz) in early 1980s. The stray inductive and capacitive components in the power circuits and power devices still cause considerable transient effects, which in turn give rise to electromagnetic interference (EMI) problems. Figure 16.2 shows ideal
FIGURE 16.2   Typical: (a) ideal and (b) practical switching waveforms.

switching waveforms and typical practical waveforms of the switch voltage. The transient ringing effects are major causes of EMI.

In the 1980s, lots of research efforts were diverted towards the use of resonant converters. The concept was to incorporate resonant tanks in the converters to create oscillatory (usually sinusoidal) voltage and/or current waveforms so that zero-voltage switching (ZVS) or zero-current switching (ZCS) conditions can be created for the power switches. The reduction of switching loss and the continual improvement of power switches allow the switching frequency of the resonant converters to reach hundreds of kilo-Hertz (typically 100–500 kHz). Consequently, the size of magnetic components can be reduced and the power density of the converters increased. Various forms of resonant converters have been proposed and developed. However, most of the resonant converters suffer several problems. When compared with the conventional PWM converters, the resonant current and the voltage of resonant converters have high peak values, leading to higher conduction loss and higher *V* and *I* rating requirements for the power devices. Also, many resonant converters require frequency modulation (FM) for output regulation. Variable switching frequency operation makes the filter design and control more complicated.

In late 1980s and throughout 1990s, further improvements have been made in converter technology. New generations of soft-switched converters that combine the advantages of conventional PWM converters and resonant converters have been developed. These soft-switched converters have switching waveforms similar to those of conventional PWM converters except that the rising and falling edges of the waveforms are "smoothed" with no transient spikes. Unlike the resonant converters, new soft-switched converters usually utilize the resonance in a controlled manner. Resonance is allowed to occur just before and during the turn-on and turn-off processes so as to create ZVS and ZCS conditions. Other than that, they behave just like conventional PWM converters. With simple modifications, many customized control integrated circuits (ICs) designed for conventional converters can be employed for soft-switched converters. Because the switching loss and stress have been reduced, soft-switched converter can be operated at the very high frequency (typically 500 kHz to a few Mega-Hertz). Soft-switching converters also provide an effective solution to suppress EMI and have been applied to DC–DC, AC–DC, and DC–AC converters. This chapter covers the basic technology of resonant and soft-switching converters. Various forms of soft-switching techniques such as ZVS, ZCS, voltage clamping, zero-voltage transition methods, etc. are addressed. The emphasis is placed on the basic operating principle and practicality of the converters without using much mathematical analysis.

16.2 Classification
16.3 Resonant Switch

Prior to the availability of fully controllable power switches, thyristors were the major power devices used in power electronic circuits. Each thyristor requires a commutation circuit, which usually consists of a *LC* resonant circuit, for forcing the current to zero in the turn-off process [1]. This mechanism is in fact a type of zero-current turn-off process. With the recent advancement in semiconductor technology, the voltage and current handling capability, and the switching speed of fully controllable switches have significantly been improved. In many high power applications, controllable switches such as gate turn-offs (GTOs) and insulated gate bipolar transistors (IGBTs) have replaced thyristors [2, 3]. However, the use of resonant circuit for achieving ZCS and/or ZVS [4–8] has also emerged as a new technology for power converters. The concept of resonant switch that replaces conventional power switch is introduced in this section.

A resonant switch is a sub-circuit comprising a semiconductor switch S and resonant elements, L_r and C_r [9–11]. The switch S can be implemented by a unidirectional or bidirectional switch, which determines the operation mode of the resonant switch. Two types of resonant switches [12], including zero-current (ZC) resonant switch and

zero-voltage (ZV) resonant switches, are shown in Figs. 16.3 and 16.4, respectively.

16.3.1 ZC Resonant Switch

In a ZC resonant switch, an inductor L_r is connected in series with a power switch S in order to achieve zero-current switching (ZCS). If the switch S is a unidirectional switch, the switch current is allowed to resonate in the positive half cycle only. The resonant switch is said to operate in *half-wave* mode. If a diode is connected in anti-parallel with the unidirectional switch, the switch current can flow in both directions. In this case, the resonant switch can operate in *full-wave* mode. At turn-on, the switch current will rise slowly from zero. It will then oscillate, because of the resonance between L_r and C_r. Finally, the switch can be commutated at the next zero current duration. The objective of this type of switch is to shape the switch current waveform during conduction time in order to create a zero-current condition for the switch to turn off [13].

16.3.2 ZV Resonant Switch

In a ZV resonant switch, a capacitor C_r is connected in parallel with the switch S for achieving zero-voltage switching (ZVS).
FIGURE 16.3 Zero-current (ZC) resonant switch.
FIGURE 16.4 Zero-voltage (ZV) resonant switch.

If the switch S is a unidirectional switch, the voltage across the capacitor C_r can oscillate freely in both positive and negative half-cycle. Thus, the resonant switch can operate in *full-wave* mode. If a diode is connected in anti-parallel with the unidirectional switch, the resonant capacitor voltage is clamped by the diode to zero during the negative half-cycle. The resonant switch will then operate in *half-wave* mode. The objective of a ZV switch is to use the resonant circuit to shape the switch voltage waveform during the off time in order to create a zero-voltage condition for the switch to turn on [13].

16.4 Quasi-resonant Converters

Quasi-resonant converters (QRCs) can be considered as a hybrid of resonant and PWM converters. The underlying principle is to replace the power switch in PWM converters with the resonant switch. A large family of conventional converter circuits can be transformed into their resonant converter counterparts. The switch current and/or voltage waveforms are forced to oscillate in a quasi-sinusoidal manner, so that ZCS and/or ZVS can be achieved. Both ZCS-QRCs and ZVS-QRCs have *half-wave* and *full-wave* mode of operations [8–10, 12].

16.4.1 ZCS-QRCs

A ZCS-QRC designed for *half-wave* operation is illustrated with a buck type DC–DC converter. The schematic is shown in Fig. 16.5a. It is formed by replacing the power switch in conventional PWM buck converter with the ZC resonant switch in Fig. 16.3a. The circuit waveforms in steady state are shown in Fig. 16.5b. The output filter inductor L_f is sufficiently large so

that its current is approximately constant. Prior to turning the switch on, the output current I_o freewheels through the output diode D_f. The resonant capacitor voltage V_{Cr} equals zero. At t_0, the switch is turned on with ZCS. A quasi-sinusoidal current I_S flows through L_r and C_r, the output filter, and the load. S is then softly commutated at t_1 with ZCS again. During and after the gate pulse, the resonant capacitor voltage V_{Cr} rises and then decays at a rate depending on the output current. Output voltage regulation is achieved by controlling the switching frequency. Operation and characteristics of the converter depend mainly on the design of the resonant circuit $L_r C_r$. The following parameters are defined: voltage conversion ratio M, characteristic impedance Z_r, resonant frequency f_r, normalized load resistance r, normalized switching frequency γ.

$$M = \frac{V_o}{V_i} \tag{16.1a}$$

$$Z_r = \sqrt{\frac{L_r}{C_r}} \tag{16.1b}$$

$$f_r = \frac{1}{2\pi\sqrt{L_r C_r}} \tag{16.1c}$$

$$r = \frac{R_L}{Z_r} \tag{16.1d}$$

$$\gamma = \frac{f_s}{f_r} \tag{16.1e}$$

It can be seen from the waveforms that if $I_o > V_i/Z_r$, I_S will not come back to zero naturally and the switch will have to be

(a)

(b)

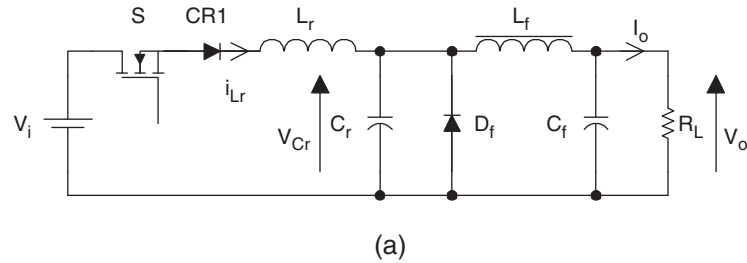
(c)


FIGURE 16.5   Half-wave, quasi-resonant buck converter with ZCS: (a) schematic diagram; (b) circuit waveforms; and (c) relationship between M and γ.

forced off, thus resulting in turn-off losses. The relationships between M and γ at different r are shown in Fig. 16.5c. It can be seen that M is sensitive to the load variation. At light load conditions, the unused energy is stored in C_r, leading to an increase in the output voltage. Thus, the switching frequency has to be controlled, in order to regulate the output voltage.

If an anti-parallel diode is connected across the switch, the converter will be operating in *full-wave* mode. The circuit schematic is shown in Fig. 16.6a. The circuit waveforms in steady state are shown in Fig. 16.6b. The operation is similar to the one in *half-wave* mode. However, the inductor current is allowed to reverse through the anti-parallel

diode and the duration for the resonant stage is lengthened. This permits excess energy in the resonant circuit at light loads to be transferred back to the voltage source V_i. This significantly reduces the dependence of V_o on the output load. The relationships between M and γ at different r are shown in Fig. 16.6c. It can be seen that M is insensitive to load variation.

By replacing the switch in the conventional converters, a family of QRC [9] with ZCS is shown in Fig. 16.7.

16.4.2 ZVS-QRC

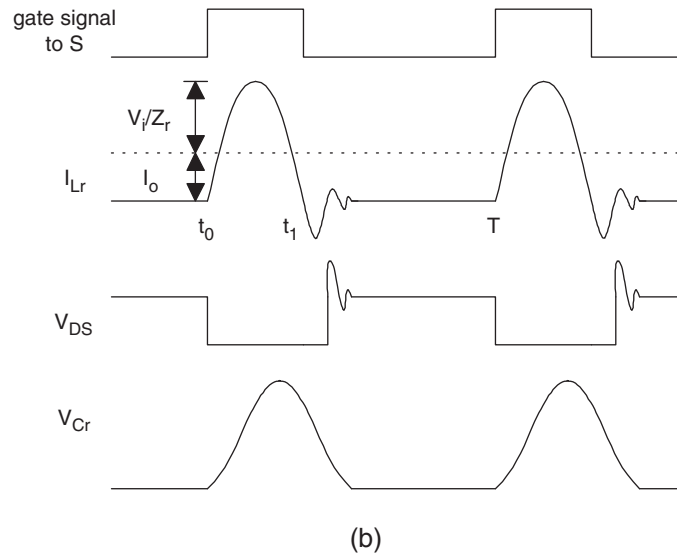
In these converters, the resonant capacitor provides a zero-voltage condition for the switch to turn on and off.


FIGURE 16.6 Full-wave, quasi-resonant buck converter with ZCS: (a) schematic diagram; (b) circuit waveforms; and (c) relationship between M and γ.
FIGURE 16.7   A family of quasi-resonant converter with ZCS.

A quasi-resonant buck converter designed for *half-wave* operation is shown in Fig. 16.8a – using a ZV resonant switch in Fig. 16.4b. The steady-state circuit waveforms are shown in Fig. 16.8b. Basic relations of ZVS-QRCs are given in Eqs. (16.1a–e). When the switch S is turned on, it carries the output current I_o. The supply voltage V_i reverse biases the diode D_f. When the switch is zero-voltage (ZV) turned off, the output current starts to flow through the resonant capacitor C_r. When the resonant capacitor voltage V_{Cr} is equal to V_i, D_f turns on. This starts the resonant stage. When V_{Cr} equals zero, the anti-parallel diode turns on. The resonant capacitor is shorted and the source voltage is applied to the resonant inductor L_r. The resonant inductor current I_{Lr} increases linearly until it reaches I_o. Then D_f turns off. In order to achieve ZVS, S should be triggered during the time when the anti-parallel diode conducts. It can be seen from the waveforms that the peak amplitude of the resonant capacitor voltage should be greater or equal to the input voltage (i.e. $I_o Z_r > V_{in}$). From Fig. 16.8c, it can be seen that the voltage conversion ratio is load-sensitive. In order to regulate the output voltage for different loads r, the switching frequency should also be changed accordingly.

ZVS converters can be operated in *full-wave* mode. The circuit schematic is shown in Fig. 16.9a. The circuit waveforms in steady state are shown in Fig. 16.9b. The operation is similar to *half-wave* mode of operation, except that V_{Cr} can swing between positive and negative voltages. The relationships between M and γ at different r are shown in Fig. 16.9c.

Comparing Fig. 16.8c with Fig. 16.9c, it can be seen that M is load-insensitive in *full-wave* mode. This is a desirable feature. However, as the series diode limits the direction of the switch current, energy will be stored in the output capacitance of the switch and will dissipate in the switch during turn on. Hence, the *full-wave* mode has the problem of capacitive turn-on loss, and is less practical in high frequency operation. In practice, ZVS-QRCs are usually operated in *half-wave* mode rather than *full-wave* mode.

By replacing the ZV resonant switch in the conventional converters, various ZVS-QRCs can be derived. They are shown in Fig. 16.10.

16.4.3 Comparisons between ZCS and ZVS

ZCS can eliminate the switching losses at turn off and reduce the switching losses at turn on. As a relatively large capacitor is connected across the output diode during resonance, the converter operation becomes insensitive to the diode's junction capacitance. When power MOSFETs are zero-current switched on, the energy stored in the device's capacitance will be dissipated. This capacitive turn-on loss is proportional to the switching frequency. During turn on, considerable rate of change of voltage can be coupled to the gate drive circuit through the Miller capacitor, thus increasing switching loss and noise. Another limitation is that the switches are under high

current stress, resulting in higher conduction loss. However, it should be noted that ZCS is particularly effective in reducing switching loss for power devices (such as IGBT) with large tail current in the turn-off process.

ZVS eliminates the capacitive turn-on loss. It is suitable for high-frequency operation. For single-ended configuration, the switches could suffer from excessive voltage stress, which is proportional to the load. It will be shown in Section 16.5 that the maximum voltage across switches in half-bridge and full-bridge configurations is clamped to the input voltage.

For both ZCS and ZVS, output regulation of the resonant converters can be achieved by variable frequency control. ZCS operates with constant on-time control, while ZVS operates with constant off-time control. With a wide input and load range, both techniques have to operate with a wide switching frequency range, making it not easy to design resonant converters optimally.

16.5 ZVS in High Frequency Applications

By the nature of the resonant tank and ZCS, the peak switch current in resonant converters is much higher than that in the square-wave counterparts. In addition, a high voltage will be established across the switch in the off state after the resonant stage. When the switch is switched on again, the energy stored in the output capacitor will be discharged through the switch, causing a significant power loss at high frequencies and high voltages. This switching loss can be reduced by using ZVS.

ZVS can be viewed as square-wave power utilizing a constant off-time control. Output regulation is achieved by controlling the on time or switching frequency. During the off time, the resonant tank circuit traverses the voltage across the switch from zero to its peak value and then back to zero again. At that ZV instant, the switch can be reactivated. Apart from the conventional single-ended converters, some other examples of converters with ZVS are illustrated in the following section.

16.5.1 ZVS with Clamped Voltage

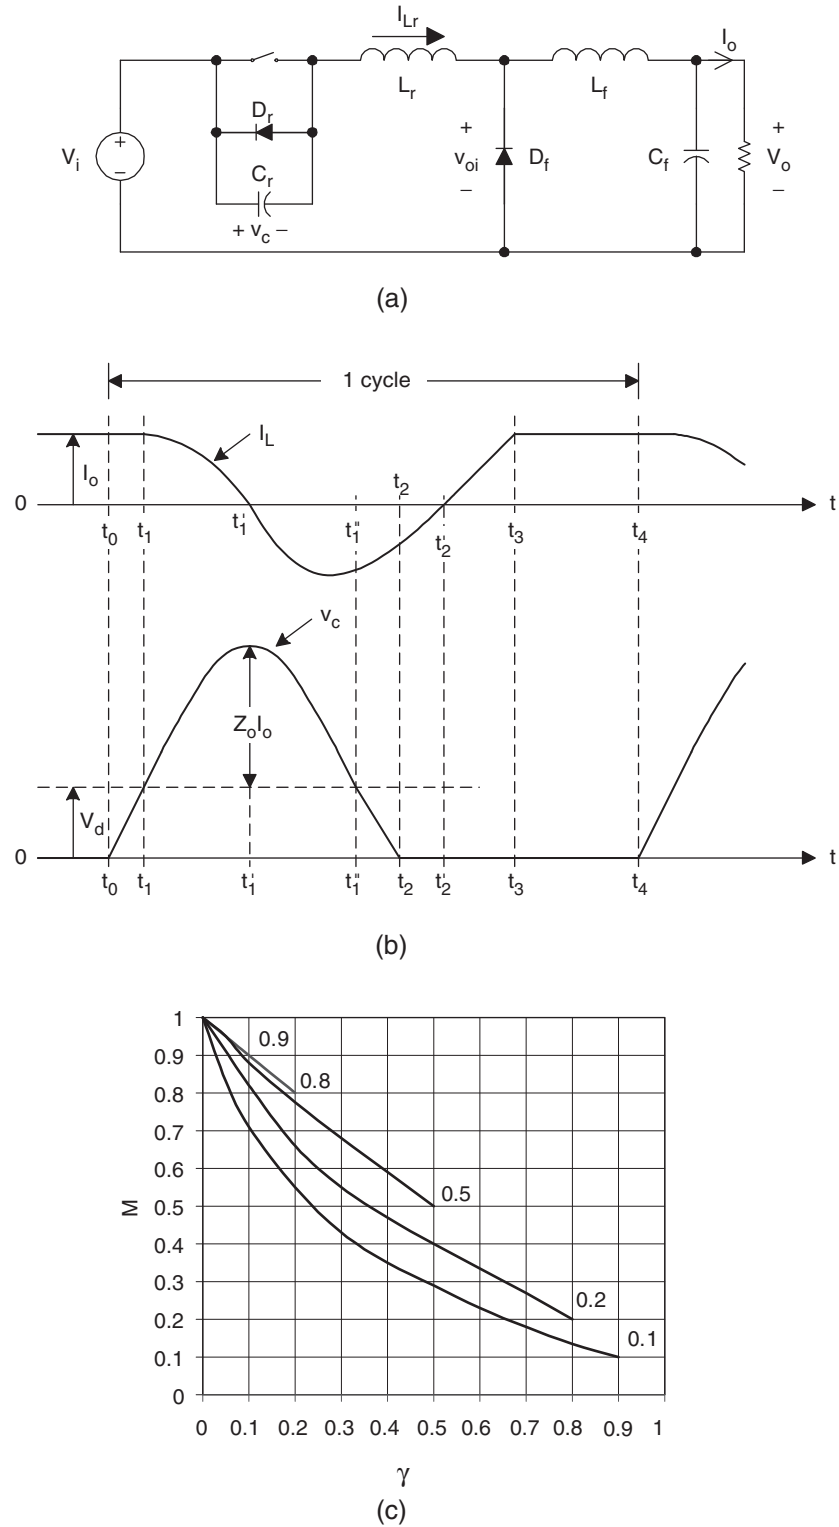
The high voltage stress problem in the single-switch configuration with ZVS can be avoided in half-bridge (HB) and full-bridge (FB) configurations [14–17]. The peak switch voltage can be clamped to the dc supply rail, and thus reducing the switch voltage stress. In addition, the series transformer leakage and circuit inductance can form parts of the resonant path. Therefore, these parasitic components, which are undesirable in hard-switched converter become useful components in ZVS ones. Figures 16.11 and 16.12 show the ZVS HB and FB circuits, respectively, together with the circuit waveforms.


FIGURE 16.8   Half-wave, quasi-resonant buck converter with ZVS: (a) schematic diagram; (b) circuit waveforms; and (c) relationship between M and γ.

(a)

(b)

(c)
FIGURE 16.9 Full-wave, quasi-resonant buck converter with ZVS: (a) schematic diagram; (b) circuit waveforms; and (c) relationship between M and γ.

The resonant capacitor is equivalent to the parallel connection of the two capacitors $(C_r/2)$ across the switches. The off-state voltage of the switches will not exceed the input voltage during resonance because they will be clamped to the supply rail by the anti-parallel diode of the switches.

16.5.2 Phase-shifted Converter with Zero Voltage Transition

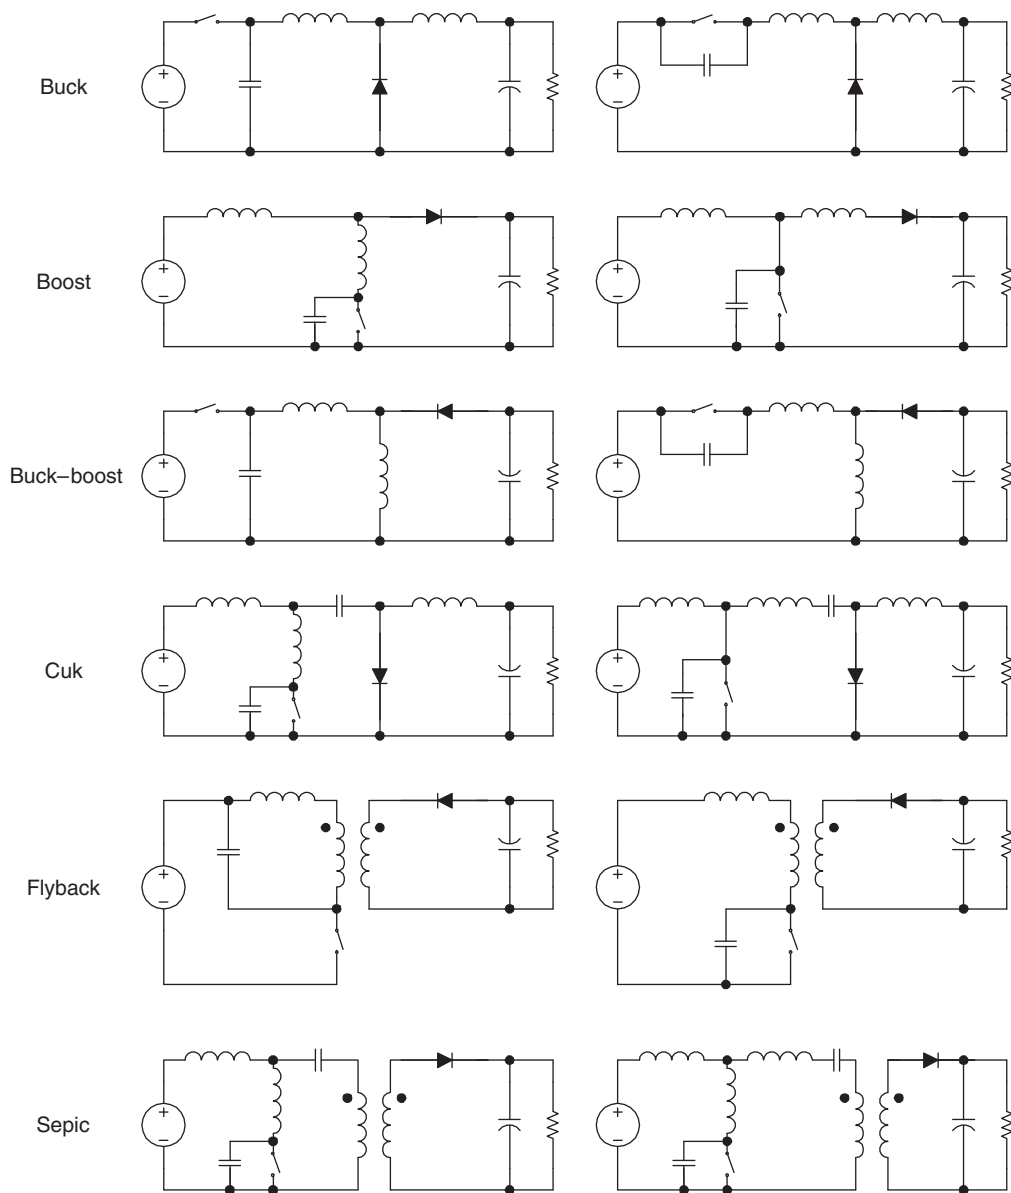
In a conventional FB converter, the two diagonal switch pairs are driven alternatively. The output transformer is fed with an


FIGURE 16.10   A family of quasi-resonant converter with ZVS.

ac rectangular voltage. By applying a phase-shifting approach, a deliberate delay can be introduced between the gate signals to the switches [18]. The circuit waveforms are shown in Fig. 16.13. Two upper or lower switches can be conducting (either through the switch or the anti-parallel diode), yet the applied voltage to the transformer is zero. This zero-voltage condition appears in the interval $[t_1, t_2]$ of V_{pri} in Fig. 16.13. This operating stage corresponds to the required off time for that particular switching cycle. When the desired switch is turned off, the primary transformer current flows into the switch output capacitance causing the switch voltage to resonate to the opposite input rail. Effects of the parasitic circuit components are used advantageously to facilitate the resonant

transitions. This enables a ZVS condition for turning on the opposite switch. Thus, varying the phase shift controls the effective duty cycle and hence the output power. The resonant circuit is necessary to meet the requirement of providing sufficient inductive energy to drive the capacitors to the opposite bus rail. The resonant transition must be achieved within the designed transition time.

16.6 Multi-resonant Converters (MRC)

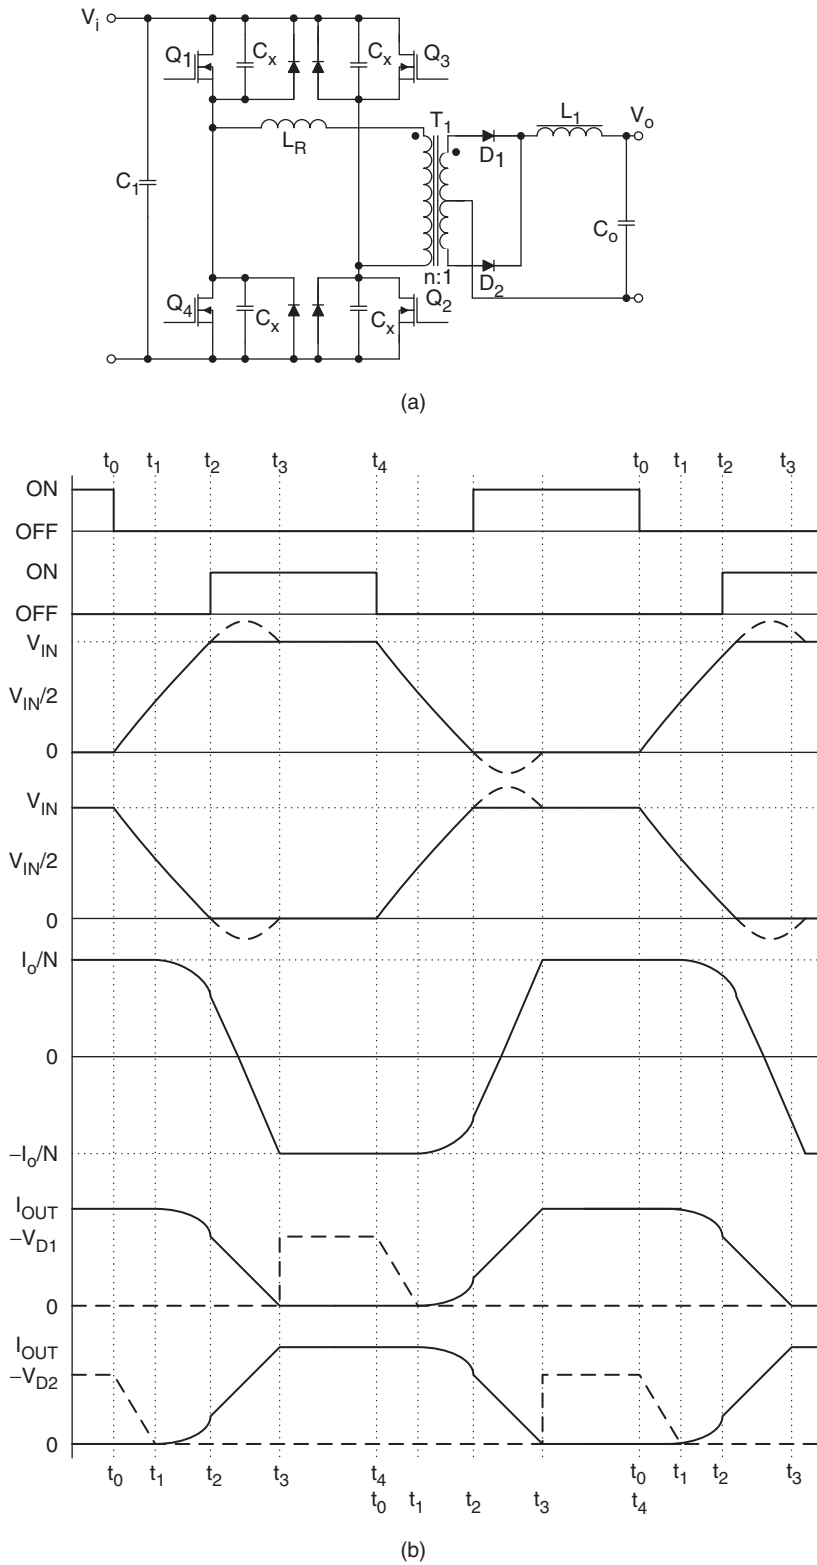
The ZCS- and ZVS-QRCs optimize the switching condition for either the active switch or the output diode only, but not
FIGURE 16.11   Half-bridge converter with ZVS: (a) circuit diagram and (b) circuit waveforms.


FIGURE 16.12   Full-bridge converter with ZVS: (a) circuit schematics and (b) circuit waveforms.
FIGURE 16.13 Circuit waveforms of the phase-shifted, ZVT FB converter.

for both of them simultaneously. Multi-resonant switch concept, which is an extension of the concept of the resonant switch, has been developed to overcome such limitation. The zero-current multi-resonant (ZC-MR) and zero-voltage multiresonant (ZV-MR) switches [12, 17] are shown in Fig. 16.14.

The multi-resonant circuits incorporate all major parasitic components, including switch output capacitance, diode junction capacitance, and transformer leakage inductance into the resonant circuit. In general, ZVS (*half-wave* mode) is more favorable than ZCS in DC–DC converters for high-frequency operation because the parasitic capacitance of the active switch and the diode will form a part of the resonant circuit.

An example of a buck ZVS-MRC is shown in Fig. 16.15. Depending on the ratio of the resonant capacitance C_D/C_S, two possible topological modes, namely mode I and mode II, can be operated [19]. The ratio affects the time at which the voltages across the switch S and the output diode D_f become zero. Their waveforms are shown in Figs. 16.16a and b, respectively. If diode voltage V_D falls to zero earlier than the switch

FIGURE 16.14 Multi-resonant switches: (a) ZC-MR switch and (b) ZV-MR switch.
FIGURE 16.15 Buck ZVS-MRC.
FIGURE 16.16   Possible modes of the buck ZVS-MRC: (a) mode I and (b) mode II.

voltage V_S, the converter will follow mode I. Otherwise, the converter will follow mode II.

Instead of having one resonant stage, there are three in this converter. The mode I operation in Fig. 16.16a is described first. Before the switch S is turned on, the output diode D_f is conducting and the resonant inductor current I_{Lr} is negative (flowing through the anti-parallel diode of S). S is then turned on with ZVS. The resonant inductor current I_{Lr} increases linearly and D_f is still conducting. When I_{Lr} reaches the output current I_o, the first resonant stage starts. The resonant circuit is formed by the resonant inductor L_r and the capacitor C_D across the output diode. This stage ends when S is turned off with ZVS. Then, a second resonant stage starts. The resonant circuit consists of L_r, C_D, and the capacitor across the switch C_s. This stage ends when the output diode becomes forward biased. A third resonant stage will then start. L_r and C_s form the resonant circuit. This stage ends and completes one operation cycle when the diode C_s becomes forward biased.

The only difference between mode I and mode II in Fig. 16.16b is in the third resonant stage, in which the resonant circuit is formed by L_r and C_D. This stage ends when D_f becomes forward biased. The concept of the multi-resonant switch can be applied to conventional converters [19–21]. A family of MRCs are shown in Fig. 16.17.

Although the variation of the switching frequency for regulation in MRCs is smaller than that of QRCs, a wide-band frequency modulation is still required. Hence, the optimal design of magnetic components and the EMI filters in MRCs is not easy. It would be desirable to have a constant switching frequency operation. In order to operate the MRCs with constant switching frequency, the diode in Fig. 16.14 can be replaced with an active switch S_2 [22]. A constant-frequency multi-resonant (CF-MR) switch is shown in Fig. 16.18. The output voltage is regulated by controlling the on-time of the two switches. This concept can be illustrated with the buck converter as shown in Fig. 16.19, together with the gate drive waveforms and operating stages. S_1 and S_2 are turned on during the time when currents flow through the anti-parallel diodes of S_1 and S_2. This stage ends when S_2 is turned off with ZVS. The first resonant stage is then started. L_r and C_{S2} form the resonant circuit. A second resonant stage begins. L_r resonates with C_{S1} and C_{S2}. The voltage across S_1 oscillates to zero. When I_{Lr} becomes negative, S_1 will be turned on with ZVS. Then, L_r resonates with C_{S2}. S_2 will be turned on when current flows through D_{S2}. As the output voltage is the average voltage across S_2, output voltage regulation is achieved by controlling the conduction time of S_2.

All switches in MRCs operate with ZVS, which reduces the switching losses and switching noise and eliminates the oscillation due to the parasitic effects of the components (such as the junction capacitance of the diodes). However, all switches are under high current and voltage stresses, resulting in an increase in the conduction loss.

16.7 Zero-voltage-transition (ZVT) Converters

By introducing a resonant circuit in parallel with the switches, the converter can achieve ZVS for both power switch and diode without significantly increasing their voltage and current

stresses [23]. Figure 16.20a shows a buck type ZVT-PWM converter and Fig. 16.20b shows the associated waveforms. The converter consists of a main switch S and an auxiliary switch S_1. It can be seen that the voltage and current waveforms of the switches are square-wave-like except during turn-on and turn-off switching intervals, where ZVT takes place. The main switch and the output diode are under ZVS and are subjected to low voltage and current stresses. The auxiliary switch is under ZCS, resulting in low switching loss.

The concept of ZVT can be extended to other PWM circuits by adding the resonant circuit. Some basic ZVT-PWM converters are shown in Fig. 16.21.

16.8 Non-dissipative Active Clamp Network

The active-clamp circuit can utilize the transformer leakage inductance energy and can minimize the the turn-off voltage stress in the isolated converters. The active clamp circuit provides a means of achieving ZVS for the power switch and reducing the rate of change of the diode's reverse recovery current. An example of a flyback converter with active clamp is shown in Fig. 16.22a and the circuit waveforms are shown in Fig. 16.22b. Clamping action is obtained by using a series combination of an active switch (i.e. S_2) and a large capacitor so that the voltage across the main switch (i.e. S_1) is clamped to a minimum value. S_2 is turned on with ZVS. However, S_2 is turned off with finite voltage and current, and has turn-off switching loss. The clamp-mode ZVS-MRCs is discussed in [24–26].

16.9 Load Resonant Converters

Load resonant converters (LRCs) have many distinct features over conventional power converters. Due to the soft commutation of the switches, no turn-off loss or stress is present. LRCs are specially suitable for high-power applications because they allow high-frequency operation for equipment size/weight reduction, without sacrificing the conversion efficiency and imposing extra stress on the switches. Basically, LRCs can be divided into three different configurations, namely series resonant converters, parallel resonant converters, and series–parallel resonant converters.

16.9.1 Series Resonant Converters

Series resonant converters (SRCs) have their load connected in series with the resonant tank circuit, which is formed by L_r and C_r [15, 27–29]. The half-bridge configuration is shown in Fig. 16.23. When the resonant inductor current i_{Lr} is positive, it flows through T_1 if T_1 is on; otherwise it flows through the diode D_2. When i_{Lr} is negative, it flows through T_2 if T_2 is on;

(a)

(b)
FIGURE 16.20 Buck ZVT-PWM converter: (a) circuit schematics and (b) waveforms.

otherwise it flows through the diode D_1. In the steady-state symmetrical operation, both the active switches are operated in a complementary manner. Depending on the ratio between the switching frequency ω_S and the converter resonant frequency ω_r, the converter has several possible operating modes.

A. Discontinuous Conduction Mode (DCM) with $\omega_S < 0.5\omega_r$

Figure 16.24a shows the waveforms of i_{Lr} and the resonant capacitor voltage v_{Cr} in this mode of operation. From 0 to t_1, T_1 conducts. From t_1 to t_2, the current in T_1 reverses its direction. The current flows through D_1 and back to the
FIGURE 16.21 Conventional ZVT-PWM converters.

supply source. From t_2 to t_3, all switches are in the off state. From t_3 to t_4, T_2 conducts. From t_4 to t_5, the current in T_2 reverses its direction. The current flows through D_2 and back to the supply source. T_1 and T_2 are switched on under ZCS condition and they are switched off under zero-current and zero-voltage conditions. However, the switches are under high current stress in this mode of operation and thus have higher conduction loss.

B. Continuous Conduction Mode (CCM) with

$0.5\omega_r < \omega_S < \omega_r$

Figure 16.24b shows the circuit waveforms. From 0 to t_1, i_{Lr} transfers from D_2 to T_1. T_1 is switched on with finite switch current and voltage, resulting in turn-on switching loss. Moreover, the diodes must have good reverse recovery characteristics in order to reduce the reverse recovery current. From t_1 to t_2, D_1 conducts and T_1 is turned off softly with zero voltage and zero current. From t_2 to t_3, T_2 is switched on with finite switch current and voltage. At t_3, T_2 is turned off softly and D_2 conducts until t_4.

C. Continuous Conduction Mode (CCM) with $\omega_r < \omega_S$

Figure 16.24c shows the circuit waveforms. From 0 to t_1, i_{Lr} transfers from D_1 to T_1. Thus, T_1 is switched on with zero

current and zero voltage. At t_1, T_1 is switched off with finite voltage and current, resulting in turn-off switching loss. From t_1 to t_2, D_2 conducts. From t_2 to t_3, T_2 is switched on with zero current and zero voltage. At t_3, T_2 is switched off. i_{Lr} transfers from T_2 to D_1. As the switches are turned on with ZVS, lossless snubber capacitors can be added across the switches.

The following parameters are defined: voltage conversion ratio M, characteristic impedance Z_r, resonant frequency f_r, normalized load resistance r, normalized switching frequency γ.

$$M = nV_o/V_{in} \tag{16.2a}$$

$$Z_r = \sqrt{L_r/C_r} \tag{16.2b}$$

$$f_r = 1/\left(2\pi\sqrt{L_r C_r}\right) \tag{16.2c}$$

$$r = n^2 R_L/Z_r \tag{16.2d}$$

$$\gamma = f_s/f_r \tag{16.2e}$$

$$M = 1\left/\sqrt{(\gamma - 1/\gamma)^2/(r^2 + 1)}\right. \tag{16.2f}$$

The relationships between M and γ for different value of r are shown in Fig. 16.25. The boundary between CCM and DCM

(a)

(b)
FIGURE 16.22   Active-clamp flyback converter: (a) circuit schematics and (b) circuit waveforms.
FIGURE 16.23   SRC half-bridge configuration.

is at $r = 1.27\gamma$. When the converter is operating in DCM and $0.2 < \gamma < 0.5$, $M = 1.27\, r\gamma$.

The SRC has the following advantages. Transformer saturation can be avoided since the series capacitor can block the dc component. The light load efficiency is high because the device current and conduction loss are low. However, the major disadvantages are that there is difficulty in regulating the output voltage under light load and no load conditions. Moreover, the output dc filter capacitor has to carry high ripple current, which could be a major problem in low-output voltage and high-output current applications [29].

16.9.2   Parallel Resonant Converters

Parallel resonant converters (PRCs) have their load connected in parallel with the resonant tank capacitor C_r [27–30]. The half-bridge configuration is shown in Fig. 16.26. SRC behaves as a current source, whereas the PRC acts as a voltage source. For voltage regulation, PRC requires a smaller operating frequency range than the SRC to compensate for load variation.

A. Discontinuous Conduction Mode (DCM)

The steady-state waveforms of the resonant inductor current i_{Lr} and the resonant capacitor voltage v_{Cr} are shown in Fig. 16.27a. Initially both i_{Lr} and v_{Cr} are zero. From 0 to t_2, T_1 conducts and is turned on with zero current. When i_{Lr} is less than the output current I_o, i_{Lr} increases linearly from 0 to t_1 and the output current circulates through the diode bridge. From t_1 to t_3, L_r resonates with C_r. Starting from t_2, i_{Lr} reverses its direction and flows through D_1. T_1 is then turned off with zero current and zero voltage. From t_3 to t_4, v_{Cr} decreases linearly due to the relatively constant value of I_o. At t_4, when v_{Cr} equals zero, the output current circulates through the diode bridge again. Both i_{Lr} and v_{Cr} will stay at zero for an interval. From t_5 to t_9, the above operations will be repeated for T_2 and D_2. The output voltage is controlled by adjusting the time interval of $[t_4, t_5]$.

B. Continuous Conduction Mode $\omega_S < \omega_r$

This mode is similar to the operation in the DCM, but with a higher switching frequency. Both i_{Lr} and v_{Cr} become continuous. The waveforms are shown in Fig. 16.27b. The switches T_1 and T_2 are hard turned on with finite voltage and current and are soft turned off with ZVS.

C. Continuous Conduction Mode $\omega_S > \omega_r$

If the switching frequency is higher than ω_r (Fig. 16.27c), the anti-parallel diode of the switch will be turned on before the switch is triggered. Thus, the switches are turned on with ZVS. However, the switches are hard turned off with finite current and voltage.

The parameters defined in Eq. (16.2) are applicable. The relationships between M and γ for various values of r are shown in Fig. 16.28. During the DCM (i.e. $\gamma < 0.5$), M is in linear relationship with γ. Output voltage regulation can be achieved easily. The output voltage is independent on the output current. The converter shows a good voltage source characteristics. It is also possible to step up and step down the input voltage.

The PRC has the advantages that the load can be short-circuited and the circuit is suitable for low-output voltage, high-output current applications. However, the major disadvantage of the PRC is the high device current. Moreover, since the device current do not decrease with the load, the efficiency drops with a decrease in the load [29].

16.9.3   Series–Parallel Resonant Converter

Series–Parallel Resonant Converter (SPRC) combines the advantages of the SRC and PRC. The SPRC has an additional capacitor or inductor connected in the resonant tank circuit [29–31]. Figure 16.29a shows an LCC-type SPRC, in which an additional capacitor is placed in series with the resonant inductor. Figure 16.29b shows an LLC-type SPRC, in which an additional inductor is connected in parallel with the resonant capacitor in the SRC. However, there are many possible combinations of the resonant tank circuit. Detailed analysis can be found in [31].

16.10   Control Circuits for Resonant Converters

Since the 1985s, various control integrated circuits (ICs) for resonant converters have been developed. Some common ICs for different converters are described in this section.

16.10.1   QRCs and MRCs

Output regulations in many resonant-type converters, such as QRCs and MRCs, are achieved by controlling the
FIGURE 16.24   Circuit waveforms under different operating conditions: (a) $\omega_S < 0.5\,\omega_r$; (b) $0.5\,\omega_r < \omega_S < \omega$; and (c) $\omega_r < \omega_S$.
FIGURE 16.25 M vs γ in SRC.
FIGURE 16.26   PRC half-bridge configuration.

switching frequency. ZCS applications require controlled switch-on times while ZVS applications require controlled switch-off times. The fundamental control blocks in the IC include an error amplifier, voltage controlled oscillator (VCO), one shot generator with a zero wave-crossing detection comparator, and an output stage to drive the active switch. Typical ICs include UC1861–UC1864 for ZVS applications and UC 1865–UC 1868 for ZCS applications [32]. Figure 16.30 shows the controller block diagram of UC 1864.

The maximum and minimum switching frequencies (i.e. f_{max} and f_{min}) are controlled by the resistors R_{ange} and R_{min} and the capacitor C_{vco}. f_{max} and f_{min} can be expressed as

$$f_{max} = \frac{3.6}{(R_{ange}//R_{min})C_{VCO}} \quad \text{and} \quad f_{min} = \frac{3.6}{R_{min}C_{VCO}}$$
(16.3)

The frequency range Δf is then equal to

$$\Delta f = f_{max} - f_{min} = \frac{3.6}{R_{ange}C_{VCO}}$$
(16.4)

The frequency range of the ICs is from 10 kHz to 1 MHz. The output frequency of the oscillator is controlled by the error

amplifier (E/A) output. An example of a ZVS-MR forward converter is shown in Fig. 16.31.

16.10.2 Phase-shifted, ZVT FB Circuit

The UCC3895 is a phase shift PWM controller that can generate a phase shifting pattern of one half-bridge with respect to the other. The application diagram is shown in Fig. 16.32.

The four outputs "OUTA," "OUTB," "OUTC," and "OUTD" are used to drive the MOSFETs in the full-bridge. The dead time between "OUTA" and "OUTB" is controlled by "DELAB" and the dead time between "OUTC" and "OUTD" is controlled by "DELCD." Separate delays are provided for the two half-bridges to accommodate differences in resonant capacitor charging currents. The delay in each set is approximated by

$$t_{DELAY} = \frac{25 \times 10^{-12}R_{DEL}}{0.75(V_{CS} - V_{ADS}) + 0.5} + 25 \ ns$$
(16.5)

where R_{DEL} is the resistor value connected between "DELAB" or "DELCD" to ground.

The oscillator period is determined by R_T and C_T. It is defined as

$$t_{OSC} = \frac{5R_TC_T}{48} + 120 \ ns$$
(16.6)

The maximum operating frequency is 1 MHz. The phase shift between the two sets of signals is controlled by the ramp voltage and the error amplifier output having a 7 MHz bandwidth.

16.11 Extended-period Quasi-resonant (EP-QR) Converters

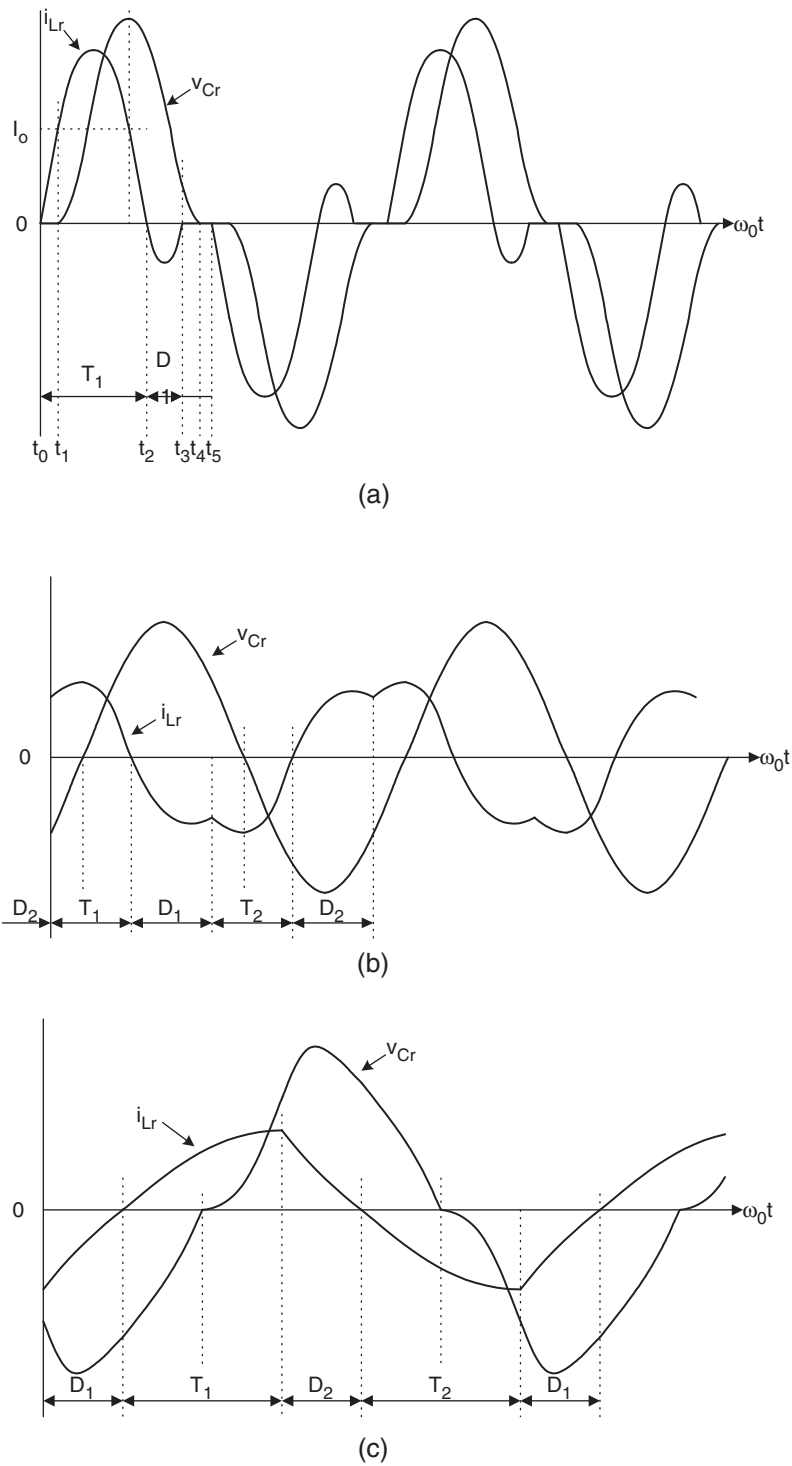
Generally, resonant and quasi-resonant converters operate with frequency control. The extended-period quasi-resonant converters proposed by Barbi [33] offer a simple solution to modify existing hard-switched converters into soft-switched ones with constant frequency operation. This makes both output filter design and control simple. Figure 16.33 shows a standard hard-switched boost type PFC converter. In this hard-switched circuit, the main switch SW1 could be subject to significant switching stress because the reverse recovery current of the diode D_F could be excessive when SW1 is turned on. In practice, a small saturable inductor may be added in series with the power diode D_F in order to reduce the di/dt of the reverse-recovery current. In addition, an optional $R–C$ snubber may be added across SW1 to reduce the dv/dt of SW1. These extra reactance components can in fact be used in the EP-QR circuit to achieve soft switching, as shown in Fig. 16.34. The resonant components L_r and C_r are of small


FIGURE 16.27   Circuit waveforms under different operating conditions: (a) discontinuous conduction mode; (b) continuous conduction mode $\omega_S < \omega_r$; and (c) continuous conduction mode $\omega_S > \omega_r$.
FIGURE 16.28 M vs γ in PRC.

values and can come from the snubber circuits of a standard hard-switched converter. Thus, the only additional component is the auxiliary switch Q2. The small resonant inductor is put in series with the main switch SW1 so that SW1 can be switched on under ZC condition and the di/dt problem of the reverse-recovery current be eliminated. The resonant capacitor C_r is used to store energy for creating condition for soft switching. Q2 is used to control the resonance during the main switch transition. It should be noted that all power devices including SW1, Q1 and main power diode D_F are turned on and off under ZV and/or ZC conditions. Therefore, the large di/dt problem due to the reverse recovery of the power diode can be eliminated. The soft-switching method is an effective technique for EMI suppression.

Together with power factor correction technique, soft-switching converters offer a complete solution to meet EMI regulations for both conducted and radiated EMI. The operation of the EP-QR boost PFC circuit [34, 35] can be described in six modes as shown in Fig. 16.35. The corresponding idealized waveforms are included in Fig. 16.36.

A. Circuit Operation

Interval I: (t_0–t_1)   Due to the resonant inductor L_r which limits the di/dt of the switch current, switch SW1 is turned on at zero-current condition with a positive gating signal V_{GS1} to start a switching cycle at $t = t_0$. Current in D_F is diverted to inductor L_r. Because D_F is still conducting during this short period, D_{S2} is still reverse biased and is thus not conducting. The equivalent circuit topology for the conducting paths is shown in Fig. 16.35a. Resonant switch Q_2 remains off in this interval.

Interval II: (t_1–t_a)   When D_F regains its blocking state, D_{S2} becomes forward biased. The first half of the resonance cycle occurs and resonant capacitor C_r starts to discharge and current flows in the loop C_r–Q_2–L_r–SW_1. The resonance half-cycle stops at time $t = t_a$ because D_{S2} prevents the loop

current i_{Cr} from flowing in the opposition direction. The voltage across C_r is reversed at the end of this interval. The equivalent circuit is shown in Fig. 16.35b.

Interval III: (t_a–t_b)   Between t_a and t_b, current in L_F and L_r continues to build up. This interval is the extended-period for the resonance during which energy is pumped into L_r. The corresponding equivalent circuit is showed in Fig. 16.35c.

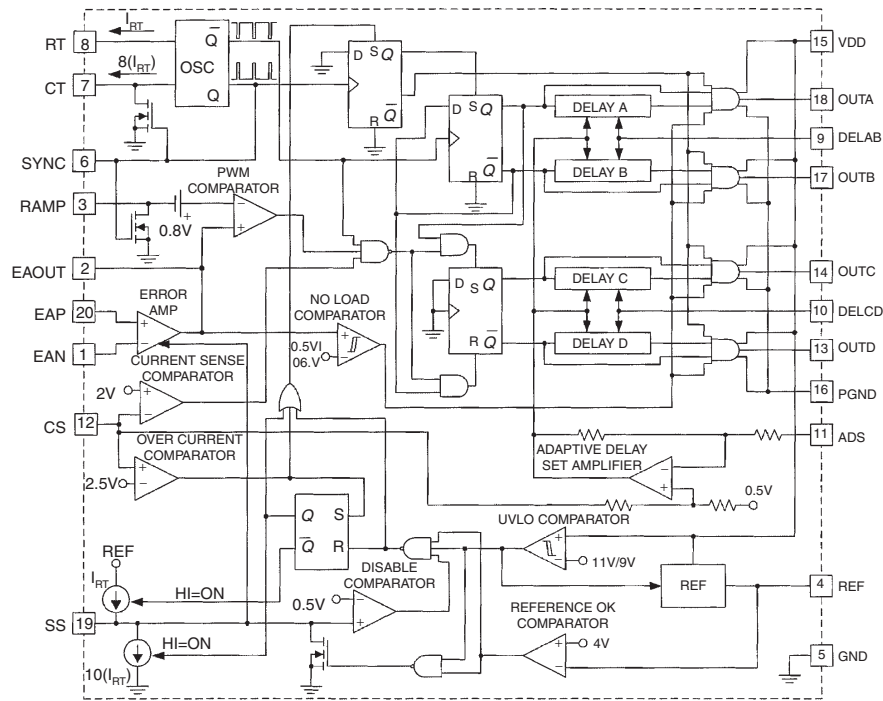
Interval IV: (t_b–t_2)   Figure 16.35d shows the equivalent circuit for this operating mode. Before SW_1 is turned off, the second half of the resonant cycle needs to take place in order that a zero-voltage condition can be created for the turn-off process of SW_1. The second half of the resonant cycle starts when auxiliary switch Q_2 is turned on at $t = t_b$. Resonant current then flows through the loop L_r–Q_2–C_r-anti-parallel diode


FIGURE 16.32   Application diagram of UCC3895 (Courtesy of Unitrode Corp. and Texas Instruments).
FIGURE 16.33   Boost-type AC–DC power factor correction circuit.
FIGURE 16.34   EP-QR boost-type AC–DC power factor correction circuit.

of SW_1. This current is limited by L_r and thus Q_2 is turned on under zero-current condition. Since the anti-parallel diode of SW_1 is conducting, the voltage across SW_1 is clamped to the on-state voltage of the anti-parallel diode. SW_1 can therefore be turned off at (near) zero-voltage condition before $t = t_2$ at which the second half of the resonant cycle ends.

Interval V: (t_2-t_3)   During this interval, the voltage across C_r is less than the output voltage V_o. Therefore D_F is still reverse

biased. Inductor current I_s flows into C_r until V_{Cr} reaches V_o at $t = t_3$. The equivalent circuit is represented in Fig. 16.35e.

Interval VI: (t_3-t_4)   During this period, the resonant circuit is not in action and the inductor current I_s charges the output capacitor C_F via D_F, as in the case of a classical boost-type PFC circuit. C_r is charged to V_o, therefore Q_2 can be turned off at zero-voltage and zero-current conditions. Figure 16.35f shows the equivalent topology of this operating mode.

In summary, SW1, Q2, and D_F are fully soft-switched. Since the two resonance half-cycles take place within a closed loop outside the main inductor, the high resonant pulse will not occur in the inductor current, thus making a well-established averaged current mode control technique applicable for such QR circuit. For full soft-switching in the turn-off process, the resonant components need to be designed so that the peak resonant current exceeds the maximum value of the inductor current. Typical measured switching waveforms and trajectories of SW1, Q2 and D_F are shown in Figs. 16.37, 16.38, and 16.39, respectively.

B. Design Procedure

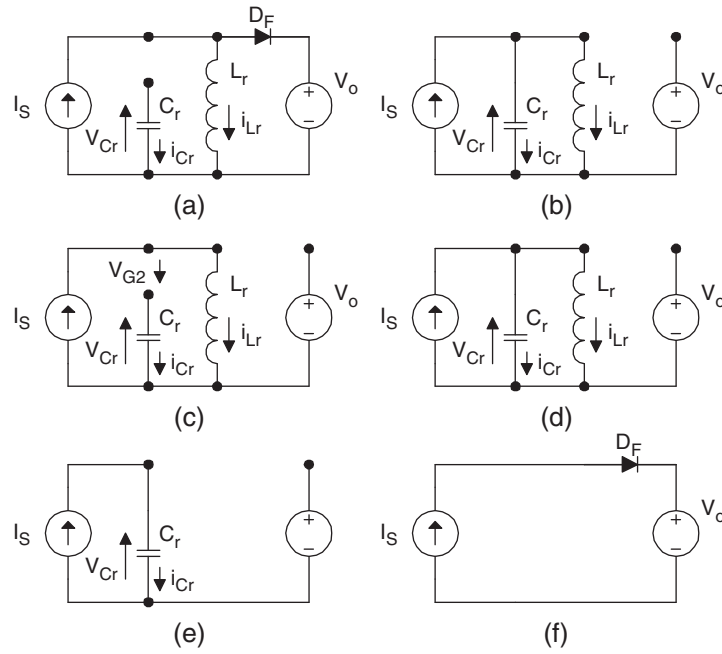
Given: Input AC voltage $= V_s$ (V)
  Peak AC voltage $= V_s(max)$ (V)
  Nominal output DC voltage $= V_o$ (V)
  Switching frequency $= f_{sw}$ (Hz)
  Output power $= P_o$ (W)


FIGURE 16.35 Operating modes of EP-QR boost-type AC–DC power factor correction circuit.
FIGURE 16.36 Idealized waveforms of EP-QR boost-type AC–DC power factor correction circuit.
FIGURE 16.37   (a) Drain-source voltage and current of SW1 and (b) switching locus of SW1.
FIGURE 16.38   (a) Drain-source voltage and current of Q2 and (b) switching locus of Q2.
FIGURE 16.39   (a) Diode voltage and current and (b) switching locus of diode.

Input current ripple $= \Delta I$ (A)
Output voltage ripple $= \Delta V$ (V)

(I) Resonant tank design:
Step 1: Because the peak resonant current must be greater than the peak inductor current (same as peak input line current) in order to achieve soft-turn-off, it is necessary to determine the peak input current $I_s(max)$. Assuming lossless AC–DC power conversion, $I_s(max)$ can be estimated from the following equation

$$I_{s(max)} \approx \frac{2V_o I_o}{V_{s(max)}} \qquad (16.7)$$

where $I_o = P_o/V_o$ is the maximum output current.
Step 2: Soft-switching criterion is

$$Z_r \leq \frac{V_o}{I_{s(max)}} \qquad (16.8)$$

where $Z_r = \sqrt{\frac{L_r}{C_r}}$ is the impedance of the resonant tank.

For a chosen resonant frequency f_r, L_r, and C_r can be obtained from:

$$2\pi f_r = \frac{1}{\sqrt{L_r C_r}} \qquad (16.9)$$

(II) Filter component design:
The minimum conversion ratio is

$$M_{(min)} = \frac{V_o}{V_{s(max)}}$$

$$= \frac{1}{1 - \left(\frac{f_{sw}}{f_r} + \frac{t_e}{T_{sw}} \right)} \qquad (16.10)$$

where $T_{sw} = 1/f_{sw}$ and t_e is the extended period. From Eq. (16.10), minimum t_e can be estimated.

The turn-on period of the SW1 is

$$T_{on}(sw1) = t_e + 1/f_r \qquad (16.11)$$

Inductor value L is obtained from:

$$L \geq \left(\frac{T_{on(sw1)}}{\Delta I} \right) V_{s(max)} \qquad (16.12)$$

The filter capacitor value C can be determined from:

$$C \left(\frac{\Delta V}{\frac{T_s}{\pi} \sin^{-1} \left(\frac{I_o}{I_{s(max)}} \right)} \right) = I_o \qquad (16.13)$$

where $T_s = 1/f_s$ is the period of the AC voltage supply frequency.

16.11.1 Soft-switched DC–DC Flyback Converter

A simple approach that can turn an existing hard-switched converter design into a soft-switched one is shown in Fig. 16.40. The key advantage of the proposal is that many well proven and reliable hard-switched converter designs can be kept. The modification required is the addition of a simple circuit (consisting an auxiliary winding, a switch, and a small capacitor) to an existing isolated converter [36]. This principle, which is the modified version of the EPQR technique for isolated converter, is demonstrated in an isolated soft-switched flyback converter with multiple outputs. Other advantageous features of the proposal are:

- All switches and diodes of the converter are 'fully' soft-switched, i.e. soft-switched at both turn-on and turn-off transitions under zero-voltage and/or zero-current conditions.
- The leakage inductance of each winding in the flyback transformer forms part of the resonant circuit for achieving ZVS and ZCS of all switches and diodes.
- The control technique is simply PWM-based as in standard hard-switched converters.
- The soft-switched technique is a proven method for EMI reduction [37].

16.11.2 A ZCS Bidirectional Flyback DC–DC Converter

A bi-directional flyback dc–dc converter that uses one auxiliary circuit for both power flow directions is proposed in Fig. 16.41 [38]. The methodology is based on extending the unidirectional soft-switched flyback converter in [36] and replacing the output diode with a controlled switch, which acts as either a rectifier [39] or a power control switch in the corresponding power flow direction. An auxiliary circuit that consists of a winding in the coupled inductor, a switch, and a capacitor converts the hard-switched design into a soft-switched one. The operation is the same as [36] in the forward mode. An extended-period resonant stage [34] is introduced when the power control switch is on. Conversely, in the reverse mode, a complete resonant stage is initiated before the main switch is off. In both the power flow operations, the leakage inductance of the coupled inductor is used to create zero-current switching conditions for all switches.

16.12 Soft-switching and EMI Suppression

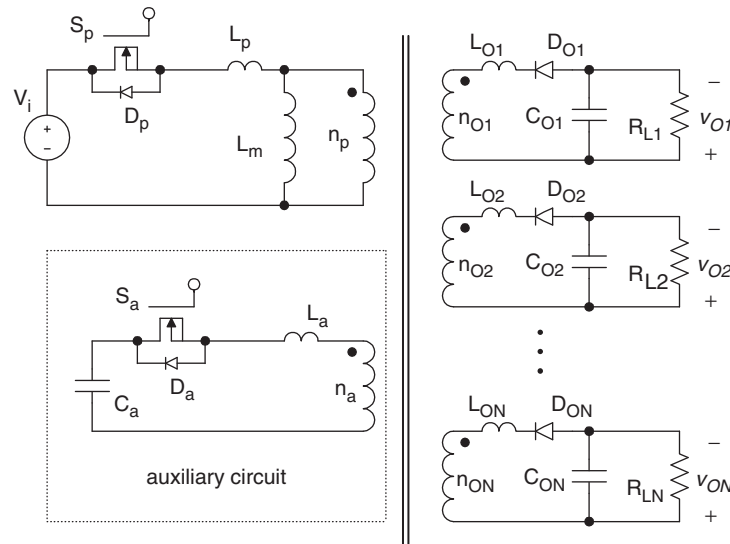
A family of EP-QR converters are displayed in Fig. 16.42. Their radiated EMI emission have been compared with that from their hard-switched counterparts [37]. Figures 16.43a, b show the conducted EMI emission from a hard-switched flyback


FIGURE 16.40   Fully soft-switched isolated flyback converter.
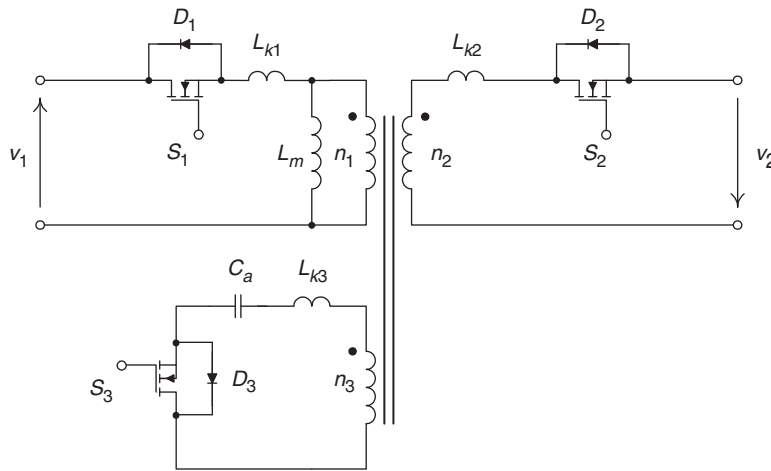

FIGURE 16.41   Bidirectional soft-switched isolated flyback converter.

converter and a soft-switched one, respectively. Their radiated EMI emissions are included in Fig. 16.44. Both converters are tested at an output power of 50 W. No special filtering or shielding measures have been taken during the measurement. It is clear from the measurements that soft-switching is an effective means to EMI suppression.

16.13 Snubbers and Soft-switching for High Power Devices

Today, most of the medium power (up to 200 kVA) and medium voltage (up to 800 V) inverter are hard-switched. Compared with low-power switched mode power supplies, the high voltage involved in the power inverters makes the *dv/dt*,

di/dt, and the switching stress problems more serious. In addition, the reverse recovery of power diodes in the inverter leg may cause very sharp current spike, leading to severe EMI problem. It should be noted that some high power devices such as GTO thyristors do not have a square safe operating area (SOA). It is therefore essential that the switching stress they undergone must be within their limits. Commonly used protective measures are to use snubber circuits for protecting high power devices.

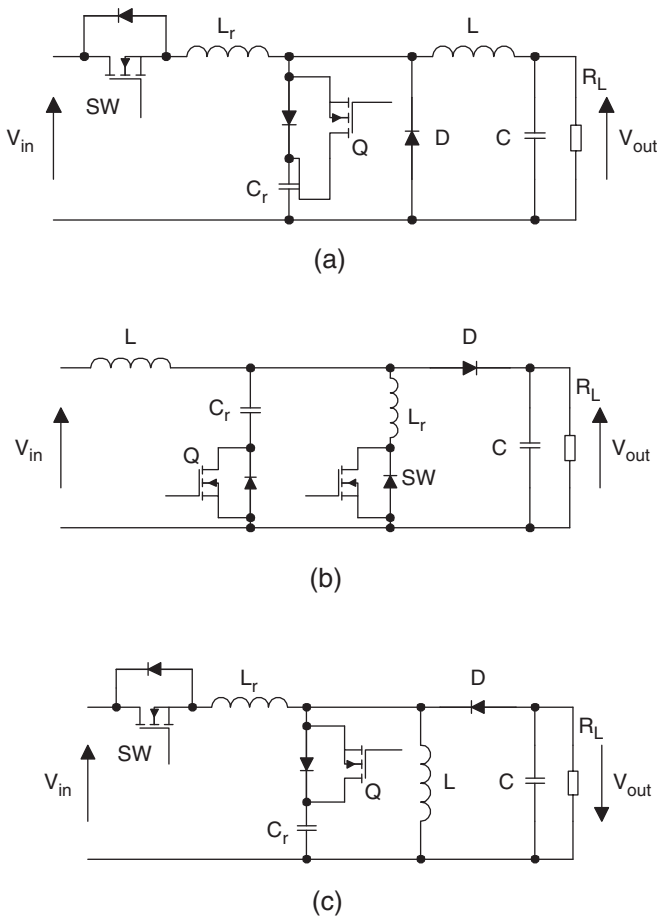
Among various snubbers, two snubber circuits are most well-known for applications in power inverters. They are the Undeland snubber [40] (Fig. 16.45) and McMurray snubber circuits [41] (Fig. 16.46). The Undeland snubber is an asymmetric snubber circuit with one turn-on inductor and one turn-off capacitor. The turn-off snubber capacitor C_s is clamped by another capacitor C_c. At the end of each switching


FIGURE 16.42   A family of EP-QR converters: (a) buck converter;
(b) boost converter; and (c) flyback converter.

cycle, the snubber energy is dumped into C_c and then discharged into the dc bus via a discharge resistor. In order to reduce the snubber loss, the discharge resistor can be replaced by a switched mode circuit. In this way, the Undeland snubber can become a snubber with energy recovery. The McMurray

snubber is symmetrical. Both the turn-off snubber capacitors share current in parallel during turn off. The voltage transient is limited by the capacitor closest to the turning-off device because the stray inductance to the other capacitor will prevent instantaneous current sharing. The turn-on inductors require mid-point connection. Snubber energy is dissipated into the snubber resistor. Like the Undeland snubber, the McMurray snubber can be modified into an energy recovery snubber. By using an energy recovery transformer as shown in Fig. 16.47, this snubber becomes a regenerative one. Although other regenerative circuits have been proposed, their complexity makes them unattractive in industrial applications. Also, they do not necessarily solve the power diode reverse-recovery problems.

Although the use of snubber circuits can reduce the switching stress in the power devices, the switching loss is actually damped into the snubber resistors unless regenerative snubbers are used. The switching loss is still a limiting factor to the high frequency operation of power inverters. However, the advent of soft-switching techniques opens a new way to high-frequency inverter operation. Because the switching trajectory of a soft-switched switch is close to the voltage and current axis, faster power electronic devices with smaller SOAs can in principle be used. In general, both ZVS and ZCS can reduce switching loss in high-power power switches. However, for power switches with tail currents, such as IGBT, ZCS is more effective than ZVS.

16.14 Soft-switching DC–AC Power Inverters

Soft-switching technique not only offers a reduction in switching loss and thermal requirement, but also allows the possibility of high frequency and snubberless operation. Improved circuit performance and efficiency, and reduction of EMI emission can be achieved. For zero-voltage switching (ZVS) inverter applications, two major approaches which enable
FIGURE 16.43   (a) Conducted EMI from hard-switched flyback converter and (b) radiated EMI from hard-switched flyback converter.
FIGURE 16.44   (a) Conducted EMI from soft-switched flyback converter and (b) radiated EMI from soft-switched flyback converter.
FIGURE 16.45   Undeland snubber.
FIGURE 16.46   McMurray snubber.
FIGURE 16.47   McMurray snubber with energy recovery.

inverters to be soft-switched have been proposed. The first approach pulls the dc link voltage to zero momentarily so that the inverter's switches can be turned on and off with ZVS. Resonant dc link and quasi-resonant inverters belong to this category. The second approach uses the resonant pole idea. By incorporating the filter components into the inverter operation, resonance condition and thus zero voltage/current conditions can be created for the inverter switches.

In this section, the following soft-switched inverters are described.

Approach 1: Resonant dc link inverters

1. Resonant (pulsating) dc link inverters
2. Actively-clamped resonant dc link inverters
3. Resonant inverters with minimum voltage stress
4. Quasi-resonant soft-switched inverter
5. Parallel resonant dc link inverter.

Approach 2: Resonant pole inverters

1. Resonant pole inverters
2. Auxiliary resonant pole inverters
3. Auxiliary resonant commutated pole inverters.

Type 1 is the resonant dc link inverter [42–44] which sets the dc link voltage into oscillation so that the zero-voltage instants are created periodically for ZVS. Despite the potential advantages that this soft-switching approach can offer, a recent review on existing resonant link topologies for inverters [45] concludes that the resonant dc link system results in an increase in circuit complexity and the frequency spectrum is restricted by the need of using integral pulse density modulation (IPDM) when compared with a standard hard-switched inverter. In addition, the peak pulsating link voltage of resonant link inverters is twice the dc link voltage in a standard hard-switched inverter. Although clamp circuits (Type 2) can be used to limit the peak voltage to 1.3–1.5 per unit [44], power devices with higher than normal voltage ratings have to be used.

Circuits of Type 3–5 employ a switched mode front stage circuit which pulls the dc link voltage to zero momentarily whenever inverter switching is required. This soft-switching approach does not cause extra voltage stress to the inverter and hence the voltage rating of the power devices is only 1 per unit. As ZVS conditions can be created at any time, there is virtually no restriction in the PWM strategies. Therefore, well established PWM schemes developed in the last two decades can be employed. In some ways, this approach is similar to some dc-side commutation techniques proposed in the past for thyristor inverters [46, 47], although these dc-side commutation techniques were used for turning off thyristors in the inverter bridge and were not primarily developed for soft-switching.

Circuits of Type 6–8 retain the use of a constant dc link voltage. They incorporate the use of the resonant components and/or filter components into the inverter circuit operation. This approach is particularly useful for inverter applications in which output filters are required. Examples include uninterruptible power supplies (UPS) and inverters with output filters for motor drives. The LC filter components can form the auxiliary resonant circuits that create the soft-switching conditions. However, these tend to have high power device count and require complex control strategy.

16.14.1 Resonant (Pulsating) DC Link Inverter

Resonant DC link converter for DC–AC power conversion was proposed in 1986 [42]. Instead of using a nominally constant DC link voltage, a resonant circuit is added to cause the DC link voltage to be pulsating at a high frequency. This resonant circuit theoretically creates periodic zero-voltage duration at which the inverter switches can be turned on or off. Figure 16.48 shows the schematics of the pulsating link inverter. Typical dc link voltage, inverter's phase voltage and the line voltages are shown in Fig. 16.49. Because the inverter switching can only occur at zero voltage duration, integral pulse density modulation (IPDM) has to be adopted in the switching strategy.

Analysis of the resonant dc link converter can be simplified by considering that the inverter system is highly inductive. The equivalent circuit is shown in Fig. 16.50.

The link current I_x may vary with the changing load condition, but can be considered constant during the short resonant cycle. If switch S is turned on when the inductor current is I_{Lo}, the resonant dc link voltage can be expressed as

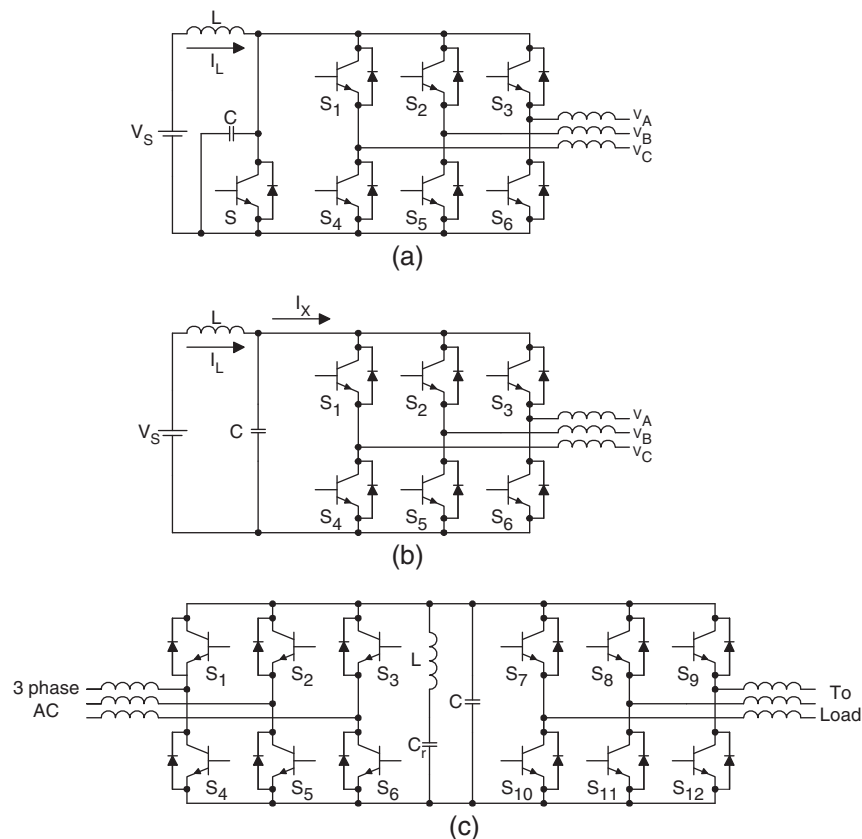
$$V_c(t) = V_s + e^{-\alpha t} \left[-V_s \cos(\omega t) + \omega L I_M \sin(\omega t) \right] \quad (16.14)$$


FIGURE 16.48   Resonant-link inverters.
FIGURE 16.49   Typical dc link voltage (V_0), phase voltages (V_A, V_B), and line voltage (V_{AB}) of resonant link inverters.
FIGURE 16.50   Equivalent circuit of resonant link inverter.

and inductor current i_L is

$$i_L(t) \approx I_x + e^{-\alpha t}\left[I_M \cos(\omega t) + \frac{V_s}{\omega L}\sin(\omega t)\right] \qquad (16.15)$$

where $\alpha = \dfrac{R}{2L}$ \hfill (16.16)

$\omega_o = (LC)^{-0.5}$ \hfill (16.17)

$\omega = \left(\omega_o^2 - \alpha^2\right)^{0.5}$ \hfill (16.18)

and $I_M = I_{Lo} - I_x$ \hfill (16.19)

The resistance in the inductor could affect the resonant behavior because it dissipates some energy. In practice, $(i_L - I_x)$ has to be monitored when S is conducting. S can be turned on when $(i_L - I_x)$ equal to a desired value. The objective is to ensure that the dc link voltage can be resonated to zero voltage level in the next cycle.

The pulsating dc link inverter has the following advantages:

- Reduction of switching loss.
- Snubberless operation.

- High switching frequency (> 18 kHz) operation becomes possible, leading to the reduction of acoustic noise in inverter equipment.
- Reduction of heatsink requirements and thus improvement of power density.

This approach has the following limitations:

- The peak dc pulsating link voltage (2.0 per unit) is higher than the nominal dc voltage value of a conventional inverter. This implies that power devices and circuit components of higher voltage ratings must be used. This could be a serious drawback because power components of higher voltage ratings are not only more expensive, but usually have inferior switching performance than their low-voltage counterparts.
- Although voltage clamp can be used to reduce the peak dc link voltage, the peak voltage value is still higher than normal and the additional clamping circuit makes the control more complicated.
- Integral pulse-density modulation has to be used. Many well-established PWM techniques cannot be employed.

Despite these advantages, this resonant converter concept has paved the way for other soft-switched converters to develop.

16.14.2 Active-clamped Resonant DC Link Inverter

In order to solve the high voltage requirement in the basic pulsating dc link inverters, active clamping techniques (Fig. 16.51) have been proposed. The active clamp can reduce the per-unit peak voltage from 2.0 to about 1.3–1.5 [44]. It has been reported that operating frequency in the range of 60–100 kHz has been achieved [48] with an energy efficiency of 97% for a 50 kVA drive system.
FIGURE 16.51   Active-clamp resonant link inverter.

The design equations for active-clamped resonant link inverter are

$$T_L = \frac{1}{f_L} = 2\sqrt{L_r C_r}\left(\cos^{-1}(1-k) + \frac{\sqrt{k(2-k)}}{k-1}\right) \quad (16.20)$$

where T_L is the minimum link period, f_L is the maximum link frequency, and k is the clamping ratio. For the active-clamped resonant inverter, k is typically 1.3–1.4 per unit.

The rate of rise of the current in the clamping device is

$$\frac{di}{dt} = \frac{(k-1)\,V_s}{L_r} \quad (16.21)$$

The peak clamping current required to ensure that the dc bus return to zero volt is

$$I_{sp} = V_s\sqrt{\frac{k\,(2-k)\,C_r}{L_r}} \quad (16.22)$$

In summary, resonant (pulsating) dc link inverters offer significant advantages such as:

- High switching frequency operation.
- Low dv/dt for power devices.
- ZVS with reduced switching loss.
- Suitable for 1–250 kW.
- Rugged operation with few failure mode.

16.14.3 Resonant DC Link Inverter with Low Voltage Stress [49]

A resonant dc link inverter with low voltage stress is shown in Fig. 16.52. It consists of a front-end resonant converter that can pull the dc link voltage down just before any inverter switching. This resonant dc circuit serves as an interface between the dc power supply and the inverter. It essentially retains all the advantages of the resonant (pulsating) dc link inverters. But it offers extra advantages such as:

- No increase in the dc link voltage when compared with conventional hard-switched inverter. That is, the dc link voltage is 1.0 per unit.
- The zero voltage condition can be created at any time. The ZVS is not restricted to the periodic zero-voltage instants as in resonant dc link inverter.
- Well-established PWM techniques can be employed.
- Power devices of standard voltage ratings can be used.

The timing program and the six operating modes of this resonant circuit are as shown in Figs. 16.53 and 16.54, respectively.
FIGURE 16.53 Timing diagram of resonant link inverter with minimum voltage stress.

(1) *Normal mode:*
This is the standard PWM inverter mode. The resonant inductor current $i_{Lr}(t)$ and the resonant voltage $V_{cr}(t)$ are given by

$$i_{Lr}(t) = 0$$

$$v_{Cr}(t) = V_s$$

where V_s is the nominal dc link voltage.
FIGURE 16.52 Resonant DC link inverter with low voltage stress.
FIGURE 16.54   Operating modes of resonant link inverter with minimum voltage stress.

(2) *Mode 1 (initiating mode): ($t_0 - t_1$)*
At t_0, mode 1 begins by switching on T2 and T3 on with zero current. $i_{Lr}(t)$ increases linearly with a *di/dt* of V_s/L_r. If $i_{Lr}(t)$ is equal to the initialized current I_i, T1 is zero-voltage turned off. If $(I_s - I_o) < I_i$, then the initialization is ended when $i_{Lr}(t)$ is equal to I_i, where I_s is the current flowing into the dc inductor L_{dc}. If $(I_s - I_o) > I_i$, then this mode continues until $i_{Lr}(t)$ is equal to $(I_s - I_o)$. The equations in this interval are

$$i_{Lr}(t) = \frac{V_s}{L_r} t$$

$$v_{Cr}(t) = V_s$$

$$i_{Lr}(t_1) = \frac{V_s}{L_r} t_1 = I_i$$

(3) *Mode 2 (Resonant mode): ($t_1 - t_2$)*
After T1 is turned off under ZVS condition, resonance between L_r and C_r occurs. $V_{cr}(t)$ decreases from V_s to 0. At t_2, $i_{Lr}(t)$ reaches the peak value in this interval. The equations are:

$$i_{Lr}(t) = \frac{V_s}{Z_r} \sin(\omega_r t) + [I_1 + (I_o - I_s)] \cos(\omega_r t) - (I_o - I_s)$$

$$V_{Cr}(t) = -V_s \cos(\omega_r t) - [I_1 + (I_o - I_s)] Z_r \sin(\omega_r t)$$

$$i_{Lr}(t_2) = I_2 = I_{Lr,peak}$$

$$V_{Cr}(t_2) = 0$$

where

$$Z_r = \sqrt{\frac{L_r}{C_r}} \quad \text{and} \quad \omega_r = \frac{1}{\sqrt{L_r C_r}}$$

(4) *Mode 3 (Freewheeling mode): $(t_2 - t_3)$*
The resonant inductor current flows through two freewheeling paths (T2-Lr-D2 and T3-D1-Lr). This duration is the zero voltage period created for ZVS of the inverter, and should be longer than the minimum on and off times of the inverter's power switches.

$$i_{Lr}(t) = I_2$$

$$v_{Cr}(t) = 0$$

(5) *Mode 4 (Resonant mode): $(t_3 - t_4)$*
This mode begins when T2 and T3 are switched off under ZVS. The second half of the resonance between L_r and C_r starts again. The capacitor voltage $V_{cr}(t)$ increases back from 0 to V_s and is clamped to V_s. The relevant equations in this mode are

$$i_{Lr}(t) = [I_2 - (I_{on} - I_s)]\cos(\omega_r t) - (I_{on} - I_s)$$

$$V_{Cr}(t) = [I_2 - (I_{on} - I_s)]Z_r\sin(\omega_r t)$$

$$i_{Lr}(t_4) = I_3$$

$$V_{Cr}(t_4) = V_s$$

where I_{on} is the load current after the switching state.

(6) *Mode 5 (Discharging mode): $(t_4 - t_5)$*
In this period, T1 is switched on under ZV condition because $V_{cr}(t) = V_s$. The inductor current decreases linearly. This mode finishes when $i_{Lr}(t)$ becomes zero.

$$i_{Lr}(t) = -\frac{V_s}{L_r}t + I_3$$

$$v_{Cr}(t) = V_s$$

$$i_{Lr}(t_5) = 0$$

16.14.4 Quasi-resonant Soft-switched Inverter [50]

(A) Circuit Operation
Consider an inverter fed by a dc voltage source vs a front-stage interface circuit shown in Fig. 16.55, can be added between the dc voltage source and the inverter. The front-stage circuit consists of a quasi-resonant circuit in which the first half of the resonance cycle is set to occur to create the zero-voltage condition whenever inverter switching is needed. After inverter switching has been completed, the second half of the resonance cycle takes place so that the dc link voltage is set back to its normal level. To avoid excessive losses in the resonant circuit, a small capacitor C_{r1} is normally used to provide the dc link voltage whilst the large smoothing dc link capacitor C_1 is isolated from the resonant circuit just before the zero-voltage
FIGURE 16.55   Quasi-resonant circuit for soft-switched inverter.
FIGURE 16.56   Typical waveforms for V_{cr1} and V_{cr2}.

duration. This method avoids the requirement for pulling the dc voltage of the bulk capacitor to zero.

The period for this mode is from t_0 to t_1 in Fig. 16.56. In this mode, switch S_b is turned on and switches S_{r1} and S_{r2} are turned off. The inverter in Fig. 16.55 works like a conventional dc link inverter. In this mode, $V_{cr1} = V_{c1}$. The voltage across switch S_b is zero. Before an inverter switching takes place, when switch S_{r1} is triggered at t_1 to discharge C_{r1}. This operating mode ends at t_2 when V_{cr1} approaches zero. The equivalent circuit in this mode is shown in Fig. 16.57a. The switch S_b must be turned off at zero voltage when switch S_{r1} is triggered. After S_{r1} is triggered, C_{r1} will be discharged via the loop $C_{r1}, C_{r2}, L_r,$ and S_{r1}. Under conditions of $V_{cr2} \leq 0$ and $C_{r1} \leq C_{r2}$, the energy stored in C_{r1} will be transferred to C_{r2} and V_{cr1} falls to zero in the first half of the resonant cycle in the equivalent circuit of Fig. 16.57a. V_{cr1} will be clamped to zero by the freewheel diodes in the inverter bridge and will not become negative. Thus, V_{cr1} can be pulled down to zero for zero-voltage switching. When the current in inductor L_r becomes zero, switch S_{r1} can be turned off at zero current.

Inverter switching can take place in the period from t_2 to t_3 in which V_{cr1} remains zero. This period must be longer than the turn-on and turn-off times of the switches. When inverter switching has been completed, it is necessary to reset the voltage of capacitor C_{r1}. The equivalent circuit in this mode is shown in Fig. 16.57b. The current in inductor L_r reaches zero at t_3. Due to the voltage in V_{cr2} and the presence

(a) Mode 2

(b) Mode 4

(c) Mode 5
FIGURE 16.57 Equivalent circuits of the quasi-resonant circuit for different modes.

of diode D_r, this current then flows in the opposite direction. C_{r1} will be recharged via L_r, C_{r2}, C_{r1}, and D_r. The diode D_r turns off when the current in L_r becomes zero. V_{cr1} will not go beyond 1 per unit because C_{r1} is clamped to supply voltage by diode D_b. The switch S_b can be turned on again at zero-voltage condition when V_{cr1} returns to normal dc supply voltage. After D_r turns off, V_{cr2} may not be zero. Some positive residual capacitor voltage remains in C_2 at t_4, as shown in Fig. 16.56. In case V_{cr2} is positive, V_{cr1} cannot be pulled down to zero again in the next switching cycle. Therefore, S_{r2} should be triggered after t_4 to reverse the residual voltage in C_{r2}. At time t_5, S_{r2} turns off at zero-current condition and V_{cr2} is now reversed to negative. The equivalent circuit in this mode is shown in Fig. 16.57c. When $V_{cr2} \leq 0$ and $C_{r1} \leq C_{r2}$, V_{cr1} can be pulled down to zero again before the next inverter switching. The operation can then be repeated in next switching cycle.

(B) Design Considerations

(1) C_{r1} and C_{r2}

The criterion for getting zero capacitor voltages V_{cr1} is:

$$(C_{r1} - C_{r2})V_s + 2C_{r2}V_{o2} - \Delta I \pi \sqrt{L_r C_e} \leq 0 \qquad (16.23)$$

where

- V_{o1} is the initial voltage of C_{r1};
- V_{o2} is the initial voltage of C_{r2};
- i_{L0} is the initial current of inductor L_r;
- $\Delta I = I_o - I_s$, which is the difference between load current and supply current. It is assumed to be a constant within a resonant cycle;
- R_r is the equivalent resistance in the resonant circuit.
- $C_e = \dfrac{C_{r1} C_{r2}}{C_{r1} + C_{r2}}$

When $\Delta I \geq 0$, the above criterion is always true under conditions of:

$$C_{r1} \leq C_{r2}, \quad V_{o2} \leq 0$$

The criterion for recharging voltage V_{cr1} to 1 per unit dc link voltage is:

$$\frac{2C_{r2}}{C_{r1} + C_{r2}}V_{o2} - \frac{\Delta I}{C_{r1} + C_{r2}}\pi\sqrt{L_r C_e} \geq V_s \qquad (16.24)$$

(2) Inductor L_r

The inductor L_r should be small so that the dc link voltage can be decreased to zero quickly. However, a small L_r could result in large peak resonant current and therefore requirement of power devices with large current pulse ratings. An increase in the inductance of L_r can limit the peak current in the quasi-resonant circuit. Because the resonant frequency depends on both the inductor and the capacitor, therefore, the selection of L_r can be considered together with the capacitors C_{r1} and C_{r2} and with other factors such as the current ratings of power devices, the zero-voltage duration and the switching frequency required in the soft-switching circuit.

(3) Triggering instants of the switches

The correct triggering instants for the switches are essential for the successful operation of this soft-switched inverter. For the inverter switches, the triggering instants are determined from a PWM modulation. Let T_s be the time at which the inverter switches change states. To get the zero-voltage inverter switching, switch S_{r1} should be turned on half resonant cycle before the inverter switching instant. The turn-on instant of S_{r1}, which is t_1 in Fig. 16.56, can be written as:

$$t_1 = T_s - \frac{\pi}{\omega} \qquad (16.25)$$

where $\omega = \sqrt{\omega_0^2 - \alpha^2}$, $\alpha = \frac{R_r}{2L_r}$, $\omega_0 = \sqrt{\frac{1}{L_r C_e}}$. The switch S_b is turned off at t_1.

S_{r1} may be turned off during its zero current period when diode D_r is conducting. For easy implementation, its turn-off time can be selected as $T_s + \pi/\omega$. Because the dc link voltage can be pulled down to zero in less than half resonant cycle, T_s should occur between t_2 and t_3.

At time t_3 (the exact instant depends on the ΔI), the diode D_r turns on in the second half of the resonant cycle to recharge C_{r1}. At t_4, V_{cr1} reaches 1 per unit and diode D_b clamps V_{cr1} to 1 per unit. The switch S_b can be turned on again at t_4, which is half resonant cycle after the start of t_3:

$$t_4 \approx t_3 + \frac{\pi}{\omega} \qquad (16.26)$$

As t_3 cannot be determined accurately, a voltage sensor in principle can be used to provide information for t_4 so that S_b can be turned on to reconnect C_1 to the inverter. In practice, however, S_b can be turned on a few microseconds (longer than $T_s + \pi/\omega$) after t_2 without using a voltage sensor (because it is not critical for S_b to be on exactly at the moment V_{cr} reaches the nominal voltage). As for switch S_{r2}, it can be turned on a few microseconds after t_4. It will be turned off half of resonant cycle ($\pi\sqrt{L_r C_{r2}}$) in the $L_r - C_{r2}$ circuit later. In practice, the timing of S_{r1}, S_{r2}, and S_b can be adjusted in a simple tuning procedure for a given set of parameters. Figure 16.58 shows the measured gating signals of S_{r1}, S_{r2}, and S_b with the dc link voltage V_{cr1} in a 20 kHz switching inverter. Figures 16.59 and 16.60 show the measured waveforms of I_s, I_o, and V_{cr1} under no load condition and loaded condition, respectively.

(C) Control of Quasi-resonant Soft-switched Inverter Using Digital Time Control (DTC) [51]

Based on the zero-average-current error (ZACE) control concept, a digital time control method has been developed for a current-controlled quasi-resonant soft-switched inverter. The basic ZACE concept is shown in Fig. 16.61. The current error is obtained from the difference of a reference current and the sensed current. The idea is to make the areas of each transition (A1 and A2) equal. If the switching frequency is significantly greater than the fundamental frequency of the reference signal,

FIGURE 16.59 Typical I_s, I_o, and V_{cr1} under no-load condition.
FIGURE 16.60 Typical I_s, I_o, and V_{cr1} under loaded condition.
FIGURE 16.61 Zero-average-current error (ZACE) control concept.

the rising and falling current segments can be assumed to be linear. The following simplified equation can be established.

$$\Delta t_{n+1} = t_{n+1} - t_n \qquad (16.27)$$

The control algorithm for the inverter is

$$\Delta t_{n+3} = \Delta t_{n+2} + D\left[\frac{T_{sw}}{2} - (t_{n+2} - t_n)\right] \qquad (16.28)$$

FIGURE 16.58 Gating signals for S_{r1}, S_{r2}, and S_b with V_{cr1}.

where $D = \dfrac{\Delta t_{n+2}}{t_{n+2} - t_n}$ and $T_{sw} = t_{n+4} - t_n$.
FIGURE 16.62 Implementation of DTC.

The schematic of a digital signal processor (DSP) based controller for the DTC method is shown in Fig. 16.62. The duty cycle can be approximated from the reference sine wave by level shifting and scaling it between 0 and 1. The time $t_{n+2} - t_n$ is the sum of Δt_{n+1} and Δt_{n+2}. These data provide information for the calculation of the next switching time Δt_{n+1}.

The switches are triggered by the changing edge of the switch control Q. Approximate delays are added to the individual switching signals for both the inverter switches and the quasi-resonant switches. Typical gating waveforms are shown in Fig. 16.63. The use of the quasi-resonant soft-switched inverter is a very effective way in suppressing switching transient and EMI emission. Figures 16.64a,b show the inverter switch voltage waveforms of a standard hard-switched inverter and a quasi-resonant soft-switched inverter, respectively. It is clear that the soft-switched waveform has much less transient than the hard-switched waveform.

16.14.5 Resonant Pole Inverter (RPI) and Auxiliary Resonant Commutated Pole Inverter (ARCPI)

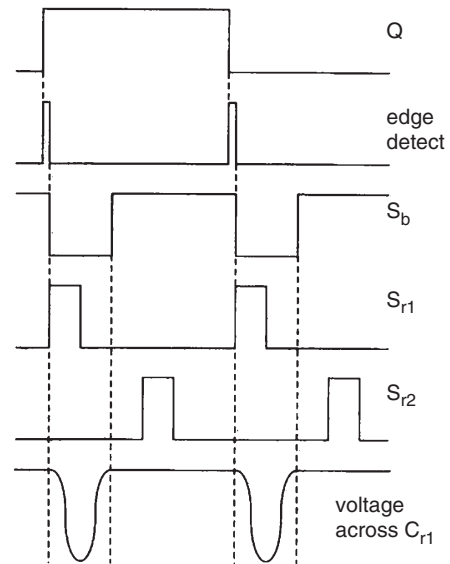
The resonant pole inverter integrates the resonant components with the output filter components L_f and C_f. The load


FIGURE 16.63 Timing diagrams for the gating signals.
FIGURE 16.64 (a) Typical switch voltage under hard turn-off and (b) typical switch voltage under soft turn-off.
FIGURE 16.65   One leg of a resonant pole inverter.
FIGURE 16.66   Single-phase resonant pole inverter.

is connected to the mid-point of the dc bus capacitors as shown in Fig. 16.65. It should however be noted that the RPI can be described as a resonant inverter. Figure 16.66 shows a single-phase RPI. Its operation can be described with the timing diagram in Fig. 16.67. The operating modes are included in Fig. 16.68. The RPI provides soft-switching for all power switches. But it has two disadvantages. First, the power devices have to be switched continuously at the resonant frequency

determined by the resonant components. Second, the power devices in the RPI circuit require a 2.2–2.5 p.u. current turn-off capability.

An improved version of the RPI is the auxiliary resonant commutated pole inverter (ARCPI). The ARCPI for one inverter leg is shown in Fig. 16.69. Unlike the basic RPI, the ARCPI allows the switching frequency to be controlled. Each of the primary switches is closely paralleled with a snubber capacitor to ensure ZV turn off. Auxiliary switches are connected in series with an inductor, ensuring that they operate under ZC conditions. For each leg, an auxiliary circuit comprising two extra switches A1 and A2, two freewheeling diodes, and a resonant inductor L_r is required. This doubles the number of power switches when compared with hard-switched inverters. Figure 16.70 shows the three-phase ARCPI system. Depending on the load conditions, three commutation modes are generally needed. The commutation methods at low and high current are different. This makes the control of the ARCPI very complex. The increase in control and circuit complexity represents a considerable cost penalty [52, 53].

17.1 Introduction

Numerous industrial applications require higher power apparatus in recent years. Some medium-voltage motor drives and utility applications require medium voltage and megawatt power level. For a medium-voltage grid, it is troublesome to connect only one power semiconductor switch directly. Hence, a multilevel power converter structure has been introduced as an alternative in high power and medium voltage situations. A multilevel converter not only achieves high power ratings but also enables the use of renewable energy sources. Renewable energy sources such as photovoltaic, wind, and fuel cells can be easily interfaced to a multilevel converter system for a high-power application [1–3].

The concept of multilevel converters has been introduced since 1975 [4]. The term *multilevel* began with the three-level converter [5]. Subsequently, several multilevel converter topologies have been developed [6–13]. However, the basic concept of a multilevel converter to achieve higher power is to use a series of power semiconductor switches with several lower voltage dc sources to perform the power conversion by synthesizing a staircase voltage waveform. Capacitors, batteries, and renewable energy voltage sources can be used as the multiple dc voltage sources. The commutation of the power switches aggregate these multiple dc sources to achieve high voltage at the output; however, the rated voltage of the power semiconductor switches depends only on the rating of the dc voltage sources to which they are connected.

A multilevel converter has several advantages over a conventional two-level converter that uses high switching frequency pulse width modulation (PWM). The attractive features of a multilevel converter are summarized as follows.

- *Staircase waveform quality*: Multilevel converters not only can generate the output voltages with very low distortion but also can reduce the dv/dt stresses; therefore, electromagnetic compatibility (EMC) problems can be reduced.
- *Common-mode (CM) voltage*: Multilevel converters produce smaller CM voltage; therefore, the stress in the bearings of a motor connected to a multilevel motor drive can be reduced. Furthermore, CM voltage can be eliminated by using advanced modulation strategies such as that proposed in [14].
- *Input current*: Multilevel converters can draw input current with low distortion.
- *Switching frequency*: Multilevel converters can operate at both fundamental switching frequency and high switching frequency PWM. It should be noted that lower switching frequency usually means lower switching loss and higher efficiency.

Unfortunately, multilevel converters do have some disadvantages. One particular disadvantage is the requirement of greater number of power semiconductor switches. Although lower voltage rated switches can be utilized in a multilevel converter, each switch requires a related gate drive circuit. This may cause the overall system to be more expensive and complex.

Many multilevel converter topologies have been proposed during the last two decades. Contemporary research has engaged novel converter topologies and unique modulation schemes. Moreover, three different major multilevel converter structures have been reported in the literature: cascaded H-bridges converter with separate dc sources, diode clamped (neutral clamped), and flying capacitors (capacitor clamped). Moreover, abundant modulation techniques and control paradigms have been developed for multilevel converters, such as sinusoidal pulse width modulation (SPWM), selective harmonic elimination (SHE-PWM), space vector modulation (SVM), and so on. In addition, many multilevel converter applications focus on industrial medium-voltage motor drives [11,15], utility interface for renewable energy systems [16], flexible ac transmission system (FACTS) [17], and traction drive systems [18].

This chapter reviews the state of the art of multilevel power-converter technology. Fundamental multilevel converter structures and modulation paradigms are discussed including the pros and cons of each technique. The main focus is on modern and more practical industrial applications of multilevel converters. A procedure for calculating the required ratings for the active switches, clamping diodes, and dc link capacitors including a design example is described. Finally, the possible future developments of multilevel converter technology are noted.

17.2 Multilevel Power Converter Structures

As mentioned earlier, three different major multilevel converter structures have been used in industrial applications: cascaded H-bridge converter with separate dc sources, diode clamped, and flying capacitors. It should be noted that the term *multilevel converter* is utilized to refer to a power electronic circuit that could operate in an inverter or rectifier mode. The multilevel inverter structures are the focus of this chapter; however, the illustrated structures can be implemented for rectifying operation as well.

17.2.1 Cascaded H-Bridges

A single-phase structure of an m-level cascaded inverter is illustrated in Fig. 17.1. Each separate dc source (SDCS) is connected to a single-phase full-bridge or H-bridge inverter.

Each inverter level can generate three different voltage outputs, $+V_{dc}$, 0, and $-V_{dc}$, by connecting the dc source to the
FIGURE 17.1   Single-phase structure of a multilevel cascaded H-bridge inverter.

ac output by different combinations of the four switches: S_1, S_2, S_3, and S_4. To obtain $+V_{dc}$, switches S_1 and S_4 are turned on, whereas to obtain $-V_{dc}$, switches S_2 and S_3 are turned on. By turning on either S_1 and S_2 or S_3 and S_4, the output voltage will be zero. The ac outputs of each of the different full-bridge inverter levels are connected in series such that the synthesized voltage waveform is the sum of the inverter outputs. The number of output phase voltage levels, m, in a cascade inverter is defined by $m = 2s + 1$, where s is the number of separate dc sources. An example of phase voltage waveform for a 11-level cascaded H-bridge inverter with five SDCSs and five full bridges is shown in Fig. 17.2. The phase voltage $v_{an} = v_{a1} + v_{a2} + v_{a3} + v_{a4} + v_{a5}$.

For a stepped waveform such as the one depicted in Fig. 17.2 with s steps, the Fourier transform for this waveform follows [14, 18]

$$V(\omega t) = \frac{4V_{dc}}{\pi} \sum_n [\cos(n\theta_1) + \cos(n\theta_2) + \cdots + \cos(n\theta_s)]$$

$$\times \frac{\sin(n\omega t)}{n}, \quad \text{where } n = 1, 3, 5, 7, \ldots \quad (17.1)$$

From Eq. (17.1), the magnitudes of the Fourier coefficients when normalized with respect to V_{dc} are as follows

$$H(n) = \frac{4}{\pi n}[\cos(n\theta_1) + \cos(n\theta_2) + \cdots$$

$$+ \cos(n\theta_s)], \quad \text{where } n = 1, 3, 5, 7, \ldots \quad (17.2)$$
FIGURE 17.2   Output phase voltage waveform of a 11-level cascade inverter with five separate dc sources.

The conducting angles, $\theta_1, \theta_2, \ldots, \theta_s$, can be chosen such that the voltage total harmonic distortion is minimum. Generally, these angles are chosen so that predominant lower frequency harmonics, 5, 7, 11, and 13 are eliminated [19]. More details on harmonic elimination techniques will be discussed in the following section.

Multilevel cascaded inverters have been proposed for such applications as static var generation, an interface with renewable energy sources, and for battery-based applications.

Three-phase cascaded inverters can be connected in wye, as shown in Fig. 17.3, or in delta. Peng *et al.* has demonstrated a prototype multilevel cascaded static var generator connected in parallel with an electrical system that could supply or draw reactive current from an electrical system [20–23]. The inverter could be controlled to regulate either the power factor of the current drawn from the source or the bus voltage of the electrical system where the inverter was connected. Peng *et al.*[20] and Joos *et al.* [24] have also shown that a cascade inverter can be directly connected in series with the electrical system for static var compensation. Cascaded inverters are ideal for connecting renewable energy sources with an ac grid because of the need for separate dc sources in applications such as photovoltaics or fuel cells.

Cascaded inverters have also been proposed for use as the main traction drive in electric vehicles where several batteries or ultracapacitors are well suited to serve as SDCSs [18, 25]. The cascaded inverter could also serve as a rectifier or charger for the batteries of an electric vehicle while the vehicle was connected to an ac supply as shown in Fig. 17.3. In addition, the cascade inverter can act as a rectifier in a vehicle that uses regenerative braking.

Manjrekar and Lipo have proposed a cascade topology that uses multiple dc levels, which instead of being identical in value are multiples of each other [26, 27]. They also used a combination of fundamental frequency switching for some of the levels and PWM switching for part of the levels to achieve the output voltage waveform. This approach enables a wider diversity of output voltage magnitudes; however, it also results in unequal voltage and current ratings for each of the levels and loses the advantage of being able to use identical modular units for each level.

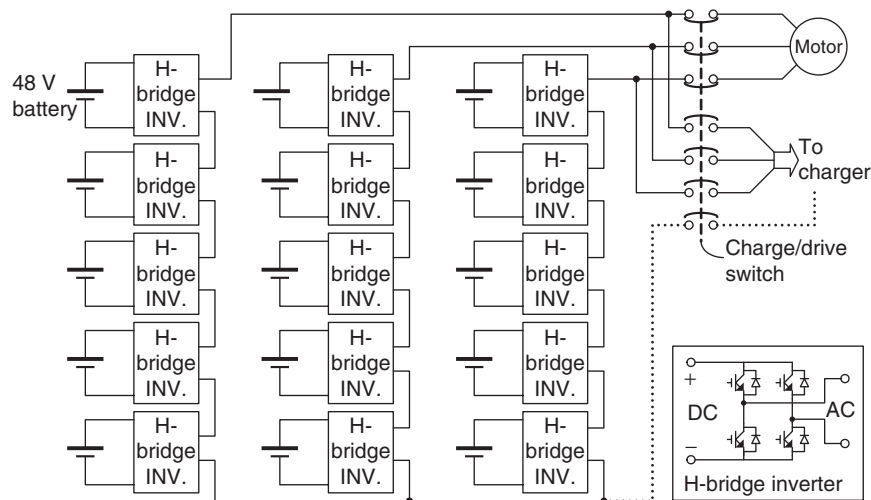
The main advantages and disadvantages of multilevel cascaded H-bridge converters are as follows [28, 29].


FIGURE 17.3   Three-phase wye-connection structure for electric vehicle motor drive and battery charging.

17.2.1.1 Advantages

- The number of possible output voltage levels is more than twice the number of dc sources ($m = 2s + 1$).
- The series of H-bridges makes for modularized layout and packaging. This will enable the manufacturing process to be done more quickly and cheaply.

17.2.1.2 Disadvantages

- Separate dc sources are required for each of the H-bridges. This will limit its application to products that already have multiple SDCSs readily available.

Another kind of cascaded multilevel converter with transformers using standard three-phase bi-level converters has been proposed [14]. The circuit is shown in Fig. 17.4. The converter uses output transformers to add different voltages. In order to add up the converter output voltages, the outputs of the three converters need to be synchronized with a separation of 120° between each phase. For example, for obtaining a three-level voltage between outputs a and b, the output voltage can be synthesized by $V_{ab} = V_{a1-b1} + V_{b1-a2} + V_{a2-b2}$. An isolated transformer is used to provide voltage boost. With three converters synchronized, the voltages, V_{a1-b1}, V_{b1-a2}, V_{a2-b2}, are all in phase, and thus, the output level can be tripled [1].

The advantage of the cascaded multilevel converters with transformers using standard three-phase bi-level converters is that the three converters are identical, and thus, control is more simple. However, the three converters need separate dc sources, and a transformer is needed to add up the output voltages.
FIGURE 17.4 Cascaded multilevel converter with transformers using standard three-phase bi-level converters.

17.2.2 Diode-Clamped Multilevel Inverter

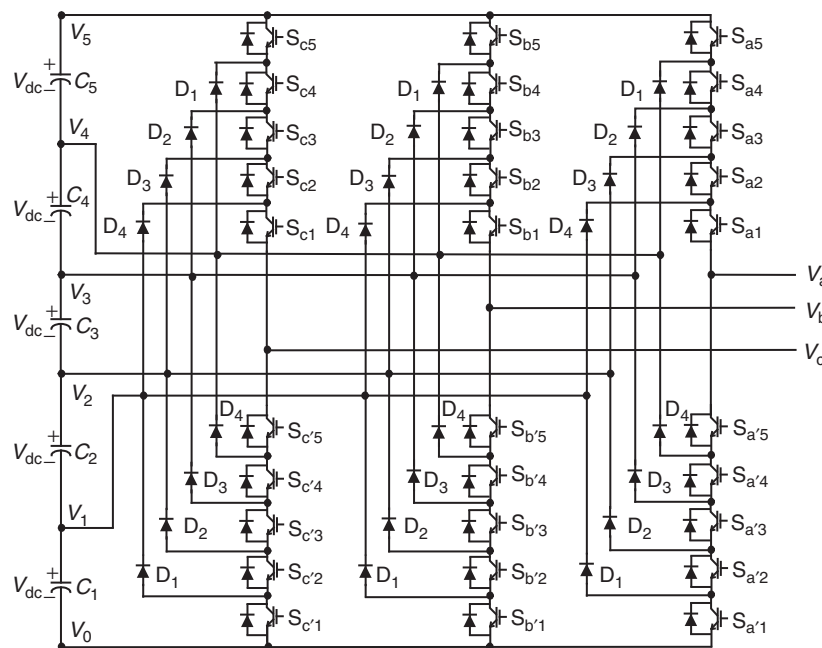
The neutral point converter proposed by Nabae, Takahashi, and Akagi in 1981 was essentially a three-level diode-clamped inverter [5]. In the 1990s, several researchers published articles that have reported experimental results for four-, five-, and six-level diode-clamped converters for uses such as static var compensation, variable speed motor drives, and high-voltage system interconnections [17–30]. A three-phase six-level diode-clamped inverter is shown in Fig. 17.5. Each of the three phases of the inverter shares a common dc bus, which


FIGURE 17.5 Three-phase six-level structure of a diode-clamped inverter.

TABLE 17.1 Diode-clamped six-level inverter voltage levels and corresponding switch states

Voltage V_{a0}	Switch state									
	S_{a5}	S_{a4}	S_{a3}	S_{a2}	S_{a1}	$S_{a'5}$	$S_{a'4}$	$S_{a'3}$	$S_{a'2}$	$S_{a'1}$
$V_5 = 5V_{dc}$	1	1	1	1	1	0	0	0	0	0
$V_4 = 4V_{dc}$	0	1	1	1	1	1	0	0	0	0
$V_3 = 3V_{dc}$	0	0	1	1	1	1	1	0	0	0
$V_2 = 2V_{dc}$	0	0	0	1	1	1	1	1	0	0
$V_1 = 1V_{dc}$	0	0	0	0	1	1	1	1	1	0
$V_0 = 0$	0	0	0	0	0	1	1	1	1	1

has been subdivided by five capacitors into six levels. The voltage across each capacitor is V_{dc}, and the voltage stress across each switching device is limited to V_{dc} through the clamping diodes. Table 17.1 lists the output voltage levels possible for one phase of the inverter with the negative dc rail voltage V_0 as a reference. State condition 1 means the switch is on, and 0 means the switch is off. Each phase has five complementary switch pairs such that turning on one of the switches of the pair requires the other complementary switch to be turned off. The complementary switch pairs for phase leg *a* are $(S_{a1}, S_{a'1})$, $(S_{a2}, S_{a'2})$, $(S_{a3}, S_{a'3})$, $(S_{a4}, S_{a'4})$, and $(S_{a5}, S_{a'5})$. Table 17.1 also shows that in a diode-clamped inverter, the switches that are on for a particular phase leg are always adjacent and in series. For a six-level inverter, a set of five switches should be on at any given time.

Figure 17.6 shows one of the three line–line voltage waveforms for a six-level inverter. The line voltage V_{ab} consists of a phase-leg "a" voltage and a phase-leg "b" voltage. The resulting line voltage is a 11-level staircase waveform. This means that an *m*-level diode-clamped inverter has an *m*-level output phase voltage and a $(2m - 1)$-level output line voltage.

Although each active switching device is required to block only a voltage level of V_{dc}, the clamping diodes require different ratings for reverse voltage blocking. Using phase *a* of Fig. 17.5 as an example, when all the lower switches $S_{a'1}$ through $S_{a'5}$ are turned on, D_4 must block four voltage levels, or $4V_{dc}$. Similarly, D_3 must block $3V_{dc}$, D_2 must block $2V_{dc}$, and D_1
FIGURE 17.6 Line voltage waveform for a six-level diode-clamped inverter.

must block V_{dc}. If the inverter is designed such that each blocking diode has the same voltage rating as the active switches, D_n will require *n* diodes in series; consequently, the number of diodes required for each phase would be $(m - 1) \times (m - 2)$. Thus, the number of blocking diodes is quadratically related to the number of levels in a diode-clamped converter [28].

One application of the multilevel diode-clamped inverter is an interface between a high-voltage dc transmission line and an ac transmission line [29]. Another application would be a variable speed drive for high-power medium-voltage (2.4–13.8 kV) motors as proposed in [3, 6, 19, 28–30]. Several authors have proposed for the diode-clamped converter that static var compensation is an additional function. The main advantages and disadvantages of multilevel diode-clamped converters are as follows [1–3].

17.2.2.1 Advantages

- All the phases share a common dc bus, which minimizes the capacitance requirements of the converter. For this reason, a back-to-back topology is not only possible but also practical for uses such as a high-voltage back-to-back interconnection or an adjustable speed drive.
- The capacitors can be precharged as a group.
- Efficiency is high for fundamental frequency switching.

17.2.2.2 Disadvantages

- Real-power flow is difficult for a single inverter because the intermediate dc levels will tend to overcharge or discharge without precise monitoring and control.
- The number of clamping diodes required is quadratically related to the number of levels, which can be cumbersome for units with a high number of levels.

17.2.3 Flying-Capacitor Multilevel Inverter

Meynard and Foch introduced a flying-capacitor-based inverter in 1992 [31]. The structure of this inverter is similar to that of the diode-clamped inverter except that instead of using clamping diodes, the inverter uses capacitors. The circuit topology of the flying-capacitor multilevel inverter is shown in Fig. 17.7. This topology has a ladder structure of dc side capacitors, where the voltage on each capacitor differs from that of the next capacitor. The voltage increment between two adjacent capacitor legs gives the size of the voltage steps in the output waveform.

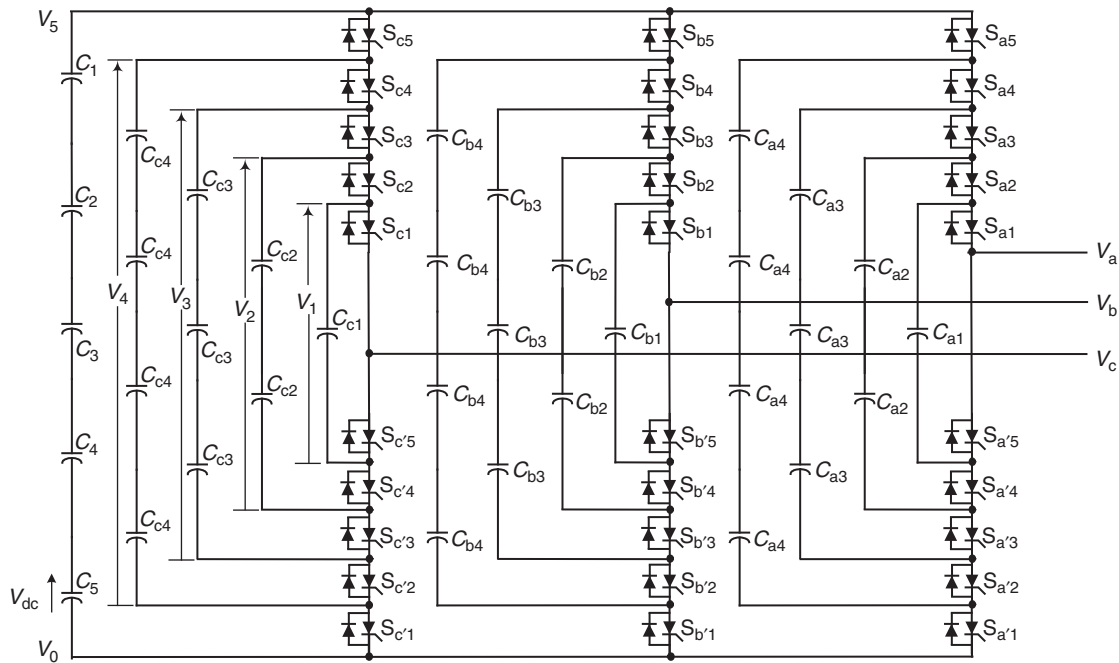
One advantage of the flying-capacitor-based inverter is that it has redundancies for inner voltage levels, that is, in other words, two or more valid switch combinations can synthesize an output voltage. Table 17.2 shows a list of all the combinations of phase voltage levels that are possible for the six-level circuit shown in Fig. 17.7. Unlike the diode-clamped inverter, the flying-capacitor inverter does not require all of the switches that are "on" (conducting) be in a consecutive series. Moreover,


FIGURE 17.7   Three-phase six-level structure of a flying-capacitor inverter.

the flying-capacitor inverter has "phase" redundancies, whereas the diode-clamped inverter has only "line–line" redundancies [2, 3, 32]. These redundancies allow a choice of charging or discharging specific capacitors and can be incorporated in the control system for balancing the voltages across the various levels.

In addition to the $(m - 1)$ dc link capacitors, the m-level flying-capacitor multilevel inverter will require $(m - 1) \times (m - 2)/2$ auxiliary capacitors per phase if the voltage rating of the capacitors is identical to that of the main switches. One application proposed in the literature for the multilevel flying capacitor is static var generation [2, 3]. The main advantages and disadvantages of multilevel flying-capacitor converters are as follows [2, 3].

17.2.3.1 Advantages
- Phase redundancies are available for balancing the voltage levels of the capacitors.
- Real and reactive power flow can be controlled.
- The large number of capacitors enables the inverter to ride through short duration outages and deep voltage sags.

17.2.3.2 Disadvantages
- Control is complicated to track the voltage levels for all of the capacitors. Also, precharging all of the capacitors to the same voltage level and start-up are complex.

- Switching utilization and efficiency are poor for real-power transmission.
- The large number of capacitors are both more expensive and bulky than clamping diodes in multilevel diode-clamped converters. Packaging is also more difficult in inverters with a high number of levels.

17.2.4 Other Multilevel Inverter Structures

Besides the three basic multilevel inverter topologies discussed earlier, other multilevel converter topologies have been proposed; however, most of these are "hybrid" circuits that are combinations of two of the basic multilevel topologies or slight variations to them. In addition, the combination of multilevel power converters can be designed to match with a specific application based on the basic topologies. In the interest of completeness, some of these will be identified and briefly described.

17.2.4.1 Generalized Multilevel Topology

Existing multilevel converters such as diode-clamped and capacitor-clamped multilevel converters can be derived from the generalized converter topology called P2 topology proposed by Peng [33] as shown in Fig. 17.8. The generalized multilevel converter topology can balance each voltage level by itself regardless of load characteristics, active or reactive power conversion, and without any assistance from other circuits at any number of levels automatically. Thus, the topology

TABLE 17.2   Flying-capacitor six-level inverter redundant voltage levels and corresponding switch states

Voltage V_{a0}	Switch state									
	S_{a5}	S_{a4}	S_{a3}	S_{a2}	S_{a1}	$S_{a'5}$	$S_{a'4}$	$S_{a'3}$	$S_{a'2}$	$S_{a'1}$
$V_{a0} = 5V_{dc}$ (no redundancies)

$3V_{dc} - V_{dc}$	0	0	1	1	0	1	1	0	0	1
$3V_{dc} - 2V_{dc} + V_{dc}$	0	0	1	0	1	1	1	0	1	0
$2V_{dc}$	0	0	0	1	1	1	1	1	0	0
$V_{a0} = V_{dc}$ (4 redundancies)										
$5V_{dc} - 4V_{dc}$	1	0	0	0	0	0	1	1	1	1
$4V_{dc} - 3V_{dc}$	0	1	0	0	0	1	0	1	1	1
$3V_{dc} - 2V_{dc}$	0	0	1	0	0	1	1	0	1	1
$2V_{dc} - V_{dc}$	0	0	0	1	0	1	1	1	0	1
V_{dc}	0	0	0	0	1	1	1	1	1	0
$V_{a0} = 0$ (n redundancies)										
0	0	0	0	0	0	1	1	1	1	1

provides a complete multilevel topology that embraces the existing multilevel converters in principle.

Figure 17.8 shows the P2 multilevel converter structure per phase leg. Each switching device, diode, or capacitor's voltage is $1V_{dc}$, for instance, $1/(m - 1)$ of the dc-link voltage. Any converter with any number of levels, including the conventional bi-level converter, can be obtained using this generalized topology [1, 33].

17.2.4.2 Mixed-Level Hybrid Multilevel Converter

To reduce the number of separate dc sources for high-voltage, high-power applications with multilevel converters, diode-clamped or capacitor-clamped converters can be used to replace the full-bridge cell in a cascaded converter [34]. An example is shown in Fig. 17.9. The nine-level cascade converter incorporates a three-level diode-clamped converter as the cell.

The original cascaded H-bridge multilevel converter requires four separate dc sources for one phase leg and 12 for a three-phase converter. If a five-level converter replaces the full-bridge cell, the voltage level is effectively doubled for each cell. Thus, to achieve the same nine voltage levels for each phase, only two separate dc sources are needed for one phase leg and six for a three-phase converter. The configuration has mixed-level hybrid multilevel units because it embeds multilevel cells as the building block of the cascade converter. The advantage of the topology is it needs less separate dc sources. The disadvantage for the topology is its control will be complicated due to its hybrid structure.

17.2.4.3 Soft-Switched Multilevel Converter

Some soft-switching methods can be implemented for different multilevel converters to reduce the switching loss and to
FIGURE 17.8   Generalized P2 multilevel converter topology for one phase leg.
FIGURE 17.10   Zero-voltage-switching capacitor-clamped inverter circuit.

increase efficiency. For the cascaded converter, because each converter cell is a bi-level circuit, the implementation of soft switching is not at all different from that of conventional bi-level converters. For capacitor-clamped or diode-clamped converters, soft-switching circuits have been proposed with different circuit combinations. One of the soft-switching circuits is a zero-voltage-switching type that includes auxiliary resonant commutated pole (ARCP), coupled inductor with zero-voltage transition (ZVT), and their combinations [1, 35] as shown in Fig. 17.10.

17.2.4.4 Back-to-Back Diode-Clamped Converter

Two multilevel converters can be connected in a back-to-back arrangement, and then the combination can be connected to the electrical system in a series–parallel arrangement as shown in Fig. 17.11. Both the current demanded from the utility and the voltage delivered to the load can be controlled at the same time. This series–parallel active-power filter has been referred to as a universal power conditioner [36–42] when used on electrical distribution systems and as a universal power flow controller [43–47] when applied at the transmission level. Earlier, Lai and Peng [29] proposed the back-to-back diode-clamped topology shown in Fig. 17.12 for use as a high-voltage dc interconnection between two asynchronous ac systems or as a rectifier or inverter for an adjustable speed drive for high-voltage motors. The diode-clamped inverter has been chosen over the other two basic multilevel circuit topologies for use in a universal power conditioner for the following reasons:

- All six phases (three on each inverter) can share a common dc link. Conversely, the cascade inverter requires that each dc level to be separate, and this is not conducive to a back-to-back arrangement.
- The multilevel flying-capacitor converter also shares a common dc link; however, each phase leg requires several additional auxiliary capacitors. These extra capacitors would add substantially to the cost and the size of the conditioner.
FIGURE 17.9   Mixed-level hybrid unit configuration using the three-level diode-clamped converter as the cascaded converter cell to increase the voltage levels.
FIGURE 17.11   Series–parallel connection to electrical system of two back-to-back inverters.
FIGURE 17.12   Six-level diode-clamped back-to-back converter structure.

Because a diode-clamped converter acting as a universal power conditioner will be expected to compensate for harmonics and/or operate in low-amplitude modulation index regions, a more sophisticated higher frequency switch control than the fundamental frequency switching method will be needed. For this reason, multilevel space vector and carrier-based PWM approaches are compared in the next section, as well as novel carrier-based PWM methodologies.

17.3 Multilevel Converter PWM Modulation Strategies

Pulse width modulation strategies used in a conventional inverter can be modified to use in multilevel converters. The advent of the multilevel converter PWM modulation methodologies can be classified according to switching frequency as

shown in Fig. 17.13. The three multilevel PWM methods most discussed in the literature have been multilevel carrier-based PWM, selective harmonic elimination, and multilevel space vector PWM, which are all extensions of traditional two-level PWM strategies to several levels. Other multilevel PWM methods have been used to a much lesser extent by researchers; therefore, only the three major techniques will be discussed in this chapter.

17.3.1 Multilevel Carrier-Based PWM

Several different two-level, carrier-based PWM techniques have been extended to multiple levels as a means for controlling the active devices in a multilevel converter. The most popular and easiest technique to implement uses several triangle carrier signals and one reference, or modulation, signal per phase. Figure 17.14 illustrates three major carrier-based techniques used in a conventional inverter that can be applied in a
FIGURE 17.13   Classification of PWM multilevel converter modulation strategies.

multilevel inverter: sinusoidal PWM (SPWM), third harmonic injection PWM (THPWM), and space vector PWM (SVM). SPWM is a very popular method in industrial applications.

In order to achieve better dc link utilization at high modulation indices, the sinusoidal reference signal can be injected by a third harmonic with a magnitude equal to 25% of the fundamental, its line–line output voltage is shown in Fig. 17.14b. As can be seen in Fig. 17.14b, c, the reference signals have some margin at unity amplitude modulation index. Obviously, the dc utilization of THPWM and SVM are better than SPWM in the linear modulation region. The dc utilization means the ratio of the output fundamental voltage to the dc link voltage. Other interesting carrier-based multilevel PWM are subharmonic PWM (SH-PWM) and switching frequency optimal PWM (SFO-PWM). In addition, some particular aspects of these carrier-based methods are also discussed as follows.

17.3.1.1 Subharmonic PWM

Carrara *et al.* [48] extended SH-PWM to multiple levels as follows: for an *m*-level inverter, $m - 1$ carriers with the same frequency f_c and the same amplitude A_c are disposed such that the bands they occupy are contiguous. The reference waveform has peak-to-peak amplitude A_m, a frequency f_m, and its zero centered in the middle of the carrier set. The reference signal is continuously compared with each of the carrier signals. If the reference signal is greater than a carrier signal, then the active device corresponding to that carrier is switched on, and if the reference signal is lesser than a carrier signal, then the active device corresponding to that carrier is switched off.

In multilevel inverters, the amplitude modulation index, m_a, and the frequency ratio, m_f, are defined as

$$m_a = \frac{A_m}{(m - 1) \cdot A_c} \tag{17.3}$$

$$m_f = \frac{f_c}{f_m} \tag{17.4}$$

Figure 17.15 shows a set of carriers ($m_f = 21$) for a six-level diode-clamped inverter and a sinusoidal reference, or modulation waveform, with an amplitude modulation index of 0.8. Figure 17.15 also shows the resulting output voltage of the inverter.

17.3.1.2 Switching Frequency Optimal PWM

Another carrier-based method that was extended to multilevel applications by Menzies *et al.* is termed *SFO-PWM*, and it is similar to SH-PWM except that a zero-sequence (triplen harmonic) voltage is added to each of the carrier waveforms [49]. This method takes the instantaneous average of the maximum and minimum of the three reference voltages $\left(V_a^*, V_b^*, V_c^*\right)$ and subtracts this value from each of the individual reference voltages, i.e.

$$V_{\text{offset}} = \frac{\max\left(V_a^*, V_b^*, V_c^*\right) + \min\left(V_a^*, V_b^*, V_c^*\right)}{2} \tag{17.5}$$

$$V_{a\text{SFO}}^* = V_a^* - V_{\text{offset}} \tag{17.6}$$

$$V_{b\text{SFO}}^* = V_b^* - V_{\text{offset}} \tag{17.7}$$

$$V_{c\text{SFO}}^* = V_c^* - V_{\text{offset}} \tag{17.8}$$

FIGURE 17.16   Analog circuit for zero-sequence addition in SFO-PWM.

The addition of this triplen-offset voltage centers all of the three reference waveforms in the carrier band, which is equivalent to using space vector PWM [50,51]. The analog equivalent of Eqs. (17.5–17.8) is shown in Fig. 17.16 [52]. The SFOPWM is shown in Fig. 17.17 for the same reference voltage waveform that was used in Fig. 17.15. The resulting output voltage of the

inverter is also shown in Fig. 17.17. The SFOPWM technique enables the modulation index to be increased by 15% before the overmodulation region is reached.

For the SH-PWM and SFO-PWM techniques shown in Figs. 17.15 and 17.17, the top and bottom switches are switched much more often than the intermediate devices. Methods to balance or reduce the device switchings without an adverse effect on a multilevel inverter's output voltage total harmonic distortion would be beneficial. The development of such methods is discussed in [53]. A novel method to balance device switchings for all of the levels in a diode-clamped inverter has been demonstrated for SH-PWM and SFO-PWM by varying the frequency for the different triangle wave carrier bands as shown in Fig. 17.18 [53].

17.3.1.3 Modulation Index Effect on Level Utilization

For low-amplitude modulation indices, a multilevel inverter will not make use of all of its levels, and at very low modulation indices, it operates as if it is a traditional two-level inverter. Figure 17.19 shows two simulation results of what the output voltage waveform looks like at amplitude modulation
FIGURE 17.17   Multilevel carrier-based SFO-PWM showing carrier bands, modulation waveform, and inverter output waveform ($m=6$, $m_f = 21$, $m_a = 0.8$).
FIGURE 17.18   SFO-PWM where carriers have different frequencies ($m_a = 0.85$, $m_f = 15$ for Band$_2$, Band$_{-2}$; $m_f = 55$ for Band$_1$, Band$_{-1}$; Band$_0$, $\phi = 0.10$ rad).
FIGURE 17.19   Level reduction in a six-level inverter at low modulation indices: (a) SH-PWM, $m = 6$, $m_a = 0.5$ and (b) SH-PWM, $m = 6$, $m_a = 0.15$.

indices of 0.5 and 0.15. Figure 17.19a shows how the bottom and top switches ($S_{a1} - S_{a'1}$, $S_{a5} - S_{a'5}$ in Fig. 17.5) are unused for amplitude modulation indices less than 0.6 in a six-level inverter. Figure 17.19b shows how only the middle switches ($S_{a3} - S_{a'3}$ in Fig. 17.5) change states when a six-level inverter is operated at an amplitude modulation index less than 0.2. The output waveform in Fig. 17.19b appears to be that of a traditional two-level inverter rather than a multilevel inverter.

The minimum modulation index $m_{a\,min}$, for which a multi-level inverter controlled with SH-PWM makes use of all of its levels, m, is

$$m_{a\,min} = \frac{m-3}{m-1} \qquad (17.9)$$

Table 17.3 lists the minimum modulation index in which a multilevel inverter uses all its constituent levels for both SH-PWM and SFO-PWM techniques. Table 17.3 also shows that the maximum modulation index before pulse dropping (overmodulation) occurs is 1.000 for SH-PWM and 1.155 for SFO-PWM. As shown in Table 17.3, when a multilevel inverter operates at modulation indices much less than 1.000, not all of its levels are involved in the generation of the output voltage and simply remain in an unused state until the modulation index increases sufficiently. The table also shows that level usage is more likely to suffer to a greater extent as the number of levels in the inverter increases.

One way to make use of the multiple levels, even during low modulation periods, is to take advantage of the redundant output voltage states by rotating level usage in the inverter after each modulation cycle. This will reduce the switching stresses on some of the inner levels by making use of those outer voltage levels that otherwise would go unused.

As mentioned earlier, diode-clamped inverters have redundant line–line voltage states for low modulation indices but have no phase redundancies [54]. For an output voltage state

TABLE 17.3 Modulation index ranges without level reduction (min) or pulse dropping because of overmodulation (max)

5	30	0	30
Total	91	–	216

(i, j, k) in an m-level diode-clamped inverter, the number of redundant states available is given by

$$N_{\substack{\text{redundancies} \\ \text{available}}} = m - 1 - [\max(i, j, k) - \min(i, j, k)]$$

$$(17.10)$$

As the modulation index decreases, more redundant states are available. Table 17.4 shows the number of distinct and redundant line–line voltage states available in a six-level inverter for different output voltages.

In the next section, a carrier-based method is given that uses line–line redundancies in a diode-clamped inverter operating at a low modulation index so that active device usage is more balanced among the levels.

17.3.1.4 Increasing Switching Frequency at Low Modulation Indices

For amplitude modulation indices less than 0.5, the level usage in odd-level inverters can be sufficiently rotated so that the switching frequency can be doubled and still keep the thermal losses within the limits of the device. For inverters with an even number of levels, the modulation index at which frequency doubling can be accomplished varies with the levels as shown in Table 17.5. This increase in switching frequency enables the inverter to compensate for higher frequency harmonics and yields a waveform that more closely tracks a reference.

As an example of how to accomplish this doubling of inverter frequency, an analysis of a seven-level diode-clamped inverter with an amplitude modulation index of 0.4 is conducted. During the first cycle, the reference waveform is centered in the upper three carrier bands, and during the next cycle, the reference waveform is centered in the lower three carrier bands as shown in Fig. 17.20. This technique enables half of the switches to "rest" every other cycle and does not incur any switching losses. With this method, the switching frequency (or carrier frequency f_c in the case of multilevel inverters) can effectively be doubled to $2f_c$, but the switches will have the same thermal losses as if they were switching at f_c but every cycle.

TABLE 17.5 Increased switching frequency possible at lower modulation indices

Inverter levels	Modulation index, m_a		Frequency multiplier
	Min	Max	
3	0.000	0.500	2×

	0.000	0.200	5×
12	0.272	0.454	2×
	0.181	0.272	3×
	0.090	0.181	5×
	0.000	0.090	11×
13	0.333	0.500	2×
	0.250	0.333	3×
	0.167	0.250	4×
	0.0833	0.167	6×
	0.000	0.0833	12×

This method is possible only for three-wire systems because the diode-clamped inverter has line–line redundancies and no phase redundancies. This means that at the discontinuity where the reference moves from one carrier band set to another, the transition has to be synchronized such that all three phases are moved from one carrier set to the next set at the same time. In the case of frequency doubling, all three phases add or subtract the following number of states (or levels) every other reference cycle

$$h_a(j+1) = h_a(j) + (-1)^j \cdot \frac{\lfloor m - 1 \rfloor}{2} \qquad (17.11)$$

At modulation indices closer to zero, the switching frequency can be increased even more. This is possible because the reference waveform can be rotated among the carrier bands for a few cycles before returning to a previous set of switches for use. The switches are allowed to "rest" for a few cycles and thus are able to absorb higher losses during the cycle they are switched. Table 17.5 shows the possible increased switching frequencies available at lower amplitude modulation indices for several different inverter levels.

Some additional switching loss is associated with the redundant switchings of the three phases at the end of each modulation cycle when rotating among carrier bands. For instance, for Fig. 17.20, each of the three phases in the seven-level inverter will have three switch pairs that change states at the end of every reference cycle. However, compared with the switching loss associated with just the normal PWM switchings, this redundant switching loss is quite small, typically less than 5% of the total switching loss.

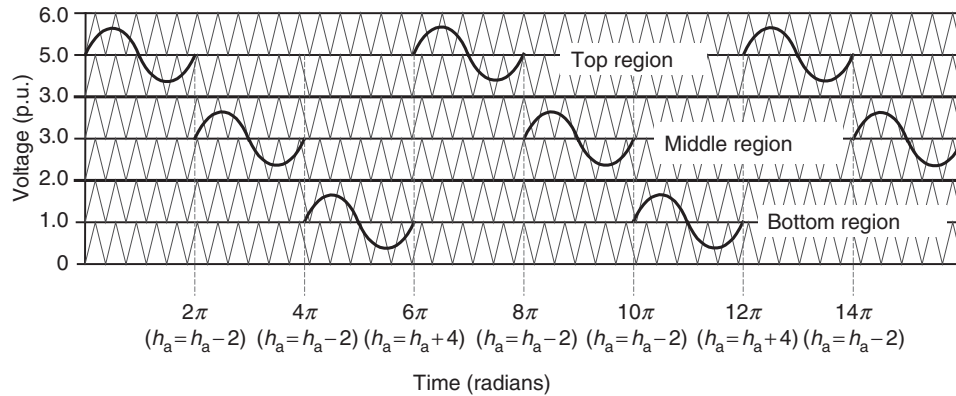
Figures 17.21 and 17.22 show two different methods of rotating the reference waveform among three different regions (top, middle, and bottom) for modulation indices less than 0.333 in a seven-level inverter to enable the carrier frequency to be increased by a factor of three. The method shown in Fig. 17.21 is preferred over that shown in Fig. 17.22 because of less redundant state switching. The method shown in Fig. 17.21 requires only four redundant state switchings for every three reference cycles, whereas the method shown in Fig. 17.22 requires eight redundant switchings for every three reference cycles. In general for any multilevel inverter regardless of the number of levels or number of rotation regions, using the preferred
FIGURE 17.20 Reference rotation among carrier bands at low modulation indices ($m_a < 0.5$).
FIGURE 17.21 Preferred method of reference rotation among carrier bands with 3× carrier frequency at very low modulation indices.


FIGURE 17.22 Alternate method of reference rotation among carrier bands with 3× carrier frequency at very low modulation indices.

reference rotation method will have half of the redundant switching losses that the alternate method would have.

Unlike the diode-clamped inverter, the cascaded H-bridge inverter has phase redundancies in addition to the aforementioned line–line redundancies. Phase redundancies are much easier to exploit than line–line redundancies because the output voltage in each phase of a three-phase inverter can be generated independently of the other two phases when only phase redundancies are used. A method was given in [18] that makes use of these phase redundancies in a cascaded inverter so that duty cycle of each active device is balanced over $(m-1)/2$ modulation waveform cycles regardless of the modulation index. The same pulse rotation technique used for fundamental frequency switching of cascade inverters was used but with a PWM output voltage waveform [55], which is a much more effective means of controlling a driven motor at low speeds than continuing to do fundamental frequency switching. The effect of this control is that the output waveform can have a high switching frequency, but the individual levels can still switch at a constant switching frequency of 60 Hz if desired.

17.3.2 Multilevel Space Vector PWM

Choi *et al.* [56] was the first author to extend the two-level space vector PWM technique to more than three levels for the diode-clamped inverter. Figure 17.23 shows how the space vector d–q plane looks like for a six-level inverter. Figure 17.24 represents the equivalent dc link of a six-level inverter as a multiplexer that connects each of the three output phase voltages to one of the dc link voltage tap points [57]. Each integral point on the space vector plane represents a particular three-phase output voltage state of the inverter. For instance, the point (3, 2, 0) on the space vector plane means, that with respect to ground, "a" phase is at $3V_{dc}$, "b" phase is at $2V_{dc}$, and "c" phase is at $0V_{dc}$. The corresponding connections between the dc link and the output lines for the six-level inverter are also shown in Fig. 17.24 for the point (3, 2, 0). An algebraic way to represent the output voltages in terms of the switching states and dc link capacitors is described in the following [58]. For $n = m - 1$, where m is the number of levels in the inverter,

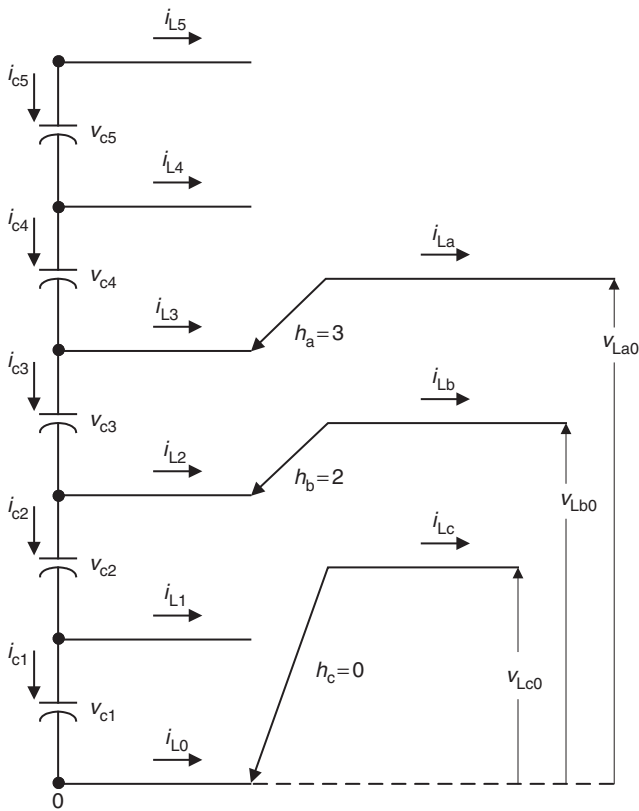
$$V_{abc0} = H_{abc}V_c \qquad (17.12)$$
FIGURE 17.23   Voltage space vectors for a six-level inverter.


FIGURE 17.24   Multiplexer model of diode-clamped six-level inverter.

where,

$$V_c = [V_{c1} \ V_{c2} \ V_{c3} \cdots V_{cn}]^T;$$

$$H_{abc} = \begin{bmatrix} h_{a1} \ h_{a2} \ h_{a3} \dots h_{an} \\ h_{b1} \ h_{b2} \ h_{b3} \dots h_{bn} \\ h_{c1} \ h_{c2} \ h_{c3} \dots h_{cn} \end{bmatrix}; \ V_{abc0} = \begin{bmatrix} V_{a0} \\ V_{b0} \\ V_{c0} \end{bmatrix}$$

and

$$h_{aj} = \sum_{j}^{n} \delta(h_a - j)$$

where h_a is the switch state and j is an integer from 0 to n, and where $\delta(x) = 1$ if $x \geq 0, \delta(x) = 0$ if $x < 0$.

Besides the output voltage state, the point (3, 2, 0) on the space vector plane can also represent the switching state of the converter. Each integer indicates how many upper switches in each phase leg are on for a diode-clamped converter. As an example, for $h_a = 3, h_b = 2, h_c = 0$, the H_{abc} matrix for this particular switching state of a six-level inverter would be

$$H_{abc} = \begin{bmatrix} 0 \ 0 \ 1 \ 1 \ 1 \\ 0 \ 0 \ 0 \ 1 \ 1 \\ 0 \ 0 \ 0 \ 0 \ 0 \end{bmatrix}$$

Redundant switching states are those states for which a particular output voltage can be generated by more than one switch combination. Redundant states are possible at lower modulation indices or at any point other than those on the outermost hexagon shown in Fig. 17.23. Switch state (3, 2, 0) has redundant states (4, 3, 1) and (5, 4, 2). Redundant switching states differ from each other by an identical integral value, i.e. (3, 2, 0) differs from (4, 3, 1) by (1, 1, 1) and from (5, 4, 2) by (2, 2, 2).

For an output voltage state (x, y, z) in an m-level diode-clamped inverter, the number of redundant states available is given by $m - 1 - \max(x, y, z)$. As the modulation index decreases (or the voltage vector in the space vector plane gets closer to the origin), more redundant states are available. The number of possible zero states is equal to the number of levels, m. For a six-level diode-clamped inverter, the zero-voltage states are (0, 0, 0), (1, 1, 1), (2, 2, 2), (3, 3, 3), (4, 4, 4), and (5, 5, 5).

The number of possible switch combinations is equal to the cube of the level (m^3). For this six-level inverter, there are 216 possible switching states. The number of distinct or unique states for an m-level inverter can be given by

$$m^3 - (m-1)^3 = \left\lceil 6 \sum_{n=1}^{m-1} n \right\rceil + 1 \qquad (17.13)$$

Therefore, the number of redundant switching states for an m-level inverter is $(m-1)^3$. Table 17.6 summarizes the available redundancies and distinct states for a six-level diode-clamped inverter.

In two-level PWM, a reference voltage is tracked by selecting the two nearest voltage vectors and a zero vector, and then by calculating the time required to be at each of these three vectors such that their sum equals the reference vector. In multilevel PWM, generally the nearest three triangle vertices,

V_1, V_2, and V_3, to a reference point V^* are selected to minimize the harmonic components of the output line–line voltage [59]. The respective time duration, T_1, T_2, and T_3, required for these vectors is then solved from the following equations

$$\vec{V}_1 T_1 + \vec{V}_2 T_2 + \vec{V}_3 T_3 = V^* T_s \qquad (17.14)$$

$$T_1 + T_2 + T_3 = T_s \qquad (17.15)$$

where T_s is the switching period. Equation (17.14) actually represents two equations, one with the real part of the terms and one with the imaginary part of the terms

$$V_{1d} T_1 + V_{2d} T_2 + V_{3d} T_3 = V_d^* T_s \qquad (17.16)$$

$$V_{1q} T_1 + V_{2q} T_2 + V_{3q} T_3 = V_q^* T_s \qquad (17.17)$$

Equations (17.15) – (17.18) can then be solved for T_1, T_2, and T_3 as follows:

$$\begin{bmatrix} T_1 \\ T_2 \\ T_3 \end{bmatrix} = \begin{bmatrix} V_{1d} & V_{2d} & V_{3d} \\ V_{1q} & V_{2q} & V_{3q} \\ 1 & 1 & 1 \end{bmatrix}^{-1} \begin{bmatrix} V_d^* T_s \\ V_q^* T_s \\ T_s \end{bmatrix} \qquad (17.18)$$

Others have proposed space vector methods that did not use the nearest three vectors, but these methods generally add complexity to the control algorithm. Figure 17.25 shows what a sinusoidal reference voltage (circle of points) and the inverter output voltages look like in the d–q plane.

Redundant switch levels can be used to help manage the charge on the dc link capacitors [60]. Generalizing from

TABLE 17.6 Line–line redundancies of six-level three-phase diode-clamped inverter

Redundancies	Distinct states	Redundant states	Unique state coordinates: (a, b, c), where $0 \le a, b, c \le 5$
5	1	5	(0,0,0)
4	6	24	(0,0,1),(0,1,0),(1,0,0),(1,0,1),(1,1,0), (0,0,1)
3	12	36	$(p,0,2),(p,2,0),(0,p,2),(2,p,0),(0,2,p),$ $(2,0,p)$, where $p \le 2$
2	18	36	$(0,3,p),(3,0,p),(p,3,0),(p,0,3),(3,p,0),$ $(0,p,3)$, where $p \le 3$

0	30	0	$(0,5,p),(5,0,p),(p,5,0),(p,0,5),(5,p,0),$ $(0,p,5)$, where $p \ge 5$
Total	91	125	216 total states

FIGURE 17.25 Sinusoidal reference and inverter output voltage states in d–q plane.

Fig. 17.24, the equations for the currents through the dc link capacitors can be given as

$$i_{cn} = -i_{Ln} \qquad (17.19)$$

and

$$i_{c(n-j)} = -i_{L(n-j)} + i_{c(n-j+1)}, \text{ where } j = 1, 2, 3 \ldots, n-1 \qquad (17.20)$$

The dc link currents for $h_a = 3, h_b = 2, h_c = 0$ would be $i_{c5} = i_{c4} = 0, i_{c3} = -i_a, i_{c2} = -i_a - i_b, i_{c1} = -i_a - i_b$. To see how redundant states affect the dc link currents, consider the two redundant states for (3, 2, 0). In state (4, 3, 1), the dc link currents would be $i_{c5} = 0, i_{c4} = -i_a, i_{c3} = -i_a - i_b, i_{c2} = -i_a - i_b, i_{c1} = -i_a - i_b - i_c = 0$; and for the state (5, 4, 2), the dc link currents would be $i_{c5} = -i_a, i_{c4} = -i_a - i_b, i_{c3} = -i_a - i_b, i_{c2} = i_{c1} = -i_a - i_b - i_c = 0$.

From this example, one can see that the choice of redundant switching states can be used to determine which capacitors will be charged/discharged or unaffected during the switching period. Although this control is helpful in balancing the individual dc voltages across the capacitors that make up the dc link, this method is quite complicated in selecting which of the redundant states to use. Constant use of redundant switching states also results in a higher switching frequency and lower efficiency of the inverter because of the extra switchings. Optimized space vector switching sequences for multilevel inverters have been proposed in [61].

17.3.3 Selective Harmonic Elimination

17.3.3.1 Fundamental Switching Frequency

The selective harmonic elimination method is also called fundamental switching frequency method based on the harmonic elimination theory proposed by Patel and Hoft [62,63]. A typical 11-level multilevel converter output with fundamental frequency switching scheme is shown in Fig. 17.2. The Fourier series expansion of the output voltage waveform as shown in Fig. 17.2 is expressed in Eqs. (17.1) and (17.2).

The conducting angles, $\theta_1, \theta_2, \ldots, \theta_s$, can be chosen such that the voltage total harmonic distortion is a minimum. Normally, these angles are chosen so as to cancel the predominant lower frequency harmonics [19].

For the 11-level case in Fig. 17.2, the 5th, 7th, 11th, and 13th harmonics can be eliminated with the appropriate choice of the conducting angles. One degree of freedom is used so that the magnitude of the fundamental waveform corresponds to the reference waveform's amplitude or modulation index, m_a, which is defined as V_L^*/V_{Lmax}. V_L^* is the amplitude command of the inverter for a sine wave output phase voltage, and V_{Lmax} is the maximum attainable amplitude of the converter,

i.e. $V_{Lmax} = s \cdot V_{dc}$. The equations from Eq. (17.2) will now be as follows

$$\cos(5\theta_1) + \cos(5\theta_2) + \cos(5\theta_3) + \cos(5\theta_4) + \cos(5\theta_5) = 0$$

$$\cos(7\theta_1) + \cos(7\theta_2) + \cos(7\theta_3) + \cos(7\theta_4) + \cos(7\theta_5) = 0$$

$$\cos(11\theta_1) + \cos(11\theta_2) + \cos(11\theta_3) + \cos(11\theta_4) + \cos(11\theta_5) = 0$$

$$\cos(13\theta_1) + \cos(13\theta_2) + \cos(13\theta_3) + \cos(13\theta_4) + \cos(13\theta_5) = 0$$

$$\cos(\theta_1) + \cos(\theta_2) + \cos(\theta_3) + \cos(\theta_4) + \cos(\theta_5) = 5m_a \qquad (17.21)$$

The above equations are nonlinear transcendental equations that can be solved by an iterative method such as the Newton–Raphson method. For example, using a modulation index of 0.8 obtains the following: $\theta_1 = 6.57°, \theta_2 = 18.94°, \theta_3 = 27.18°, \theta_4 = 45.14°, \theta_5 = 62.24°$. Thus, if the inverter output is symmetrically switched during the positive half cycle of the fundamental voltage to $+V_{dc}$ at $6.57°, +2V_{dc}$ at $18.94°, +3V_{dc}$ at $27.18°, +4V_{dc}$ at $45.14°$, and $+5V_{dc}$ at $62.24°$ and similarly in the negative half cycle to $-V_{dc}$ at $186.57°, -2V_{dc}$ at $198.94°, -3V_{dc}$ at $207.18°, -4V_{dc}$ at $225.14°, -5V_{dc}$ at $242.24°$, the output voltage of the 11-level inverter will not contain the 5th, 7th, 11th, and 13th harmonic components [18]. Other methods to solve these equations include using genetic algorithms [64] and resultant theory [65–67].

Practically, the precalculated switching angles are stored as the data in memory (look-up table). Therefore, a microcontroller could be used to generate the PWM gate drive signals.

17.3.3.2 Selective Harmonic Elimination PWM

In order to achieve a wide range of modulation indexes with minimized THD for the synthesized waveforms, a generalized selective harmonic modulation method [68, 69] was proposed, which is called virtual stage PWM [64]. An output waveform is shown in Fig. 17.26. The virtual stage PWM is a combination of the unipolar programmed PWM and the fundamental
FIGURE 17.26 Output waveform of virtual stage PWM control.
FIGURE 17.27   Unipolar switching output waveform.

frequency switching scheme. The output waveform of unipolar programmed PWM is shown in Fig. 17.27. When unipolar programmed PWM is employed on a multilevel converter, typically one dc voltage is involved, where the switches connected to the dc voltage are switched "on" and "off" several times per fundamental cycle. The switching pattern decides what the output voltage waveform looks like.

For fundamental switching frequency method, the number of switching angles is equal to the number of dc sources. However, for the virtual stage PWM method, the number of switching angles is not equal to the number of dc voltages. For example, in Fig. 17.26, only two dc voltages are used, whereas there are four switching angles.

Bipolar programmed PWM and unipolar programmed PWM could be used for modulation indices too low for the applicability of the multilevel fundamental frequency switching method. Virtual stage PWM can also be used for low modulation indices. Virtual stage PWM will produce output waveforms with a lower THD most of the time [64]. Therefore, virtual stage PWM provides another alternative to bipolar programmed PWM and unipolar programmed PWM for low modulation index control.

The major difficulty for selective harmonic elimination methods, including the fundamental switching frequency method and the virtual stage PWM method, is to solve the transcendental Eq. (17.21) for switching angles. Newton's method can be used to solve Eq. (17.21), but it needs good initial guesses, and solutions are not guaranteed. Therefore, Newton's method is not feasible to solving equations for large number of switching angles if good initial guesses are not available [70].

Recently, the resultant method has been proposed in [65–67] to solve the transcendental equations for switching angles. The transcendental equations characterizing the harmonic content can be converted into polynomial equations. Elimination resultant theory has been employed to determine the switching angles to eliminate specific harmonics, such as the 5th, 7th, 11th, and 13th. However, as the number of dc voltages or the number of switching angles increases, the degrees of the polynomials in these equations become bulky.

To overcome this problem, the fundamental frequency switching angle computation is solved by Newton's method. The initial guess can be provided by the results of lower order transcendental equations by the resultant method [70].

17.4 Multilevel Converter Design Example

The objective of this section is to give a general idea how to design a multilevel converter in a specific application. Different applications for multilevel converters might have different specification requirements. Therefore, the multilevel universal power conditioner (MUPC) is utilized to demonstrate as the design example in this section.

Multilevel diode-clamped converters can be designed where different levels have unequal voltage and current ratings; however, this approach would lose the advantage of being able to use identical, modular units for each leg of the inverter. The method used in this chapter to specify a back-to-back diode-clamped converter for use as a universal power conditioner is for all voltage levels and legs in each of the two inverters to be the same. (The current ratings in the series inverter may be different than those in the parallel inverter.) This approach also allows the control system to extend the frequency range of the inverter by exploiting the additional voltage redundancies available at lower modulation indices as discussed in [71].

17.4.1 Interface with Electrical System

Figure 17.28 illustrates the proposed electrical system connection topology for two diode-clamped inverters connected back-to-back and sharing a common dc bus. One inverter interfaces with the electrical system by means of a parallel connection through output inductors L_{PI}. The other inverter interfaces with the electrical system through a set of single-phase transformers in a series fashion. The primaries of the transformers are inserted in series with each of the three-phase conductors supplied from a utility. The secondaries of the transformers are connected to an ungrounded wye and to the output of the series inverter. By having two inverters, this arrangement allows both the source voltage and the load current to be compensated independently of each other [71, 72]. With only a single inverter, regulating the load voltage and source current at the same time would not be possible.

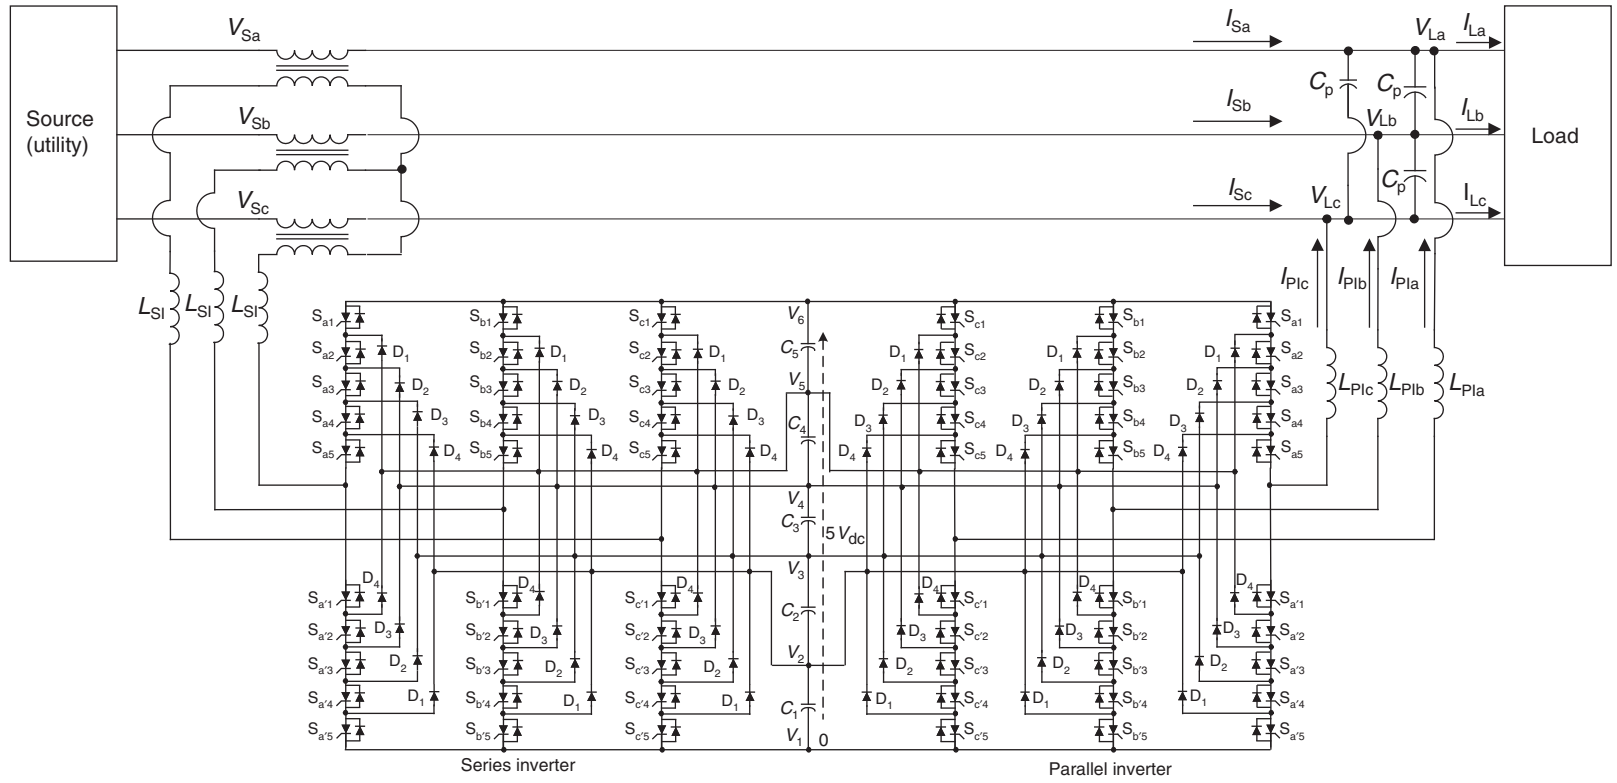
The voltage injected into the electrical system by the series inverter compensates for deviations in the source voltage such that a regulated distortion-free waveform is supplied to the load. The parallel inverter injects current into the electrical system to compensate for current harmonics or reactive current demanded by the load such that the current drawn from the utility is in phase with the source voltage and contains no harmonic components.


FIGURE 17.28   Electrical system connection of multilevel diode-clamped power conditioner.

17.4.2 Number of Levels and Voltage Rating of Active Devices

In a multilevel inverter, determining the number of levels will be one of the most important factors because this affects many of the other sizing factors and control techniques. Tradeoffs, in specifying the number of levels that the power conditioner will need and the advantages and complexity of having multiple voltage levels available, are the primary differences that set a multilevel filter apart from a single-level filter.

The nominal RMS voltage rating, V_{nom}, of the electrical system is known to which the diode-clamped power conditioner will be connected. The dc link voltage must be at least as high as the amplitude of the nominal line–neutral voltage at the point of connection, or $\sqrt{2} \cdot V_{\text{nom}}$.

The parallel inverter must be able to inject currents by imposing a voltage across the parallel inductors, L_{PI}, which is the difference between the load voltage V_{L} and parallel inverter output voltage V_{PI}. It is difficult to impose a voltage across the inductors when the load voltage waveform is at its maximum or minimum. Simulation results have shown that the amplitude of the desired load voltage V_{nom} should not be more than 70% of the overall dc link voltage for the parallel inverter to have sufficient margin to inject appropriate compensation currents. Without this margin, complete compensation of reactive currents may not be possible. This margin can be incorporated into a design factor for the inverter. Because the dc link voltage and the voltage at the connection point can vary, the design factor used in the rating selection process incorporates these elements and the small voltage drops that occur in the inverters during active device conduction.

The product of the number of the active devices in series $(m-1)$ and the voltage rating of the devices V_{dev} must then be such that

$$V_{\substack{\text{device} \\ \text{rating}}} \cdot (m-1) \geq \sqrt{2} \cdot V_{\text{nom}} \cdot D_{\substack{\text{design} \\ \text{factor}}} \qquad (17.22)$$

The minimum number of levels and the voltage rating of the active devices (IGBTs, GTOs, power MOSFETs, etc.) are inversely related to each other. More levels in the inverter will lower the required voltage device rating of individual devices, or looking at it another way, a higher voltage rating of the devices will enable a fewer minimum number of levels to be used.

Increasing the number of levels does not affect the total voltage blocking capability of the active devices in each phase leg because lower device ratings can be used. Some of the benefits of using more than the minimum required number of levels in a diode-clamped inverter are as follows:

1. Voltage stress across each device is lower. Both active devices and dc link capacitors could be used that have lower voltage ratings (which sometimes are much cheaper and have greater availability).
2. The inverter will have a lower EMI because the dv/dt during each switching will be lower.
3. The output of the waveform will have more steps, or degrees of freedom, which enables the output waveform to closely track a reference waveform.
4. Lower individual device switching frequency will achieve the same results as an inverter with a fewer number of levels and higher device switching frequency. Or the switching frequency can be kept the same as that in an inverter with a fewer number of levels to achieve a better waveform.

The drawbacks of using more than the required minimum number of levels are as follows:

1. Six active device control signals (one for each phase of the parallel inverter and the series inverter) are needed for each hardware level of the inverter, i.e. $6(m-1)$ control signals. Additional levels require more computational resources and add complexity to the control.
2. If the blocking diodes used in the inverter have the same rating as the active devices, their number increases dramatically because $6(m-2)(m-1)$ diodes would be required for the back-to-back structure.

Considering the tradeoffs between the number of levels and the voltage rating of the devices will generally lead the designer to choose an appropriate value for each.

17.4.3 Number and Voltage Rating of Clamping Diodes

As mentioned in the previous section, $6(m-1)(m-2)$ clamping diodes are required for an m-level back-to-back converter if the diodes have the same voltage rating as the active devices. As discussed in Section 17.2, the voltage rating of each series of clamping diodes is designated by the subscript of the diode shown in Fig. 17.28. For instance, D_4 must block $4V_{\text{dc}}$, D_3 must block $3V_{\text{dc}}$, and so on.

If diodes that have higher voltage ratings than the active devices are available, then the number of diodes required can be reduced accordingly. When considering diodes of different ratings, the minimum number of clamping diodes per phase leg of the inverter is $2(m-2)$ and for the complete back-to-back converter is $12(m-2)$. Unlike the active devices, additional levels do *not* enable a decrease in the voltage rating of the clamping diodes. In each phase leg, note that the voltage rating of each pair of diodes adds up to the overall dc link voltage $(m-1)V_{\text{dc}}$. Considering the six-level converter in Fig. 17.28, connected to voltage level V_5 are the anode of D_1 and the cathode of D_4. D_1 must be able to block V_{dc}, and D_4 must

block $4V_{dc}$; the sum of their voltage blocking capabilities is $5V_{dc}$. For voltage level V_4, the anode of D_2 and the cathode of D_3 are connected together to this point. Again, the sum of their voltage blocking capability is $2V_{dc} + 3V_{dc} = 5V_{dc}$. The same is true for the other intermediate voltage levels. Therefore, the total voltage blocking capability per phase of an m-level converter is $(m - 2)(m - 1)V_{dc}$ and for the back-to-back converter,

$$V_{\substack{\text{clamp} \\ \text{total}}} = 6(m - 2)(m - 1)V_{dc} \qquad (17.23)$$

Each additional level added to the converter will require an additional $6(m - 1)V_{dc}$ in voltage blocking capabilities. From this, one can see that unnecessarily adding more than the required number of voltage levels can quickly become cost prohibitive.

17.4.4 Current Rating of Active Devices

In order to determine the required current rating of the active switching devices for the parallel and series portions of the back-to-back converter shown in Fig. 17.28, the maximum apparent power that each inverter will either supply or draw from the electrical system must be known. These ratings will largely depend on the compensation objectives and on the limits they are specified to maintain. Of the three voltage compensation objectives (voltage sag, unbalanced voltages, voltage harmonics), the greatest power demands of the series inverter will almost always occur during voltage sag conditions. For the parallel inverter, generally the reactive power compensation demands will dominate the design of the converter, as opposed to harmonic current compensation.

For this analysis, balanced voltage sag conditions will be considered in the specification of the power ratings of the two inverters. A one-line diagram circuit is shown in Fig. 17.29 for the converter and electrical system represented in Fig. 17.28. Equations can be developed for the apparent power required for each of the inverters based on the three phase–rated apparent load power S_{Lnom}, rated line–line load voltage V_{Lnom}, and line–line source voltage V_S [73].

17.4.4.1 Series Inverter Power Rating

First, the rating of the series inverter will be considered. The voltage V_{SI} across the series transformer shown in Fig. 17.29, is given by the vector equation

$$\vec{V}_{SI} = \vec{V}_L - \vec{V}_S \qquad (17.24)$$

The apparent power delivered from the series converter can then be given as

$$\vec{S}_{SI} = \left(\vec{V}_L - \vec{V}_S \right) \vec{I}_S^* \qquad (17.25)$$

where the conjugate $\vec{I}_S^*$ is the conjugate of $\vec{I}_S$, the source current.

If the load voltage V_L is regulated such that it is in phase with the source voltage V_S, then Eq. (17.24) can be rewritten as an algebraic equation

$$V_{SI} = V_L - V_S \qquad (17.26)$$

Assuming that the back-to-back converter is lossless, the entire real power P_L drawn by the load must be supplied by the utility source, $P_S = P_L$. If the source current is regulated such that it is in phase with the source voltage, then

$$P_S = V_S \cdot I_S = P_L \qquad (17.27)$$

Combining Eqs. (17.25)–(17.27), the real power delivered from the series converter is

$$P_{SI} = (V_L - V_S)I_S \qquad (17.28)$$

Multiplying and dividing the right side of Eq. (17.28) by V_s yields

$$P_{SI} \left(\frac{V_L}{V_S} - \frac{V_S}{V_S} \right) I_S \cdot V_S \qquad (17.29)$$
FIGURE 17.29   One-line diagram of a MUPC connected to the electrical system.

Substituting Eq. (17.27) into Eq. (17.29) provides the following equation for the rated apparent power of the series inverter

$$S_{SI} = P_{SI} = P_L\left(\frac{V_L}{V_S} - 1\right) \qquad (17.30)$$

Choosing the rated load power S_L and the rated load voltage V_L as bases, Fig. 17.30 shows the apparent power S_{SI} in per unit that the series inverter must provide as a function of the source voltage V_S. Each of the curves in Fig. 17.30 is for loads of different power factors. As shown in Fig. 17.30, the apparent power that the series inverter has to transfer is proportional to the power factor of the load [73].

Figure 17.30a shows that for voltage sags less than 50% of nominal, the series inverter would have to be rated to transfer more power than the rated load power, which in most applications would not be practical. Figure 17.30b shows that for sags that are small in magnitude, the series inverter would have a rating much less than that of the rated load power. For example, for a 20% voltage sag ($V_s = 0.8 V_{nom}$), the required power rating of the series inverter is only 25% of the rated load.

When considering selection of the active devices for the series inverter, as shown in Fig. 17.30, the magnitude of the voltage sag to be compensated will play a large role in determining the current rating required. The formula for determining the current rating of each of the devices as a function of the minimum source voltage to be compensated, $\min(V_s)$, is given in Eq. (17.31)

$$I_{SI_{\substack{device \\ rating}}} = \frac{S_{Lnom} \cdot ((V_{nom})/(V_{nom} - \min(V_S)) - 1)}{\sqrt{3} \cdot V_{nom}} \cdot D_{\substack{safety \\ factor}}$$

$$(17.31)$$

The safety factor, or design factor, in Eq. (17.31) should be chosen to allow for future growth in the load supplied by the utility and compensated by the power conditioner.

17.4.4.2 Parallel Inverter Power Rating

The power rating of the parallel inverter will now be considered. From Fig. 17.29, the apparent power delivered to the electrical system by the parallel inverter can be expressed as

$$\vec{S}_{PI} = \vec{S}_L - \vec{V}_L\vec{I}_S^* = (P_L + jQ_L) - V_LI_S \qquad (17.32)$$

because the source current I_s and load voltage V_L are controlled such that they are in phase with the source voltage [73]. Multiplying and dividing the second term of Eq. (17.32) by V_S and substituting Eq. (17.27) yields the following

$$V_LI_S = \frac{V_L}{V_S} \cdot V_SI_S = \frac{V_L}{V_S} \cdot P_L \qquad (17.33)$$

Substituting Eq. (17.33) into Eq. (17.32) and combining like terms yields

$$\vec{S}_{PI} = P_L\left(1 - \frac{V_L}{V_S}\right) + jQ_L \qquad (17.34)$$

Figure 17.31 shows the apparent power S_{PI} in per unit that the parallel inverter must provide as a function of the source voltage V_S for loads of different power factors. Because the power transferred for voltage declines to less than 50% of nominal is predominantly real power, the parallel inverter would have to have an extraordinarily high rating if the conditioner were designed to compensate for such large voltage sags, just like the series inverter. From Fig. 17.31b, one can see that for a voltage sag to 50% of nominal, the parallel inverter has to draw a current I_{PI} equal to that drawn by the rated load I_L. However, unlike the series inverter, the dominant factor in determining the power rating of the parallel inverter is the load power factor if the conditioner is designed to compensate for only marginal voltage sags as shown in Fig. 17.31b.

If the design of the universal power conditioner is to compensate for voltage sags to less than 50% of nominal voltage, then Eq. (17.31) should be used to determine the current rating of the parallel inverter. If the design of the conditioner is for marginal voltage sags (to 70% of nominal voltage) and the MUPC will be applied to a customer load that has a power factor of less than 0.9, then the following equation is more suited for calculating the current rating of the parallel inverter's active devices

$$I_{PI_{\substack{device \\ rating}}} = \frac{Q_{Lnom}}{\sqrt{3} \cdot V_{nom}} \cdot D_{\substack{design \\ factor}} = \frac{S_{Lnom}\left(1 - (p.f.)^2\right)^{1/2}}{\sqrt{3} \cdot V_{nom}} \cdot D_{\substack{design \\ factor}}$$

$$(17.35)$$

One common design for the parallel inverter in a universal power conditioner is for the inverter to have a current rating equal to that of the rated load current I_L.

17.4.5 Current Rating of Clamping Diodes

When a multilevel inverter outputs an intermediate voltage level, not 0 or $(m - 1)V_{dc}$, only one clamping diode in each phase leg conducts current at any instant in time, whereas half of the active switches are conducting at all times. The diode that is conducting current is determined by the intermediate dc voltage level, which is connected to the output phase conductor, and by the direction of the current flow, positive or negative. For instance, when a phase leg of the series inverter in Fig. 17.28 is connected to level V_4, diode D_2 conducts for current flowing from the inverter to the electrical system, and then diode D_3 conducts for current flowing into the inverter from the electrical system.
(a)
(b)

FIGURE 17.30   Apparent power requirements of series inverter during voltage sags.
(a)
(b)

FIGURE 17.31   Apparent power requirements of parallel inverter during voltage sags.

This example illustrates that for current flowing out of an inverter, only the clamping diodes in the top half of a phase leg will conduct, and for current flowing into an inverter, only the clamping diodes in the bottom half of the phase leg will conduct. In all likelihood, the current waveforms will be odd symmetric. These facts alone enable the *average* current rating for the clamping diodes to be at most one half that of the active devices. The clamping diodes should all have a *pulse or short-time* current rating equal to the amplitude of the maximum compensation current that the inverter is expected to conduct. Generally, this is equal to $\sqrt{2}$ times the value calculated in Eq. (17.31) or (17.35) for the series and parallel inverters.

The average current that flows through each clamping diode is dependent on currents i_{SI} and i_{PI}, the modulation index, and the control of the voltage level outputs of the inverter. Because all of these are widely varying attributes in a power conditioner, an explicit formula for determining their ratings would be difficult at best. Nonetheless, for the assumption that each clamping diode conducts an equal amount of current and that each level of the inverter is "on" for an equal duration of time, their average current ratings for the series and parallel inverter could be found from the following equations

$$I_{SI_{\substack{\text{clamping} \\ \text{diode}}}} = \frac{I_{SI_{\substack{\text{device} \\ \text{rating}}}}}{2(m-1)} \tag{17.36}$$

or

$$I_{PI_{\substack{\text{clamping} \\ \text{diode}}}} = \frac{I_{PI_{\substack{\text{device} \\ \text{rating}}}}}{2(m-1)} \tag{17.37}$$

17.4.6 DC Link Capacitor Specifications

Unipolar capacitors can be used for the dc link capacitors. Just like the voltage rating of the active devices in Eq. (17.22), the sum of the voltage ratings of the dc link capacitors should be greater than or equal to the overall dc link voltage, which is equal to the right side of Eq. (17.22). The design factors in this case includes the dc link voltage ripple plus safety factors necessary to maintain the capacitors within their safe operating range.

The capacitance of each capacitor in the dc link is determined by the equation

$$C_n = \frac{\Delta q_n}{\Delta V_n} \tag{17.38}$$

where $n = 1, 2, 3, \ldots, m-1$, Δq_n is the change in charge, and V_n is the change in voltage over a specified period.

The required capacitance of the dc link and the voltage ripple are inversely related to each other. An increase in the capacitance will decrease the amount of ripple in the dc
FIGURE 17.32 Capacitance required as a function of the maximum voltage ripple on dc bus.

voltage. By assuming that each level has the same voltage V_{dc} across it,

$$\Delta V_n = \% \ V_{\text{ripple}} \cdot V_{dc} \tag{17.39}$$

Figure 17.32 shows a graph of the required capacitance as a function of the maximum permissible voltage ripple on the dc link. The graph indicates that an unnecessarily strict tolerance on the voltage ripple of the dc bus will result in extraordinarily large capacitor values. For this reason, the maximum voltage ripple is normally chosen to be in the 5–10% range.

The current that flows through the capacitor determines the change in charge Δq_n for a capacitor C_n. This current is a function of what input and output voltage states the inverter progresses through each cycle and will largely be dependent on the control method implemented by the series and parallel inverter in maintaining the voltage on the dc link. In addition, the current waveforms i_{PI} and i_{SI} also will depend largely on the system conditions, i.e. in other words, the type of compensation that the converter is conducting. Although the current that flows through each capacitor C_n that makes up the dc link will be different, for the reasons mentioned previously in Section 17.4.2, normally each of the capacitors will be identically sized such that Eq. (17.38) can then be rewritten as

$$C_n = C_{dc} = \frac{\max(\Delta q_n)}{\% \ V_{\text{ripple}} \cdot V_{dc}} \tag{17.40}$$

Suppose a UPFC is connected to a distribution system with a voltage of 13.8 kV line–line (7970 V line–ground). From Eq. (17.22), $V_{\substack{\text{device} \\ \text{rating}}}(m-1) \geq \sqrt{2} \cdot 7970 \cdot 1.5 = 16,900$ V. If 3300 V IGBTs are chosen for the design, then the number of levels m would be 6. The next lower rating of available IGBTs is 2500 V, and the use of these devices would require seven levels. Because of the added complexity and computational burden of seven levels, the design with six levels of 3300-V IGBTs is chosen.

TABLE 17.7 Back-to-back MUPC clamping diode ratings

Per unit voltage rating	Blocking voltage required	Voltage rating of diode used	Number of diodes per leg	Total number per phase
$1\,V_{dc}$	3000 V	3000 V	1	2
$2\,V_{dc}$	6000 V	3000 V	2	4
$3\,V_{dc}$	9000 V	3000 V	3	6
$4\,V_{dc}$	12,000 V	3000 V	4	8

A 13.8-kV line–line ac waveform from an inverter requires a minimum dc link voltage of approximately 11.3 kV. The nominal dc voltage for each level would be approximately 2000 V. For a design factor of 1.5, the design voltage for each level of the inverter would be approximately 3000 V.

From Eq. (17.23), the minimum total voltage blocking capability for a back-to-back converter would be $V_{\text{clamp}_{\text{total}}} = 6(6-2)(6-1)3000\,\text{V} = 360\,\text{kV}$. Each phase of the converter will require the blocking voltages shown in Table 17.7.

The current rating of the active devices in the series inverter is found from Eq. (17.31)

$$I_{\text{SI}_{\substack{\text{device} \\ \text{rating}}}} = \frac{20\,\text{MVA} \cdot ((1/1 - 0.3) - 1)}{\sqrt{3} \cdot 13,800\,\text{V}} \cdot 1.5 = 540\,\text{A}$$

The current rating of the active devices in the parallel inverter is found from Eq. (17.35):

$$I_{\text{PI}_{\substack{\text{device} \\ \text{rating}}}} = \frac{20\,\text{MVA} \cdot \left(1 - 0.85^2\right)^{1/2}}{\sqrt{3} \cdot 13,800\,\text{V}} \cdot 1.5 = 661\,\text{A}$$

Use of 3300 V, 800 A IGBTs would be sufficient for both the series and the parallel inverters.

The current rating of the clamping diodes in the series inverter is found from Eq. (17.36)

$$I_{\text{SI}_{\substack{\text{clamping} \\ \text{diode}}}} = \frac{540\,\text{A}}{2(6-1)} = 54\,\text{A}$$

Likewise, the current rating of the clamping diodes in the parallel inverter is found from Eq. (17.37)

$$IE = \frac{660\,\text{A}}{2(6-1)} = 66\,\text{A}$$

Use of 3000 V, 75 A diodes would be sufficient for both the series and the parallel inverters.

17.5 Fault Diagnosis in Multilevel Converters

Since a multilevel converter is normally used in medium- to high-power applications, the reliability of the multilevel converter system is very important. For instance, industrial drive applications in manufacturing plants are dependent upon induction motors and their inverter systems for process control. Generally, the conventional protection systems are passive devices such as fuses, overload relays, and circuit breakers to protect the inverter systems and the induction motors. The protection devices will disconnect the power sources from the multilevel inverter system whenever a fault occurs, stopping the operated process. Downtime of manufacturing equipment can add up to be thousands or hundreds of thousands of dollars per hour; therefore, fault detection and diagnosis is vital to a company's bottom line. In order to maintain continuous operation for a multilevel inverter system, knowledge of fault behaviors, fault prediction, and fault diagnosis is necessary. Faults should be detected immediately because if a motor drive runs continuously under abnormal conditions, the drive or motor may quickly fail.

The possible structure for a fault diagnosis system is shown in Fig. 17.33. The system is composed of four major states: feature extraction, neural network classification, fault diagnosis, and switching pattern calculation with gate signal output. The feature extraction performs the voltage input signal transformation, with rated signal values as important features, and the output of the transformed signal is transferred to the neural network classification. The networks are trained with both normal and abnormal data for the multilevel inverter drive (MLID); thus, the output of this network is nearly 0 and 1 as binary code. The binary code is sent to the fault diagnosis to decode the fault type and its location. Then, the switching pattern is calculated to reconfigure the multilevel inverter.

Switching patterns and the modulation index of other active switches can be adjusted to maintain voltage and current in a balanced condition after reconfiguration recovers from a fault. The MLID can continuously operate in a balanced condition; of course, the MLID will not be able to operate at its rated power. Therefore, the MLID can operate in balanced condition at reduced power after the fault occurs until the operator locates and replaces the damaged switch [74].

17.6 Renewable Energy Interface

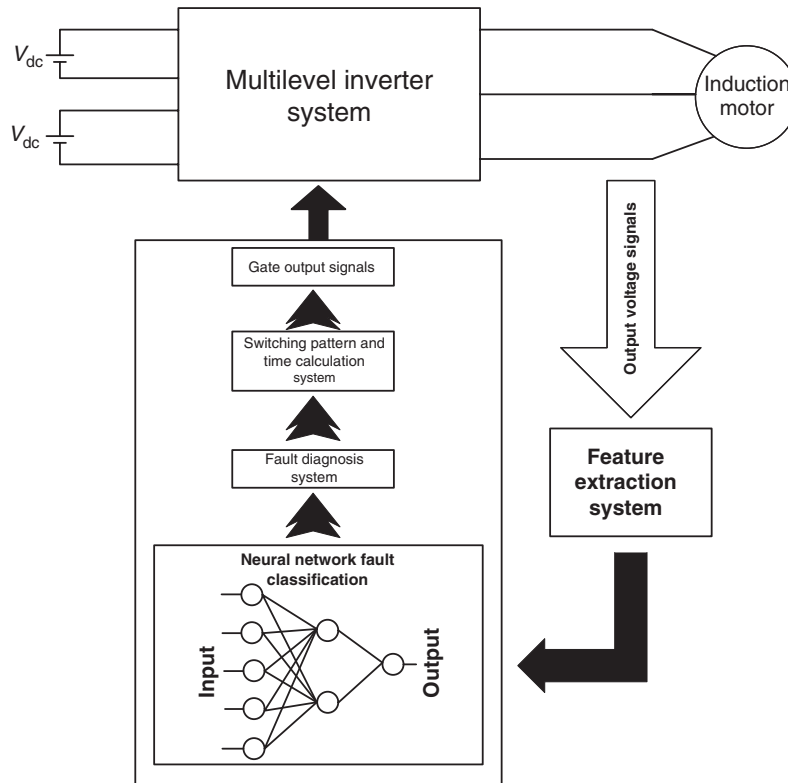
Multilevel converters can be used to interface with renewable energy or distributed energy resources because several batteries, fuel cells, solar cells, wind turbines, and microturbines can be connected through a multilevel converter to supply a load or


FIGURE 17.33   Structure of fault diagnosis system of a multilevel cascaded H-bridge inverter.
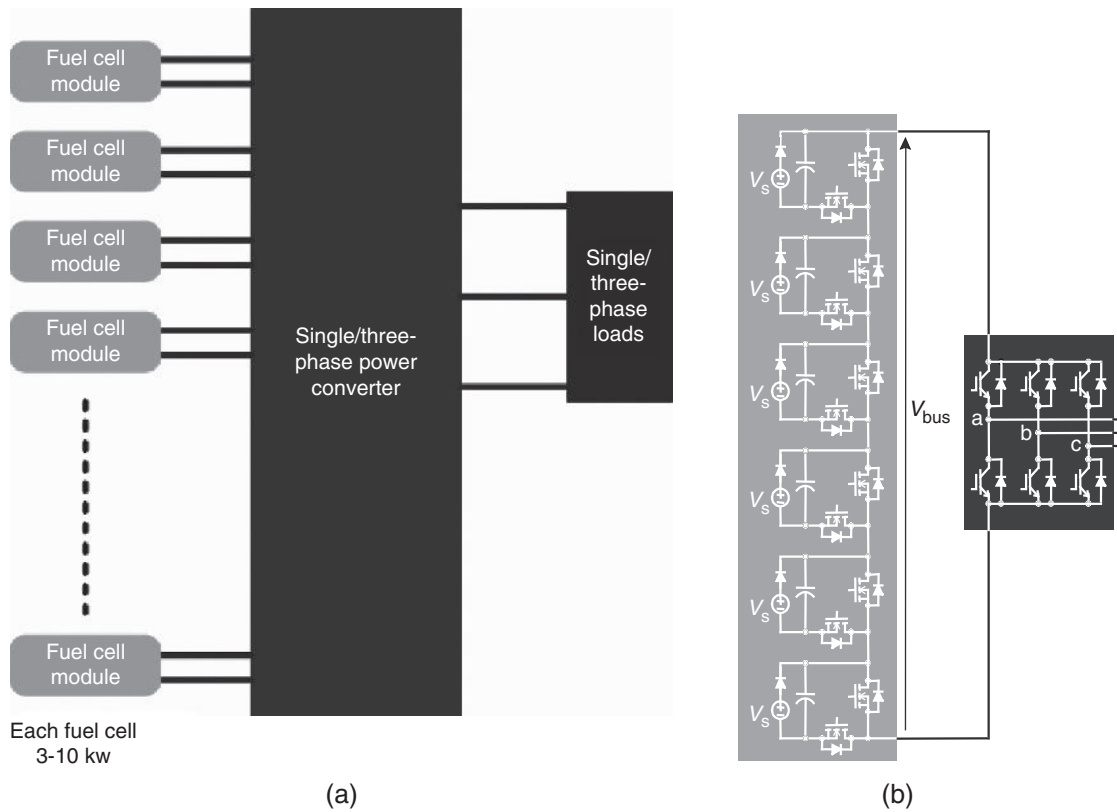

FIGURE 17.34   (a) Block diagram of the multilevel configuration and (b) six-level dc–dc converter connected with three-phase conventional inverter.

the ac grid without voltage balancing problems. Nevertheless, the intrinsic characteristics of renewable energy sources might have some trouble with their energy source utilization; for instance, fuel-cell energy sources have some problems associated with their V–I characteristics. The static V–I characteristic of fuel cells illustrates more than 30% difference in the output voltage between no-load and full-load conditions. This unavoidable decrease, caused by internal losses, reduces fuel-cell utilization factor. Therefore, a multilevel dc–dc converter might be used to overcome the problem as shown in Fig. 17.34. To overcome the fuel-cell voltage drop, either voltage regulators have to be connected at the fuel-cell outputs or fuel-cell voltages have to be monitored and the control signals have to be modified accordingly.

Five different approaches for integrating numerous fuel-cell modules have been evaluated and compared with respect to cost, control complexity, ease of modularity, and fault tolerance in [75]. In addition, the optimum fuel-cell utilization technique with a multilevel dc–dc converter has been proposed in [76, 77].

17.7 Conclusion

This chapter has demonstrated the state of the art of multilevel power converter technology. Fundamental multilevel converter structures and modulation paradigms including the pros and cons of each technique have been discussed. Most of the chapter focuses on modern and more practical industrial applications of multilevel converters. A procedure for calculating the required ratings for the active switches, clamping diodes, and dc link capacitors with a design example has been described. The possible future enlargements of multilevel converter technology such as fault diagnosis system and renewable energy sources have been noted. It should be noted that this chapter could not cover all multilevel, power converter–related applications however the basic principles of different multilevel converters have been discussed methodically. The main objective of this chapter is to provide a general notion to readers who are interested in multilevel power converters and their applications.

AC–AC Converters

A. K. Chattopadhyay,
Ph.D., Life Fellow IEEE

*Department of Electrical
Engineering, Bengal Engineering
& Science University, Shibpur,
Howrah, India*

18.1 Introduction

A power electronic ac–ac converter, in generic form, accepts electric power from one system and converts it for delivery to another ac system with waveforms of different amplitude, frequency, and phase. They may be single-phase or three-phase types depending on their power ratings. The ac–ac converters employed to vary the rms voltage across the load at constant frequency are known as *ac voltage controllers or ac regulators*. The voltage control is accomplished either by (1) *phase control* under natural commutation using pairs of silicon-controlled rectifiers (SCRs) or triacs or (2) by *on/off control* under forced commutation/self-commutation using fully controlled self-commutated switches, such as gate turn-off thyristors (GTOs), power transistors, integrated gate bipolar transistor (IGBTs), MOS-controlled thyristors (MCTs), integrated gate-commutated thyristor (IGCTs), etc. The ac–ac power converters in which ac power at one frequency is directly converted to ac power at another frequency without any intermediate dc conversion link (as in the case of inverters) are known as *cycloconverters*, the majority of which use naturally commutated SCRs for their operation when the maximum output frequency is limited to a fraction of the input frequency. With rapid advancements of fast-acting fully controlled switches, forced commutated cycloconverters, or recently developed *matrix converters* with bidirectional on/off control switches provide independent control of the magnitude and the frequency of the generated output voltage, as well as sinusoidal modulation of output voltage and current.

Although typical applications of ac voltage controllers include lighting and heating control, online transformer tap changing, soft-starting, and speed control of pump and fan drives, the cycloconverters are mainly used for high-power, low-speed, large ac motor drives for application in cement kilns, rolling mills, and ship propellers. The power circuits, control methods, and the operation of the ac voltage

controllers, cycloconverters, and matrix converters are introduced in this chapter. A brief review is also made regarding their applications.

18.2 Single-Phase AC–AC Voltage Controller

The basic power circuit of a single-phase ac–ac voltage controller, as shown in Fig. 18.1a, comprises a pair of SCRs connected back-to-back (also known as inverse-parallel or anti-parallel) between the ac supply and the load. This connection provides a *bidirectional full-wave symmetrical* control, and the SCR pair can be replaced by a triac (Fig. 18.1b) for low-power applications. Alternate arrangements are shown in Fig. 18.1c with two diodes and two SCRs to provide a common cathode connection for simplifying the gating circuit without requiring isolation and in Fig. 18.1d with one SCR and four diodes to reduce the device cost but with increased device

conduction loss. An SCR and diode combination known as *thyrode controller*, as shown in Fig. 18.1e, provides a *unidirectional half-wave asymmetrical voltage* control with device economy, but introduces dc component and more harmonics, and thus it is not so practical to use except for very low-power-heating load.

With phase control, the switches conduct the load current for a chosen period of each input cycle of voltage and with on/off control, the switches connect the load either for a few cycles of input voltage and disconnect it for the next few cycles (*integral cycle control*) or the switches are turned on and off several times within alternate half cycles of input voltage (*ac chopper or pulse width modulated [PWM] ac voltage controller*).

18.2.1 Phase-Controlled Single-phase AC Voltage Controller

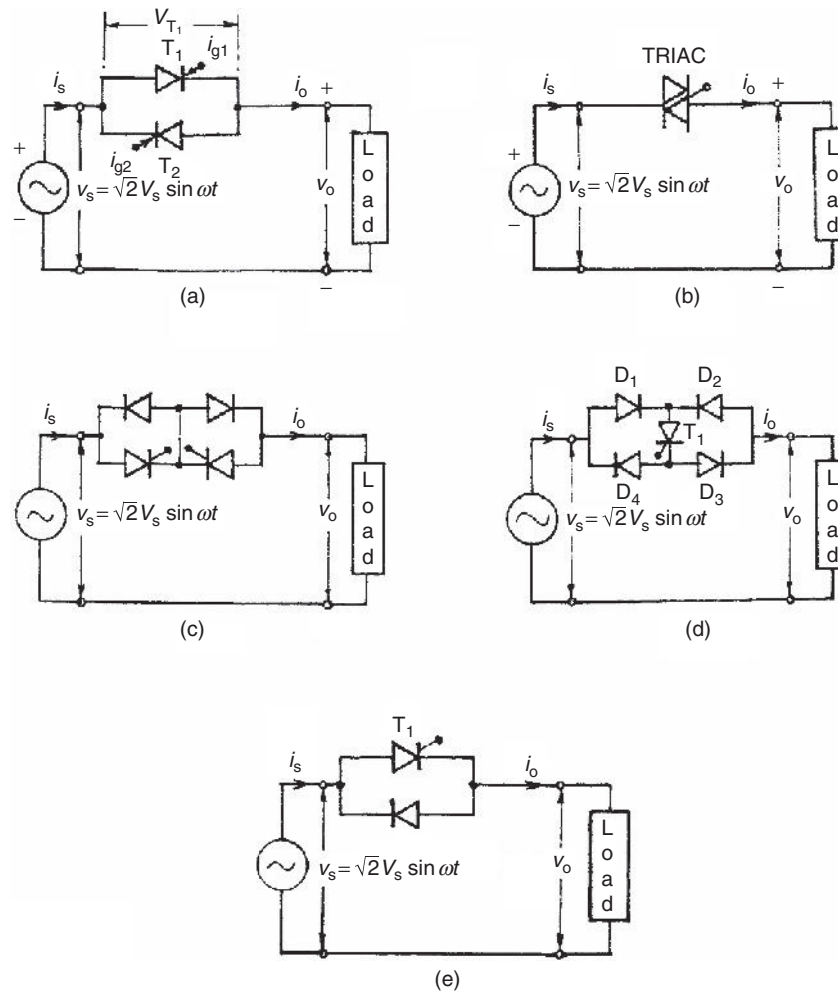
For a full-wave symmetrical phase control, the SCRs T_1 and T_2 in Fig. 18.1a are gated at α and $\pi + \alpha$, respectively, from the zero


FIGURE 18.1 Single-phase ac voltage controllers: (a) full wave, two SCRs in inverse-parallel; (b) full wave with triac; (c) full wave with two SCRs and two diodes; (d) full wave with four diodes and one SCR; and (e) half wave with one SCR and one diode in antiparallel.

crossing of the input voltage; by varying α, the power flow to the load is controlled through voltage control in alternate half cycles. As long as one SCR is carrying current, the other SCR remains reverse-biased by the voltage drop across the conducting SCR. The principle of operation in each half cycle is similar to that of the controlled half-wave rectifier, and one can use the same approach for analysis of the circuit.

Operation with R-load: Figure 18.2 shows the typical voltage and current waveforms for the single-phase bidirectional phase-controlled ac voltage controller of Fig. 18.1a with a resistive load. The output voltage and current waveforms have half-wave symmetry and so no dc component.

If $v_s = \sqrt{2}V_s \sin \omega t$ is the source voltage, the rms output voltage with T_1 triggered at α can be found from the half-wave symmetry as

$$V_o = \left[\frac{1}{\pi} \int_\alpha^\pi 2V_s^2 \sin^2 \omega t\, d(\omega t) \right]^{\frac{1}{2}} = V_s \left[1 - \frac{\alpha}{\pi} + \frac{\sin 2\alpha}{2\pi} \right]^{\frac{1}{2}}$$

$$(18.1)$$

Note that V_o can be varied from V_s to 0 by varying α from 0 to π.

$$\text{The rms value of load current, } I_o = \frac{V_o}{R} \qquad (18.2)$$

The input power factor $= \dfrac{P_o}{VA} = \dfrac{V_o}{V_s} = \left[1 - \dfrac{\alpha}{\pi} + \dfrac{\sin 2\alpha}{2\pi} \right]^{\frac{1}{2}}$

$$(18.3)$$

The average SCR current, $I_{A,SCR} = \dfrac{1}{2\pi R} \displaystyle\int_\alpha^\pi \sqrt{2}V_s \sin \omega t\, d(\omega t)$

$$(18.4)$$

Since each SCR carries half the line current, the rms current in each SCR is

$$I_{o,SCR} = \frac{I_o}{\sqrt{2}} \qquad (18.5)$$

Operation with RL Load: Figure 18.3 shows the voltage and current waveforms for the controller in Fig. 18.1a with RL load. Due to the inductance, the current carried by the SCR T_1 may not fall to zero at $\omega t = \pi$ when the input voltage goes negative and may continue till $\omega t = \beta$, the extinction angle, as shown. The conduction angle,

$$\theta = \beta - \alpha \qquad (18.6)$$

of the SCR depends on the firing delay angle α and the load impedance angle ϕ.

(a)

(b)

FIGURE 18.2 Waveforms for single-phase ac full-wave voltage controller with R-load.

(b)
FIGURE 18.3 Typical waveforms of single-phase ac voltage controller with an RL load.

The expression for the load current $I_o(\omega t)$, when conducting from α to β, can be derived in the same way as that used for a phase-controlled rectifier in a discontinuous mode by solving the relevant Kirchoff's voltage equation:

$$i_o(\omega t) = \frac{\sqrt{2}V}{Z}\left[\sin(\omega t - \phi)\right.$$

$$\left. - \sin(\alpha - \phi)e^{(\alpha - \omega t)/\tan\phi}\right], \quad \alpha < \omega t < \beta \quad (18.7)$$

where $Z = (R^2 + \omega^2 L^2)^{\frac{1}{2}}$ = load impedance and ϕ = load impedance angle = $\tan^{-1}(\omega L/R)$.

The angle β, when the current i_o falls to zero, can be determined from the following transcendental equation resulted by using $i_o(\omega t = \beta) = 0$ in Eq. (18.7).

$$\sin(\beta - \phi) = \sin(\alpha - \phi) - \sin(\alpha - \phi)\,e^{(\alpha - \beta)/\tan\phi} \quad (18.8)$$

From Eqs. (18.6) and (18.8), one can obtain a relationship between θ and α for a given value of ϕ, as shown in Fig. 18.4, which shows that as α is increased, the conduction angle θ decreases, and thus the rms value of the current decreases.

The rms output voltage

$$V_o = \left[\frac{1}{\pi}\int_{\alpha}^{\beta} 2V_s^2\sin^2\omega t\,d(\omega t)\right]^{\frac{1}{2}}$$

$$= \frac{V_s}{\pi}\left[\beta - \alpha + \frac{\sin2\alpha}{2} - \frac{\sin2\beta}{2}\right]^{\frac{1}{2}} \quad (18.9)$$

V_o can be evaluated for two possible extreme values of $\phi = 0$ when $\beta = \pi$, and $\phi = \pi/2$ when $\beta = 2\pi - \alpha$, and the envelope of the voltage control characteristics for this controller is shown in Fig. 18.5.
FIGURE 18.4 θ versus α curves for single-phase ac voltage controller with RL load.
FIGURE 18.5 Envelope of control characteristics of a single-phase ac voltage controller with RL load.

The rms SCR current can be obtained from Eq. (18.7) as follows:

$$I_{o,SCR} = \left[\frac{1}{2\pi}\int_{\alpha}^{\beta} i_o^2 d(\omega t)\right]^{\frac{1}{2}} \quad (18.10)$$

The rms load current, $I_o = \sqrt{2}\,I_{o,SCR}$ \quad (18.11)

The average value of SCR current, $I_{A,SCR} = \frac{1}{2\pi}\int_{\alpha}^{\beta} i_o d(\omega t)$

$$(18.12)$$

Gating Signal Requirements: For the inverse-parallel SCRs as shown in Fig. 18.1a, the gating signals of SCRs must be isolated from one another because there is no common cathode. For R-load, each SCR stops conducting at the end of each half cycle and under this condition, single short pulses may be used for gating as shown in Fig. 18.2. With RL load, however, this single short pulse gating is not suitable as shown in Fig. 18.6. When SCR T_2 is triggered at $\omega t = \pi + \alpha$, SCR T_1 is still conducting due to the load inductance. By the time the SCR T_1 stops conducting at β, the gate pulse for SCR T_2 has already ceased and T_2 will fail to turn on resulting the converter to operate as a single-phase rectifier with conduction of T_1 only. This necessitates the application of a sustained gate pulse either in the form of a continuous signal for the half-cycle period, which increases the dissipation in SCR gate circuit and a large isolating pulse transformer or better a *train of pulses* (*carrier frequency gating*) to overcome these difficulties.

Operation with $\alpha < \phi$***:*** If $\alpha = \phi$, then from Eq. (18.8),

$$\sin(\beta - \phi) = \sin(\beta - \alpha) = 0 \quad (18.13)$$

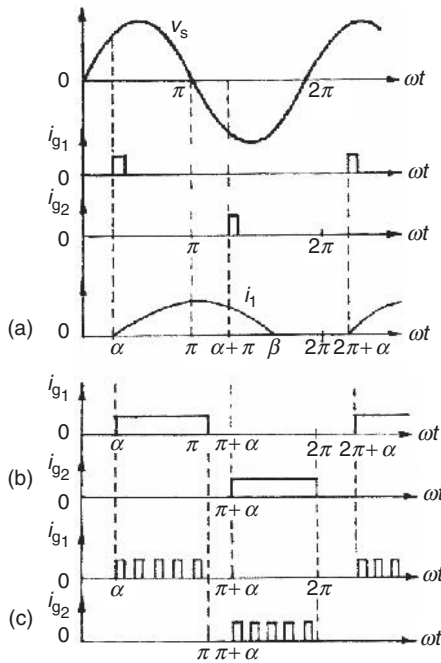
$$\text{and} \quad \beta - \alpha = \theta = \pi \quad (18.14)$$


FIGURE 18.6   Single-phase full-wave controller with RL load: gate pulse requirements.

FIGURE 18.7   Harmonic content as a function of the firing angle for a single-phase voltage controller with RL load.

As the conduction angle θ cannot exceed π and the load current must pass through zero, the control range of the firing angle is $\phi \le \alpha \le \pi$. With narrow gating pulses and $\alpha < \phi$, only one SCR will conduct resulting in a rectifier action as shown. Even with a train of pulses, if $\alpha < \phi$, the changes in the firing angle will not change the output voltage and current but both the SCRs will conduct for the period π with T_1 becoming on at $\omega t = \pi$ and T_2 at $\omega t + \pi$.

The duration of this *dead zone* ($\alpha = 0$ to ϕ), which varies with the load impedance angle ϕ is not a desirable feature in closed-loop control schemes. An alternative approach to the phase control with respect to the input voltage zero crossing has been visualized in which the firing angle is defined with respect to the instant when it is the load current, not the input voltage, that reaches zero, this angle being called *the hold-off angle* (γ) *or the control angle* (as marked in Fig. 18.3). This method needs sensing the load current, which may otherwise be required in a closed-loop controller for monitoring or control purposes.

Power Factor and Harmonics: As in the case of phase-controlled rectifiers, the important limitations of the phase-controlled ac voltage controllers are the poor power factor and the introduction of harmonics in the source currents. As seen from Eq.(18.3), the input power factor depends on α and as α increases, the power factor decreases.

The harmonic distortion increases and the quality of the input current decreases with increase of firing angle. The variations of low-order harmonics with the firing angle as computed by Fourier analysis of the voltage waveform of Fig. 18.2

(with R-load) are shown in Fig. 18.7. Only odd harmonics exist in the input current because of half-wave symmetry.

18.2.2 Single-Phase AC–AC Voltage Controller with On/Off Control

Integral Cycle Control: As an alternative to the phase control, the method of integral cycle control or burst-firing is used for heating loads. Here, the switch is turned on for a time t_n with n integral cycles and turned off for a time t_m with m integral cycles (Fig. 18.8). As the SCRs or triacs used here are turned on at the zero crossing of the input voltage and turn off occurs at zero current, supply harmonics and radio frequency interference are very low.

However, subharmonic frequency components may be generated, which are undesirable because they may set up subharmonic resonance in the power supply system, cause lamp flicker, and may interfere with the natural frequencies of motor loads causing shaft oscillations.

For sinusoidal input voltage, $v = \sqrt{2}V_s \sin\omega t$, the rms output voltage,

$$V_o = V_s\sqrt{k} \text{ where } k = n/(n+m) = \text{duty cycle} \qquad (18.15)$$

and V_s = rms phase voltage

$$\text{The power factor} = \sqrt{k}, \qquad (18.16)$$

which is poorer for lower values of the duty cycle k.
FIGURE 18.8 Integral cycle control: (a) typical load voltage waveforms and (b) power factor with the duty cycle *k*.

PWM AC Chopper: As in the case of controlled rectifier, the performance of ac voltage controllers can be improved in terms of harmonics, quality of output current, and input power factor by PWM control in PWM ac choppers; the circuit configuration of one such single-phase unit is shown in Fig. 18.9. Here, fully controlled switches S_1 and S_2 connected in antiparallel are turned on and off many times during the positive and negative half cycles of the input voltage, respectively. S_1' and S_2' provide the freewheeling paths for the load current when S_1 and S_2 are off. An input capacitor filter may be provided to attenuate the high switching frequency currents drawn from the supply and also to improve the input power factor. Figure 18.10 shows the typical output voltage and load current

FIGURE 18.9 Single-phase PWM ac chopper circuit.

FIGURE 18.10 Typical output voltage and current waveforms of a single-phase PWM ac chopper.

waveform for a single-phase PWM ac chopper. It can be shown that the control characteristics of an ac chopper depend on the *modulation index M*, which theoretically varies from 0 to 1.

Three-phase PWM choppers consist of three single-phase choppers either connected in delta or four-wire (star) configuration.

18.3 Three-Phase AC–AC Voltage Controllers

18.3.1 Phase-Controlled Three-Phase AC Voltage Controllers

Various Configurations: Several possible circuit configurations for three-phase phase-controlled ac regulators with star or delta connected loads are shown in Fig. 18.11a–h.

The configurations in (a) and (b) can be realized by three single-phase ac regulators operating independently of each other, and they are easy to analyze. In (a), the SCRs are to be rated to carry line currents and withstand phase voltages, whereas in (b) they should be capable to carry phase currents and withstand the line voltage. In (b), the line currents are free from triplen harmonics while these are present in the closed delta. The power factor in (b) is slightly higher. The firing angle control range for both these circuits is 0–180° for R-load.

The circuits in (c) and (d) are three-phase three-wire circuits and are complicated to analyze. In both these circuits, at least two SCRs, one in each phase, must be gated simultaneously to get the controller started by establishing a current path between the supply lines. This necessitates two firing pulses spaced at 60° apart per cycle for firing each SCR. The operation modes are defined by the number of SCRs conducting in these modes. The firing control range is 0–150°. The triplen harmonics are absent in both these configurations.

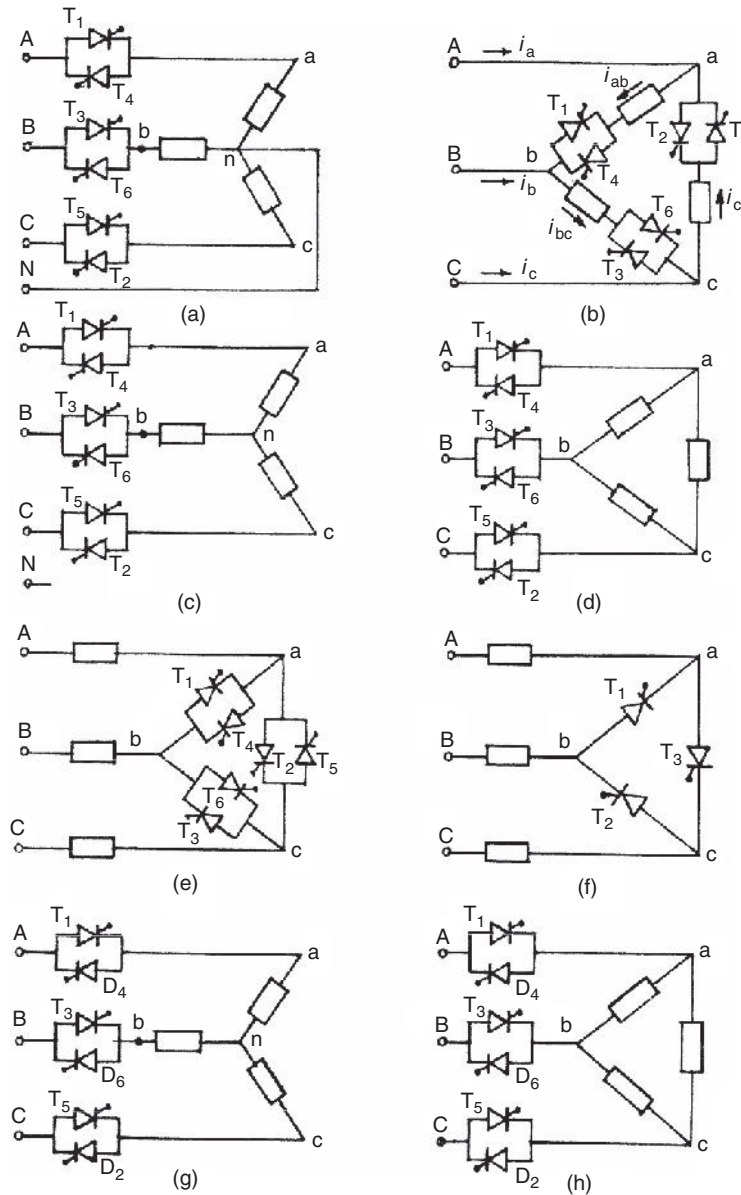
Another configuration is shown in (e) when the controllers are connected in delta and the load is connected between the supply and the converter. Here, current can flow between two lines even if one SCR is conducting so each SCR requires one


FIGURE 18.11   Three-phase ac voltage controller circuit configurations.

firing pulse per cycle. The voltage and current ratings of SCRs are nearly the same as that of the circuit (b). It is also possible to reduce the number of devices to three SCRs in delta as shown in (f), connecting one source terminal directly to one load circuit terminal. Each SCR is provided with gate pulses in each cycle spaced at 120° apart. In both (e) and (f), each end of each phase must be accessible. The number of devices in (f) is less, but their current ratings must be higher.

As in the case of single-phase phase-controlled voltage regulator, the total regulator cost can be reduced by replacing six SCRs by three SCRs and three diodes, resulting in three-phase *half-wave controlled* unidirectional ac regulators as shown in (g) and (h) for star- and delta-connected loads. The main drawback of these circuits is the large harmonic content

in the output voltage – particularly, the second harmonic because of the asymmetry. However, the dc components are absent in the line. The maximum firing angle in the half-wave controlled regulator is 210°.

18.3.2 Fully Controlled Three-Phase Three-Wire AC Voltage Controller

Star-connected Load with Isolated Neutral: The analysis of operation of the full-wave controller with isolated neutral as shown in Fig. 18.11c is, as mentioned, quite complicated in comparison to that of a single-phase controller, particularly for an RL or motor load. As a simple example, the operation of this controller with a simple star-connected R-load is considered

here. The six SCRs are turned on in the sequence 1-2-3-4-5-6 at 60° intervals, and the gate signals are sustained throughout the possible conduction angle.

The output phase voltage waveforms for $\alpha = 30°$, 75°, and 120° for a balanced three-phase R-load are shown in Fig. 18.12. At any interval, either three SCRs, or two SCRs, or no SCRs may be on, and the instantaneous output voltages to the load are either a line-to-neutral voltage (three SCRs on), or one-half of the line-to-line voltage (two SCRs on), or zero (no SCR on).

Depending on the firing angle α, there may be *three* operating modes:

Mode I (also known as Mode 2/3): $0 \leq \alpha \leq 60°$; There are periods when *three* SCRs are conducting, one in each phase for either direction, and there are periods when just *two* SCRs conduct.
(a)
(b)
(c)

FIGURE 18.12 Output voltage waveforms for a three-phase ac voltage controller with star-connected R-load: (a) v_{an} for $\alpha = 30°$; (b) v_{an} for $\alpha = 75°$; and (c) $v_{an} = 120°$.

For example, with $\alpha = 30°$ in Fig. 18.12a, assume that at $\omega t = 0$, SCRs T_5 and T_6 are conducting, and the current through the R-load in a-phase is zero making $v_{an} = 0$. At $\omega t = 30°$, T_1 receives a gate pulse and starts conducting; T_5 and T_6 remain on and $v_{an} = v_{AN}$. The current in T_5 reaches zero at 60°, turning T_5 off. With T_1 and T_6 staying on, $v_{an} = \frac{1}{2}v_{AB}$. At 90°, T_2 is turned on, the three SCRs T_1, T_2, and T_6 are then conducting and $v_{an} = v_{AN}$. At 120°, T_6 turns off, leaving T_1 and T_2 on, so $v_{an} = \frac{1}{2}v_{AC}$. Thus with the progress of firing in sequence till $\alpha = 60°$, the number of SCRs conducting at a particular instant alternates between two and three.

Mode II (also known as Mode 2/2): $60° \leq \alpha \leq 90°$; *Two* SCRs, one in each phase, always conduct.

For $\alpha = 75°$ as shown in Fig. 18.12b, just prior to $\alpha = 75°$, SCRs T_5 and T_6 were conducting and $v_{an} = 0$. At 75°, T_1 is turned on, and T_6 continues to conduct, whereas T_5 turns off as v_{CN} is negative. $v_{an} = \frac{1}{2}v_{AB}$. When T_2 is turned on at 135°, T_6 is turned off and $v_{an} = \frac{1}{2}v_{AC}$. The next SCR to turn on is T_3, which turns off T_1 and $v_{an} = 0$. One SCR is always turned off when another is turned on in this range of α, and the output voltage is either one-half line-to-line voltage or zero.

Mode III (also known as Mode 0/2): $90° \leq \alpha \leq 150°$; When *none* or *two* SCRs conduct.

For $\alpha = 120°$, Fig. 18.12c, earlier no SCRs were on and $v_{an} = 0$. At $\alpha = 120°$, SCR T_1 is given a gate signal, whereas T_6 has a gate signal already applied. Since v_{AB} is positive, T_1 and T_6 are forward-biased and they begin to conduct and $v_{an} = \frac{1}{2}v_{AB}$. Both T_1 and T_6 turn off when v_{AB} becomes negative. When a gate signal is given to T_2, it turns on and T_1 turns on again.

For $\alpha > 150°$, there is no period when two SCRs are conducting and the output voltage is zero at $\alpha = 150°$. Thus, the range of the firing angle control is $0 \leq \alpha \leq 150°$.

For *star-connected R-load*, assuming the instantaneous phase voltages as

$$v_{AN} = \sqrt{2}V_s \sin \omega t$$

$$v_{BN} = \sqrt{2}V_s \sin \omega t - 120° \qquad (18.17)$$

$$v_{CN} = \sqrt{2}V_s \sin \omega t - 240°$$

the expressions for the rms output phase voltage V_o can be derived for the three modes as follows:

$$0 \leq \alpha \leq 60° \quad V_o = V_s \left[1 - \frac{3\alpha}{2\pi} + \frac{3}{4\pi} \sin 2\alpha \right]^{\frac{1}{2}} \qquad (18.18)$$

$$60° \leq \alpha \leq 90° \quad V_o = V_s \left[\frac{1}{2} + \frac{3}{4\pi} \sin 2\alpha + \sin(2\alpha + 60°) \right]^{\frac{1}{2}} \qquad (18.19)$$

$$90° \leq \alpha \leq 150° \quad V_o = V_s \left[\frac{5}{4} - \frac{3\alpha}{2\pi} + \frac{3}{4\pi} \sin(2\alpha + 60°) \right]^{\frac{1}{2}} \qquad (18.20)$$

For *star-connected pure L-load*, the effective control starts at $\alpha > 90°$, and the expressions for two ranges of α are as follows:

$$90° \leq \alpha \leq 120° \quad V_o = V_s \left[\frac{5}{2} - \frac{3\alpha}{\pi} + \frac{3}{2\pi} \sin 2\alpha \right]^{\frac{1}{2}} \quad (18.21)$$

$$120° \leq \alpha \leq 150° \quad V_o = V_s \left[\frac{5}{2} - \frac{3\alpha}{\pi} + \frac{3}{2\pi} \sin(2\alpha + 60°) \right]^{\frac{1}{2}}$$
$$(18.22)$$

The control characteristics for these two limiting cases ($\phi = 0$ for R-load and $\phi = 90°$ for L-load) are shown in Fig. 18.13. Here also, like the single-phase case, the dead zone may be avoided by controlling the voltage with respect to the control angle or hold-off angle (γ) from the zero crossing of current in place of the firing angle α.

RL Load: The analysis of the three-phase voltage controller with star-connected RL load with isolated neutral is quite complicated, since the SCRs do not cease to conduct at voltage zero, and the extinction angle β is to be known by solving the transcendental equation for the case. In this case, the Mode II operation disappears [1], and the operation shift from Mode I to Mode III depends on the so-called critical angle α_{crit} [2, 3], which can be evaluated from a numerical solution of the relevant transcendental equations. Computer simulation either by PSPICE program [4, 5] or a switching-variable approach coupled with an iterative procedure [6] is a practical means of obtaining the output voltage waveform in this case. Figure 18.14 shows typical simulation results using the later approach [6] for a three-phase voltage controller fed RL load for $\alpha = 60°$, $90°$, and $105°$, which agree with the corresponding practical oscillograms given in [7].
FIGURE 18.13   Envelope of control characteristics for a three-phase full-wave ac voltage controller.

Delta-Connected R-Load: The configuration is shown in Fig. 18.11b. The voltage across an R-load is the corresponding line-to-line voltage when one SCR in that phase is on. Figure 18.15 shows the line and phase currents for $\alpha = 130°$ and $90°$ with an R-load. The firing angle α is measured from the zero crossing of the line-to-line voltage, and the SCRs are turned on in the sequence as they are numbered. As in the single-phase case, the range of firing angle is $0 \leq \alpha \leq 180°$. The line currents can be obtained from the phase currents as follows:

$$i_a = i_{ab} - i_{ca}$$
$$i_b = i_{bc} - i_{ab} \quad (18.23)$$
$$i_c = i_{ca} - i_{bc}$$

The line currents depend on the firing angle and may be discontinuous as shown. Due to the delta connection, the triplen harmonic currents flow around the closed delta and do not appear in the line. The rms value of the line current varies between the range

$$\sqrt{2}I_\Delta \leq I_{L,rms} \leq \sqrt{3}I_{\Delta.rms} \quad (18.24)$$

as the conduction angle varies from very small (large α) to $180°$ ($\alpha = 0$).

18.4 Cycloconverters

In contrast to the ac voltage controllers operating at constant frequency, discussed so far, a cycloconverter operates as a direct ac–ac frequency changer with inherent voltage control feature. The basic principle of this converter to construct an alternating voltage wave of lower frequency from successive segment of voltage waves of higher frequency ac supply by a switching arrangement was conceived and patented in 1920s. Grid-controlled mercury-arc rectifiers were used in these converters installed in Germany in 1930s to obtain $16\frac{2}{3}$-Hz single-phase supply for ac series traction motors from a three-phase 50-Hz system, while at the same time a cycloconverter using 18 thyratrons supplying a 400 hp synchronous motor was in operation for some years as a power station auxiliary drive in the United States. However, the practical and commercial utilization of these schemes waited till the SCRs became available in 1960s. With the development of large-power SCRs and micropocessor-based control, the cycloconverter today is a matured practical converter for application in large-power low-speed variable-voltage variable-frequency (VVVF) ac drives in cement and steel rolling mills, as well as in variable-speed constant-frequency (VSCF) systems in aircrafts and naval ships.

A cycloconverter is a naturally commuted converter with inherent capability of bidirectional power flow, and there is
FIGURE 18.14 Typical simulation results for three-phase ac voltage controller-fed RL load ($R = 1\Omega, L = 3.2\,\text{mH}$) for $\alpha = 60°$, $90°$, and $105°$.
FIGURE 18.15   Waveforms of a three-phase ac voltage controller with a delta connected R-load: (a) $\alpha = 120°$ and (b) $\alpha = 90°$.

FIGURE 18.16   (a) Power circuit for a single-phase bridge cycloconverter and (b) simplified equivalent circuit of a cycloconverter.

no real limitation on its size unlike an SCR inverter with commutation elements. Here, the switching losses are considerably low, the regenerative operation at full power over complete speed range is inherent and it delivers a nearly sinusoidal waveform resulting in minimum torque pulsation and harmonic heating effects. It is capable of operating even with blowing out of individual SCR fuse (unlike inverter), and the requirements regarding turn-off time, current rise time, and dv/dt sensitivity of SCRs are low. The main limitations of a naturally commutated cycloconverter are (1) limited frequency range for subharmonic free and efficient operation and (2) poor input displacement/power factor, particularly at low-output voltages.

18.4.1 Single-Phase to Single-Phase Cycloconverter

Though rarely used, the operation of a single-phase to single-phase cycloconverter is useful to demonstrate the basic principle involved. Figure 18.16a shows the power circuit of a

single-phase bridge type of cycloconverter, which has the same arrangement as that of a single-phase dual converter. The firing angles of the individual two-pulse two-quadrant bridge converters are continuously modulated here, so that each ideally produces the same fundamental ac voltage at its output terminals as marked in the simplified equivalent circuit in Fig. 18.16b. Because of the unidirectional current carrying property of the individual converters, it is inherent that the positive half cycle of the current is carried by the P-converter and the negative half cycle of the current by the N-converter regardless of the phase of the current with respect to the voltage. This means that for a reactive load, each converter operates in both rectifying and inverting region during the period of the associated half cycle of the low-frequency output current.

Operation with R-Load: Figure 18.17 shows the input and output voltage waveforms with a pure R-load for a 50–$16\frac{2}{3}$-Hz cycloconverter. The P- and N-converters operate for alternate $T_o/2$ periods. The output frequency ($1/T_o$) can be varied by varying T_o and the voltage magnitude by varying the firing
FIGURE 18.17   Input and output waveforms of a 50–$16\frac{2}{3}$-Hz cyclocon-verter with RL load.

angle α of the SCRs. As shown in the figure, three cycles of the ac input wave are combined to produce one cycle of the output frequency to reduce the supply frequency to one-third across the load.

If α_P is the firing angle of the P-converter, the firing angle of the N-converter α_N is $\pi - \alpha_P$ and the average voltage of the P-converter is equal and opposite to that of the N-converter.

The inspection of Fig. 18.17 shows that the waveform with α remaining fixed in each half cycle generates a square wave having a large low-order harmonic content. A near approximation to sine wave can be synthesized by a phase modulation of the firing angles as shown in Fig. 18.18 for a 50–10-Hz cycloconverter. The harmonics in the load voltage waveform are less compared to earlier waveform. The supply current, however, contains a subharmonic at the output frequency for this case as shown.

Operation with RL Load: The cycloconverter is capable of supplying loads of any power factor. Figure 18.19 shows the idealized output voltage and current waveforms for a lagging power factor load where both the converters are operating as rectifier and inverter at the intervals marked. The load current lags the output voltage and the load current direction determines which converter is conducting. Each converter continues to conduct after its output voltage changes polarity and during this period, the converter acts as an inverter and the power is returned to the ac source. Inverter operation continues till the
FIGURE 18.18   Waveforms of a single-phase single-phase cycloconverter (50–10 Hz) with RL load: (a) load voltage and load current and (b) input supply current.
FIGURE 18.19   Idealized load voltage and current waveform for a cyclo-converter with RL load.

other converter starts to conduct. By controlling the frequency of oscillation and the *depth of modulation* of the firing angles of the converters (as shown later), it is possible to control the frequency and the amplitude of the output voltage.

The load current with RL load may be continuous or discontinuous depending on the load phase angle, ϕ. At light load inductance or for $\phi \leq \alpha \leq \pi$, there may be discontinuous load current with short zero-voltage periods. The current wave may contain even harmonics and subharmonic components. Further, as in the case of dual converter, although the mean output voltage of the two converters is equal and opposite, the instantaneous values may be unequal and a circulating current can flow within the converters. This circulating current can be limited by having a center-tapped reactor connected between the converters or can be completely eliminated by logical control similar to the dual converter case when the gate pulses to the converter remaining idle are suppressed, when the other converter is active. In practice, a zero-current interval of short duration is needed, in addition, between the operation of the P- and N-converters to ensure that the supply lines of the two converters are not short-circuited. With circulating current-free operation, the control scheme becomes complicated if the load current is discontinuous.

In the case of the circulating current scheme, the converters are kept in virtually continuous conduction over the whole range, and the control circuit is simple. To obtain reasonably good sinusoidal voltage waveform using the line-commutated two quadrant converters and eliminate the possibility of the short circuit of the supply voltages, the output frequency of the cycloconverter is limited to a much lower value of the supply frequency. The output voltage waveform and the output frequency range can be improved further by using converters of higher pulse numbers.

18.4.2 Three-Phase Cycloconverters

18.4.2.1 Three-Phase Three-Pulse Cycloconverter

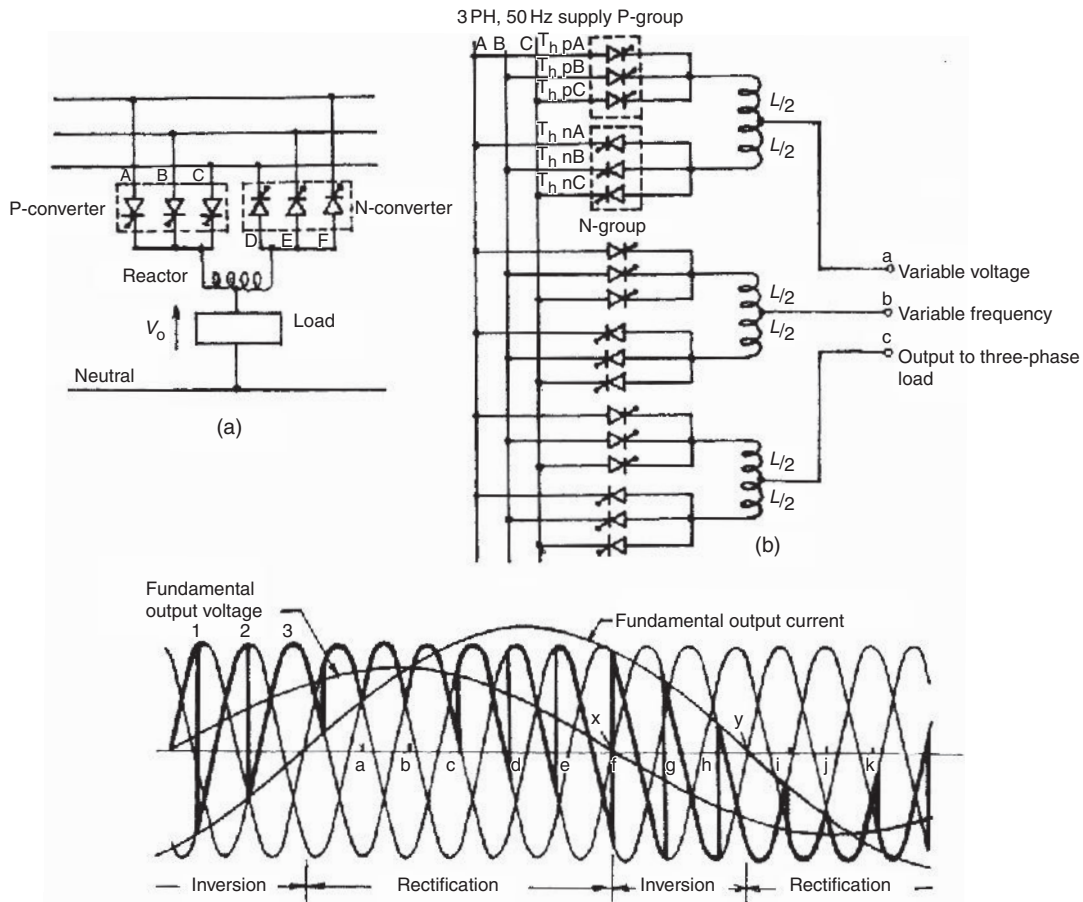
Figure 18.20a shows the schematic diagram of a three-phase half-wave (three-pulse) cycloconverter feeding a single-phase load and Fig. 18.20b, the configuration of a three-phase half-wave (three-pulse) cycloconverter feeding a three-phase load.


FIGURE 18.20 (a) Three-phase half-wave (three-pulse) cycloconverter supplying a single-phase load; (b) three-pulse cycloconverter supplying a three-phase load; and (c) output voltage waveform for one phase of a three-pulse cycloconverter operating at 15 Hz from a 50-Hz supply and 0.6-power factor lagging load.

The basic process of a three-phase cycloconversion is illustrated in Fig. 18.20c at 15 Hz, 0.6-power factor lagging load from a 50-Hz supply. As the firing angle α is cycled from zero at "a" to 180° at "j," half a cycle of output frequency is produced (the gating circuit is to be suitably designed to introduce this oscillation of the firing angle). For this load, it can be seen that although the mean output voltage reverses at X, the mean output current (assumed sinusoidal) remains positive until Y. During XY, the SCRs A, B, and C in P-converter are "inverting."

A similar period exists at the end of the negative half cycle of the output voltage when D, E, and F SCRs in N-converter are "inverting." Thus, the operation of the converter follows in the order of "rectification" and "inversion" in a cyclic manner, the relative durations are dependent on load power factor. The output frequency is that of the firing angle oscillation about a quiescent point of 90° (condition when the mean output voltage, given by $V_o = V_{do} \cos \alpha$, is zero). For obtaining the positive half cycle of the voltage, firing angle α is varied from 90° to 0° and then to 90° and for the negative half cycle, from 90° to 180° and back to 90°. Variation of α within the limits of 180° automatically provides for "natural" line commutation of

the SCRs. It is shown that a complete cycle of low-frequency output voltage is fabricated from the segments of the three-phase input voltage by using the phase-controlled converters. The P-converter or N-converter SCRs receive firing pulses, which are timed such that each converter delivers the same mean output voltage. This is achieved, as in the case of single-phase cycloconverter or the dual converter, by maintaining the firing angle constraints of the two groups as $\alpha_P = 180° - \alpha_N$. However, the instantaneous voltages of two converters are not identical and large circulating current may result unless limited by inter-group reactor as shown (*circulating-current cycloconverter*) or completely suppressed by removing the gate pulses from the non-conducting converter by an intergroup blanking logic (*circulating-current-free cycloconverter*).

Circulating-Current Mode Operation: Figure 18.21 shows typical waveforms of a three-pulse cycloconverter operating with circulating current. Each converter conducts continuously with rectifying and inverting modes as shown, and the load is supplied with an average voltage of two converters reducing some of the ripple in the process, the intergroup reactor
FIGURE 18.21   Waveforms of a three-pulse cycloconverter with circulating current.

behaving as a potential divider. The reactor limits the circulating current; the value of its inductance to the flow of load current is one-fourth of its value to the flow of circulating current as the inductance is proportional to the square of the number of turns. The fundamental wave produced by both the converters is the same. The reactor voltage is the instantaneous difference between the converter voltages, and the time integral of this voltage divided by the inductance (assuming negligible circuit resistance) is the circulating current. For a three-pulse cycloconverter, it can be observed that this current reaches its peak when $\alpha_P = 60°$ and $\alpha_N = 120°$.

   Output Voltage Equation: A simple expression for the fundamental rms output voltage of the cycloconverter and the required variation of the firing angle α can be derived with the following assumptions: (1) the firing angle α in successive half cycles is varied slowly resulting in a low-frequency output; (2) the source impedance and the commutation overlap are neglected; (3) the SCRs are ideal switches; and (4) the current is continuous and ripple-free. The average dc output voltage of a p-pulse dual converter with fixed α is

$$V_{do} = V_{domax} \cos \alpha, \quad \text{where } V_{domax} = \sqrt{2} V_{ph} \frac{p}{\pi} \sin \frac{\pi}{p}$$
(18.25)

   For the p-pulse dual converter operating as a cycloconverter, the average phase voltage output at any point of the low

frequency should vary according to the equation

$$V_{o,av} = V_{o1,\,max} \sin \omega_o t$$
(18.26)

where $V_{o1,max}$ is the desired maximum value of the fundamental output of the cycloconverter.

   Comparing Eq. (18.25) with Eq. (18.26), the required variation of α to obtain a sinusoidal output is given by

$$\alpha = \cos^{-1}[(V_{o1,\,max}/V_{domax}) \sin \omega_o t] = \cos^{-1}[r \sin \omega_o t]$$
(18.27)

where r is the ratio $(V_{o1,\,max}/V_{domax})$, the *voltage magnitude control ratio.*

   Equation (18.27) shows α as a nonlinear function with $r \ (\leq 1)$ as shown in Fig. 18.22.

   However, the firing angle α_P of the P-converter cannot be reduced to $0°$ as this corresponds to $\alpha_N = 180°$ for the N-converter which, in practice, cannot be achieved because of allowance for commutation overlap and finite turn-off time of the SCRs. Thus, the firing angle α_P can be reduced to a certain finite value α_{min}, and the maximum output voltage is reduced by a factor $\cos \alpha_{min}$.

   The fundamental rms voltage per phase of either converter is

$$V_{or} = V_{oN} = V_{op} = r V_{ph} \frac{p}{\pi} \sin \frac{\pi}{p}$$
(18.28)
FIGURE 18.22   Variations of the firing angle (α) with r in a cycloconverter.

Though the rms values of the low-frequency output voltage of the P-converter and that of the N-converter are equal, the actual waveforms differ and the output voltage at the midpoint of the circulating current-limiting reactor (Fig. 18.21), which is the same as the load voltage, is obtained as the mean of the instantaneous output voltages of the two converters.

Circulating Current-free Mode Operation: Figure 18.23 shows the typical waveforms for a three-pulse cycloconverter operating in this mode with RL load assuming *continuous-current* operation. Depending on the load current direction, only one converter operates at a time and the load voltage is the same as the output voltage of the conducting converter. As explained earlier in the case of single-phase cycloconverter,

there is a possibility of short circuit of the supply voltages at the cross-over points of the converter unless taken care of in the control circuit. The waveforms drawn also neglect the effect of overlap due to the ac supply inductance. A reduction in the output voltage is possible by retarding the firing angle gradually at the points a, b, c, d, e in Fig. 18.23. (This can be easily implemented by reducing the magnitude of the reference voltage in the control circuit). The circulating current is completely suppressed by blocking all the SCRs in the converter, which is not delivering the load current. A current sensor is incorporated in each output phase of the cycloconverter, which detects the direction of the output current and feeds an appropriate signal to the control circuit to inhibit or blank the gating pulses to the nonconducting converter in the same way as in the case of a dual converter for dc drives. The circulating current-free operation improves the efficiency, and the displacement factor of the cycloconverter and also increases the maximum usable output frequency. The load voltage transfers smoothly from one converter to the other.

18.4.2.2   Three-Phase Six-Pulse and Twelve-Pulse Cycloconverter

A six-pulse cycloconverter circuit configuration is shown in Fig. 18.24. Typical load voltage waveforms for 6-pulse (with 36 SCRs) and 12-pulse (with 72 SCRs) cycloconverters are shown in Fig. 18.25, the 12-pulse converter being obtained by connecting two 6-pulse configurations in series and appropriate transformer connections for the required phase-shift. It may be seen that the higher pulse numbers will generate waveforms closer to the desired sinusoidal form and thus permit higher frequency output. The phase loads may be isolated from

each other as shown or interconnected with suitable secondary winding connections.

18.4.3 Cycloconverter Control Scheme

Various possible control schemes, analog as well as digital, for deriving trigger signals and for controlling the basic cyclocon-verter have been developed over the years.

Out of the several possible signal combinations, it has been shown [8] that a sinusoidal reference signal $(e_r = E_r \sin \omega_o t)$ at desired output frequency f_o and a cosine modulating signal $(e_m = E_m \cos \omega_i t)$ at input frequency f_i is the best combina-tion possible for comparison to derive the trigger signals for the SCRs (Fig. 18.26 [9]), which produces the output waveform with the lowest total harmonic distortion. The modulating voltages can be obtained as the phase-shifted voltages (B-phase for A-phase SCRs, C-phase voltage for B-phase SCRs, and
FIGURE 18.26 Deriving firing signals for one converter group of a three-pulse cycloconverter.

so on) as explained in Fig. 18.27, where at the intersection point "a"

$$E_m \sin(\omega_i t - 120°) = -E_r \sin(\omega_o t - \phi)$$

$$\text{or} \cos(\omega_i t - 30°) = (E_r/E_m) \sin(\omega_o t - \phi)$$
FIGURE 18.27   Derivation of the cosine modulating voltages.

From Fig. 18.27, the firing delay for A-phase SCR, $\alpha = (\omega_i t - 30°)$

So, $\cos \alpha = (E_r/E_m) \sin(\omega_o t - \phi)$

The cycloconverter output voltage for continuous current operation,

$$V_o = V_{do} \cos \alpha = V_{do}(E_r/E_m) \sin(\omega_o t - \phi) \qquad (18.29)$$

in which the equation shows that the amplitude, frequency, and phase of the output voltage can be controlled by controlling corresponding parameters of the reference voltage, thus making the transfer characteristic of the cycloconverter linear. The derivation of the two complimentary voltage waveforms for the P-group or N-group converter "banks" in this way is illustrated in Fig. 18.28. The final cycloconverter output wave shape is composed of alternate half cycle segments of the complementary P-converter and the N-converter output voltage wave forms which coincide with the positive and negative current half cycles, respectively.

Control Circuit Block Diagram: Figure 18.29 [10] shows a simplified block diagram of the control circuit for a circulating
FIGURE 18.28   Derivation of P-converter and N-converter output voltages.

current-free cycloconverter implemented with ICs in the early seventies in the Power Electronics Laboratory at IIT Kharagpur in India. The same circuit is also applicable to a circulating current cycloconverter with the omission of the *converter group selection and blanking* circuit.

The *synchronizing circuit* produces the modulating voltages $(e_a = -Kv_b, e_b = -Kv_c, e_c = -Kv_a)$, synchronized with the mains through step-down transformers and proper filter circuits.

The *reference source* produces variable voltage variable frequency reference signal (e_{ra}, e_{rb}, e_{rc}) (three-phase for a three-phase cycloconverter) for comparison with the modulation voltages. Various ways, analog or digital, have been developed to implement this reference source as in the case of the PWM inverter. In one of the early analog schemes Fig. 18.30 [10], for a three-pulse cycloconverter, a variable-frequency UJT relaxation oscillator of frequency $6f_d$ triggers a ring counter to produce a three-phase square-wave output of frequency f_d which is used to modulate a single-phase fixed frequency (f_c) variable amplitude sinusoidal voltage in a three-phase full-wave transistor chopper. The three-phase output contains $(f_c - f_d), (f_c + f_d), (3f_d + f_c)$, etc. frequency components from where the "wanted" frequency component $(f_c - f_d)$ is filtered out for each phase using a low-pass filter. For example, with $f_c = 500$ Hz and frequency of the relaxation oscillator varying between 2820 and 3180 Hz, a three phase 0–30-Hz reference output can be obtained with the facility for phase sequence reversal.

The *logic and trigger circuit* for each phase involves comparators for comparison of the reference and modulating voltages, and inverters acting as buffer stages. The outputs of the comparators are used to clock the flip-flops or latches whose outputs in turn feed the SCR gates through AND gates and pulse amplifying and isolation circuits; the second input to the AND gates is from the *converter group selection and blanking circuit.*

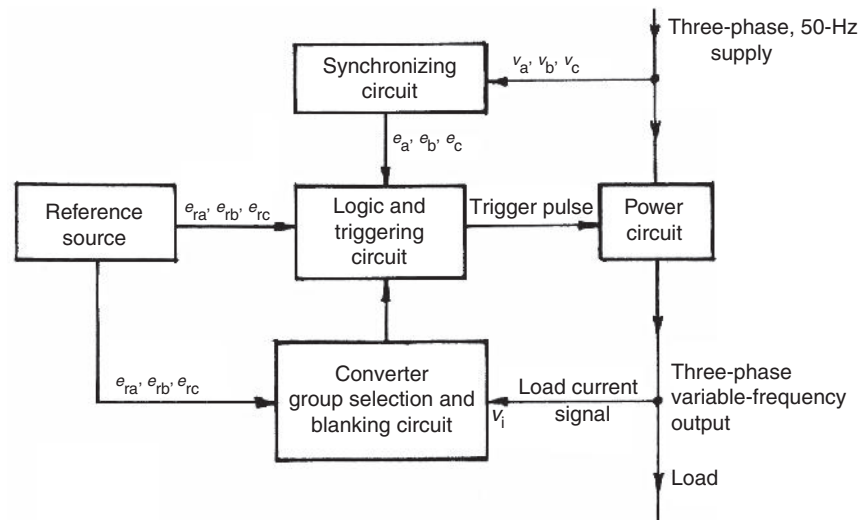
In the *converter group selection and blanking circuit,* the zero crossing of the current at the end of each half cycle is detected and is used to regulate the control signals either to P-group or N-group converters depending on whether the current goes to zero from negative to positive or positive to negative, respectively. However, in practice, the current being discontinuous passes through multiple zero crossings while changing direction, which may lead to undesirable switching of the converters. So, in addition to the current signal, the


FIGURE 18.29 Block diagram for a circulating current-free cycloconverter control circuit.
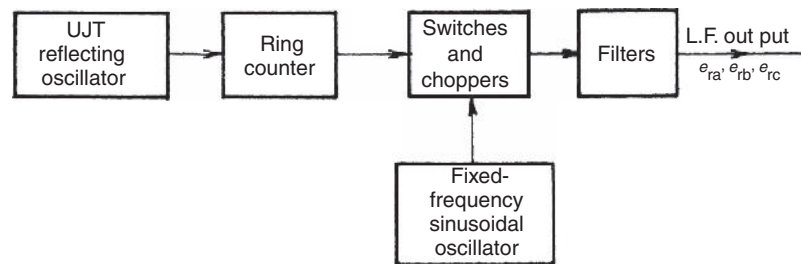

FIGURE 18.30 Block diagram of a variable-voltage variable-frequency three-phase reference source.

reference voltage signal is also used for the group selection, and a *threshold* band is introduced in the current signal detection to avoid inadvertent switching of the converters. Further, a delay circuit provides a blanking period of appropriate duration between the converter groups switching to avoid line-to-line short circuits [10]. In some schemes, the delays are not introduced when a small circulating current is allowed during cross-over instants limited by reactors of limited size, and this scheme operates in the so-called "dual mode" – circulating current and circulating current-free mode for minor and major portions of the output cycle, respectively. A different approach to the converter group selection, based on the closed-loop control of the output voltage where a bias voltage is introduced between the voltage transfer characteristics of the converters to reduce circulating current, is discussed in [8].

Improved Control Schemes: With the development of microprocessors and PC-based systems, digital software control has taken over many tasks in modern cycloconverters, particularly in replacing the low-level reference waveform generation and analog signal comparison units. The reference waveforms can be easily generated in the computer, stored in the

EPROMs and accessed under the control of a stored program and microprocessor clock oscillator. The analog signal voltages can be converted to digital signals by using analog-to-digital converters (ADCs). The waveform comparison can then be made with the comparison features of the microprocessor system. The addition of time delays and intergroup blanking can also be achieved with digital techniques and computer software. A modification of the cosine firing control using communication principles, such as *regular sampling* in preference to the *natural sampling* (discussed so far) of the reference waveform, yielding a stepped sine wave before comparison with the cosine wave [11] has been shown to reduce the presence of *sub harmonics* (discussed later) in the circulating current-cycloconverter and facilitate microprocessor-based implementation, as in the case of PWM inverter.

For a six-pulse noncirculating current cycloconverter-fed synchronous motor drive with a vector control scheme and a flux observer, a PC-based hybrid control scheme (a combination of analog and digital control) has been reported in [12]. Here, the functions such as comparison, group selection, blanking between the groups and triggering signal generation, filtering and phase conversion are left to the analog controller and digital controller that take care of more serious tasks such as voltage decoupling for current regulation, flux estimation

using observer, speed, flux and field current regulators using PI-controllers, position and speed calculation leading to an improvement of sampling time and design accuracy.

18.4.4 Cycloconverter Harmonics and Input Current Waveform

The exact wave shape of the output voltage of the cycloconverter depends on (1) the pulse number of the converter; (2) the ratio of the output to input frequency (f_o/f_i); (3) the relative level of the output voltage; (4) load displacement angle; (5) circulating current or circulating current-free operation; and (6) the method of control of the firing instants. The harmonic spectrum of a cycloconverter output voltage is different and more complex than that of a phase-controlled converter. It has been revealed [8] that because of the continuous "to-and-fro" phase modulation of the converter firing angles, the harmonic distortion components (known as *necessary distortion terms*) have frequencies which are sums and differences between multiples of output and input supply frequencies.

Circulating Current-Free Operation: A derived general expression for the output voltage of a cycloconverter with circulating current-free operation [8] shows the following spectrum of harmonic frequencies for the 3-pulse, 6-pulse, and 12-pulse cycloconverters employing cosine modulation technique:

$$3\text{-pulse:} \quad f_{oH} = \left| 3(2k-1)f_i \pm 2nf_o \right| \quad \text{and}$$
$$\left| 6kf_i \pm (2n+1)f_o \right|$$
$$6\text{-pulse:} \quad f_{oH} = \left| 6kf_i \pm (2n+1)f_o \right|$$
$$12\text{-pulse:} \quad f_{oH} = \left| 6kf_i \pm (2n+1)f_o \right| \qquad (18.30)$$

where k is any integer from 1 to infinity and n is any integer from 0 to infinity.

It may be observed that for certain ratios of f_o/f_i, the order of harmonics may be less or equal to the desired output frequency. All such harmonics are known as *subharmonics*, since they are not higher multiples of the input frequency. These subharmonics may have considerable amplitudes (e.g., with a 50-Hz input frequency and 35-Hz output frequency, a subharmonic of frequency $3 \times 50 - 4 \times 35 = 10$ Hz is produced whose magnitude is 12.5% of the 35-Hz component [11]) and are difficult to filter and so objectionable. Their spectrum increase with the increase of the ratio f_o/f_i and so limits its value at which a tolerable waveform can be generated.

Circulating-Current Operation: For circulating-current operation with continuous current, the harmonic spectrum in the output voltage is the same as that of the circulating current-free operation except that each harmonic family now terminates at a definite term, rather than having infinite number of

components. They are

$$3\text{-pulse:} \quad f_{oH}\left| 3(2k-1)f_i \pm 2nf_o \right|, \quad n \leq 3(2k-1)+1$$
$$\text{and} \left| 6kf_i \pm (2n+1)f_o \right|, \quad (2n+1) \leq (6k+1)$$
$$6\text{-pulse:} \quad f_{oH}\left| 6kf_i \pm (2n+1)f_o \right|, \quad (2n+1) \leq (6k+1)$$
$$12\text{-pulse:} \quad f_{oH}\left| 6kf_i \pm (2n+1)f_o \right|, \quad (2n+1) \leq (12k+1)$$
$$(18.31)$$

The amplitude of each harmonic component is a function of the output voltage ratio for the circulating-current cycloconverter and the output voltage ratio as well as the load displacement angle for the circulating current-free mode.

From the point of view of maximum useful attainable output-to-input frequency ratio (f_i/f_o) with the minimum amplitude of objectionable harmonic components, a guideline is available in [8] for it as 0.33, 0.5, and 0.75 for 3-, 6-, and 12-pulse cycloconverter, respectively. However, with the modification of the cosine wave modulation timings like *regular sampling* [11] in the case of circulating-current cycloconverters only and using a *subharmonic detection and feedback control concept* [13, 14] for both circulating- and circulating-current-free cases, the subharmonics can be suppressed and useful frequency range for the naturally commutated cycloconverters can be increased.

Other Harmonic Distortion Terms: Besides the harmonics as mentioned, other harmonic distortion terms consisting of frequencies of integral multiples of desired output frequency appear, if the transfer characteristic between the output and reference voltages is not linear. These are called *unnecessary distortion terms* which are absent when the output frequencies are much less than the input frequency. Further, some *practical distortion terms* may appear due to some practical nonlinearities and imperfections in the control circuits of the cycloconverter, particularly at relatively lower levels of output voltage.

Input Current Waveform: Although the load current, particularly for higher pulse cycloconverters can be assumed to be sinusoidal, the input current is more complex being made of pulses. Assuming the cycloconverter to be an ideal switching circuit without losses, it can be shown from the instantaneous power balance equation that in cycloconverter supplying a single-phase load, the input current has harmonic components of frequencies ($f_I \pm 2f_o$), called *characteristic harmonic frequencies* which are independent of pulse number and they result in an oscillatory power transmittal to the ac supply system. In the case of cycloconverter feeding a balanced three-phase load, the net instantaneous power is the sum of the three oscillating instantaneous powers when the resultant power is constant and the net harmonic component is much reduced compared to that of a single-phase load case. In general, the total rms value of the input current waveform consists of three

components: in-phase, quadrature, and the harmonic. The in-phase component depends on the active power output while the quadrature component depends on the net average of the oscillatory firing angle and is always lagging.

18.4.5 Cycloconverter Input Displacement/Power Factor

The input supply performance of a cycloconverter such as displacement factor or fundamental power factor, input power factor, and the input current distortion factor are defined similar to those of the phase-controlled converter. The harmonic factor for the case of a cycloconverter is relatively complex as the harmonic frequencies are not simple multiples of the input frequency but are sums and differences between multiples of output and input frequencies.

Irrespective of the nature of the load, leading, lagging, or unity power factor, the cycloconverter requires reactive power decided by the average firing angle. At low output voltage, the average phase displacement between the input current and the voltage is large and the cycloconverter has a low input displacement and power factor. Besides load displacement factor and output voltage ratio, another component of the reactive current arises due to the modulation of the firing angle in the fabrication process of the output voltage [8]. In a phase-controlled converter supplying dc load, the maximum displacement factor is unity for maximum dc output voltage. However, in the case of the cycloconverter, the maximum input displacement factor is 0.843 with unity power factor load [8, 15]. The displacement factor decreases with reduction in the output voltage ratio. The distortion factor of the input current is given by (I_1/I) which is always less than 1 and the resultant power factor ($=$ distortion factor $\times$ displacement factor) is thus much lower (around 0.76 maximum) than the displacement factor and this is a serious disadvantage of the naturally commutated cycloconverter (NCC).

18.4.6 Effect of Source Impedance

The source inductance introduces commutation overlap and affects the external characteristics of a cycloconverter similar to the case of a phase-controlled converter with the dc output. It introduces delay in transfer of current from one SCR to another, results in a voltage loss at the output and a modified harmonic distortion. At the input, the source impedance causes "rounding off" of the steep edges of the input current waveforms, resulting in reduction in the amplitudes of higher order harmonic terms and a decrease in the input displacement factor.

18.4.7 Simulation Analysis of Cycloconverter Performance

The nonlinearity and discrete time nature of practical cycloconverter systems, particularly for discontinuous current conditions make an exact analysis quite complex and a valuable design and analytical tool is a digital computer simulation of the system. Two general methods of computer simulation of the cycloconverter waveforms for RL and induction motor loads with circulating current and circulating current-free operation have been suggested in [16] where one of the methods which is very fast and convenient is the *cross-over points method* that gives the cross-over points (intersections of the modulating and reference waveforms) and the conducting phase numbers for both P- and N-converters from which the output waveforms for a particular load can be digitally computed at any interval of time for a practical cycloconverter.

18.4.8 Power Quality Issues

Degradation of power quality (PQ) in a cycloconverter-fed system due to subharmonics/interharmonics in the input and the output has been a subject of recent studies [14, 17]. In [17], the study includes the impact of cycloconverter control strategies on the total harmonic distortion (THD), distribution transformers, and communication lines while in [14], the PQ indices are suitably defined and the effect on THD, input/output displacement factor and input/output power factor for a cycloconverter-fed synchronous motor drive are studied together with a development of a simple feedback method of reduction of subharmonics/low frequency interharmonics for improvement of the power quality. The implementation of this scheme, detailed in [14], requires a simple modification of the control circuit of the cycloconverter in contrast to the expensive power level active filters otherwise required for suppression of such harmonics [18].

18.4.9 Forced Commutated Cycloconverter

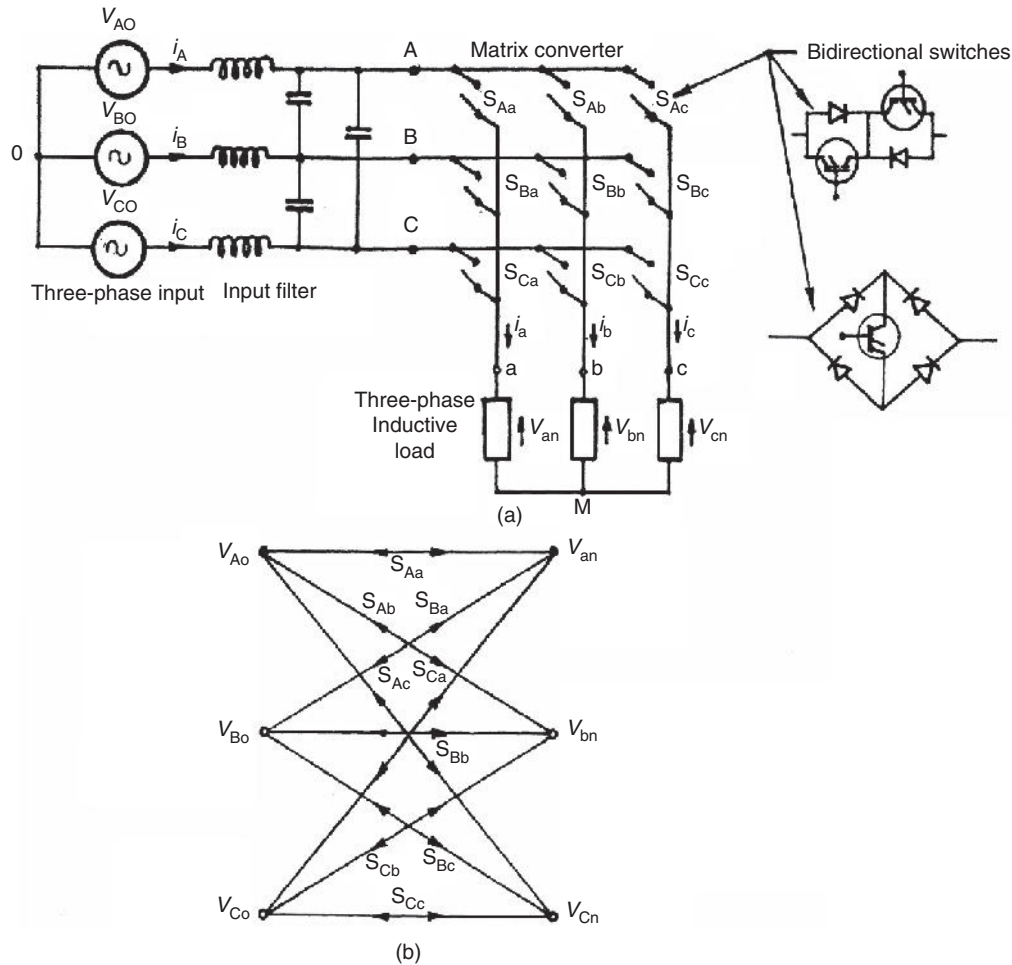
The naturally commutated cycloconverter (NCC) with SCRs as devices, so far discussed, is sometimes referred to as, a *restricted frequency changer* as in view of the allowance on the output voltage quality ratings, the maximum output voltage frequency is restricted ($f_o \ll f_i$), as mentioned earlier. With devices replaced by fully controlled switches like forced commutated SCRs, power transistors, IGBTs, GTOs, etc., a forced commutated cycloconverter can be built where the desired output frequency is given by $f_o = |f_s - f_i|$, where f_s is the switching frequency, which may be larger or smaller than the f_i. In the case when $f_o \geq f_i$, the converter is called *unrestricted frequency changer (UFC)* and when $f_o \leq f_i$, it is called a *slow switching frequency changer (SSFC)*. The early FCC structures have been comprehensively treated in [15]. It has been shown that in contrast with the NCC, when the input displacement factor (IDF) is always lagging, in UFC it is leading when the load displacement factor is lagging and vice versa, and in SSFC, it is identical to that of the load. Further, with proper control in an FCC, the input displacement factor can be made unity displacement factor frequency changer (UDFFC) with concurrent composite


FIGURE 18.31   (a) 3ϕ-3ϕ Matrix converter (forced commutated cycloconverter) circuit with input filter and (b) switching matrix symbol for converter in (a).

voltage waveform or controllable displacement factor frequency changer (CDFFC), where P-converter and N-converter voltage segments can be shifted relative to the output current wave for control of IDF continuously from lagging via unity to leading.

In addition to allowing bilateral power flow, UFCs offer an unlimited output frequency range, offer good input voltage utilization, do not generate input current and output voltage subharmonics and require only nine bidirectional switches (Fig. 18.31) for a three-phase to three-phase conversion. The main disadvantage of the structures treated in [15] is that they generate large unwanted low-order input current and output voltage harmonics which are difficult to filter out, particularly for low output voltage conditions. This problem has largely been solved with an introduction of an imaginative PWM voltage control scheme in [19], which is the basis of the newly designated converter called the *matrix converter (also known as PWM cycloconverter)* which operates as a *generalized solid-state transformer* with significant improvement in voltage and input current waveforms resulting in sine-wave input and sine-wave output as discussed in the next section.

18.5 Matrix Converter

The matrix converter (MC) is a development of the FCC based on bidirectional fully controlled switches, incorporating PWM voltage control, as mentioned earlier. With the initial progress made by Venturini [19–21], it has received considerable attention in recent years as it provides a good alternative to the double-sided PWM voltage source rectifier–inverters having the advantages of being a single stage converter with only nine switches for three-phase to three-phase conversion and inherent bidirectional power flow, sinusoidal input/output waveforms with moderate switching frequency, possibility of a compact design due to the absence of dc link reactive components, and controllable input power factor independent of the output load current. The main disadvantages of the matrix converters developed so far are the inherent restriction of the *voltage transfer ratio* (0.866), a more complex control, commutation and protection strategy, and above all the nonavailability of a fully controlled bidirectional high frequency switch integrated in a silicon chip (triac, though bilateral, cannot be fully controlled).

The power circuit diagram of the most practical three-phase to three-phase (3φ–3φ) matrix converter is shown in Fig. 18.31a which uses nine bidirectional switches so arranged that any of the three input phases can be connected to any output phase as shown in the switching matrix symbol in Fig. 18.31b. Thus, the voltage at any input terminal may be made to appear at any output terminal or terminals while the current in any phase of the load may be drawn from any phase or phases of the input supply. For the switches, the inverse-parallel combination of reverse-blocking self-controlled devices like power MOSFETs or IGBTs or transistor embedded diode bridge as shown have been used so far. New perspective configuration of the bidirectional switch is to use two RB-IGBTs with reverse blocking capability in antiparallel, eliminating the diodes reducing the conducting losses in the converter significantly. The circuit is called a *matrix converter* as it provides exactly one switch for each of the possible connections between the input and the output. The switches should be controlled in such a way that, at any time, one and only one of the three switches connected to an output phase must be closed to prevent "short circuiting" of the supply lines or interrupting the load current flow in an inductive load. With these constraints, it can be visualized that out of the possible 512 (= 2^9) states of the converter, only 27 switch combinations are allowed as given in Table 18.1 which includes the resulting output line voltages and input phase currents. These combinations are divided into three groups. Group-I consists of six combinations when each output phase is connected to a different input phase. In Group-II, there are three subgroups each having six combinations with two output phases short-circuited (connected to the same input phase). Group-III includes three combinations with all output phases short-circuited.

With a given set of input three-phase voltages, any desired set of three-phase output voltages can be synthesized by adopting a suitable switching strategy. However, it has been shown [21, 22] that regardless of the switching strategy, there are physical limits on the achievable output voltage with these converters as the maximum peak-to-peak output voltage cannot be greater than the minimum voltage difference between two phases of the input. To have complete control of the synthesized output voltage, the envelope of the three-phase reference or target voltages must be fully contained within the continuous envelope of the three-phase input voltages. Initial strategy with the output frequency voltages as references reported the limit as 0.5 of the input as shown in Fig. 18.32a. This can be increased to 0.866 by adding a third-harmonic voltage of input frequency
FIGURE 18.32   Output voltage limits for three-phase ac-ac matrix converter: (a) basic converter input voltages and (b) maximum attainable with inclusion of third harmonic voltages of input and output frequency to the target voltages.

$(V_i/4) \cos 3\omega_i t$ to all target output voltages and subtracting from them a third harmonic voltage of output frequency $(V_o/6) \cos 3\omega_o t$ as shown in Fig. 18.32b [21, 22]. However, this process involves considerable amount of additional computations in synthesizing the output voltages. The other alternative is to use the space vector modulation (SVM) strategy as used in PWM inverters without adding third harmonic components but it also yields the maximum voltage transfer ratio as 0.866.

An ac input LC filter is used to eliminate the switching ripples generated in the converter and the load is assumed to be sufficiently inductive to maintain continuity of the output currents.

18.5.1 Operation and Control of the Matrix Converter

The converter in Fig. 18.31 connects any input phase (A, B, and C) to any output phase (a, b, and c) at any instant. When connected, the voltages v_{an}, v_{bn}, v_{cn} at the output terminals are related to the input voltages V_{Ao}, V_{Bo}, V_{Co} as

$$\begin{bmatrix} v_{an} \\ v_{bn} \\ v_{cn} \end{bmatrix} = \begin{bmatrix} S_{Aa} & S_{Ba} & S_{Ca} \\ S_{Ab} & S_{Bb} & S_{Cb} \\ S_{Ac} & S_{Bc} & S_{Cc} \end{bmatrix} \begin{bmatrix} v_{Ao} \\ v_{Bo} \\ v_{Co} \end{bmatrix} \qquad (18.32)$$

where S_{Aa} through S_{Cc} are the switching variables of the corresponding switches shown in Fig. 18.31. For a balanced linear star-connected load at the output terminals, the input phase currents are related to the output phase currents by

$$\begin{bmatrix} i_A \\ i_B \\ i_C \end{bmatrix} = \begin{bmatrix} S_{Aa} & S_{Ab} & S_{Ac} \\ S_{Ba} & S_{Bb} & S_{Bc} \\ S_{Ca} & S_{Cb} & S_{Cc} \end{bmatrix} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} \qquad (18.33)$$

Note that the matrix of the switching variables in Eq. (18.33) is a transpose of the respective matrix in Eq. (18.32). The matrix converter should be controlled using a specific and appropriately timed sequence of the values of the switching variables, which will result in balanced output voltages having the desired frequency and amplitude, while the input currents are balanced and in phase (for unity IDF) or at an arbitrary angle (for controllable IDF) with respect to the input voltages. As the matrix converter, in theory, can operate at any frequency, at the output or input, including zero, it can be employed as a three-phase ac–dc converter, dc/three-phase ac converter, or even a buck/boost dc chopper and thus as a *universal power converter*.

The control methods adopted so far for the matrix converter are quite complex and are subjects of continuing research [21–38]. Out of several methods proposed for independent control of the output voltages and input currents, two methods are of wide use and will be briefly reviewed here: (1) the *Venturini* method based on a mathematical approach of transfer function analysis and (2) the *space vector modulation* (SVM) approach (as has been standardized now in the case of PWM control of the dc link inverter).

Venturini Method: Given a set of three-phase input voltages with constant amplitude V_i and frequency $f_i = \omega_i/2\pi$, this method calculates a switching function involving the duty cycles of each of the nine bidirectional switches and generate the three-phase output voltages by sequential piecewise sampling of the input waveforms. These output voltages follow a predetermined set of reference or target voltage waveforms and with a three-phase load connected, a set of input currents I_i and angular frequency ω_i should be in phase for unity IDF or at a specific angle for controlled IDF.

A transfer function approach is used in [29] to achieve the above-mentioned features by relating the input and output

voltages and the output and input currents as

$$\begin{bmatrix} V_{o1}(t) \\ V_{o2}(t) \\ V_{o3}(t) \end{bmatrix} = \begin{bmatrix} m_{11}(t) & m_{12}(t) & m_{13}(t) \\ m_{21}(t) & m_{22}(t) & m_{23}(t) \\ m_{31}(t) & m_{32}(t) & m_{33}(t) \end{bmatrix} \begin{bmatrix} V_{i1}(t) \\ V_{i2}(t) \\ V_{i3}(t) \end{bmatrix} \quad (18.34)$$

$$\begin{bmatrix} I_{i1}(t) \\ I_{i2}(t) \\ I_{i3}(t) \end{bmatrix} = \begin{bmatrix} m_{11}(t) & m_{21}(t) & m_{31}(t) \\ m_{12}(t) & m_{22}(t) & m_{32}(t) \\ m_{13}(t) & m_{23}(t) & m_{33}(t) \end{bmatrix} \begin{bmatrix} I_{o1}(t) \\ I_{o2}(t) \\ I_{o3}(t) \end{bmatrix} \quad (18.35)$$

where the elements of the modulation matrix, $m_{ij}(t)$ ($i, j = 1, 2, 3$) represent the duty cycles of a switch connecting output phase i to input phase j within a sample switching interval. The elements of $m_{ij}(t)$ are limited by the constraints

$$0 \le m_{ij}(t) \le 1 \quad \text{and} \quad \sum_{j=1}^{3} m_{ij}(t) = 1 \quad (i = 1, 2, 3)$$

The set of three-phase target or reference voltages to achieve the maximum voltage transfer ratio for unity IDF is

$$\begin{bmatrix} V_{o1}(t) \\ V_{o2}(t) \\ V_{o3}(t) \end{bmatrix} = V_{om} \begin{bmatrix} \cos \omega_o t \\ \cos(\omega_o t - 120°) \\ \cos(\omega_o t - 240°) \end{bmatrix} + \frac{v_{im}}{4} \begin{bmatrix} \cos(3\omega_i t) \\ \cos(3\omega_i t) \\ \cos(3\omega_i t) \end{bmatrix}$$

$$- \frac{V_{om}}{6} \begin{bmatrix} \cos(3\omega_o t) \\ \cos(3\omega_o t) \\ \cos(3\omega_o t) \end{bmatrix} \quad (18.36)$$

where V_{om} and V_{im} are the magnitudes of output and input fundamental voltages of angular frequencies ω_o and ω_i, respectively. With $V_{om} \le 0.866\, V_{im}$, a general formula for the duty cycles $m_{ij}(t)$ is derived in [29]. For unity IDF condition, a simplified formula is

$$m_{ij} = \frac{1}{3} \left\{ 1 + 2q \cos(\omega_1 t - 2(j-1)\,60°) \right.$$

$$\times \left[\cos(\omega_o t - 2(i-1)\,60°) + \frac{1}{2\sqrt{3}} \cos(3\omega_i t) - \frac{1}{6} \cos(3\omega_o t) \right]$$

$$- \frac{2q}{3\sqrt{3}} \left[\cos(4\omega_i t - 2(j-1)\,60°) \right.$$

$$\left. \left. - \cos(2\omega_i t - 2(1-j)\,60°) \right] \right\} \quad (18.37)$$

where $i, j = 1, 2, 3$ and $q = V_{om}/V_{im}$.

The method developed as above is based on a *Direct Transfer Function (DTF)* approach using a single modulation matrix for the matrix converter, employing the switching combinations of all the three groups in Table 18.1. Another approach called *indirect transfer function (ITF)* approach [23, 24] considers the matrix converter as a combination of PWM voltage source rectifier–PWM voltage source inverter (VSR–VSI) and employs

the already well-established VSR and VSI PWM techniques for MC control utilizing the switching combinations of Group-II and Group-III only of Table 18.1. The drawback of this approach is that the IDF is limited to unity and the method also generates higher and fractional harmonic components in the input and the output waveforms.

SVM Method: The space vector modulation is a well-documented inverter PWM control technique which yields high voltage gain and less harmonic distortion compared to the other modulation techniques. Here, the three-phase input currents and output voltages are represented as space vectors and SVM is simultaneously applied to the output voltage and input current space vectors, while the matrix converter is modeled as a rectifying and inverting stage by the *indirect modulation method* (Fig. 18.33). Applications of SVM algorithm to control of matrix converters have appeared extensively in the literature [27–37] and shown to have inherent capability to achieve full control of the instantaneous output voltage vector and the instantaneous current displacement angle even under supply voltage disturbances. The algorithm is based on the concept that the MC output line voltages for each switching combination can be represented as a voltage space vector defined by

$$v_o = \frac{2}{3} \left[v_{ab} + v_{bc} \exp(j120°) + v_{ca} \exp(-j120°) \right] \quad (18.38)$$

Out of the three groups in Table 18.1, only the switching combinations of Group-II and Group-III are employed for the SVM method. Group-II consists of switching state voltage vectors having constant angular positions and are called *active* or *stationary* vectors. Each subgroup of Group-II determines the position of the resulting output voltage space vector and the six state space voltage vectors form a six-sextant hexagon used to synthesize the desired output voltage vector. Group-III comprises the *zero* vectors positioned at the center of the output voltage hexagon and these are suitably combined with the active vectors for the output voltage synthesis.

The modulation method involves selection of the vectors and their on-time computation. At each sampling period T_s, the algorithm selects four active vectors related to any possible combinations of output voltage and input current sectors in addition to the zero vector to construct a desired reference voltage. The amplitude and the phase angle of the reference voltage vector are calculated, and the desired phase angle of the input current vector is determined in advance. For computation of the on-time periods of the chosen vectors, these are combined into two sets leading to two new vectors adjacent to the reference voltage vector in the sextant and having the same direction as the reference voltage vector. Applying the standard SVM theory, the general formulae derived for the vector on-times which satisfy, at the same time, the reference output voltage and input
FIGURE 18.33   Indirect modulation model of a matrix converter: (a) VSR–VSI conversion; (b) output voltage switching vector hexagon; and (c) input current switching vector hexagon.

current displacement angle in [29] are

$$t_1 = \frac{2qT_s}{\sqrt{3}\cos\phi i} \sin(60° - \theta_o) \cdot \sin(60° - \theta_i)$$

$$t_2 = \frac{2qT_s}{\sqrt{3}\cos\phi_i} \sin(60° - \theta_o) \cdot \sin\theta_i$$

$$t_3 = \frac{2qT_s}{\sqrt{3}\cos\phi_i} \sin\theta_o \cdot \sin(60° - \theta_i)$$
(18.39)

$$t_4 = \frac{2qT_s}{\sqrt{3}\cos\phi_i} \sin\theta_o \cdot \sin\theta_i$$

where q is voltage transfer ratio, ϕ_i is the input displacement angle chosen to achieve the desired input power factor (with $\phi_i = 0$, a maximum value of $q = 0.866$ is obtained), θ_o and θ_i are the phase displacement angles of the output voltage and input current vectors, respectively, whose values are limited within the 0–60° range. The on-time of the zero vector is

$$t_o = T_s - \sum_{i=1}^{4} t_i$$
(18.40)

The integral value of the reference vector is calculated over one sample time interval as the sum of the products of the two adjacent vectors and their on-time ratios and the process is repeated at every sample instant.

Control Implementation and Comparison of the Two Methods: Both the methods need a digital signal processor (DSP) based system for their implementation. In one scheme [29] for the Venturini method, the programmable timers, as available, are used to time out the PWM gating signals. The processor calculates the six switch duty cycles in each sampling interval, converts them to integer counts and stores them in the memory for the next sampling period. In the SVM method, an erasable programmable read only memory (EPROM) is used to store the selected sets of active and zero vectors and the DSP calculates the on-times of the vectors. Then, with an identical procedure as in the other method, the timers are loaded with the vector on-times to generate PWM waveforms through suitable output ports. The total computation time of the DSP for the SVM method has been found to be much less that of the Venturini method. Comparison of the two schemes shows that while in the SVM method the switching losses are lower, the

Venturini method shows better performance in terms of input current and output voltage harmonics.

A *direct control* method as used in conjunction with the voltage source converters has been developed recently and implemented with a 10-kVA matrix converter [38].

18.5.2 Commutation and Protection Issues in a Matrix Converter

As the matrix converter has no dc link energy storage, any disturbance in the input supply voltage will affect the output voltage immediately and a proper protection mechanism has to be incorporated, particularly against over-voltage from the supply and over-current in the load side. As mentioned, two types of bidirectional switch configurations have hitherto been used, one, the transistor (now IGBT) embedded in a diode bridge and the other, the two IGBTs in antiparallel with reverse voltage blocking diodes. (shown in Fig. 18.31). In the latter configuration, each diode and IGBT combination operates in two quadrants only which eliminates the circulating currents otherwise built up in the diode bridge configuration that can be limited by only bulky commutation inductors in the lines.

Commutation: The MC does not contain freewheeling diodes which usually achieve safe commutation in the case of other converters. To maintain the continuity of the output current as each switch turns off, the next switch in sequence must be immediately turned on. In practice, with bidirectional switches, a momentary short circuit may develop between the input phases when the switches cross-over and one solution is to use a *semisoft current commutation* using a multi-stepped switching procedure to ensure safe commutation [39–41]. This method requires independent control of each two quadrant switches, sensing the direction of the load current and introducing a delay during the change of switching states. The switching rule for proper commutation from S1 to S2 of the arrangement shown in Fig. 18.34 for $i_L > 0$ with the two quadrant switches for *four-stepped commutation* [39, 41] is
(a) turn off S1B, (b) turn on S2A, (c) turn off S1A, and (d) turn on S2B.

Analogously, for $i_L < 0$, the switching rule will be (a) turn off S1A, (b) turn on S2B, (c) turn off S1B, and (d) turn on S2A.

Typically, these commutation strategies are now implemented using programmable logic devices such as field programmable gate array (FPGA), programmable logic device (PLD) [41, 42], etc.

A robust voltage commutation scheme without sacrificing the line side current waveform quality and with minimal information requirement has been reported recently [43].

Protection Strategies: A clamp capacitor (typically 2 μF for a 3-kW permanent magnet (PM) motor) connected through two three-phase full-bridge diode rectifiers involving additional 12 diodes as shown in Fig. 18.35 (a new configuration has been reported in [44] where the number of additional diodes are reduced to six using the antiparallel switch diodes at the input and output lines of the MC) serves as a voltage clamp for possible voltage spikes under normal and fault conditions. A new passive protection strategy involving suppressor diodes and varistors for excellent over-voltage protection is discussed recently in [45], which allows the removal of the large and expensive diode clamp. A snubberless solution for over-voltage protection is presented in [46].

Input Filter: A three-phase single stage LC filter at the input consisting of three capacitors in star and three inductors in the line is used to adequately attenuate the higher order harmonics and render sinusoidal input current. Typical values of *L* and *C* based on a 415 V converter with a maximum line current of 6.5 A and a switching frequency of 20 kHz are 3 mH and 1.5 μF only [47]. The filter may cause minor phase-shift in the input displacement angle which needs correction.

Figure 18.36 shows typical experimental waveforms of output line voltage and line current of an MC. The output line current is mostly sinusoidal except a small ripple, when the switching frequency is around 1 kHz only.

FIGURE 18.36 Experimental waveforms for a matrix converter at 30-Hz frequency from a 50-Hz input: (a) output line voltage and (b) output line current.

18.5.3 Multilevel Matrix converter

Erickson and Al-Naseem [48] introduced a multilevel matrix converter with four-quadrant dc link H-bridge switching cells as shown in Fig 18.37 in 2001. These are suitable for medium or high voltage ac-to-ac power conversion. The use of four transistors in the switch cell of Fig. 18.37a allows the average current to be doubled , relative to the conventional matrix converter whose four-quadrant switches are realized using two transistors and two diodes. With dc capacitor, the switch cell is capable of producing instantaneous voltages $+V$, 0, $-V$. These converters can both increase and decrease the voltage amplitude with arbitrary power factors. With series connection of switch cells in each branch of the matrix, multilevel switching can be attained with device voltages locally clamped to dc capacitor voltages. Several types of multilevel matrix converter topologies have been proposed, over the years, including a novel capacitor-clamped one and with space vector modulation [49, 50]. In [50], the converter utilizes flying capacitors to balance voltage distribution of series connected bidirectional switches and provide middle voltage levels.

Recently, with cascaded combination of multiple MC (Matrix Converter) modules, principles of high power multi-modular matrix converters (MMMCs) built from three-input two-output matrix converter (3×2 MC) have been presented in [51] with modulation schemes to synthesize sinusoidal wave forms on both sides of the converters. These topologies feature modular design, bidirectional power flow and enable the use of low-voltage power devices. They may serve as potential candidates for high power applications where regenerative capability and power density are of importance. However, the drawbacks of them are large number of devices and the use of the input transformer.

18.5.4 Sparse Matrix Converter

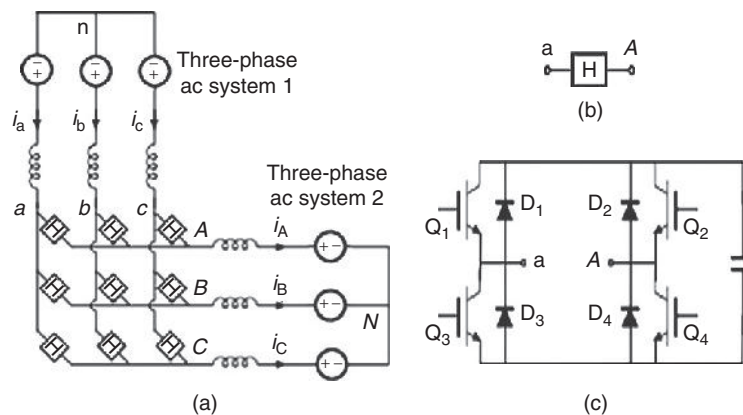
As described in [52], sparse matrix converters (SMC) are functionally equivalent to conventional matrix converters (CMC) but based on the structure of an indirect matrix converter (IMC), Fig 18.38, with possibilities of a reduced number of power devices and less control complexity. A CMC as shown in 18.31a requires 9 bidirectional switches, usually constructed using 18 IGBTs, to switch the three input phases between the three out phases. The SMC (Fig. 18.39) is derived from the IMC which is split into an input stage and output stage without any capacitance in the DC Link. The input stage is arranged so that only 9 switches are required, while the output stage has a standard 6 switch configuration. Thus, the SMC has a total of 15 switches compared to 18 for a CMC. The functional equivalence, the controllability and the operating range of the SMC is the same as CMC despite the reduced number of unipolar turn-off power switches [52]. Further reduction of the number of IGBTs is possible with Ultra sparse matrix converter (USMC) [53], Fig. 18.40 having 12 IGBTs, with restricted operation to a unidirectional power flow and controllability of the phase displacement of input voltage and current fundamental to $\pm\pi/6$ [53]. Very recently, a space vector modulation scheme for an indirect 3-level sparse matrix converter (I3 SMC), which is a combination of a three-level neutral clamped voltage source


FIGURE 18.37 Multilevel matrix converter (a) configuration (b) switch symbol and (c) switch realization.
FIGURE 18.38 Indirect matrix converter (IMC).

FIGURE 18.40 Ultra sparse matrix converter (USMC).

inverter and an indirect matrix converter has been discussed in [54]. A 100-kHz SiC sparse matrix converter using 1300-V, 4-A SiC JFET cascade devices have been reported in [55] which is suitable for aircraft applications where a low volume/weight converter is desired.

18.6 High Frequency Linked Single-Phase to Three-Phase Matrix Converters

Several kinds of single-phase to three-phase high frequency (typically, 20 kHz) cycloconverters (actually, matrix converters with MCT switches) using "soft switching" were reported for ac motor drive applications [56–58]. Figure 18.41 [56] shows a typical configuration of such a converter in which an H-bridge inverter produces a high-frequency single-phase voltage, which is fed to the cycloconverter through a high-frequency transformer. The high frequency ac may be either

sinusoidal generated by a resonant link inverter or quasi-square wave as shown. These systems have been developed at laboratories but not yet available commercially [56].

18.6.1 High Frequency Integral-Pulse Cycloconverter

The input to these converters may be sinusoidal or quasi-square wave and it is possible to use integral half-cycle pulse width modulation (IPM) principle to synthesize the output voltage waves. The advantage is that the devices can be switched at zero voltage reducing the switching loss. This converter can only work at output frequency, which are multiples of the input frequency [56].

18.6.2 High-Frequency Phase-Controlled Cycloconverter

Here, phase control principle as explained earlier is used to synthesize the output voltage. A sawtooth carrier wave is compared with the sine modulating wave to generate the firing instants of the switches. The phase control provides switching at zero current reducing switching loss but this scheme has more complex control circuit compared to the previous one. However, it can work at any frequency [57].

18.7 Applications of AC–AC Converters

18.7.1 Applications of AC Voltage Controllers

AC voltage controllers are used either for control of the rms value of voltage or current in lighting control, domestic and industrial heating, speed control of fan, pump or hoist drives, soft starting of induction motors, etc. or as *static ac switches (on/off control)* in transformer tap changing, temperature control, speed stabilization of high inertia induction motor drives like centrifuge, capacitor switching in static reactive power compensation, etc.

In *fan or pump drives* with induction motors, the torque varies as the square of the speed. So the speed control is required in a narrow range and an ac voltage controller is suitable for an induction motor with a full load slip of 0.1–0.2 in such applications. For these drives, braking or reverse operations are not needed but for the crane hoist drive, both motoring and braking are needed and a four quadrant ac voltage controller can be obtained by a modification of the ac voltage controller circuit as shown in Fig. 18.42. SCR pairs A, B, and C provide operation in quadrants I and IV and A, B, and C in quadrants II and III. While changing from one set of SCR pairs to another, care should be taken to ensure that the incoming pair is activated only after the outgoing pair is fully turned off.

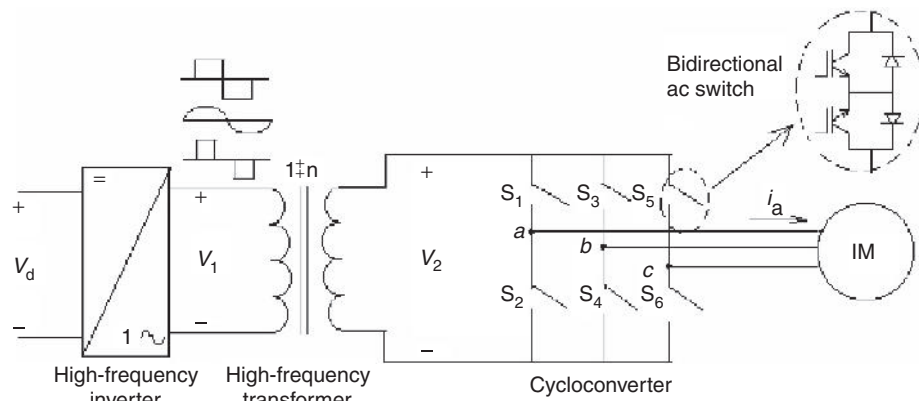
AC voltage controllers are being increasingly used for *soft-starting* of induction motors, as they have a number of


FIGURE 18.41   High frequency linked single-phase to three-phase matrix converter.
FIGURE 18.42   Four quadrant ac voltage controller.

advantages over the conventional starters such as smooth acceleration and deceleration, ease in implementation of current control, simple protection against single-phasing or unbalanced operation, reduced maintenance and losses, absence of current inrush, etc. Even for the fixed-speed industrial applications, the voltage controllers can be used to provide a reduced stator voltage to an induction motor to improve its efficiency at light load and result in energy saving. Operation at an optimum voltage reduces the motor flux which, in turn, reduces the core-loss and the magnetizing component of the stator copper loss. Considerable savings in energy can be obtained in applications where a motor operates at no load for a significant time such as in drills, machine tools, woodworking machines, reciprocating air-compressors, etc. A popular approach to find an optimum operating voltage is to maximize the motor power factor by maintaining a minimum phase-shift between the voltage and current after sensing them.

The ac switch with on/off control used in driving a high inertia centrifuge involves switching on of the motor when the speed of the centrifuge drops below the minimum allowable level and switching off when the speed reaches the maximum allowable level – thus maintaining a constant average speed. An identical scheme of control is used with an ac switch for temperature control of an electric heater or air conditioner.

Integral cycle control is well suited to heating control while it may cause flicker in normal incandescent lighting control and speed fluctuations in motor control. However, with this control, less voltage distortion is produced in the ac supply system and less radio-frequency interference is propagated when compared with the phase-controlled system.

18.7.2 Applications of Cycloconverters

Cycloconverters as frequency changers essentially find well-established applications in (1) high-power low-speed reversible ac motor drives with constant-frequency input; and (2) constant-frequency power supplies with a variable-frequency input as in VSCF (variable-speed constant frequency) system, whereas they find potential applications in (3) controllable VAR (volt-amperes reactive) generators for power factor correction; and (4) ac system interties linking two independent power systems as demonstrated in [15].

Variable Speed AC Drives: In this category, the applications of cycloconverter-controlled induction motor and synchronous motor drives have been adequately reviewed in [9]. Cycloconverter-fed synchronous motors are well suited for low-speed drives with high torque at standstill, and high-capacity gear-less cement mills (tube or ball-mill above 5 MW) have been the first applications of these drives.

Since 1960s, as developed by Siemens and Brown Boveri, one of the early installations employs a motor rating of 6.4 MW having a rotor diameter of 5 m and length of 18.5 m, whereas the stator construction is similar to that of a hydroelectric generator with 44 poles requiring 5.5 Hz for maximum speed of 15 rpm. The motor is flanged with the mill cylinder without additional bearings or "wrapped" directly around it, known as *ring motor* [59]. With the evolution of *field orientation* or *vector control*, cycloconverter-fed synchronous motors have replaced or are replacing the dc drives in the reversing rolling mills (2/4 MW) with extreme high-dynamic requirements for torque and speed control [60–62], in mine winders and haulage [62, 63] of similar high ratings and in

icebreakers and ships equipped with diesel generators with power ratings of about 20 MW/unit [64]. In these applications, the cycloconverter-fed synchronous motor is in *self-controlled* mode and known as *ac commutator-less motor* when the cyclo-converter firing signals are derived from a rotor shaft position sensor, so that the frequency is slaved to the rotor speed and not vice versa with the result that the hunting and stability prob-lems are eliminated and the torque is not limited to pull-out value. Further, with field control, the motor can be operated at leading power factor when the cycloconverter can operate with *load commutation* from the motor side at high speed in addi-tion to the line commutation from the supply at low speed, thus providing speed control over a wide range. A cycloconverter-fed ac commutator-less motor is reported in [65] where the cycloconverter is operated both in sinusoidal and trapezoidal mode – the latter is attractive for better system power factor and higher voltage output at the cost of increased harmonic content [1]. A stator-flux oriented vector control scheme for a six-pulse circulating current-free cycloconverter-fed syn-chronous motor with a flux observer suitable for a rolling mill drive (300–0–300 rpm) is reported in [12]. A 12-pulse, 9.64-MVA, 120/33.1-Hz cycloconverter-linear synchronous motor combination for Maglev Vehicle ML-500, a high-speed train, (517 km/h) is in the process of development in Japan since early 1980s [66]. Several recent projects involving very high-power (larger than 15 MW) semiautogenous grinding (SAG) mills with cycloconverter-fed synchronous motor drives in mining applications in peru and Brazil are reported in [67]. Latest technological advances, applications, and future trends of cycloconverters in industrial medium voltage drives have been discussed in [68].

Regarding cycloconverter-fed induction motors, early appli-cations were for control of multiple run-out table motors of a hot strip mill, high performance servo drives, and controlled slip-frequency drive for diesel electric locomotives. Slip-power controlled drives in the form of static Scherbius drives with very high ratings using cycloconverter in the rotor of a dou-bly fed slip-ring induction motor have been in operation for high capacity pumps, compressors [69], and even in a proton–synchrotron accelerator drive in CERN, Geneva [70]. Though synchronous motors have been preferred for very high-capacity low-speed drives because of their high rating, ability to control power factor, and precisely set speed independent of sup-ply voltage and load variations, induction motors, because of their absence of excitation control loop, simple structure, easy maintainability, and quick response, have been installed for cycloconverter-fed drives in Japan. For example, a seemless tube piercing mill [71] where a squirrel cage 6-pole 3-MW, 188/300-rpm, 9.6/15.38-Hz, 2700-V motor is controlled by a cycloconverter bank of capacity 3750 KVA and output voltage 3190 V.

***Constant Frequency Power Supplies*:**   Some applications such as aircraft and naval ships need a well-regulated constant-frequency power output from a variable-frequency ac power source. For example, in aircraft power conversion, the alter-nator connected to the engine operating at a variable speed of 10,000–20,000 rpm provides a variable frequency output power over 1200–2400 Hz range which can be converted to an accurately regulated fixed frequency output power at 400 Hz through a cycloconverter with a suitable filter placed within a closed loop. The output voltages of the cycloconverter are pro-portional to the fixed frequency (400 Hz) sine wave reference voltage generator in the loop.

Both synchronous and induction motors can be used for VSCF generation. The static Scherbius system can be modi-fied (known as Kramer drive) by feeding slip-power through a cycloconverter to a shaft mounted synchronous machine with a separate exciter for VSCF generation. A new application in very high power ratings of constant frequency variable speed motor generators with cycloconverter is in pumped storage schemes using reversible pump turbines for adaptation of the generated power to varying loads or keeping the ac system fre-quency constant. In 1993, a 400 MW variable speed pumped storage system was commissioned by Hitachi at Okhawachi hydropower plant [72] in Japan where the field windings of a 20-pole generator/motor are excited with three-phase low-frequency ac current via slip-rings by a 72-MVA, three-phase 12-pulse line-commuted cycloconverter. The armature terminals rated at 18 kV are connected to a 500-kV utility grid through a step-up transformer. The output frequency of the circulating current-free cycloconverter is controlled within ± 5 Hz and the line frequency is 60 Hz. The variable speed system has a synchronous speed of 360 rpm with a speed range 330 −390 rpm. The operational system efficiency in the pump mode is improved by 3% when compared to the earlier constant speed system.

***Static VAR Generation*:**   Cycloconverters with a high fre-quency (HF) base, either a HF generator or an oscillating LC tank, can be used for reactive power generation and con-trol, replacing synchronous condensers or switched capacitors as demonstrated in [15]. If the cycloconverter is controlled to generate output voltage waves whose wanted components are in phase with the corresponding system voltages, reactive power can be supplied in either direction to the ac system by amplitude control of the cycloconverter output voltages. The cycloconverter will draw leading current from (that is, it will supply lagging current to) the ac system when its out-put voltage is greater than that of the system voltage and vice versa.

***Interties between AC Power Systems*:**   The naturally commu-tated cycloconverter (NCC) was originally developed for this application to link a three-phase, 50-Hz ac system with a single-phase $16\frac{2}{3}$-Hz railway supply system in Germany in the 1930s. Applications involve slip-power controlled motors with sub-synchronous and super-synchronous speeds. The stator of the
FIGURE 18.43   Schematic of a multicell matrix converter with 3 cells in series in each phase.

motor is connected to 50-Hz supply, which is connected to the rotor as well as through a cycloconverter, and the motor drives a single-phase synchronous generator feeding to $16\frac{2}{3}$-Hz system [73, 74]. A static asynchronous intertie between two different systems of different frequency can be obtained by using two NCCs in tandem, each with its input terminals connected to a common HF base. As long as the base frequency is appropriately higher than that of the either system, two system frequencies can be either same or different. The power factor at either side can be maintained at any desired level [15].

18.7.3 Applications of Matrix Converters and New Developments

The practical applications of the matrix converters, as of now, are very limited. The main reasons are (1) non-availability of the bilateral fully controlled monolithic switches capable of high frequency operation; (2) complex control law implementation; (3) an intrinsic limitation of the output/input voltage ratio; and (4) commutation and protection of the switches. Till date, the switches are assembled from existing discrete devices resulting in increased cost and complexity, and only experimental circuits of conventional matrix converters (CMC) of capacity upto 150 kVA [75] for a single unit have been built. However, with the advances in device technology, it is hoped that the problems will be solved eventually, and the MC will not only replace the NCCs in all the applications mentioned under Section 18.7.2, but also take over from the PWM rectifier–inverters as well. Already, interesting applications of multilevel and multicell matrix converters for medium-voltage high-power drives have been developed [76] Super energy-saving multicell medium-voltage matrix converters (FSDrive-MX1S) of rating 3 kV, 200–3000 kVA or 6 kV, 400–6000 kVA have been built by Yaskawa Electric, Japan [77] where by intelligently phase-shifting the carrier of each cell and combining them in the motor windings, medium-voltages are achievable as shown in Fig. 18.43. The salient features of these medium voltage converters are as follows:

- Four quadrant operation;
- Excellent input current waveform due to multiple phase shifting winding of the input transformer;
- Flexible design: Three cells in series yielding 3.3 kV, 200–3000 kVA and six cells in series yielding 6 kV, 400–6000 kVA system;
- Excellent output voltage waveform due to multi-step configuration.

The applications for these drives as recommended are as follows: with heavy loads that require regenerative energy such as steel manufacturing process lines or cargo handling machinery, and also that need power regeneration for a long period such as winders for paper.

Recently, reverse blocking IGBTs have opened up the possibility of bidirectional switch (BDS) construction for a practical matrix converter with just two back-to-back devices [78–80]. A compact full matrix converter power module EconoMac [81] in a single package using 18 IGBT devices (35 A, 1200 V) and diodes in the common collector configuration (Fig. 18.44) is available with Eupec/Siemens, Germany. This packaging minimizes the stray inductance in the current commutation paths. Fuji and Powerex have developed engineering samples for matrix converter output leg in a module using RB-IGBTs. A new power electronic building block (PEBB) configuration for a low cost MC has been proposed in [82]. Recently, an efficient approach to design discrete packaging of bidirectional resonant power switch for matrix converters has been proposed by computing the magnetic field orientation inside the switching cell [83]. Several new concepts in protection, commutation, switch design, and modulation strategy have been presented in [84].
FIGURE 18.44   EconoMac matrix converter module by Eupec [81].

Several new methods like overmodulation [85], adaptive rate regulation [86], and two-side modulation control [87] have been introduced with experimental results to achieve *higher voltage transfer ratio.* A matrix converter-based three-phase open-end winding ac machine drive having matrix converters, one at each side of the open-end winding with space vector PWN has been recently described in [88] to achieve several simultaneous benefits, such as converter voltage gain up to 1.5, controllable grid power factor, and elimination of the high-frequency common-mode voltage at the machine terminals. A generalized scalar PWM (GSPWM) technique to reduce the common-mode voltage in matrix converter without degrading the input currents' quality has been studied in a recent paper [89].

Design and loss comparison of matrix converters and dc-link voltage source converters (VSC) have been discussed in [90, 91]. It is shown that although MC requires 50% more semiconductors and gate drives excluding clamp circuit, the active silicon area and the number of gate unit power supplies are comparable to that of VSC of the same power rating. The losses of both converter systems are roughly the same at the typical range of 40–70% of rated torque and speed and a switching frequency of 10 kHz. The MC realizes a distinct better efficiency (92.5–96%) at 100% torque compared with VSC for the same IGBT modules. Also, the maximum switching frequency of the MC (30 kHz at 250% rated torque) is also substantially higher. The low losses allow a reduction of current ratings (by 33%) of IGBT modules in MC. The extra harmonic losses due to use of a matrix converter for a motor drive with two commonly used modulation techniques have been computed and compared in [92].

Various potential applications of matrix converters have been proposed, and experiments conducted in the field of VSCF systems such as wind-turbine and micro-turbine [93], switched mode power supplies [94], doubly fed induction motor [95, 96] including wind power system applications [97], and marine propulsion [98]. Few modern solutions for industrial matrix converter applications including a new integrated matrix converter motor (MCM) have been reported [99, 100]. The range of published practical implementations varies from a 2-kW matrix converter using silicon carbide devices and switching at 150 kHz for aerospace applications built at ETZ in Zurikh, Switzerland to a 150 kVA converter using 600 A IGBTs built at US army research labs in collaboration with the University of Nottingham, UK [42, 75]. A matrix converter using MCTs with enhanced commutation times is described in [101].

The complex control schemes of matrix converter demand higher test requirements and one of the modern means of testing the controllers before final integration on actual apparatus is to make hardware-in-the-loop (HIL) real-time simulation tests as developed recently [102].

Matrix converter-fed adjustable speed drives (ASDs) have the advantages of inherent four-quadrant operation, absence of bulky dc-link electrolytic capacitors, clean input power characteristics with high input power factor and increased power density with the possibilities of operating at higher temperatures. However, due to the absence of the dc link, these are more susceptible to input power disturbances and a *ride-through module* is needed to be added for these drives under short-term power interruption. Such a module as developed with minimal addition of hardware and software into a matrix converter (230 V, 3 kVA) has been reported in [103]. A PWM modulation strategy for fault tolerant operation of the matrix-converter-based drives against opened switch, opened phase faults, and shorted winding failures has been proposed in [104]. This can improve the reliability of the matrix converter drives as it is possible to keep continuous by regulating the two remaining phases after isolating the faulted phase.

A novel application of a three-phase matrix converter as the static conversion unit for a ground power-supply unit for aircraft servicing has been presented in [105] to provide a compact solution with no dc link and the capability to generate a high quality 400-Hz sinusoidal waveformin the steady state. A new type of single phase Z-source buck-boost matrix converter has been proposed in [106], which can be used in various industrial applications that require step-changed frequencies and variable voltage amplitudes. A direct ac-ac current source matrix converter for applications in industrial power systems is introduced in [107]. A dynamic voltage restorer (DVR) system employing matrix converter and flywheel storage has been proposed in [108] to cope with voltage sag problem in power system. The proposed topology eliminates the dc-link passive components resulting in reduced maintenance requirement and improved power density.

19.1 Introduction

Today, our society has become very aware of the necessity of the natural environment protection of our living plant in the face of a programmed utilization of natural resource. Like the earth, the utility power supply that we are now using was clean when it was invented in nineteenth century. Over hundred years, electrical power system has benefited people in every aspect. Meanwhile, due to the intensive use of this utility, the power supply condition becomes "polluted." However, public concern about the "dirty" environment in the power system has not been drawn until the mid 1980s [1–6].

Since ac electrical energy is the most convenient form of energy to be generated, transmitted, and distributed, ac power systems had been swiftly introduced into industries and residences since the turn of the twentieth century. With the proliferation of utilization of electrical energy, more and more heavy loads have been connected into the power system. During 1960s, large electricity consumers such as electrochemical and electrometallurgical industries applied capacitors as VAR compensator to their systems to minimize the demanded charges from utility companies and to stabilize the supply voltages. As these capacitors present low impedance in the system, harmonic currents are drawn from the line. Owing to the non-zero system impedance, line voltage distortion will be incurred and propagated. The contaminative harmonics can

decline power quality and affect the system performance in several ways:

(a) The line *rms* current harmonics do not deliver any real power in Watts to the load, resulting in inefficient use of equipment capacity (i.e. low power factor).
(b) Harmonics will increase conductor loss and iron loss in transformers, decreasing transmission efficiency and causing thermal problems.
(c) The odd harmonics are extremely harmful to a three-phase system, causing overload of the unprotected neutral conductor.
(d) Oscillation in power system should be absolutely prevented in order to avoid endangering the stability of system operation.
(e) High peak harmonic currents may cause automatic relay protection devices to mistrigger.
(f) Harmonics could cause other problems such as electromagnetic interference to interrupt communication, degrading reliability of electrical equipment, increasing product defective ratio, insulation failure, audible noise, etc.

Perhaps the greatest impact of harmonic pollution appeared in early 1970s when static VAR compensators (SVCs) were extensively used for electric arc furnaces, metal rolling mills, and other high power appliances. The harmonic currents

produced by partial conduction of SVC are odd order, which are especially harmful to three-phase power system. Harmonics can affect operations of other devices that are connected to the same system and, in some situation, the operations of themselves that generate the harmonics.

The ever deteriorated supply environment did not become a major concern until the early 1980s when the first technical standard IEEE519-1981 with respect to harmonic control at point of common coupling (PCC) was issued [7]. The significance of issuing this standard was not only that it provided the technical reference for design engineers and manufactures, but also that it opened the door of research area of harmonic reduction and power factor correction (PFC). Stimulated by the harmonic control regulation, researchers and industry users started to develop low-cost devices and power electronic systems to **reduce** harmonics since it is neither economical nor necessary to eliminate the harmonics.

Research on harmonic reduction and PFC has become intensified in the early nineties. With the rapid development in power semiconductor devices, power electronic systems have matured and expanded to new and wide application range from residential, commercial, aerospace to military and others. Power electronic interfaces, such as switch mode power supplies (SMPS), are now clearly superior over the traditional linear power supplies, resulting in more and more interfaces switched into power systems. While the SMPSs are highly efficient, but because of their non-linear behavior, they draw distorted current from the line, resulting in high total harmonic distortion (THD) and low power factor (PF). To achieve a smaller output voltage ripple, practical SMPSs use a large electrolytic capacitor in the output side of the single-phase rectifier. Since the rectifier diodes conduct only when the line voltage is higher than the capacitor voltage, the power supply draws high *rms* pulsating line current. As a result, high THD and poor PF (usually less than 0.67) are present in such power systems [6–10]. Even though each device, individually, does not present much serious problem with the harmonic current, utility power supply condition could be deteriorated by the massive use of such systems. In recent years, declining power quality has become an important issue and continues to be recognized by government regulatory agencies. With the introduction of compulsory and more stringent technical standard such as IEC1000-3-2, more and more researchers from both industries and universities are focusing in the area of harmonic reduction and PFC, resulting in numerous circuit topologies and control strategies. Generally, the solution for harmonic reduction and PFC are classified into passive approach and active approach. The passive approach offers the advantages of high reliability, high power handling capability, and easy to design and maintain. However, the operation of passive compensation system is strongly dependent on the power system and does not achieve high PF. While the passive approach can be still the best choice in many high power applications, the active approach dominates the low to medium

power applications due to their extraordinary performance (PF and efficiency approach to 100%), regulation capabilities, and high density. With the power handling capability of power semiconductor devices being extended to megawatts, the active power electronic systems tend to replace most of the passive power processing devices [2–4].

Today's harmonic reduction and PFC techniques to improve distortion are still under development. Power supply industries are undergoing the change of adopting more and more PFC techniques in all off-line power supplies. This chapter presents an overview of various active harmonic reduction and PFC techniques in the open literature. The primary objective of writing this chapter is to give a brief introduction of these techniques and provide references for future researchers in this area. The discussion here includes definition of THD and PF, commonly used control strategies, and various types of converter topologies. Finally, the possible future research trends are stressed in the Summary Section.

19.2 Definition of PF and THD

Power factor is a very important parameter in power electronics because it gives a measure of how effective the real power utilization in the system is. It also represents a measure of distortion of the line voltage and the line current and phase shift between them. Referring to Fig. 19.1a, we define the input power factor (PF) at terminal a-a′ as the ratio of the average power and the apparent power measured at terminals a-a′ as described in Eq. (19.1) [7, 9, 10]

$$Power\ Factor\ (PF) = \frac{Real\ Power\ (Average)}{Apparent\ Power} \qquad (19.1)$$

where, the apparent power is defined as the product of *rms* values of $v_s(t)$ and $i_s(t)$.

In a linear system, because load draws purely sinusoidal current and voltage, the PF is only determined by the phase difference between $v_s(t)$ and $i_s(t)$. Equation (19.1) becomes

$$PF = \frac{I_{s,rms}V_{s,rms}\cos\theta}{I_{s,rms}V_{s,rms}} = \cos\theta \qquad (19.2)$$

where, $I_{s,rms}$ and $V_{s,rms}$ are *rms* values of line current and line voltage, respectively, and θ is the phase shift between line current and line voltage. Hence, in linear power systems, the PF is simply equal to the cosine of the phase angle between the current and voltage. However, in power electronic system, due to the non-linear behavior of active switching power devices, the phase-angle representation alone is not valid. Figure 19.1b shows that the non-linear load draws typical distorted line current from the line. Calculating PF for distorted waveforms is more complex when compared with the sinusoidal case. If both line voltage and line current are distorted, then Eqs. (19.3)
FIGURE 19.1   Non-linear load draws distorted line current.

and (19.4) give the Fourier expansion representations for the line current and line voltage, respectively

$$i_s(t) = I_{DC} + \sum_{n=1}^{\infty} I_{sn}\sin(n\omega t + \theta_{in})$$

$$= I_{DC} + I_{s1}\sin(\omega t + \theta_{i1}) + \sum_{n=2}^{\infty} I_{sn}\sin(n\omega t + \theta_{in}) \quad (19.3)$$

$$v_s(t) = V_{DC} + \sum_{n=1}^{\infty} V_{sn}\sin(n\omega t + \theta_{vn})$$

$$= V_{DC} + V_{s1}\sin(\omega t + \theta_{v1}) + \sum_{n=2}^{\infty} V_{sn}\sin(n\omega t + \theta_{vn}) \quad (19.4)$$

Applying the definition of PF given in Eq. (19.1) to the distorted current and voltage waveforms of Eqs. (19.3) and (19.4), PF may be expressed as

$$PF = \frac{\sum_{n=1}^{\infty} I_{sn,rms} V_{sn,rms} \cos\theta_n}{I_{s,rms} V_{s,rms}} = \frac{\sum_{n=1}^{\infty} I_{sn,rms} V_{sn,rms} \cos\theta_n}{\sqrt{\sum_{n=1}^{\infty} I_{sn,rms}^2 \sum_{n=1}^{\infty} V_{sn,rms}^2}}$$

$$(19.5)$$

where, $V_{sn,rms}$ and $I_{sn,rms}$ are the *rms* values of the *n*th harmonic voltage and current, respectively, and θ_n is the phase shift between the *n*th harmonic voltage and current.

Since most of power electronic systems draw their input voltage from a stable line voltage source $v_s(t)$, the above expression can be significantly simplified by assuming the line voltage is pure sinusoidal and distortion is only limited to $i_s(t)$, i.e.

$$v_s(t) = V_s \sin\omega t \quad (19.6)$$

$$i_s(t) = \text{distorted (non-sinusoidal)} \quad (19.7)$$

Then it can be shown that the PF can be expressed as

$$PF = \frac{I_{s1,rms}}{I_{s,rms}} \cos\theta_1 = k_{dist} \cdot k_{disp} \quad (19.8)$$

where,

θ_1: the phase angle between the voltage $v_s(t)$ and the fundamental component of $i_s(t)$;

$I_{s1,rms}$: *rms* value of the fundamental component in line current;

$I_{s,rms}$: total *rms* value of line current;

$k_{dist} = I_{s1,rms}/I_{s,rms}$: distortion factor;

$k_{disp} = \cos\theta_1$: displacement factor.

Another important parameter that measure the percentage of distortion is known as the current total harmonic distortion (THD_i) which is defined as follows

$$THD_i = \sqrt{\frac{\sum_{n=2}^{\infty} I_{sn,rms}^2}{I_{s1,rms}^2}} = \sqrt{\frac{1}{k_{dist}^2} - 1} \quad (19.9)$$

Conventionally SMPSs use capacitive rectifiers in front of the ac line which resulting in the capacitor voltage v_c and high *rms* pulsating line current $i_l(t)$ as shown in Fig. 19.2, when $v_l(t)$ is the line voltage. As a result, THD_i is as high as 70% and poor PF is usually less than 0.67.
FIGURE 19.2   Typical waveforms in a poor PF system.

As we can see from Eqs. (19.8) and (19.9), PF and THD are related to distortion and displacement factors. Therefore, improvement in PF, i.e. power factor correction (PFC), also implies harmonic reduction.

19.3 Power Factor Correction

19.3.1 Energy Balance in PFC Circuits

Figure 19.3 shows a diagram of an ac–dc PFC unit. Let $v_l(t)$ and $i_l(t)$ be the line voltage and line current, respectively. For an ideal PFC unit (PF = 1), we assume

$$v_l(t) = V_{lm} \sin \omega_l t \qquad (19.10a)$$

$$i_l(t) = I_{lm} \sin \omega_l t \qquad (19.10b)$$
FIGURE 19.3 Block diagram of ac–dc PFC unit.

where, V_{lm} and I_{lm} are amplitudes of line voltage and line current, respectively, and ω_l is the angular line frequency. The instantaneous input power is given by

$$p_{in}(t) = V_{lm} I_{lm} \sin^2 \omega_l t = P_{in} (1 - \cos 2\omega_l t) \qquad (19.11)$$

where, $P_{in} = 1/2 V_{lm} I_{lm}$ is the average input power.

As we can see from Eq. (19.11), the instantaneous input power contains not only the real power (average power) P_{in} component but also an alternative component with frequency $2\omega_l$ (i.e. 100 or 120 Hz), shown in Fig. 19.4. Therefore, the operation principle of a PFC circuit is to process the input power in a certain way that it stores the excessive input energy (area I in Fig. 19.4) when $p_{in}(t)$ is larger than $P_{in}(=P_o)$, and releases the stored energy when $p_{in}(t)$ is less than $P_{in}(=P_o)$ to compensate for area II.

The instantaneous excessive input energy, $w(t)$, is given by

$$w_{ex}(t) = \frac{P_o}{2\omega_l} (1 - \sin 2\omega_l t) \qquad (19.12)$$

At $t = 3T_l/8$, the excessive input energy reaches the peak value

$$w_{ex,max} = \frac{P_o}{\omega_l} \qquad (19.13)$$

The excessive input energy has to be stored in the dynamic components (inductor and capacitor) in the PFC circuit.
FIGURE 19.4 Energy balance in PF corrector.

In most of the PFC circuits, an input inductor is used to carry the line current. For unity PF, the inductor current (or averaged inductor current in switch mode PFC circuit) must be a pure sinusoidal and in phase with the line voltage. The energy stored in the inductor $(1/2Li_L^2(t))$ cannot completely match the change of the excessive energy as shown in Fig. 19.4. Therefore, to maintain the output power constant, another energy storage component (usually the output capacitor) is needed.

19.3.2 Passive Power Factor Corrector

Because of their high reliability and high power handling capability, passive power factor correctors are normally used in high power line applications. Series tuned LC harmonic filter is commonly used for heavy plant loads such as arc furnaces, metal rolling mills, electrical locomotives, etc. Figure 19.5 shows a connection diagram of harmonic filter together with line frequency switched reactor static VAR compensator. By tuning the filter branches to odd harmonic frequencies, the filter shunts the harmonic currents. Since each branch presents capacitive at line frequency, the filter also provides capacitive VAR for the system. The thyristor-controlled reactor keeps an optimized VAR compensation for the system so that higher PF can be maintained.

The design of the tuned filter PF corrector is particularly difficult because of the uncertainty of the system impedance and harmonic sources. Besides, this method involves too many expensive components and takes huge space.

For the applications where power level is less than 10 kW, the tuned filter PF corrector may not be a better choice. The most common off-line passive PF corrector is the inductive-input filter, shown in Fig. 19.6. Depending on the filter inductance, this circuit can give a maximum of 90% PF. For operation in continuous conduction mode (CCM), the PF is defined as [11]

$$PF = \frac{0.9}{\sqrt{1 + (0.075/K_1)^2}} \tag{19.14}$$

FIGURE 19.6   Inductive-input PF corrector.

where

$$K_1 = \frac{\omega_l L}{\pi R} \tag{19.15}$$

The PF corrector is simply a low pass inductive filter as shown in Fig. 19.7, whose transfer function and input impedance are given by

$$H(s) = \frac{1}{s^2 LC + sL/R + 1} \tag{19.16}$$

$$Z_{in}(s) = R\frac{s^2 LC + sL/R + 1}{sRC + 1} \tag{19.17}$$

The above equations show that the unavoidable phase displacement is incurred in the inductive-filter corrector. Because the filter frequency of operation is low (line frequency), large value inductor and capacitor have to be used. As a result, the following disadvantages are presented in most passive PF correctors:

(a) Only less than 0.9 PF can be achieved;
(b) THD is high;
(c) They are heavy and bulky;
(d) The output is unregulated;
(e) The dynamic response is poor;
(f) They are sensitive to circuit parameters;
(g) Optimization of the design is difficult.

FIGURE 19.5   Series tuned LC harmonic filter PF corrector.
FIGURE 19.7   Low pass inductive filter.

19.3.3 Basic Circuit Topologies of Active Power Factor Correctors

In recent years, using the switched-mode topologies, many circuits and control methods are developed to comply with certain standard (such as IEEE Std 519 and IEC1000-3-2). To achieve this, high-frequency switching techniques have been used to shape the input current waveform successfully. Basically, the active PF correctors employ the six basic converter topologies or their variation versions to accomplish PFC.

A. The Buck Corrector

Figure 19.8a shows the buck PF corrector. By using PWM switch modeling technique [12], the circuit topology can be modeled by the equivalent circuit shown in Fig. 19.8b. It should be pointed out that the circuit model is a large signal model, therefore analysis of PF performance based on this model is valid. It can be shown that the transfer function and input impedance are given by

$$H(s) = \frac{d}{s^2 LC + sL/R + 1} \tag{19.18}$$

$$Z_{in}(s) = \frac{R}{d^2} \frac{s^2 LC + sL/R + 1}{sRC + 1} \tag{19.19}$$

where d is the duty ratio of the switching signal.

Notice that Eqs. (19.18) and (19.19) are different from Eqs. (19.16) and (19.17), in that they have introduced the control variable d. By properly controlling the switching duty ratio to modulate the input impedance and the transfer function, a pure resistive input impedance and constant output voltage can be approached. Thereby, unity PF and output regulation can both be achieved. These control techniques will be discussed in the next section.

Comparing with the other type of high frequency PFC circuits, the buck corrector offers inrush-current limiting, overload or short-circuit protection, and over-voltage protection for the converter due to the existence of the power switch in front of the line. Another advantage is that the output voltage is lower than the peak of the line voltage, which is usually the case normally desired. The drawbacks of using buck corrector may be summarized as follows:

(a) When the output voltage is higher than the line voltage, the converter draws no current from the line, resulting in significant line current distortion near the zero-across of the line voltage;
(b) The input current is discontinuous, leading to high differential mode EMI;
(c) The current stress on the power switch is high;
(d) The power switch needs a floating drive.

B. The Boost Corrector

The boost corrector and its equivalent PWM switch modeling circuit are shown in Figs. 19.9a and b. Its transfer function and

FIGURE 19.8 (a) Buck corrector and (b) PWM switch model for buck corrector.
FIGURE 19.9 (a) Boost corrector and (b) PWM switch model of boost corrector.

input impedance are given by

$$H(s) = \frac{1/d'}{s^2(L/d'^2)C + s(L/d'^2)/R + 1} \qquad (19.20)$$

$$Z_{in}(s) = d'^2 R \frac{s^2(L/d'^2)C + s(L/d'^2)/R + 1}{sRC + 1} \qquad (19.21)$$

where $d' = 1 - d$.

Unlike in the buck case, it is interesting to note that in the boost case, the equivalent inductance is controlled by the switching duty ratio. Consequently, both the magnitude and the phase of the impedance, and both the dc gain and the pools of the transfer function are modulated by the duty ratio, which implies a tight control of the input current and the output voltage. Other advantages of boost corrector include less EMI and lower switch current and grounded drive. The shortcomings with the boost corrector are summarized as:

(a) The output voltage must be higher than the peak of line voltage;
(b) Inrush-current limiting, overload, and over-voltage protections are not available.

C. The Buck–Boost Corrector

The buck–boost corrector and its equivalent circuit are shown in Figs. 19.10a and b. The expressions for transfer function
and input impedance are

$$H(s) = \frac{d/d'}{s^2(L/d'^2)C + s(L/d'^2)/R + 1} \qquad (19.22)$$

$$Z_{in}(s) = \left(\frac{d'}{d}\right)^2 R \frac{s^2(L/d'^2)C + s(L/d'^2)/R + 1}{sRC + 1} \qquad (19.23)$$

The buck–boost corrector combines some advantages of the buck corrector and the boost corrector. Like a buck corrector, it can provide circuit protections and step-down output voltage, and like a boost corrector its input current waveform and output voltage can be tightly controlled. However, the buck–boost corrector has the following disadvantages:

(a) The input current is discontinued by the power switch, resulting in high differential mode EMI;
(b) The current stress on the power switch is high;
(c) The power switch needs a floating drive;
(d) The polarity of output voltage is reversed.

D. The Cuk, Sepic, and Zeta Correctors

Unlike the previous converters, the Cuk, Sepic, and Zeta converters are fourth-order switching-mode circuits. Their circuit topologies for PFC are shown in Figs. 19.11a, b, and c, respectively. Because there are four energy storage components available to handle the energy balancing involved in PFC, second harmonic output voltage ripples of these correctors are smaller when compared with the second-order buck, boost, and buck–boost topologies. These PF correctors are also able to provide overload protection. However, the increased count of components and current stress are undesired.

19.3.4 System Configurations of PFC Power Supply

The most common configurations of ac–dc power supply with PFC are two-stage scheme and one-stage (or single-stage) scheme. In two-stage scheme as shown in Fig. 19.12a, a non-isolated PFC ac–dc converter is connected to the line to create an intermediate dc bus. This dc bus voltage is usually full of second harmonic ripple. Therefore, followed by the ac–dc converter, a dc–dc converter is cascaded to provide electrical isolation and tight voltage regulation. The advantage of two-stage structure PFC circuits is that the two power stages can be controlled separately, and thus it makes it possible to have both converters optimized. The drawbacks of this scheme are lower efficiency due to twice processing of the input power, complex control circuits, higher cost, and low reliability. Although the two-stage scheme approach is commonly adopted in industry, it received limited attention by the common research, since the input stage and output stage can be studied independently. One-stage scheme combines the PFC circuit and power conversion circuit in one stage as shown in Fig. 19.12b. Due to its

simplified structure, this scheme is potentially more efficient and is very attractive in low to medium power level applications, particularly in those cost-sensitive applications. The one-stage scheme, therefore becomes the main stream of contemporary research due to the ever-increasing demands for inexpensive power supply in residential and office appliance.

For many single-stage PFC converters, one of the most important issues is the slow dynamic response under line and load changes. To remove the low frequency ripple caused by the line (120 Hz) from the output and keep a nearly constant operation duty ratio, a large volume output capacitor is normally used. Consequently, a low frequency pole (typically less than 20 Hz) must be introduced into the feedback loop. This results in very slow dynamic response of the system [13, 14].

To avoid twice power process in two-stage scheme, two converters can be connected in parallel to form so-called parallel PFC scheme [15]. In parallel PFC circuit, power from the ac main to the load flows through two parallel paths, shown in Fig. 19.12c. The main path is a rectifier, in which power is not

processed twice for PFC, whereas the other path processes the input power twice for PFC purpose. It is shown that to achieve both unity PF and tight output voltage regulation, only the difference between the input and output power within a half cycle (about 32% of the average input power) needs to be processed twice [15]. Therefore, high efficiency can be obtained by this method.

The continuous research in improving system PF has resulted in countless circuit topologies and control strategies. Classified by their principles to realize PFC, they can be mainly categorized into discontinuous conduction mode (DCM) input technique and continuous conduction mode (CCM) shaping technique. The recent research interest in DCM input technique is focused on developing PFC circuit topologies with a single power switch, result in single-stage single-switch converter (so-called S^4-converter). The CCM shaping technique emphasizes on the control strategy to
FIGURE 19.13   Overview of PFC techniques.

achieve unity input PF. The hot topics in this line of research are concentrated on degrading complexity of the control circuit and enhancing dynamic response of the system, resulting in some new control methods. Figure 19.13 shows an overview of these techniques based on conduction mode and system configuration types.

19.4 CCM Shaping Technique

Like other power electronic apparatus, the core of a PFC unit is its converter, which can operate either in DCM or in CCM. As shall be discussed in the next section, the benefit from DCM technique is that low-cost power supply can be achieved because of its simplified control circuit. However, the peak input current of a DCM converter is at least twice as high as its corresponding average input current, which causes higher current stresses on switches than that in a CCM converter, resulting in intolerable conduction and switching losses as well as transformer copper losses in high power applications. In practice, DCM technique is only suitable for low to medium level power application, whereas, CCM is used in high power cases. However, a converter operating in CCM does not have PFC ability inherently, i.e. unless a certain control strategy is applied, the input current will not follow the waveform of line voltage. This is why most of the research activities in improving PF under CCM condition have been focused on developing new current shaping control strategies. Depending on the system variable being controlled (either current or voltage), PFC control techniques may be classified as current control and voltage control. Current control is the most common control strategy since the primary objective of PFC is to force the input current to trace the shape of line voltage.

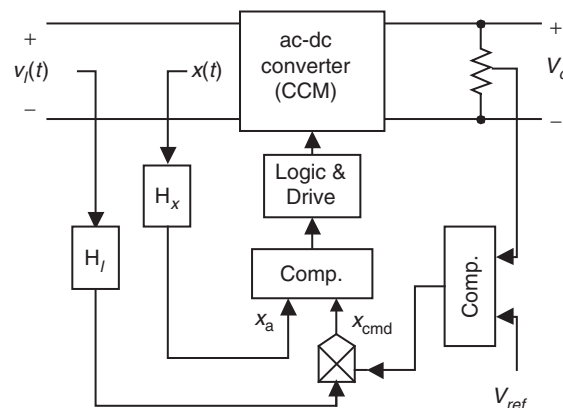
To achieve both PFC and output voltage regulation by using a converter operating in CCM, multiloop controls are generally used. Figure 19.14 shows the block diagram of ac–dc PFC


FIGURE 19.14   Block diagram of PFC converter with CCM shaping technique.

converter with CCM shaping technique, where, H_l is a line voltage compensator, H_x is a controlled variable compensator, and $x(t)$ is the control variable that can be either current or voltage.

Normally, in order to obtain a sinusoidal line current and a constant dc output voltage, line voltage $v_l(t)$, output voltage V_o, and a controlled variable $x(t)$ need to be sensed. Depending on whether the controlled variable $x(t)$ is a current (usually the line current or the switch current) or a voltage (related to the line current), the control technique is called "current mode control" or "voltage mode control," respectively. In Fig. 19.14, two control loops have been applied: the feedforward loop and the feedback loops. The feedforward loop is also called "inner loop" which keeps the line current to follow the line voltage in shape and phase, while the feedback loop (also called "outer loop") keeps the output voltage to be tightly controlled. These two loops share the same control command generated by the product of output voltage error signal and the line voltage (or rectified line voltage) signal.

19.4.1 Current Mode Control

Over many years, different current mode control techniques were developed. In this section, we will review several known methods.

A. Average Current Control

In average current control strategy, the average line current of the converter is controlled. It is more desired than the other control strategies because the line current in a SMPS can be approximated by the average current (per switching cycle) through an input EMI filter. The average current control is widely used in industries since it offers improved noise immunity, lower input ripple, and stable operation [13, 16–19].

Figure 19.15 shows a boost PFC circuit using average current control strategy. In the feedforward loop, a low value resistor R_s is used to sense the line current. Through the op-amp network formed by R_i, R_{imo}, R_f, C_p, C_z, and A_2, average line current is detected and compared with the command current signal, i_{cmd}, which is generated by the product of line voltage signal and the output voltage error signal.

There is a common issue in CCM shaping technique, i.e. when the line voltage increases, the line voltage sensor provides an increased sinusoidal reference for the feedforward loop. Since the response of feedback loop is much slow than the feedforward loop, both the line voltage and the line current increase, i.e. the line current is heading to wrong changing direction (with the line voltage increasing, the line current should decrease). This results in excessive input power, causing overshoot in the output voltage. The square block, x^2, in the line voltage-sensing loop shown in Fig. 19.15 provides a typical solution for this problem. It squares the output of the low-pass filter (LPF), which is in proportion to the amplitude of the line voltage, and provides the divider $(A * B)/C$ with a squared line voltage signal for its denominator. As a result, the

amplitude of the sinusoidal reference i_{cmd} is negatively proportional to the line voltage, i.e. when the line voltage changes, the control circuit leads the line current to change in the opposite direction, which is the desired situation. The detailed analysis and design issues can be found in [16–18].

As it can be seen, the average current control is a very complicated control strategy. It requires sensing the inductor current, the input voltage, and the output voltage. An amplifier for calculating the average current and a multiplier are needed. However, because of today's advances made in IC technology, these circuits can be integrated in a single chip.

B. Variable Frequency Peak Current Control

Although the average current control is a more desired strategy, the peak current control has been widely accepted because it improves the converter efficiency and has a simpler control circuit [14, 20–24]. In variable frequency peak control strategy, shown in Fig. 19.16, the output error signal $k(t)$ is fed back
FIGURE 19.16 Block diagram for variable frequency peak current control.
FIGURE 19.15 Boost corrector using average current control.

through its outer loop. This signal is multiplied by the line voltage signal $\alpha v_1(t)$ to form a line current command signal $i_{cmd}(t)$ ($i_{cmd}(t) = \alpha k(t) \cdot v_1(t)$). The command signal $i_{cmd}(t)$ is the desired line current shape since it follows the shape of the line voltage. The actual line current is sensed by a transducer, resulting in signal $\beta i_1(t)$ that must be reshaped to follow $i_{cmd}(t)$ by feeding it back through the inner loop. After comparing the line current signal $\beta i_1(t)$ with the command signal $i_{cmd}(t)$, the following control strategies can be realized, depending on its logic circuit:

Constant on-time control: Its input current waveform is given in Fig. 19.17a. Letting the fixed on-time to be T_s, the control rules are:

- At $t = t_k$ when $\beta i_1(t_k) = i_{cmd}(t_k)$, S is turned on;
- At $t = t_k + T_{on}$, S is turned off.

Constant off-time control: The input current waveform is shown in Fig. 19.17b. Assuming the off-time is T_{off}, the control rules are:

- At $t = t_k$ when $\beta i_1(t_k) = i_{cmd}(t_k)$, S is turned off;
- At $t = t_k + T_{off}$, S is turned on.

C. Constant Frequency Peak Current Control

Generally speaking, to make it easier to design the EMI filter and to reduce harmonics, constant switching frequency ac–dc

FIGURE 19.18 Logic circuit for constant frequency peak current control.

PFC converter is preferred. Based on the block diagram shown in Fig. 19.18, with T_s is the switching period, the following control rules can be considered to realize a constant frequency peak current control (shown in Fig. 19.19b):

- At $t = nT_s$, S is turned on;
- At $t = t_n$ when $\beta i_1(t_n) = i_{cmd}(t_n)$, S is turned off.

(a)

(a)

(b)

FIGURE 19.17 Input current waveforms for variable frequency peak current control: (a) constant on-time control and (b) constant off-time control.

(b)
FIGURE 19.19 (a) Constant frequency peak current control with stabilizing ramp compensation and (b) line current waveform for constant frequency peak current control.

The logic circuit for the above control rules can be realized by using an R–S flip-flop with a constant frequency setting clock pulse (CP), as shown in Fig. 19.18. Unfortunately, this logic circuit will result in instability when the duty ratio exceeds 50%. This problem can be solved by subtracting a stabilizing ramp signal from the original command signal. Figure 19.19a shows a complete block diagram for typical constant frequency peak current control strategy. The line current waveform is shown in Fig. 19.19b.

It should be noticed that in both variable frequency and constant frequency peak current control strategies, either the input current or the switch current could be controlled. Thus it makes possible to apply these control methods to buck type converters. There are several advantages of using peak current control:

- The peak current can be sensed by current transformer, resulting in reduced transducer loss;
- The current-error compensator for average control method has been eliminated;
- Low gain in the feedforward loop enhances the system stability;
- The instantaneous pulse-by-pulse current limit leads to increased reliability and response speed.

However the three signals, line voltage, peak current, and output voltage signals, are still necessary to be sensed and multiplier is still needed in each of the peak current control method. Comparing with the average current control method, the input current ripple of these peak current control methods may be high when the line voltage is near the peak value. As a result, considerable line current distortion exists under high line voltage and light low operation conditions.

D. Hysteresis Control

Unlike the constant on-time and the constant off-time control, in which only one current command is used to limit either the minimum input current or the maximum input current, the hysteresis control has two current commands, $i_{hcmd}(t)$ and $i_{lcmd}(t)$ ($i_{lcmd}(t) = \delta i_{hcmd}(t)$), to limit both the minimum and the maximum of input current [25–28]. To achieve smaller ripple in the input current, we desire a narrow hyster-band. However, the narrower the hyster-band, the higher the switching frequency. Therefore, the hyster-band should be optimized based on circuit components such as switching devices and magnetic components. Moreover, the switching frequency varies with the change of line voltage, resulting in difficulty in the design of the EMI filter. The circuit diagram and input current waveform are given in Figs. 19.20a and b, respectively. When $\beta i_1(t) \geq i_{hcmd}(t)$, a negative pulse is generated by comparator A_1 to reset the R–S flip-flop. When $\beta i_1(t) \leq i_{lcmd}(t)$, a negative pulse is
FIGURE 19.20 Hysteresis control: (a) block diagram for hysteresis control and (b) line current waveform of hysteresis control.

generated by comparator A_2 to set the R–S flip-flop. The control rules are:

- At $t = t_k$ when $\beta i_1(t_k) = i_{lcmd}(t)$, S is turned on;
- At $t = t_{k+1}$ $\beta i_1(t_{k+1}) = i_{hcmd}(t)$, S is turned off;
- When $\beta i_1(t) = i_{hcmd}(t) = i_{lcmd}(t)$, S stays off or on.

Like the above mentioned peak current control methods, the hysteresis control method has simpler implementation, enhanced system stability, and increased reliability and response speed. In addition, it has better control accuracy than that the peak current control methods have. However, this improvement is achieved on the penalty of wide range of variation in the switching frequency. It is also possible to improve the hysteresis control in a constant frequency operation [29, 30], but usually this will increase the complexity of the control circuit.

E. Charge Control

In order to make the average control method to be applicable for buck-derived topologies where the switch current instead
FIGURE 19.21   Flyback PFC converter using charge control.

FIGURE 19.22   Boost PFC converter using NLC control.

of the inductor current needs to be controlled, an alternative method to realize average current control, namely, charge control was proposed in [31–33]. Since the total charge of the switch current per switching cycle is proportional to the average value of the switch current, the average current can be detected by a capacitor-switch network. Figure 19.21 shows a block diagram for charge control. The switch current is sensed by current transformer T1 and charges the capacitor C_T to form average line current signal. As the switch current increases, the charge on capacitor C_T also increases. When the voltage reaches the control command v_c, the power switch turns off. At the same time, the switch S_d turns on to reset the capacitor. The next switching cycle begins with the power switch turning on and the switch S_d turning off by a clock pulse.

The advantages of charge control are:

- Ability to control average switch current;
- Better switching noise immunity than peak current control;
- Good dynamic performance;
- Elimination of turn off failure in some converters (e.g. multiresonant converter) when the switch current reaches its maximum value.

The disadvantages are:

- Synthesis of the reference v_c still requires sensing both input and output voltage and use of a multiplier;
- Subharmonic oscillation may exist.

F. Non-linear-carrier (NLC) Control

To further simplify the control circuitry, non-linear-carrier control methods were introduced [34, 35]. In CCM operation, since the input voltage is related to the output voltage through the conversion ratio, the input voltage information can be recovered by the sensed output voltage signal. Thus the sensing of input voltage can be avoided, and therefore, the

multiplier is not needed, resulting in significant simplification in the control circuitry. However, complicated NLC waveform generator and its designs are involved. Figure 19.22 shows the block diagram of the NLC charge control first introduced in [34].

19.4.2 Voltage Mode Control

Generally, current mode control is preferred in current source driven converters, as the boost converter. To develop controllers for voltage source driven converter, like the buck converter and to improve dynamic response, voltage mode control strategy was proposed [36, 37]. Figure 19.23 shows
FIGURE 19.23   Input circuit and phasor diagram for voltage control: (a) input circuit of voltage control ac–dc converter; (b) simplified input circuit; and (c) phasor diagram.

the input circuit of an ac–dc converter and its phasor diagram representation, where ϕ is the phase shift between the line current and the capacitor voltage. An *LC* network could be added to the input either before a switch mode rectifier (SMR) or after a passive rectifier to perform such kind of control. In boost type converter, the inductor L_i is the input inductor. It can be seen from the phasor diagram that to keep the line current in phase with the line voltage, we can either control the capacitor voltage or the inductor voltage. If the capacitor voltage is chosen as controlled variable, the control strategy is known as delta modulation control.

A. Capacitor Voltage Control

Figure 19.24 gives a SMR with PFC using capacitor voltage control [36]. The capacitor voltage $v_{c1}(t)$ is forced to track a sinusoidal command $v_{c1}^*(t)$ signal to indirectly adjust the line current in phase with the line voltage. The command signal is the product of the line voltage signal with a phase shift of ϕ and the feedback error signal. The phase shift ϕ is a function of the magnitudes of line voltage and line current, therefore the realization of a delta control is not really simple. In addition, since ϕ is usually very small, a small change in capacitor voltage will cause a large change in the inductor voltage, and hence in the line current. Thus it make the circuit very sensitive to parameter variations and perturbations.

B. Inductor Voltage Control

To overcome the above shortcomings, inductor voltage control strategies was reported in [37]. Figure 19.25 shows an SMR with PFC using inductor voltage control. As the phase difference between the line voltage and the inductor voltage is fixed at 90° ideally, the control circuit is simpler in implementation than that of capacitor voltage control. As the inductor voltage is sensitive to the phase shift ϕ, but not sensitive to the change in magnitude of reference, the inductor voltage control method is more effective in keeping the line current in phase
FIGURE 19.25 SMR using inductor voltage control.

with the line voltage. However, in the implementations of both the two kinds of voltage control methods hysteresis technique is normally used. Therefore, unlike the previous current mode control, variable frequency problem is encountered in these control methods.

Generally speaking, by using CCM shaping technique, the input current can trace the wave shape of the line voltage well. Hence the PF can be improved efficiently. However, this technique involves in the designing of complicated control circuits. Multiloop control strategy is needed to perform input current shaping and output regulation. In most CCM shaping techniques, current sensor, and multiplier are required, which results in higher cost in practical applications. In some cases, variable frequency control is inevitable, resulting in additional difficulties in its closedloop design. Table 19.1 gives a comparison among these control methods.

19.5 DCM Input Technique

To get rid of the complicated control circuit invoked by CCM shaping technique and reduce the cost of the electronic interface, DCM input technique can be adopted in low power to medium power level application.

In DCM, the inductor current of the core converter is no longer a valid state variable since its state in a given switching cycle is independent of the value in the previous switching cycle [38]. The peak of the inductor current is sampling the line voltage automatically, resulting in sinusoidal-like average input current (line current). This is why DCM input circuit is also called "voltage follower" or "automatic controller." The benefit of using DCM input circuit for PFC is that no feedforward control loop is required. This is also the main advantage over a CCM PFC circuit, in which multiloop control strategy is essential. However, the input inductor operating in DCM

FIGURE 19.24 SMR using capacitor voltage control.

TABLE 19.1 Comparison of CCM shaping techniques

	Average current	VF peak-current	CF peak-current	Hysteresis	Charge	Non-linear carrier	Capacitor voltage	Inductor voltage
Input ripple	Low	High	High	Low	Low	Low	Low	Low
Switching frequency	Constant	Variable	Constant	Variable	Constant	Constant	Variable	Variable

Control signal sensed for inner loop	Input current & input voltage	Input (or switch) current & input voltage	Input (or switch) current & input voltage	Input current & input voltage	Input (or switch) current & input voltage	Input (or switch) current	Input voltage & capacitor voltage	Input voltage & inductor voltage
Inner loop E/A	Yes	No	No	Yes	No	No	No	No
Multiplier	Yes	Yes	Yes	Yes	Yes	No	Yes	Yes

cannot hold the excessive input energy because it must release all its stored energy before the end of each switching cycle. As a result, a bulky capacitor is used to balance the instantaneous power between the input and output. In addition, in DCM, the input current is normally a train of triangle pulses with nearly constant duty ratio. In this case, an input filter is necessary for smoothing the pulsating input current.

19.5.1 Power Factor Correction Capabilities of the Basic Converter Topologies in DCM

The DCM input circuit can be one of the basic dc–dc converter topologies. However, when they are applied to the rectified line voltage, they may draw different shapes of average line current. In order to examine the PFC capabilities of the basic converters, we first investigate their input characteristics. Because the input currents of these converters are discrete when they are operating in DCM, only averaged input currents are considered. Since switching frequency is much higher than the line frequency, let's assume the line voltage is constant in a switching cycle. In steady state operation, the output voltage is nearly constant and the variation in duty ratio is slight. Therefore, constant duty ratio is considered in deriving the input characteristics.

A. Buck Converter

The basic buck converter topology and its input current waveform when operating in DCM are shown in Figs. 19.26a and b, respectively. It can be shown that the average input current in one switching cycle is given by

$$i_{1,avg}(t) = \frac{1}{T_s}\left[\frac{1}{2}\cdot DT_s \cdot \frac{v_1(t) - V_o}{L}DT_s\right] \qquad (19.24)$$

$$= \frac{D^2 T_s}{2L}v_1(t) - \frac{D^2 T_s}{2L}V_o$$

Figure 19.26c shows that the input voltage–input current I–V characteristic consists of two straight lines in quadrants

I and III. It should be noted that these straight lines do not go through the origin. When the rectified line voltage $v_1(t)$ is less than the output voltage V_o, negative input current would occur. This is not allowed because the bridge rectifier will block the negative current. As a result, the input current is zero near the zero crossing of the line voltage, as shown in Fig. 19.26c. Actually, the input current is distorted simply because the buck converter can work only under the condition when the input voltage is larger than the output voltage. Therefore, the basic buck converter is not a good candidate for DCM input PFC.

B. Boost Converter

The basic boost converter and its input current waveform are shown in Figs. 19.27a and b, respectively. The input I–V characteristic can be found as follows

$$i_{1,avg}(t) = \frac{1}{T_s}\left[\frac{1}{2}\cdot(D + D_1)\,T_s\frac{v_1(t)}{L}DT_s\right] \qquad (19.25)$$

$$= \frac{D^2 T_s}{2L}\frac{v_1(t)V_o}{V_o - v_1(t)}$$

where, $D_1 T_s$ is the time during which the inductor current decreases from its peak to zero.

By plotting Eq. (19.25), we obtain the input I–V characteristic curve as given in Fig. 19.27c. As we can see that as long as the output voltage is larger than the peak value of the line voltage in certain range, the relationship between $v_1(t)$ and $i_{1,avg}(t)$ is nearly linear. When the boost converter is connected to the line, it will draw almost sinusoidal average input current from the line, shown as in Fig. 19.27c. As one might notice from Eq. (19.25) that the main reason to cause the nonlinearity is the existence of D_1. Ideally, if $D_1 = 0$, the input I–V characteristic will be a linear one.

Because of the above reasons, boost converter is comparably superior to most of the other converters when applied to do PFC. However, it should be noted that boost converter can operate properly only when the output voltage is higher

(a)

(b)

(c)
FIGURE 19.26 Input *I–V* characteristic of basic buck converter operating in DCM: (a) buck converter; (b) input current; and (c) input *I–V* characteristic.

(a)

(b)

(c)

than its input voltage. When low voltage output is needed, a stepdown dc–dc converter must be cascaded.

C. Buck–Boost Converter

Figure 19.28a shows a basic buck–boost converter. The averaged input current of this converter can be found according to its input current waveform, shown in Fig. 19.28b.

$$i_{1,avg}(t) = \frac{D^2 T_s}{2L} v_1(t) \tag{19.26}$$

Equation (19.26) gives a perfect linear relationship between $i_{1,avg}(t)$ and $v_1(t)$, which proves that a buck–boost has an

excellent automatic PFC property. This is because the input current of buck–boost converter does not related to the discharging period D_1. Its input *I–V* characteristics and input voltage and current waveforms are shown in Fig. 19.28c. Furthermore, because the output voltage of buck–boost converter can be either larger or smaller than the input voltage, it demonstrates strong availability for DCM input technique to achieve PFC. So, theoretically buck–boost converter is a

(a)

(b)

(c)
FIGURE 19.28 Input *I–V* characteristic of basic buck–boost converter operating in DCM: (a) buck–boost converter; (b) input current; and (c) input *I–V* characteristic.

perfect candidate. Unfortunately, this topology has two limitations: (1) the polarity of its output voltage is reversed, i.e. the input voltage and the output voltage don't have a common ground; and (2) it needs floating drive for the power switch. The first limitation circumscribes this circuit into a very narrow scope of applications. As a result, it is not widely used.

D. Flyback Converter

Flyback converter is an isolated converter whose topology and input current waveform are shown in Figs. 19.29a and b,

(a)

(b)
FIGURE 19.29 Input *I–V* characteristic of basic flyback converter operating in DCM: (a) flyback converter and (b) input current.

respectively. The input voltage–input current relationship is similar to that of buck–boost converter

$$i_{1,avg}(t) = \frac{D^2 T_s}{2L_m} v_1(t) \tag{19.27}$$

where, L_m is the magnetizing inductance of the output transformer.

Therefore, it has the same input *I–V* characteristic, and hence the same input voltage and input current waveforms as those the buck–boost converter has, shown in Fig. 19.29c.

Comparing with buck–boost converter, flyback converter has all the advantages of the buck–boost converter. What's more, input–output isolation can be provided by flyback converter. These advantages make flyback converter well suitable for PFC with DCM input technique. Comparing with boost converter, the flyback converter has better PFC and the output voltage can be either higher or lower than the input voltage. However, due to the use of power transformer, the flyback converter has high *di/dt* noise, lower efficiency, and lower density (larger size and heavier weight).

E. Forward Converter

The circuit shown in Fig. 19.30 is a forward converter. In order to avoid transformer saturation, it is well-known that forward converter needs the 3rd winding to demagnetize (reset) the transformer. When a forward converter is connected to the rectified line voltage, the demagnetizing current through the 3rd winding is blocked by the rectifier diodes. Therefore,
FIGURE 19.30   (a) Forward converter and (b) input current waveform.

forward converter is not available for PFC purpose unless a certain circuit modification is applied.

F. Cuk Converter and Sepic Converter

It can be shown that Cuk converter and Sepic converter given in Figs. 19.31a and b, respectively, have the same input I–V characteristic. Each of these converter topologies has two inductors, with one located at its input and the other at its output. Let's consider the case when the input inductor operates in DCM while the output inductor operates in CCM. In this case, the capacitor C_1 can be designed with large value to balance the instantaneous input/output power, resulting in high PF in the input and low second harmonic ripple in the output voltage. To investigate the input characteristic of these converters, let's take the Cuk converter as an example. One should note that the results from the Cuk converter are also suitable for Sepic converter.

For the Cuk converter shown in Fig. 19.31a, the waveforms for input inductor current (the same as the input current), output inductor current, and the voltage across the output inductor are depicted in Fig. 19.31c. Assume that the capacitor C_1 is large enough to be considered as a voltage source V_c, in steady state, employing volt-second equilibrium principle on L_2, we obtain

$$V_C = \frac{1}{D} V_o \qquad (19.28)$$

The input inductor current reset time ratio D_1 is given by

$$D_1 = \frac{D^2 v_1(t)}{V_o - D v_1(t)} \qquad (19.29)$$

Therefore the averaged input current can be found as

$$i_{1,avg}(t) = \frac{1}{T_s} \left[\frac{1}{2} \cdot (D + D_1) \, T_s \frac{v_1(t)}{L} D T_s \right] \qquad (19.30)$$

$$= \frac{D^2 T_s}{2L} \frac{v_1(t) V_o}{V_o - D v_1(t)}$$

It can be seen that Eq. (19.30) is very similar to Eq. (19.25) except that the denominator in the former equation is $(V_o - D v_1(t))$ instead of $(V_o - v_1(t))$. This will lead to some improvement in that I–V characteristic in Cuk converter. Referring to the I–V characteristic shown in Fig. 19.27c, Cuk converter has a curve more close to a straight line. Such improvement, however, is achieved at the expense of using more circuit components. It can be proved that the same results can be obtained by the Sepic converter.

G. Zeta Converter

Figure 19.32a gives a Zeta converter connected to the line. In DCM operation, the key waveforms are illustrated in Fig. 19.32b, where we presume the capacitor being equivalent to a voltage source V_c. As we can see that the converter input current waveform is exactly the same as that drawn by a

(a)

(b)

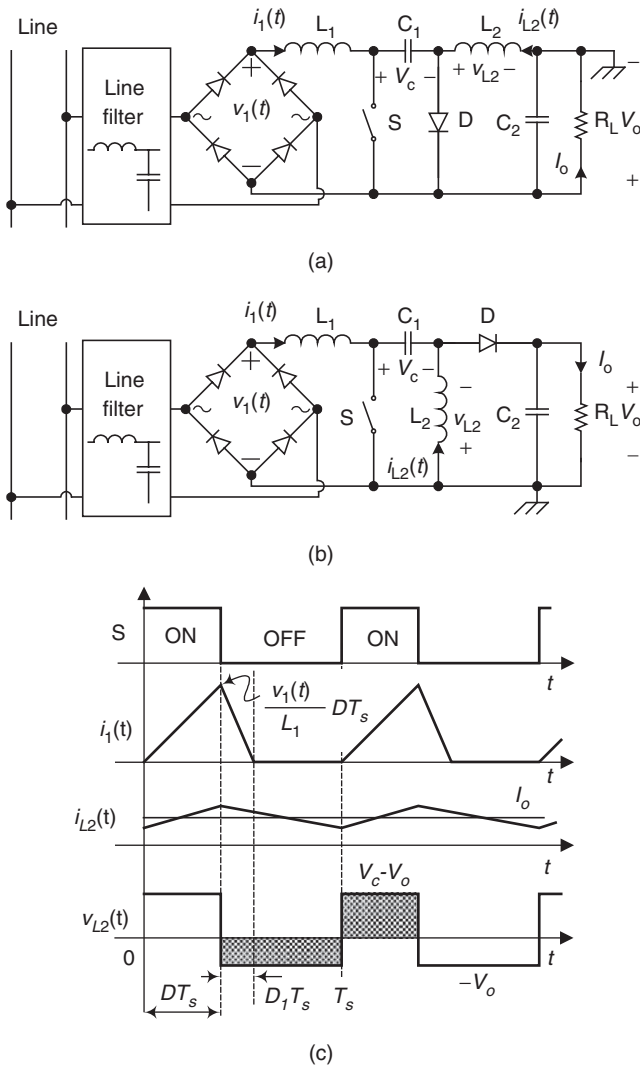
(c)


FIGURE 19.31 Input I–V characteristic of basic Cuk converter and Sepic converter operating in DCM: (a) Cuk converter; (b) Sepic converter; and (c) typical waveforms of Cuk converter with input inductor operating in DCM.

(b)

FIGURE 19.32 Input I–V characteristic of basic Zeta converter operating in DCM: (a) Zeta converter and (b) typical waveforms of Zeta converter with input inductor operating in DCM.

dc–dc converter. Hence, these two converters are most preferable by the designers for PFC purpose. The other converters could also be used to perform certain function such as circuit protection and small output voltage ripple. The characteristics of the eight basic converter topologies are summarized in Table 19.2.

19.5.2 AC–DC Power Supply with DCM Input Technique

In two-stage PFC power supply, the DCM converter is connected in front of the ac line to achieve high input PF and provide a roughly regulated dc bus voltage, as shown in Fig. 19.33. This stage is also known as "pre-regulator." The duty ratio of the pre-regulator should be maintained relatively stable so that high PF is ensured. To stabilize the dc bus voltage, a bank capacitor is used at the output of the pre-regulator. The second stage, followed by the pre-regulator, is a dc–dc converter, called post-regulator, with its output voltage being tightly controlled. This stage can operate either in DCM or in CCM. However, CCM is normally preferred to reduce the output voltage ripple.

DCM input technique has been widely used in one-stage PFC circuit configurations. Using a basic converter

buck–boost converter. Thus, the average input current for the Zeta converter is identical to that for the buck–boost converter, which is given by Eq. (19.26). As a result, the Zeta converter has as good automatic PFC capability as the buck–boost converter. The improvement achieved here is the non-inverted output voltage. However, like the buck converter, floating drive is required for the power switch.

Based on the above discussion, we may conclude that all the eight basic converters except forward converter have good inherent PFC capability and are available for DCM PFC usage. Among them, boost converter and flyback converter are especially suitable for single-stage PFC scheme because they have minimum component count and grounded switch drive, and their power switches are easy to be shared with the output

TABLE 19.2 Comparison of basic converter topologies operating for DCM input technique

	Buck	Boost	Buck–boost	Flyback	Forward*	Cuk and sepic	Zeta
Line current waveform					–		
Switch drive	Floating	Grounded	Floating	Grounded	Grounded	Grounded	Floating
Peak input current	High	Lower	High	High	–	Lower	High

Output voltage	$V_o < V_{l,m}$	$V_o > V_{l,m}$	Inverted	$V_o < V_{l,m}$ or $V_o > V_{l,m}$	–	$V_o < V_{l,m}$ or $V_o > V_{l,m}$; Inverted for Cuk	$V_o < V_{l,m}$ or $V_o > V_{l,m}$

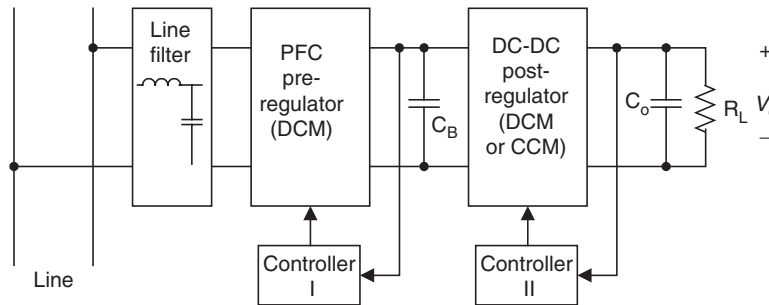
*The standard forward converter is not recommended as a PF corrector since the rectifier at the input will block the demagnetizing current through the tertiary winding.


FIGURE 19.33 DCM input pre-regulator in two-stage ac–dc power supply.

(usually boost or flyback converter) operating in DCM, combining it with another isolation converter can form a one-stage PFC circuit. A storage capacitor is generally required to hold the dc bus voltage in these combinations. Unlike the two-stage PFC circuit, in which the bus voltage is controlled, the single-stage PFC converter has only one feedback loop from the output. The input circuit and the output circuit must share the same control signal. In [39–41] a number of combinations have been studied. Figures 19.34 and 19.35 show a few examples of successful combinations. Since the input circuit and the output circuit are in a single stage, it is possible for them to share the same power switch. Thus it results in single-stage single-switch PFC (S^4-PFC) circuit, as shown in Fig. 19.35 [39, 42, 43].

Due to the simplicity and low cost, DCM boost converter is most commonly used for unity PF operation. The main drawback of using boost converter is that it shows considerable distortion of the average line current owing to the slow discharging of the inductor after the switch is turned off.

The output dc–dc converter can operate either in DCM or in CCM if small output ripple is desired. If the output circuit operates in CCM, there exists a power unbalance in S^4-PFC converter when the load changes. Because the duty ratio is only sensitive to the output voltage in CCM operation, when the output power (output current) decreases, the duty ratio

will keep unchanged. As both the input and the output circuit share the power switch, the input circuit will draw an unchanged power from the ac source. As a result, the input power is higher than the output power. The difference between the input power and the output power has to be stored in the storage capacitor, and hence increase in the dc bus voltage occurs. With the dc bus voltage's rising, the duty ratio decreases. This process will be finished until a new power balance is built. As we can see, the new power balance is achieved at the penalty of increased voltage stress, resulting in high conduction losses in circuit components. Particularly, the high bus voltage causes difficulties in developing S^4-converter for universal input (input line voltage *rms* value from ac 90 to 260 V) application.

Recent research on solving this problem can be found in [44–52]. The circuit in [44] uses two bulk capacitors that share the dc bus voltage change, shown in Fig. 19.36a. As a result, lower voltage is present at each of the capacitor. Reference [45] proposed a modified boost–forward PFC converter, in which a negative current feedback is introduced to the input circuit by the coupled windings of forward transformer, shown in Fig. 19.36b. In [46] a series resonant circuit called charge pump circuit is introduced into S^4-PFC circuit, shown in Fig. 19.36c. As the load decrease, the charge pump circuit can suppress the dc bus voltage automatically.

19.5.3 Other PFC Techniques

Extensive research in PFC continues to yield countless new techniques [15, 53–63]. The research topics are mainly focused on improvements of the PFC circuit performs such as fast performs, high efficiency, low cost, small input current distortion, and output ripple. The classification of PFC techniques presented here can only cover those methods that are frequently documented in the open literature. There are still many PFC methods which do not fall into the specified categories. The following are some examples:

- **Second-harmonic-injected method** [56]: In DCM input technique, even the converter operates at constant duty ratio, current distortion still exists. The basic idea of second-harmonic-injected method is compensating the duty ratio by injecting a certain amount of second harmonic into the duty ratio to modify the input *I–V* characteristic of the input converter. However, the output voltage may be affected by the modified duty ratio.

- **Interleaved method** [57]: An interleaved PFC circuit composed of several input converters in parallel. The peak input current of these converters follow the line voltage and are interleaved. A sinusoidal total line current is obtained by superimposing all the input current of the converters. The advantage of this method is that the converter input current can be easily smoothed by input EMI filter.

- **Waveform synthesis method** [58]: This method combines passive and active PFC techniques. Since the rectifier in the passive inductive-input PF corrector has a limited
FIGURE 19.36 Improved S^4-PFC converter: (a) boost–forward PFC circuit using two bulk capacitors; (b) boost–forward PFC circuit with reduced bus voltage; and (c) boost–flyback PFC circuit with charge pump circuit.

conduction angle, the input current is a single pulse around the peak of the line voltage, whereas the boost converter draws a non-zero current around the zero-cross of the line voltage. By controlling the operation mode of the active switch (enable and disable the boost converter at certain line voltage), the waveforms of active and passive PFC circuits are tailored to extend the conduction angle of the rectifier. The resulting current waveform has a PF greater than 0.9 and a THD lower than 20%.

19.6 Summary

To reduce losses, and decrease weight and size associated with converting ac power to dc power in linear power supply, switch mode power supplies (SMPSs) were introduced. The high non-linearity of this kind of power electronic systems handicaps itself by providing the utility power system with low power factor (PF) and high total harmonic distortion (THD). These unwanted harmonics are commonly corrected by incorporating power factor correction (PFC) technique into the SMPS. This chapter gives a technical review of current research in high frequency PFC, including the definition of PF and THD, configuration of PFC circuit, DCM input technique, and CCM shaping technique. The common issue of these techniques is to properly process the power flow so that the constant power dissipation at the output is reflected into ac power dissipation with two times the line frequency. Technically, PFC techniques encounter the following tradeoffs:

(a) *Simplicity and accuracy*: Single-stage PFC circuit has simple topology and simple control circuit, but has less control accuracy while two-stage PFC circuit has the contrary performance;

(b) *Control simplicity and power handling capability*: DCM input technique requires no input current control, but has less power handling capability while CCM has multiloop control and has more power handling capability;

(c) *Switching frequency and conversion efficiency*: To reduce weight and size of the PFC converter, higher

switching frequency is desired. However, the associated switching losses result in decrease in conversion efficiency;

(d) *Frequency response and bandwidth*: To have good dynamic response, wider bandwidth is desired, however to achieve high PF bulk storage capacitor and output capacitor has to be used.

In the past decades, research in PFC techniques has led to the development of more efficient circuits and control strategies in order to optimize the design without compromising the above tradeoffs. Moreover, since the growth in power electronics strongly relies on the development of semiconductor devices, the recent advent of higher rating power devices, it is believed that the switching mode PF correctors will completely replace the existing passive reactive compensators in power system. In the distributed power system (DPS) where small size and high efficiency are of extreme importance, a new soft-switching technique has been used in designing PFC circuits. With the ever increasing market demanding for ultra-fast computer, the need for low output voltage (typically less than 1 V!) with high output currents and high efficiency converters has never been greater. Research efforts in developing high frequency high efficiency PFC circuits will continue to grow.

Gate Drive Circuitry for Power Converters

Irshad Khan,
MTech Eng, MSc

*University of Cape Town,
Department of Electrical
Engineering, Cape Town,
South Africa*

20.1 Introduction to Gate Drive Circuitry

Global trends towards energy efficiency over the last three decades has facilitated the need for technological advancements in the design and control of power electronic converters for energy processing. These power electronic converters find widespread applications in industry such as:

Consumer electronics

- Battery chargers for cellular telephones and cameras
- Computer power supplies

Automobile industries

- Electronic ignitions and lighting

Commercial sectors

- Variable speed motor drives for conveyor belt systems
- Induction heating installations for metals processing
- Uninterruptible power supplies (UPS)
- Industrial welding

Domestic electronics

- Fluorescent, compact fluorescent, and incandescent lighting, washing machines, cooking appliances, and dish washers

Utility applications

- DC transmission for electrification purposes

All of the above applications utilize similar power converter topologies. This allows for controlled and efficient power conversion from one form of energy to another, utilizing semiconductor technologies such as BJT transistors, SCRs (thyristors), IGBTs, and power MOSFETs.

It is true that "Power is nothing without control" (Pirelli Tyres). The gate drive circuitry of a power converter forms an important interface between the high power electronics and the intelligent control processing stages.

It is therefore of utmost importance that this interface between the control and power electronics is well designed, since it can have a substantial impact on the performance and reliability of a power electronic system. (See Fig. 20.1.)
FIGURE 20.1   Generalized layout of a power electronic system showing the situation of the gate driver circuits.

20.2 Semiconductor Drive Requirements

Power semiconductor devices have three operating states commonly known as the cut-off mode, the active mode, and the saturation mode. In power electronic converters which utilize switch-mode operation, the aim is to operate these semiconductors in either the cut-off region or the saturation region, whilst making the transition through the active or linear region as short as possible in order to facilitate maximum power conversion efficiency. In order to achieve these fast transition times, a suitable gate driver circuit is required. This gate driver has to be able to supply the necessary charge to the power semiconductor device gate junction in order to achieve turn-on and turn-off.

Power semiconductors can be classified into two categories with respect to drive requirements, namely: current-driven devices and voltage-driven devices.

20.2.1 Current-driven Devices

A current-driven device is a device that requires a constant current drive for a period of time in order to initiate and/or remain in conduction. Two popular types of current controlled devices are the bipolar power transistor and the thyristor (SCRs). The SCR is mainly used in AC–DC converters such as controlled rectifiers where the input AC voltage helps to commutate (turn-off) the devices by polarity reversal. In DC–AC inverters, the gate turn-off thyristors (GTOs) are generally used due to their ability to be both turned on and off by a gate control signal. This eliminates the need for forced commutation circuitry, needed to turn-off the thyristor in these applications due to the absence of a reversing polarity AC input voltage. Thyristors and GTOs still dominate the high voltage and high current applications, like DC transmission, requiring converters up to the megawatt range. The evolution of the IGBT power semiconductor device has resulted in thyristors and GTOs being used less in conventional power converters these days. IGBTs are readily available with on-state currents of several hundred amperes and blocking voltages in excess of 1.7 kV. The IBGTs offer much faster switching speeds than thyristors and have much lower gate drive power requirements than SCRs or power bipolar junction transistors (BJT). The IGBTs have already replaced power BJTs in most applications due to their superior performance. The next generation of silicon carbide technology could realize IGBT devices with blocking voltages in excess of 4 kV and may one day even replace SCR and GTO devices completely.

20.2.2 Voltage-controlled Devices

These devices are semiconductors which require a constant voltage drive on the gate control terminal in order to remain in conduction. The input drive requirements of these devices are substantially lower than their current-driven counterparts and are the preferred choice in modern power electronics. Two such devices are the power MOSFET and the IGBT which are forced commutated switching devices being fully controlled at the gate terminal under normal operating conditions. These devices do not latch into conduction, and therefore do not require special commutation circuits. The gate input junction of a MOSFET and IGBT is purely capacitive, so, no gate drive current is needed in the steady state, unlike transistors. A minimum gate drive voltage however must be maintained (above the gate threshold voltage) at the device gate in order for it to remain in conduction. A high current low impedance drive circuit is needed to inject, or remove current, from the gate at high slew rates in order to switch the device rapidly. The gate drain capacitance, although small, can also require significant charge as at high drain voltage slew rates (the Miller effect) [1].

The process of supplying the necessary power for the efficient driving of voltage-controlled devices is an ongoing area of research. This chapter will however only focus on the gate driver circuitry required to drive power MOSFETs and IGBTs in the bridge circuit configuration. The basic symbolic representation of the power MOSFET and IGBT is shown below. Figure 20.2 represents the static model of these devices. Unlike the power MOSFET, the IGBT can be manufactured without the integral body diode. Often power MOSFETs are represented as shown below, omitting the integral body diode which is always present in the MOSFET device. Care should be taken when reading circuits, not to forget this extra unseen component.
FIGURE 20.2   Static model representation of the power MOSFET and IGBT power semiconductor devices.
FIGURE 20.3   A dynamic model of the power MOSFET shows the presence of the parasitic BJT element found in the MOSFET structure [1, 2].

FIGURE 20.4   Dynamic model of an IGBT showing the location of the parasitic thyristor responsible for uncontrolled device latch up [1].

The dynamic model for a power MOSFET is shown in Fig. 20.3 [1, 2]. It can be noted that the integral body diode situated in the power MOSFET structure is actually a parasitic bipolar transistor. This parasitic element is the result of a fabrication process used when manufacturing power MOSFETs. The base of the BJT is usually floating, and a pull down resistor Rbe is included in the chip structure in order to keep the BJT base shorted to the MOSFET source terminal at all times. This is very necessary, since a floating BJT base will result in uncontrolled turn-on of the BJT device. By shorting the BJT base to the MOSFET's source terminal, a diode structure is now created, yielding the dynamic model with the integral body diode formed by the BJT base collector junction as shown in Fig. 20.3 [1, 2]. The turn-on of the BJT element during transients substantially degrades the performance of the power MOSFET. When the MOSFET is exposed to a fast changing transient voltage (*dv/dt*) across its drain to source terminals, enough current flows in Rbe, thereby biasing the parasitic bipolar into conduction. This transient can occur during the turn-on or turn-off of the device. To avoid transient susceptibility, the device *dv/dt* rating must be adhered to at all times. The input capacitance of the power MOSFET comprises the gate to source capacitance (Cgs) and the gate to drain capacitance (Cgd) also known as the Miller capacitance. The input gate structure for the IGBT is essentially the same as for the power MOSFET. A gate driver must be capable of supplying sufficient charge to both Cgs and Cgd when switching power MOSFETs and IGBTs in power converters.

A dynamic model of the IGBT is shown in Fig. 20.4. The IGBTs are essentially bipolar devices like BJTs with a MOSFET structured high impedance input. A parasitic transistor is also found in the IGBT chip structure as part of the manufacturing process. Combined with existing bipolar power transistor, it forms a parasitic thyristor, which once latched into conduction device, turn-off is not possible via the gate terminal. To avoid this uncontrolled behavior, the maximum allowable peak current and *dv/dt* ratings of the device must be adhered to at all times [1].

Both MOSFETs and IGBTs require sufficient charge deposited into their gate junctions, whilst maintaining a minimum gate threshold voltage in order to remain in conduction. When designing a gate driver, it is always important to
understand both the static and dynamic behavior of the semiconductor device used as it aids the effectiveness of the design for a given gate driver system.

20.3 Gate Drivers for Power Converters

Power electronic converters are found in various configurations. Each has a complex switching function with the goal of achieving efficient power conversion. These converters make use of various floating potentials in order to achieve an AC or quasi-DC output characteristics. Gate drivers function as current buffers and signal converters. They convey both the switching state information and gate drive power required during the power semiconductor switching process.

20.3.1 Floating Supply

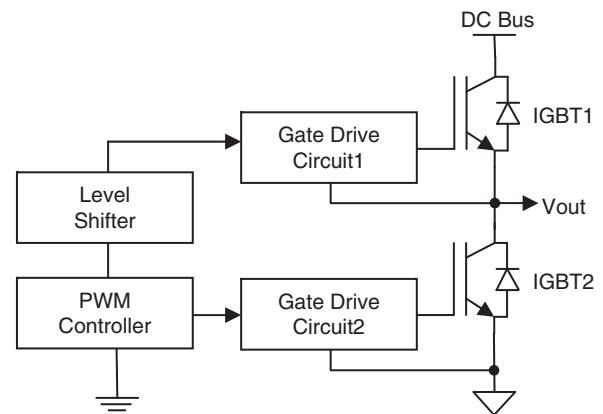
Power converters employing bridge configurations function by virtue of a high-side switch as shown in Fig. 20.5 below.


FIGURE 20.5   Simple structure of a bridge topology and driving circuit illustrating the concept of a high-side switch.

In order to drive a device like an IGBT or power MOS-FET into conduction, the gate terminal must be made positive with respect to its source or emitter. A common misconception made by many newcomers to the field of power electronics is that, because the emitter or source terminal is usually at some ground potential, it must be made positive with respect to ground. It can be noted that the emitter terminal of IGBT1, in the circuit above, can be floating anywhere from ground up to the DC bus potential, depending on the operating states of IGBT1 and IGBT2, and is therefore not referenced to the system ground potential. A supply is therefore needed in order to provide power to any circuitry associated with this floating midpoint potential. This type of supply is commonly referred to as a floating supply. Three of the most common methods of generating a floating supply are described next.

- **Isolated Supply**
  The simplest way of generating a floating supply is to use a transformer isolated supply. Compared to other methods, this type of supply is able to supply a continuous, large amount of current. A mains frequency transformer supply is cheap, but is usually very bulky. By employing a high frequency isolated DC–DC converter, fed from an existing DC supply, an isolated floating supply can be generated employing a much smaller isolation transformer.
- **Charge-pump Supply**
  The charge-pump technique superimposes the voltage of one supply onto another. It is normally used for generating a boost voltage on top of the main high-voltage supply. The charge-pump supply is not suitable for generating a boost voltage for powering floating high-side circuitry. A benefit of employing the charge-pump technique is that a continuous supply to the circuit is maintained. Due to complexity and cost, this circuit is not commonly used for power converters [3, 4].
- **Bootstrap Supply**
  A very common technique employed to generate a floating supply, the bootstrap supply is a simple circuit using only one diode and a supply storage capacitor. This technique is commonly used for low cost solutions in converters up to several kilowatts. Typical applications include electronic ballasts and variable speed motor drives.

A simplified schematic of a bootstrap circuit is shown in Fig. 20.6. When the low-side switch M2 is on, the bootstrap diode, D, conducts and charges the storage capacitor. If we assume the saturation voltage drop of the low-side power device M2 and the forward volt drop of diode D to be negligible, the capacitor will charge to approximately the low voltage supply potential. When the high-side switch M1 is on low side switch M2 is off, D is reverse-biased and the high-side circuitry is powered from C. In this condition, the voltage on C droops as it discharges when supplying the high-side circuitry.
FIGURE 20.6 Bootstrap technique employed for creating a floating supply.

The amount of voltage droop is a function of the current drawn, the size of the capacitor, and the operating frequency of the converter [3]. Detailed design and application literature on bootstrap supplies can be found in [4].

A summary and comparison of the various methods of generating a floating supply is given in Table 20.1 [5].

20.3.2 Level Shifting

The second requirement for driving a high-side switch, is that the control signal fed from the PWM electronics needs to be conveyed to the floating driver circuitry. A level-shifting circuit is required in order to achieve this.

The GD1 and GD2 are the respective high- and low-side gate drive circuits. In order to signal the high-side gate driver circuitry to commence turn-on of the high-side IGBT switch, the control signal V1 which is referenced to the control circuit ground potential needs to be referenced to the floating potential V_{out} at the IGBT1 emitter. This implies that the control signal V1 will be level shifted to V_{g1} as shown in Fig. 20.7. A level shifter can be thought of as an isolating black-box that transfers a signal across a potential barrier [6]. The maximum level attained by V_{g1} will be $V_{out} + V1$. In power converters, operating off mains voltage, these levels can be in excess of 500 V. Level shifting is achieved in one of the following ways:

- **Transformer Level Shifting**
  Transformers are an obvious choice for providing a level shifted signal. They have excellent noise immunity when compared to opto-couplers. Level shifting transformers also have the benefit of providing both the control and gate drive power signal to the power semiconductor switch (Fig. 20.8), thereby eliminating. This eliminates the need for a floating power supply. When operating at high switching frequencies, above several hundred kilohertz, careful transformer design has to be applied in order to avoid the adverse effects of transformer

TABLE 20.1 Comparison of the various techniques of creating a gate driver floating supply [5]

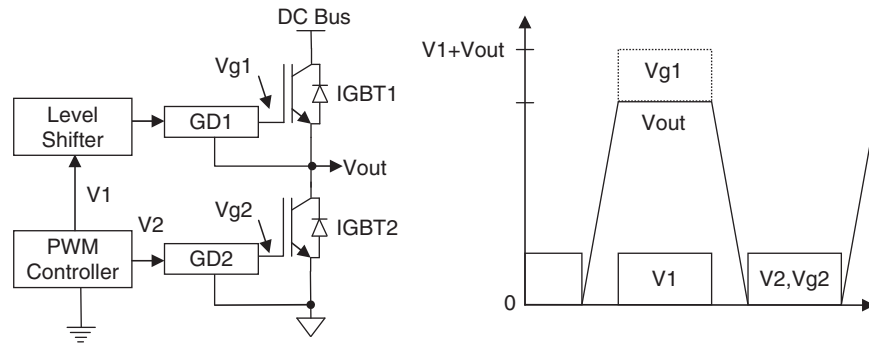
Potential isolation	Transformers			None
System	50 Hz power supply	Switch-mode power supply		Bootstrap supply
Supplied by	Auxiliary voltage or mains voltage	Auxiliary voltage	DC bus voltage	Operating voltage on bottom side
AC-frequency	Low	Very high	Medium	Medium
Smoothing requirements	High	Very low	Low	Low
For power modules	1200 V	>1700 V	1700 V	1200 V
Output voltage	Positive and negative	Positive and negative	Positive and negative	Only positive
Duty cycle restriction	No	No	No	Yes
Coupling capacitance	High	Low	Medium	Low
HF interference emission	None	High	Low	None
Cost	Low	Low	High	Very low


FIGURE 20.7 The concept of level shifting and the placement of the switching control signal on top of the inverter output voltage.
FIGURE 20.8 Combined transformer level shifter and gate driver. Capacitor $C1$ removes any DC offset in V1 thereby maintaining a zero average volt–time product across the transformer windings.

leakage inductance. Another limitation in the transformer gate driver, is when large currents are required at high speed for gate driving. The influence of the transformer parasitic components becomes significant. In the effort to deliver high peak currents at fast rise and fall times, the transformer turns are usually minimized, which leads to other transformer design limitations.

To avoid degradation of the gate drive waveform in the case of high speed and high current delivery, it is sometimes better to convey only the low power control signal via a transformer and also to employ a dedicated low-impedance output MOS-gate driver with a floating power supply [3].

A drawback of the gate drive transformer is that it cannot convey DC information (since the average volt–time product across any winding must be zero) and therefore has a limitation to its operation as shown in Fig. 20.9. When a high duty cycle is commanded, the gate drive capacitor will remove the DC offset in the signal, and could result in operation below the device threshold voltage Vge(th) as shown in Fig. 20.9c [3]. This condition will result in the device not turning on, or even operating in the linear region. This results in excessive semiconductor power dissipation.

- **Optical Level Shifting – Opto-couplers**
  Optical isolation is another technique used for achieving level shifting. The trade-off however, is that a separate floating supply is now required on the receiver end of the gate driver interface. Opto-couplers offer a cost effective, and easy solution, but are susceptible to noise and fast voltage transitions. This is common in gate drive circuits. This requirement places more demand on the power
FIGURE 20.9 Operating waveforms for the pulse transformer circuit in Fig. 20.8 under different duty cycles.

supply filtering and PCB layout around the opto-coupler in order to achieve reliable operation. Other benefits of opto-coupler technology is the small footprint (6-8 pin dual in line or surface mount package), output enable pin, and compatibility with any logic level input since its input is current-driven (an input diode). Commercially available opto-couplers cover a wide range of operating speeds of up to 15 MBd, with rise and fall times of 10–20 ns and noise immunity levels (*dv/dt* rating) of 10–15 V/ns. Typical opto-coupler isolation voltages are in the region of 5 kV which is sufficient, since most semiconductors have breakdown voltages lower than this.

- **Optical Level Shifting – Fiber Optic Link**
  Electrical conductors are susceptible to electromagnetic fields, and hence will radiate and pick up electromagnetic noise. Fiber optic links neither emit, nor receive electromagnetic noise, and pass through noisy environments unaffected. In addition, when dealing with very rapidly changing currents, ground noise can become a problem. A fiber optic link practically eliminates any ground loop or common-mode noise problems. A basic fiber optic communication system is given in Fig. 20.10.

The LED is driven by the PWM drive signal. The light emitted from the LED is sent down a length of fiber optic cable to the receiver. The receiver consists of a PIN photodiode and a trans-impedance amplifier. The output voltage of the amplifier is level detected by a comparator, and converted into a logic signal.

The galvanic isolation and *dv/dt* rating of this communication link can be increased to almost any desired value by simply lengthening the fiber optic cable. For a modest length of 10 cm of fiber optic cable, the isolation voltage is approximately 100 kV. The *dv/dt* rating is difficult to calculate, but as the coupling capacitance is practically zero, even the highest realizable *dv/dt* rating will have little effect. The bandwidth available in fiber optics systems makes operation at over 1 GHz possible [7].

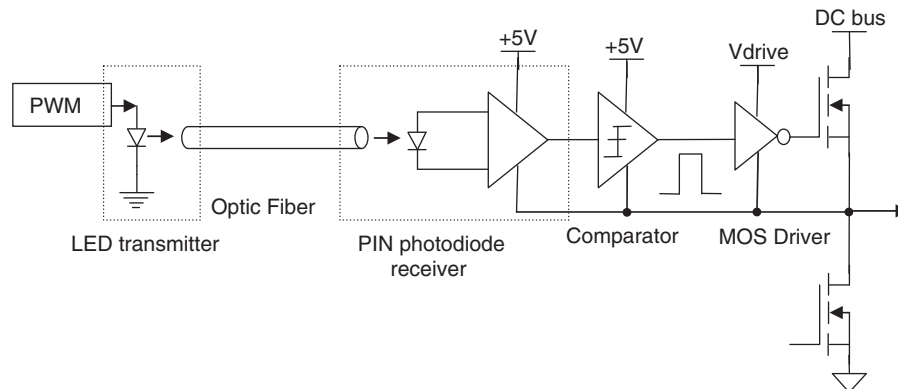
- **Electronic Level Shifting**
  Electronic level shifters work on the principle of having a current source referenced to a fixed potential. This reference potential is usually that of the low-side switches source, hence they are also called common source level shifters. The drive signal causes a certain current to be drawn through a current source regardless of the voltage


FIGURE 20.10 Fiber optic level shifting circuit used for high speed, extremely high noise immunity, and very high isolation voltage capability.
FIGURE 20.11 Electronic level shifting employed to convey the switching signal to the high-side gate drive circuitry. This technique does not offer any isolation but has widespread applications as an HV interface IC for power electronics applications.

across it. The current is sensed by the receiving side and turned into on/off information. Electronic level shifters do not provide isolation, however being an all electronic solution, allows it to be integrated onto a single chip. A simple common source non-inverting level shifter is shown in Fig. 20.11. The output capacitance and the power dissipation by the current source, limit the frequency and voltage it can feasibly work at. A better solution, that decreases the amount of power dissipated, is to use a pulsed current source, which is then latched on the receiving side. Topologies such as the single-ended and dual current pulsed latch are discussed in detail in reference [3].

A summary and comparison of the various methods of level shifting is given in Table 20.2 [5].

20.4 Gate Driver Circuit Implementation

20.4.1 Isolated Gate Drivers

Gate driver circuits incorporating electrical isolation, provide the benefit of good noise interference immunity between power and control circuits. This is as a result of the separated ground return paths. Several types of isolated driver circuits exist namely:

- **Isolated Power Supply with Opto-coupled Control Signal Inputs**
  A standard technique employed widely employed, is to generate floating supplies through the use of mains frequency transformer isolation (Fig. 20.12). Although not a very space-efficient solution (due to the mains frequency transformer size) compared to other methods, this technique is still well suited to almost any power electronic converter application. The power supply circuits can comprise standard low-voltage bridge rectifier modules. A regulated supply is easily realized using three-terminal voltage regulators, which can easily deliver continuous power to gate drive circuits in excess of 10 W. With each winding and its associated power supply, referenced to the IGBT or power MOSFET source, this system is a reliable and medium cost solution for almost any power converter up to switching frequencies well below 1 MHz. For higher operating frequencies, the inter-winding capacitance of the mains frequency transformer, leads to noise feed-through coupling. This causes spurious effects, like unscheduled turn-on of the power devices due to noise present in the driver circuit ground return path. The solution to this problem would then be to introduce a high frequency DC–DC converter, which incorporates a small HF isolation transformer with substantially reduced inter-winding capacitance.

Level shifting of the switching control signal is achieved by means of optical isolation, (U3 and U4) with the input diodes (primary side of opto-coupler) referenced to the logic ground of the signal processing circuitry. The low impedance gate driver output is achieved by employing a high speed, high current buffer integrated circuit or a discrete bipolar or MOS complementary totem pole stage. Power to the opto-coupler and buffer U5 and U6 is derived from the respective floating power supply. The circuit above does not have any operating duty cycle limitations due to the floating power supply.

The passive network comprising D1, R5, and R6 control the IGBT switching speed, and impacts on the

TABLE 20.2 Comparison of the various techniques of level shifting for gate drivers

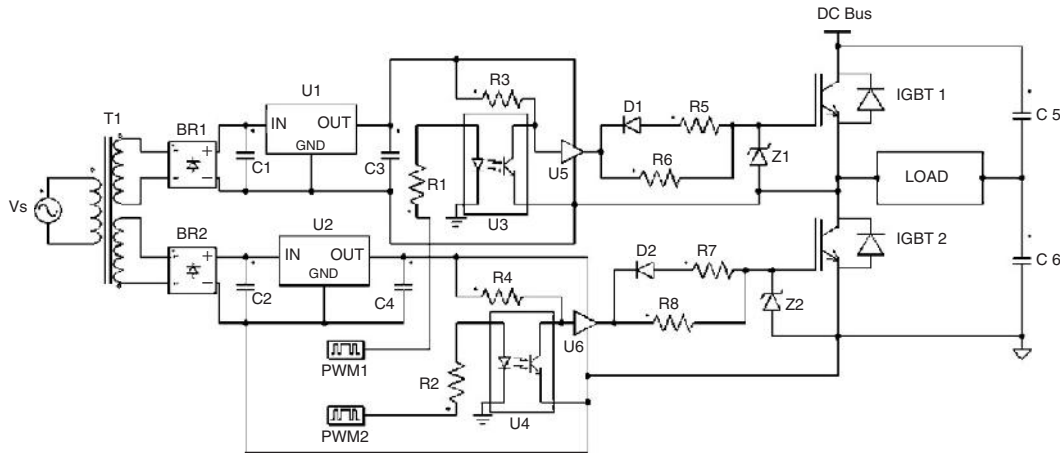
Potential isolation	Transformers		Optical	None
System	Pulse transformer	Opto-coupler	Fiber optic link	Electronic level shifting
For power modules up to	>1700 V	1700 V	>1700 V	1200 V
Signal transmission	Bi-directional	Uni-directional	Uni-/bi-directional	Uni-directional
Duty cycle restriction	Yes	No	No	No
Coupling capacitance	5–20 pF	1–5 pF	<1 pF	>20 pF
dv/dt immunity	High	Low	High	Low
Costs	Medium	Low	High	Low


FIGURE 20.12 Mains frequency transformer employed to generate a floating supply. Simple and reliable, but larger than other solutions due to its mains frequency transformer. Works well for a half-bridge but would require more isolated power supplies if a full-bridge topology was employed. A 3-phase inverter would require either six separate floating supplies or three separate and one shared supply for the low-side devices.

performance and efficiency of the power converter. The R6 controls the turn-on switching speed of IGBT1. This controls the device switching loss as well as the turn-off dv/dt characteristics of the lower devices (IGBT2) free-wheeling diode for inductive loads. Diode D1 disconnects R5 from the circuit during the IGBT turn-on. The turn-off speed of IGBT1 is controlled by R5, provided that R5 is much smaller than R6. This is a desirable feature in voltage-fed inverters, since it ensures a minimum dead-time between device transitions as shown in Fig. 20.13.

The $U5_{out}$ and $U6_{out}$ in Fig. 20.13 represent the driver output signal at exactly 50% duty cycle. The passive gate network on each IGBT, alters the drive signals due to the RC time constant formed between the gate drive resistors and the IGBT gate capacitance. This is shown as Vg_{IGBT} which is measured directly on the IGBT gate terminal. This slewing action on the IGBT gate results
in the IGBT having a delayed turn-on. Turn-on occurs when the IGBT gate voltage reaches its threshold level (Vg_{th}) and collector current starts to flow. The result is a dead-time created between switching transitions. This is required in any bridge circuit to avoid shoot through or cross-conduction of the upper and lower switches. This is depicted by the collector current trace (I_C) for a purely resistive load in Fig. 20.13.

- **Transformer Coupled Driver Supplying both Power and Control Signals**

A transformer coupled gate driver is shown in Fig. 20.14. This system provides both the floating supply, as well as the level shifting of the switching signal. The push–pull driver on the primary side of the transformer T1, is used to supply a bi-directional current in the primary, without the use of a split power supply. The transformer T1 is rated for the PWM operating frequency, and can be realized by employing either a ferrite or iron powder core. The system operation is limited to a maximum PWM duty cycle of 50%. One of the benefits of this driver circuit, is its ability to generate a negative gate bias voltage when the device is off, due to transformer action. This feature is favorable since it reduces the IGBT dv/dt susceptibility by holding the gate terminal at a negative potential during turn-off transients, thereby avoiding uncontrolled turn-on or latch up in the IGBT. Back-to-back zener diodes placed across the gate-source terminal clamp the device gate voltage, thereby avoiding over voltages generated by the uncoupled transformer (T1) leakage inductance. The parallel resistor R5, acts as a gate pull down resistor holding the device in the off state during the initial power up of the gate driver circuit. The resistor – diode network in the gate drive circuit, (consisting of D1, R1, and R2) serves the same

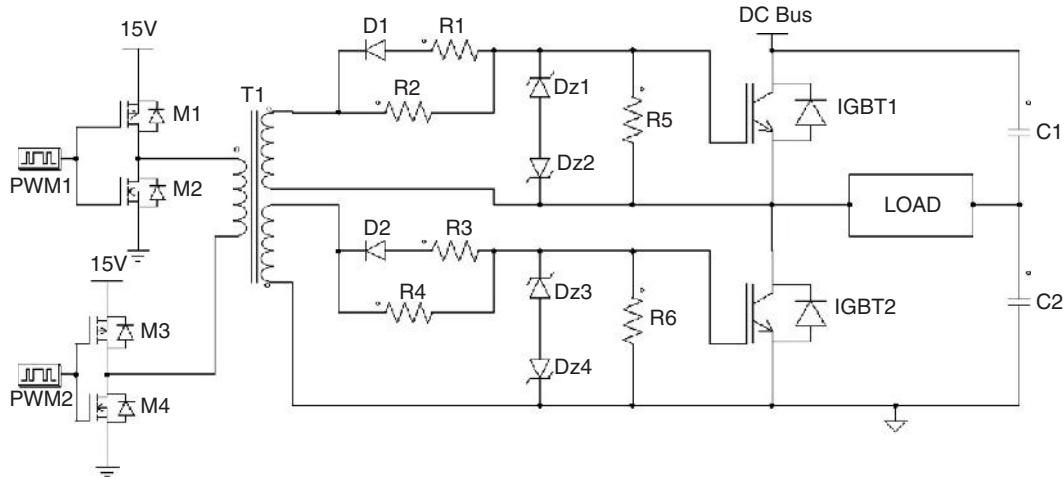
FIGURE 20.13 Switching waveforms for the circuit in Fig. 20.12.


FIGURE 20.14   Transformer coupled gate driver used to supply both the control signal and the gate drive power to the device.
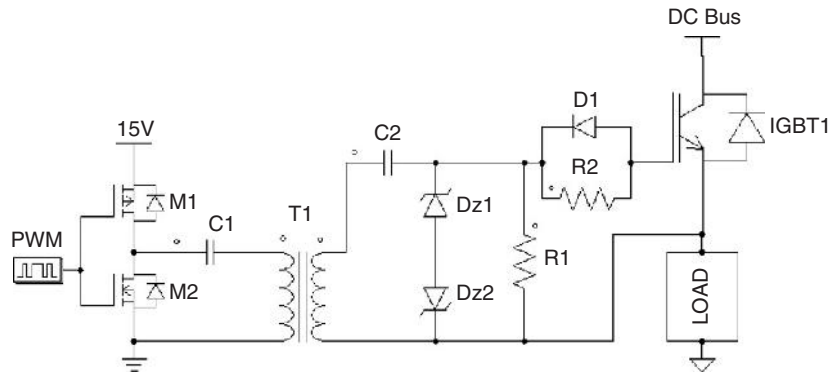

FIGURE 20.15   Transformer coupled gate driver with a large duty cycle operating range.

purpose as described in Fig. 20.12. The second function of this passive resistor network, is to dampen ringing effects. This is caused by the interaction between the IGBT or power MOSFET gate capacitance, and the gate drive transformer leakage inductance.

- **Transformer Coupled Gate Driver with Large Duty Cycle Capability**
  Transformers offer excellent noise immunity and provide simple and cost-effective gate drive solutions, whilst maintaining electrical isolation between the control and gate drive electronics. A drawback however is the limitation the transformer places on the maximum operating duty cycle. Figure 20.15 offers a simple but effective solution to the conventional limitations by the introduction of a DC restorer circuit which is formed by C2, Dz1, and Dz2. This system allows for removal of any DC information via C1, and restores the input waveform applied with the addition of a negative voltage bias needed for the IGBT gate drive. A small ferrite transformer core can be used for a MOSFET gate driver operational to

several hundred kilohertz. This circuit can be redesigned for bridge topologies, but is also well suited for high voltage DC–DC converters requiring a high-side switch. The effective duty cycle range of this driver is from 5 to 95%. Operating waveforms are shown in Fig. 20.16.

It should be noted that the gate drive voltage is clamped at fixed levels regardless of the duty cycle used, unlike the case in Fig. 20.9. This technique also supplies both the level shifted signal as well as the gate drive power, eliminating the need for an additional floating supply. The transformer turns ratio (T1) can also be adjusted to allow the circuit in Fig. 20.15 to operate from a 5 V supply, whilst generating an output voltage swing from +15 to −5 V at the IGBT gate.

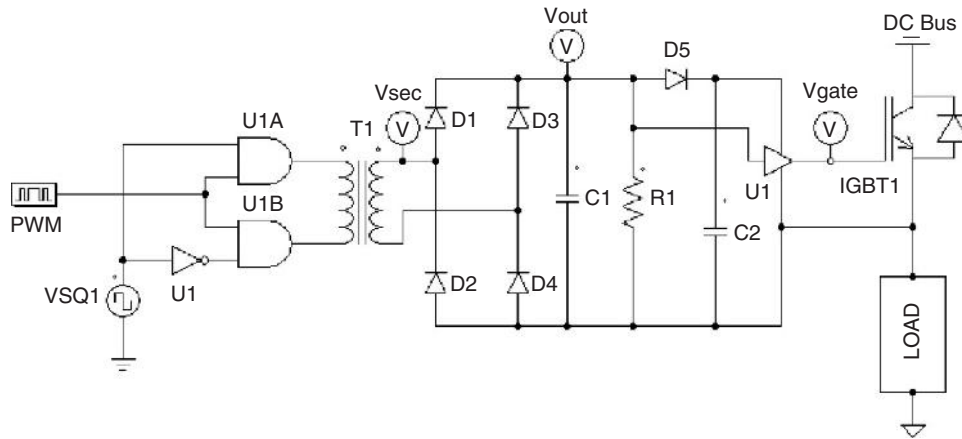
- **Transformer Coupled Signal Modulated Gate Driver**
  The circuit in Fig. 20.17 employs a high-frequency carrier signal that is modulated by a lower frequency control signal (PWM). This is used to generate on/off switching instants of power IGBT1. By employing a high-frequency carrier, the transformer size is reduced, and by
FIGURE 20.16   Operating waveforms of the transformer coupled gate driver in Fig. 20.15.


FIGURE 20.17   Signal modulated carrier used for level shifting and generation of a floating supply.
FIGURE 20.18   Signal modulated carrier used for level shifting and generation of a floating supply.

modulating the time in which the carrier operates, it controls the energy delivered to the gate of the IGBT. A carrier frequency for VSQ1 should be chosen to be much higher than the frequency of the PWM control signal. When the PWM control signal is enabled, the carrier signal is transformed to the secondary of transformer T1, which is rectified and filtered to produce a DC signal V_{out}.

When the PWM control signal goes from the on- to the off-state, the charge stored in the filter capacitor $C1$ discharges by a time constant determined by R1. This is sometimes problematic when fast switching times are required, especially in inverter bridge configurations. A solution to this problem is to employ an active driver (U1) on the secondary side of the transformer. This will detect
FIGURE 20.19   Low cost high frequency switch-mode floating supply.

the carrier, and switch the IGBT gate accordingly. Operating waveforms for this circuit is shown in Fig. 20.18 [1].

- **High Frequency Floating Power Supply**
  Often gate driver systems require extra electronics which has to be referenced to the floating switch being driven. Extra functional electronics often leads to higher power consumption, resulting in the need for a small low cost floating power supply as shown Fig. 20.19. The input section consisting of U1B, forms an oscillator used to drive a MOSFET at high frequency. This MOSFET drives a high-frequency transformer, which forms the isolation medium between the common auxiliary power supply and the floating secondary circuit. Transformer T1 produces a secondary output voltage which is rectified to form a floating DC supply for the associated gate drive circuitry. These floating power supplies are also available as monolithic DC–DC converter ICs with isolated outputs.

20.4.2 Electronic Gate Drivers

These drivers utilize electronics in order to store energy in capacitors. This is used to produce floating referenced potentials. All circuits are referenced to a common ground potential. This technique provides a very cost-effective gate driver solution over the isolated versions, and are becoming increasingly popular in industries.

- **Gate Driver with Bootstrapped Floating Supply**
  The addition of a bootstrapped capacitor voltage allows for the generation of a floating supply in Fig. 20.20. Charging of *C*1 is achieved in the direction indicated during the period when MOSFET M2 is turned on. The turn-off of M2, results in the entrapment of charge in *C*1 which now acts as the power supply to OPTO1, U1, and the MOSFET M1's gate. As current is drawn from *C*1, the capacitor voltage tends to drop and needs to be replenished cyclically. The selection of the bootstrap capacitor value is critical for reliable operation of this

circuit under extended duty cycle conditions. Diode D1 sees the full DC bus voltage when M2 is off, and therefore has to have a sufficiently high breakdown voltage. Applications with fast switching speed, require that D1 be a fast recovery diode in order to withstand the high *dv/dt* present across M2. Level shifting of the switching control signal is achieved by means of the opto-couplers in the circuit, providing the necessary control circuit isolation required.

- **Gate Driver with Floating Supply Derived from DC Bus**
  When the generation of a floating supply is required without the need for isolation, the gate drive power can be derived from the DC bus voltage. The circuit is charged during the period when IGBT1 is off, with the gate drive energy stored in *C*2. The circuit connected to the enable pin of the opto-coupler, forms an under-voltage lockout which inhibits the IGBT drive signal at low DC supply voltages, typically during the initial start-up of the inverter circuit. The control signals are level shifted through an opto-coupler which drives a totem pole complimentary buffer stage as shown in Fig. 20.21 [8].

20.5 Current Technologies

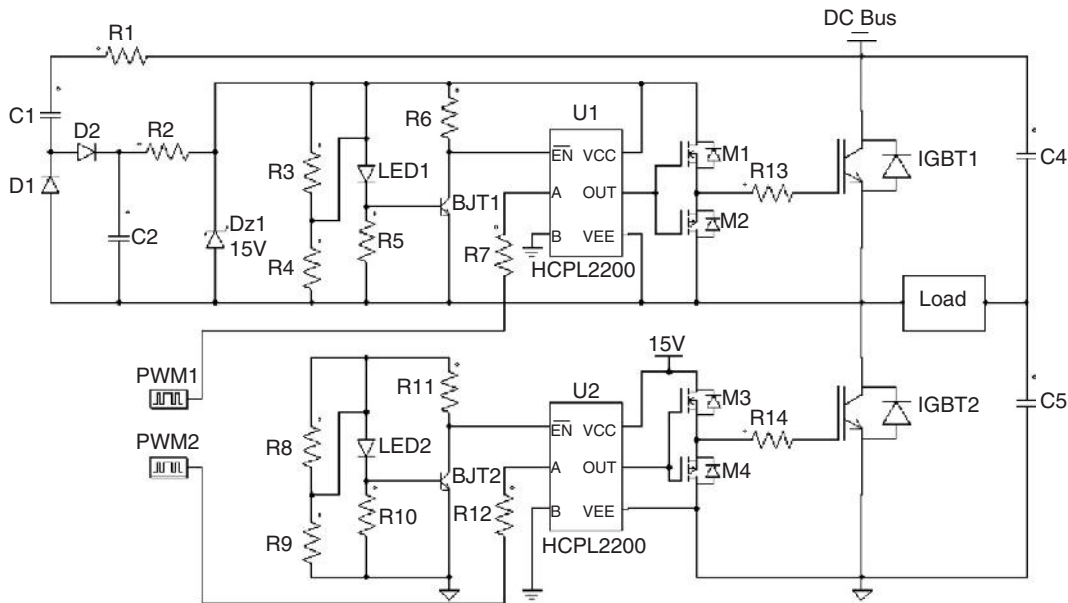
The evolution of power semiconductor technology has led to the development of smart driver IC modules. These modules offer an essentially single chip/package solution to the gate driver designer, with the inclusion of minimal external components. These smart driver ICs utilize sophisticated electronics, yielding an intelligent gate driver in a small module. Some of these functions include the electronics for generating the floating supply from the auxiliary power supplied to the IC, level shifting with or without isolation. Advanced on-board integrated functions include under-voltage lockout, thermal trip, overload and de-saturation detection, soft start, and shutdown. These features enhance the effective utilization of the power converter and also increase its reliability.
FIGURE 20.20   Optically isolated level shifter with an un-isolated bootstrapped floating supply derived from the low-side power supply.


FIGURE 20.21   Level shifted gate driver with floating supply derived from the DC bus.

20.5.1 Transformer Coupled Isolated Drivers

Semikron Corporation has developed a gate driver module that employs integrated floating supplies (Fig. 20.22) [9]. The level shifting is accomplished through transformer coupling, which is used as a bi-directional communications link for the transmission of the gate drive and fault signals.

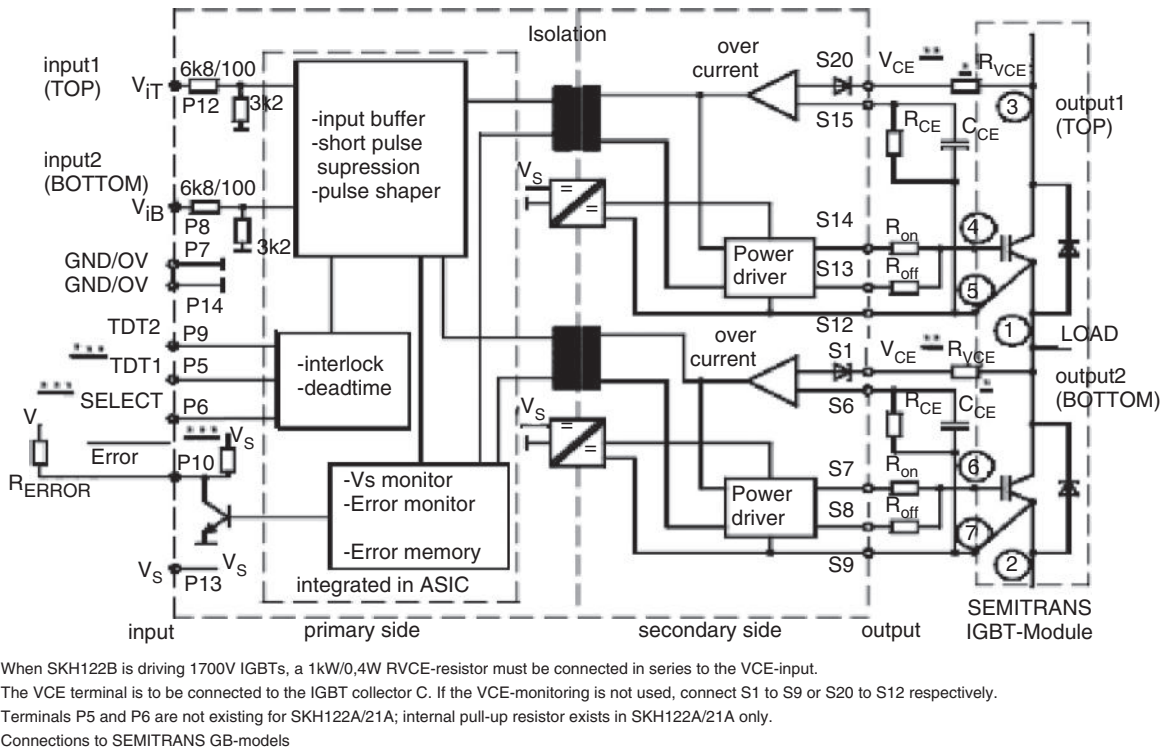
Each module is configured for a half-bridge inverter configuration and one additional driver module can be added for each inverter leg needed. The modules come in a variety of output current capabilities, depending on the IGBT drive requirements, with usable operating frequencies ranging from the low kHz range up to 30 kHz.


FIGURE 20.22 SKHI22 integrated half-bridge IGBT module capable of operation at 1200 V. A product of the Semikron Corporation.
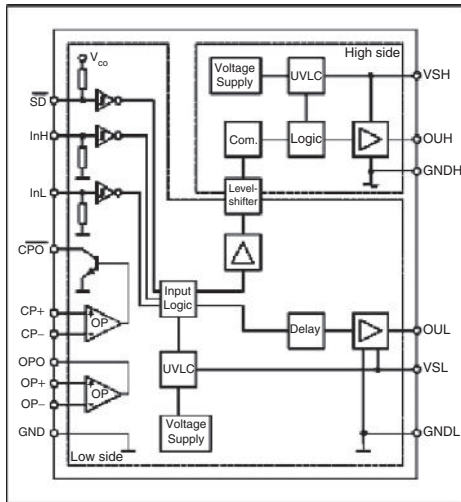

FIGURE 20.23 EUPEC EICE-Driver incorporating monolithic coreless transformer technology allowing for a substantial reduction in the device size.

Another manufacturer of isolated gate driver modules is Eupec semiconductor [10]. These modules employ a monolithically integrated coreless planar transformer design in a gate driver IC. This allows it to be substantially smaller and cheaper [6]. These modules are operational to 60 kHz with output current capabilities in excess of 2 A peak. The EUPEC EICE-Driver (2ED020I12-F) is shown in Fig. 20.23.

20.5.2 Non-isolated Electronic Level Shifted Drivers

The International Rectifier Corporation has developed a family of low cost gate driver ICs for the power electronics industry [11]. International Rectifiers, gate driver ICs (Fig. 20.24) utilize electronic level shifting for conveying the switching signal to
FIGURE 20.24   International Rectifiers IR2113 (Left) and the IR2233 (Right) high voltage gate driver ICs.

the high-side switch and a bootstrap technique for the generation of a floating supply. These ICs are relatively inexpensive and are being used mainly in the low cost consumer electronics industry. Application include Electronic Ballasts and low to medium power inverter applications such as variable speed drives and DC to single-phase AC backup inverter systems. Available in a single-channel, half-bridge, or three-phase inverter driver IC, these devices require a minimum amount of external components. Intelligent features like under voltage lockout, shut down, and current sensing inputs are included in the driver IC.

Functional diagrams of the IR2113 half-bridge driver and the IR2233 (Three-phase full-bridge) driver are shown in Fig. 20.25. The driver section of the IR2233 comprises a similar structure as the IR2113's bootstrap and level shifting circuitry. Even though the IR range of driver ICs do not provide isolation between the control and driver electronics, this device is a low cost and very compact solution for low to medium power applications where electrical noise and interference can be managed by PCB circuit layout techniques. The IR2113 half-bridge driver is capable of sourcing and sinking 2 A peak current to a capacitive load without external buffer circuitry. This feature coupled with low propagation delay times makes this device capable of operating at frequencies in excess of 100 kHz.

The IR2113 and IR2233 are capable of driving floating loads (high-side switches) at 600 and 1200 V DC bus voltages, respectively, making them suitable for most direct off-line single-phase and three-phase inverter applications.

Other driver ICs available include POWEREX's M57959L and INTERSIL's HIP2500 bridge driver.

20.5.3 High-speed Gate Drivers

In the quest for high conversion efficiency and high power densities, the trend in power electronics is the move towards high converter switching frequencies at increasingly higher power levels. The main reason for this is to reduce the size of the energy transfer and storage components such as

transformers, capacitors, and inductors. This results in a substantial reduction in component size and to a certain extent also cost. Achieving the objectives of high speed and high power switching requires fast switching power semiconductors. These devices are readily available, but as the device die-size increases with voltage and current requirements, so does its gate drive power requirements. This is due to an increase in device input capacitance as the die-size is increased. Low impedance gate driver electronics capable of delivering gate peak drive currents to large die-size IGBTs and power MOSFETs in excess of 8 A are often required. In order to meet these requirements, driver ICs must be able to deliver these large pulse currents efficiently at high switching frequencies. This is mainly due to a limitation in the maximum allowable device power dissipation. Device package power dissipation is typically limited to around 1.5 W for a DIP-14 IC without heat sinking. Many manufacturers have high speed driver solutions which realize drivers with low output impedances such as the TC4427 and the TC4422. These devices are available as single or dual channel drivers capable of delivering up to 9 A peak to a 1–10 nF capacitive load with a typical rise time of 30–50 ns. A table of available high-speed drivers from TelCom Semiconductor Inc. is shown in Table 20.3 [12].

20.5.4 Resonant Gate Drivers

High speed gate driving requires the driver and power semiconductor device impedance to be as low as possible. It is also adversely affected by parasitic inductance and capacitance caused by incorrect layout of the gate driver circuit. Sometimes these unavoidable parasitic elements tend to increase the gate drive loop impedance, (between the driver and the power semiconductor device) resulting in a limitation of the peak current drawn by the device gate. This limits the maximum achievable switching speed of the device. It also results in uncontrolled voltage excursions on the device gate, making high-speed driver circuit design quite challenging.

Resonant gate drivers utilize these parasitic elements in the gate drive loop by virtue of a controlled series resonant

mode of operation. The resonant circuit comprises the driver resistance (which is small), the device input capacitance, and its internal gate electrode resistance. By the addition of a defined amount of extra inductance to the gate drive loop, the voltage swing and switching speed of the gate driver can be controlled. A typical resonant gate driver for large die-power semiconductors has been developed by Turboswitchers Inc. A resonant gate driver called the TD-000, employs a patented low loss capacitance driver circuit topology, that reduces the driver power losses to less than half that of

conventional high-speed drivers, at all switching frequencies. Operational from a 5 V supply, the driver is capable of high-switching speeds and generates a gate drive voltage swing of up to $+24$ to -19 V, depending on the inductance values used. Performance tests show that the TD-000 driver is capable of switching a 500 V/32 A power MOSFET supplied from a 400 V DC bus, in less than 3 ns. This switching speed allows for power electronic converters operating well into the MHz range. Detailed device application information can be found in [13].

20.6 Current and Future Trends

Integrated power electronic solutions have become the current trend for applications with the development of Smart Power modules. These modules contain the entire inverter semiconductor stack as well as fully integrated gate drive circuitry. This technology eliminates the challenges of inverter and gate drive design and allows for fast turnaround times in new product development through rapid prototyping. These devices are available for low to medium power applications and have an operating frequency limit of about 20 kHz.

Power semiconductor device manufacturers are constantly developing better die-structures for their power MOSFETs and IGBTs. This is to reduce device input capacitance, resulting in lower gate drive power requirements at high switching speeds.

20.7 Summary

The aim of this chapter was to expose the reader to the basic concepts, circuits, and technologies for gate drives in power converters. The main focus has been on voltage-controlled devices like power MOSFETs and IGBTs. Once the reader gains a basic understanding of the concepts and available solutions, detailed design information on gate drivers can be found on the device manufacturer's website. This is usually found under technical application notes or technical white papers. Other useful websites for power electronic design forums and application-specific information can be found in [2, 14]. The circuits presented can be adapted for the driving of other devices such as SCRs and power BJTs.

Power Electronics in Capacitor Charging Applications

William C. Dillard, Ph.D.

Archangel Systems, Incorporated
1635 Pumphrey Avenue Auburn,
Alabama, USA

21.1 Introduction

Conventional dc power supplies operate at a given dc output voltage into a constant or near constant load. However, pulse loads such as lasers, flashlamps, railguns, and radar require short but intense bursts of energy. Typically, this energy is stored in a capacitor and then released into the load. The rate at which the capacitor is charged and discharged is called the repetition rate, T, and may vary from 0.01 Hz for large capacitor banks to a few kHz for certain lasers. Recharging the capacitor voltage to a specified voltage is tasked to a capacitor charging power supply (CCPS). The role of power electronics devices, topologies, and charging strategies for capacitor charging applications is presented in this chapter.

Figure 21.1 shows the voltage across the energy storage capacitor connected to the output of a CCPS. This figure shows that the CCPS has three modes of operation. The first mode is the charging mode in which the capacitor is charged from an initial voltage of zero to a specified final voltage. The duration of the charging mode is determined by the capacitance of the energy storage capacitor and the rate at which the CCPS delivers energy. The next mode of operation is the refresh mode, which can be considered a "standby mode," where the stored energy is simply maintained. When the output voltage drops below a predetermined value, the CCPS should turn on and deliver the energy necessary to compensate for capacitor leakage. Since energy is lost during the refresh mode, the duration of the refresh mode should be as brief as possible. Issues that lead to nonzero refresh times include safety margins for worst-case charging and discharging mode times and SOA requirements of switching devices. The final mode of operation is the discharge mode in which the load is actively discharging

the capacitor. The CCPS does not supply any energy to the load in this mode. The amount of time the CCPS remains in this mode is determined by how quickly the load can discharge the capacitor.

The instantaneous output power for a CCPS varies over a wide range in comparison to a conventional dc power supply that supplies a near-constant power to its load. This is shown in Fig. 21.2; the output power for the pulsed power load is drawn as linear for illustration purposes only. The charging mode is characterized by high peak power. At the beginning of this mode, the output power is zero (i.e. there is no voltage present but current is flowing). Thus, the load capacitor is equivalent to a short circuit. In addition, at the end of the charging mode, the output power is again zero (i.e. there is an output voltage present but no current is flowing). Now, the load capacitor is equivalent to an open circuit. The refresh mode is typically a low-power mode because the current required to compensate for capacitor leakage is small. The CCPS does not supply any power during the discharge mode when the energy storage capacitor is being discharged by the pulsed load.

The average output power for a CCPS depends on the discharge mode energy and the repetition rate of the load. It is maximum when the energy storage capacitor is discharged at the end of the charging mode (large voltage and current), which corresponds to operation without a refresh mode. Because the CCPS power is not constant, the rating of a CCPS is often given in kJ/s instead of kW. The kJ/s rating can be written as

$$\text{kJ/s} = \frac{W_{\text{LOAD}}}{T}$$

where W_{LOAD} is the energy delivered to the load per charging cycle and T is the repetition rate. In the optimum case with no
FIGURE 21.1   Three modes of operation of a capacitor charging power supply.
FIGURE 21.2   Power requirements for pulsed power and constant power loads.

refresh and instantaneous discharge, the kJ/s rating is limited to how fast a particular capacitor can be charged by its specified voltage.

21.2 High-Voltage DC Power Supply with Charging Resistor

In this technique, the energy storage capacitor is charged by a high-voltage dc power supply through a charging resistor as shown in Fig. 21.3. The charging mode ends when the capacitor voltage equals the output voltage of the power supply. The capacitor is continually refreshed by the power supply. During the discharge mode, the charging resistor isolates the power supply from the pulse load. The advantages of this technique are its simplicity, reliability, and low cost.
FIGURE 21.3   High-voltage dc power supply and charging resistor.

The major disadvantage of this technique is its poor efficiency. In the charging mode, the energy dissipated in the charging resistor is equal to the energy stored in the capacitor in the ideal case; therefore, the maximum efficiency is 50%. As a result, this technique is utilized only in applications where the charge rate is low, i.e. 200 J/s. Another disadvantage of this technique is related to the charging time, which is determined by the RC time constant. Some laser applications require that the output voltage be within 0.1% of a target voltage. For this technique, more than five time constants are required for the capacitor voltage to meet this voltage specification.

21.3 Resonance Charging

The basic resonance-charging technique is shown in Fig. 21.4. An ac input voltage is stepped up with a transformer, rectified, and filtered with capacitor C_2 to produce a high dc voltage V_0. In this circuit, C_2 is much greater than C_1. Thyristor T_1 is gated and current flows through the inductor and diode D_1 is transferring energy from C_2 to C_1. The voltage $v(t)$ and current $i(t)$ are described by the following equations assuming that $C_2 \gg C_1$. The charge time, t_c, for this circuit can be calculated by finding the time at which the current, described by Eq. (21.2), reaches zero and is given below. The voltage $v(t)$ has
FIGURE 21.4 Resonance charging.

a value of $2V_0$ at the end of the charging mode.

$$v(t) = V_0(1 - \cos\omega_0 t) \tag{21.1}$$

$$i(t) = V_0\sqrt{\frac{C_1}{L}}\sin\omega_0 t \tag{21.2}$$

$$\omega_0 = \frac{1}{\sqrt{LC_1}} \tag{21.3}$$

$$t_c = \pi\sqrt{LC_1} = \frac{\pi}{\omega_0} \tag{21.4}$$

Even though this technique is simple and efficient, it is not without its limitations. A high-voltage capacitor with a large capacitance value is needed for C_2, which increases the cost. A single thyristor is shown in Fig. 21.4. Multiple thyristors connected in series or a thyratron may be required depending on the voltage level. The repetition rate of the pulse load should be such that C_1 is fully charged and $i(t)$ has reached zero before the load discharges to prevent latch up of T_1. It is not possible for this circuit to operate in the refresh mode because of the switch characteristics. Therefore, $v(t)$ will drift due to capacitor leakage. The charge time is a function of the circuit parameters and will drift as they change with temperature or due to aging.

Because all of the energy stored in C_1 is transmitted from C_2 in a single pulse, it can be difficult to achieve precise voltage regulation with the resonance-charging technique. However, regulation can be improved with the addition of a de-queing circuit as shown in Fig. 21.5. The voltage $v(t)$ is monitored with a sensing network. Before $v(t)$ reaches the desired level, thyristor T_2 is fired, which terminates the charging mode. The remaining energy stored in the inductor is dissipated in R. The addition of the de-queing circuit reduces the circuit efficiency and increases the circuit complexity and cost but still does not enable a refresh mode to compensate for capacitor leakage.

Boost charging, a variation on the resonance-charging technique, is shown in Fig. 21.6 [1]. An extra switch is added to the circuit of Fig. 21.4, allowing energy to be stored in both C_2 and L. This can be modeled as an increase in the voltage gain of the CCPS. With switches S_1 and S_2 closed, the current $i(t)$ is given by

$$i(t) = \frac{V_0}{L}t \tag{21.5}$$

When $t = t_{on}$, S_2 is opened, and the current is now described by

$$i(t) = I_0\cos\omega_0 t + V_0\sqrt{\frac{C_1}{L}}\sin\omega_0 t \tag{21.6}$$

where

$$I_0 = \frac{V_0}{L}t_{on} \tag{21.7}$$

is the inductor current initial value at t_{on}. The voltage $v(t)$ is then

$$v(t) = I_0\sqrt{\frac{L}{C_1}}\sin\omega_0 t + V_0(1 - \cos\omega_0 t) \tag{21.8}$$

The time required for the current to reach zero and for the voltage $v(t)$ to reach its peak value can be calculated from

$$\tan(\omega_0 t_c) = -\frac{I_0\sqrt{\frac{L}{C_1}}}{V_0} = -\omega_0 t_{on} \tag{21.9}$$
FIGURE 21.5 Resonance charging with de-queing.
FIGURE 21.6 Boost charging.

This is also the charge time, t_c, or the length of the charging mode. Note from equation (21.9) that the charge time depends on t_{on}, which is the on-time of switch S_2. In addition, the peak capacitor voltage is a function of t_{on}. The peak capacitor voltage is limited to $2V_0$ without S_2; voltage gains as high as 20 are possible with the addition of S_2 [1].

The switching elements in Figs. 21.4 and 21.5 are realized with thyristors. Simple switches are shown for the boost-charging technique in Fig. 21.6. Switch S_1 could be implemented with a thyristor. The boost capability provided by switch S_2 is best realized with a gate-controlled semiconductor device such as a GTO or an IGBT.

21.4 Switching Converters

The poor efficiency when charging a capacitor through a resistor from a high-voltage power supply limits its application to low charging rates. In the resonance-charging concepts, the energy is transferred to the load capacitor in a single pulse, and it is not possible to compensate for capacitor leakage. Energy storage capacitors may be charged utilizing the same power electronic technology that has been applied in switching converters for constant power loads. Instead of charging the energy storage capacitor with a single pulse, switching converters can charge the capacitor with a series of pulses or

pulse train. The peak current is reduced when charging with a series of pulses, thus improving the efficiency of the charging process. In addition, soft-switching techniques may be used in the switching converter to increase the efficiency. The regulation of the output voltage is also improved with the pulse train because the energy is passed to the energy storage capacitor as small packets. Common control techniques such as pulse-width modulation can be used to control the size of the energy packet. This capability to control the size of the energy packet permits the CCPS to operate in the refresh mode and compensate for capacitor leakage. As a result, the CCPS may operate over a broad range of load repetition rates and still maintain tight output voltage regulation during refresh mode. During the refresh mode, energy lost due to capacitor leakage may be replaced in a burst fashion [2] or in a continuous fashion similar to trickle charging a battery [3].

In the switching converter, semiconductor switches may be operated on the lower side of the transformer permitting the use of MOSFETs or IGBTs in the CCPS. Because the CCPS begins the charging mode with a short circuit across its output, the switching converter must be capable of operating under this severe load condition. This may require the implementation of a current limiting scheme in the converter control circuit.

One switching converter as shown in Fig. 21.7 consists of a resonant converter. Note that the MOSFETs and resonant components L_r and C_r are connected on the low-voltage side
FIGURE 21.7 Series resonant converter.

of the transformer. Only the rectifier diodes and energy storage capacitor must have high voltage ratings. When the output rectifier is conducting, the energy storage capacitor C_1 is connected in series with the resonant capacitor C_r. For a transformer turns ratio of 1:N, reflecting C_1 through the transformer yields a capacitance of $N^2 C_1$. Since N is typically large, this reflected capacitance is much larger than C_r, thus the resonant frequency, which is defined in Eq. (21.10), is not affected by C_1. For high-voltage, high-frequency operation, the leakage inductance of the transformer may be utilized as L_r. Thus, the resonant frequency can be expressed as

$$\omega_r = \frac{1}{\sqrt{L_r((NC_r C_1)/(C_r + NC_1))}} \qquad (21.10)$$

One characteristic of this converter, which makes it attractive for capacitor charging, is the ability to operate under the short-circuit conditions present at the beginning of the charging mode. The voltage across C_1 is zero at the beginning of this mode. The current in the switches is limited by the input voltage and impedance Z_0 as is defined in Eq. (21.11).

$$Z_0 = \sqrt{\frac{L_r}{C_r}} \qquad (21.11)$$

Another method for current limiting is to vary the ratio of f_s, the switching frequency of the MOSFETs, and the resonant frequency, f_r, which is $\omega_r/2\pi$. This effectively controls the flow of energy from the source to C_1. The ratio f_s/f_r may be set to a low value at the beginning of the charging mode and increased toward unity as the voltage across C_1 increases. This limits the current when the voltage across C_1 is low and allows increased energy transfer as the voltage approaches the target voltage. The disadvantage of this approach is that variable frequency operation complicates device and component selection and degrades EMI/EMC performance of the CCPS.

The flyback converter, shown in Fig. 21.8, also may be utilized for capacitor-charging applications [4, 5]. When the MOSFET is turned on, current increases in the primary winding, storing energy in the magnetic field. When it reaches a specified level, the MOSFET is turned off and the energy is transferred from the magnetic field to C_1. This energy transfer is terminated when the MOSFET is turned on again.

In cases where precise output regulation is not required and the packet energy is low, the diode in Fig. 21.8 can be replaced with a Zener diode with a Zener voltage of

$$V_Z = nV_{in} + V_{O,nom}$$

where $V_{O,nom}$ is the nominal value of V_O [6]. Once $V_{O,nom}$ is reached, the next energy packet will force the diode into a brief period of breakdown with the excess energy partially recycled
FIGURE 21.8   Flyback converter.

to the input circuit. If the packet energy is small enough, the breakdown is not destructive and V_O is limited to

$$V_O = V_{O,nom} + V_{O,\Omega}$$

where $V_{O,\Omega}$ is the small excess voltage caused by the last energy packet.

Sokal and Redl [7] have investigated different control schemes for charging capacitors using the flyback converter. Their recommendation is to charge C_1 with current pulses that are nearly flat-topped. This strategy results in higher average current for a given peak current. The capacitor is charged faster because the charge delivered to it during a pulse is directly proportional to the average current. This desired pulse shape is achieved by turning on the MOSFET to terminate the transfer of energy to C_1 soon after the MOSFET is turned off, which increases the switching frequency. When the primary current rises to a preset minimum level, the MOSFET is again turned off. This switching strategy is essentially hysteretic current mode control, in which the switch current is limited between two preset bounds.

Another converter for capacitor-charging applications is the Ward converter [8–10] shown in Fig. 21.9. When the MOSFET is turned on, energy is stored in the inductor and capacitor C_a transfers energy into the energy storage capacitor C_1 and capacitor C_b. The energy stored in the inductor is transferred to C_a when the MOSFET is turned off. The leakage inductance of the transformer and C_a resonate producing a sinusoidal current that flows in the primary winding of the transformer and the MOSFET. When the primary current reaches zero and starts negative, the diode turns on, which allows the MOSFET to be turned off efficiently at zero current.

In some converter operating conditions, the voltage across C_a is very small because most of the energy has been transferred from C_a to C_1. The energy stored in C_a may be too small to ensure zero-current turn off of the MOSFET. In this case, the
FIGURE 21.9 Ward converter.

energy stored in C_b helps to ensure that the amplitude of the current is large enough for zero-current turn off of this device.

Electronic Ballasts

J. Marcos Alonso, Ph.D.

Electrical Engineering Department, University of Oviedo, Campus de Viesques s/n, Edificio de Electronica, 33204 Gijon, Asturias, Spain

22.1 Introduction

Electronic ballasts, also called solid-state ballasts, are those power electronic converters used to supply discharge lamps. The modern age of electronic ballasts began with the introduction of power bipolar transistors with low storage time, allowing to supply fluorescent lamps at frequencies of several kilohertz and increasing lamp luminous efficacy by operating at these high frequencies. Later, electronic ballasts became very popular with the development of low-cost power MOSFETs, with unique features that make them very attractive to implement solid-state ballasts. The main benefits of electronic ballasts are the increase in the lamp and ballast overall efficiency, increase in lamp life, reduction of ballast size and weight, and improvement in lighting quality. This chapter attempts to give a general overview about the more important topics related to this type of power converters.

22.1.1 Basic Notions

Discharge lamps generate electromagnetic radiation by means of an electric current passing through a gas or metal vapor. This radiation is discrete, as opposed to the continuous radiation emitted by an incandescent filament. Figure 22.1 shows the electromagnetic spectrum of an electric discharge, which consists of a number of separate spectral lines.

As can be seen in Fig. 22.1, only the electromagnetic radiation emitted within the visible region (380–780 nm) of the radiant energy spectrum is useful to provide lighting. The total power in watts emitted by an electric discharge can be obtained by integrating the spectral energy distribution. However, this is not a suitable parameter to measure the amount of light emitted by a discharge lamp.

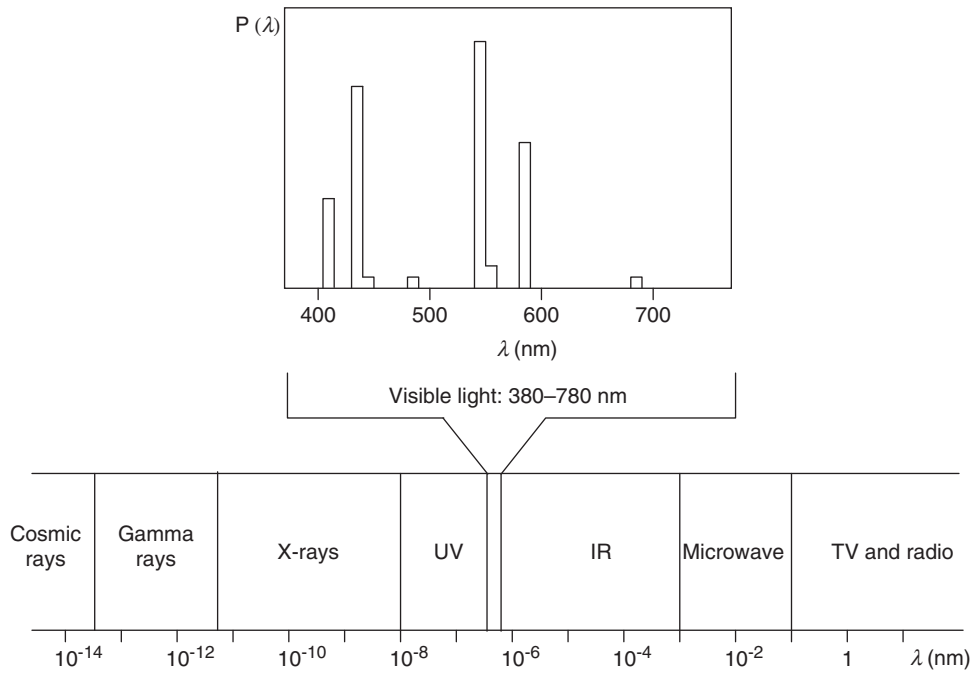
The human eye presents different responses to the different types of electromagnetic waves within the visible range. As illustrated in Fig. 22.2, there exist two response curves. First, the photopic curve, also called $V(\lambda)$, is the characteristic used to represent the human eye under normal illuminating level conditions or daylight vision. Second, the scotopic curve $V'(\lambda)$ is the response of the human eye for situations with low illuminating levels, also known as nocturnal vision. The reason for this different behavior is physiologic. The human eye consists of two types of photoreceptors: rods and cones. Rods are much more sensitive at low lighting levels than cones, but they are not sensitive to the different light colors. On the other hand, cones are responsible for normal color vision


FIGURE 22.1 Spectral energy distribution of an arc discharge and radiant energy spectrum.
FIGURE 22.2 Spectral luminous efficiency functions for standard photopic and scotopic observers.

at higher lighting levels. Normally, only the photopic function is considered in lighting design and used to calibrate photometers [29, 30].

Since the human eye responds in different ways to the different wavelengths or colors, the output power of a lamp, measured in watts, is no longer applicable to represent the amount of light generated. Thus, a new unit is used to incorporate the human eye response, which is called *lumen*. The total light output of a lamp is then measured in lumens, and it is known as luminous flux of the lamp, which is obtained by

integrating the radiant power as follows:

$$\Phi = K_\mathrm{m} \int\limits_{380\mathrm{nm}}^{780\mathrm{nm}} P(\lambda)V(\lambda)d\lambda \qquad (22.1)$$

where K_m represents the maximal spectral luminous efficacy, which is equal to 683 lumens/watt (at $\lambda = 555$ nm) for photopic vision and 1700 lumens/watt (at $\lambda = 507$ nm) for scotopic vision. The standard photopic and scotopic functions were defined by the International Commission on Illumination (CIE) in 1924 and 1951, respectively.

The measurement of the total luminous flux of the lamp is very useful to know whether the lamp is working properly. This can be measured by means of an integrating sphere and using the substitution method. The integrating sphere, also known as Ulbricht photometer, is internally coated with a perfectly diffusing material. Thus, the integral of the sphere is performed in Eq. (22.1), and the illuminance on the internal surface is proportional to the total luminous flux. A photometer with a $V(\lambda)$ filter is placed so that the internal illuminance can be measured, and a baffle is located to avoid direct illumination of the photometer probe by the lamp. The measurement is made in two steps, one with the lamp under test in place and the other with a standard lamp of known total luminous flux. From the two measurements, the total luminous flux of the lamp under test is deduced by linear relationship. Figure 22.3 illustrates an integrating sphere photometer.
FIGURE 22.3 Integrating sphere used for measurement of the lamp total luminous flux.

An important parameter related to the supply of discharge lamps is the *luminous efficacy*. Luminous efficacy is defined as the rate of the lamp total luminous flux to the total electric power consumed by the lamp, usually expressed in lumens/watt. The luminous efficacy of a discharge lamp can be increased by proper designing of the electronic ballast, which finally results in energy saving.

22.1.2 Discharge Lamps

Basically, discharge lamps consist of a discharge tube inside which the electric energy is transformed into electromagnetic radiation. The discharge tube is made of a transparent or translucent material with two sealed-in electrodes placed at both ends, as shown in Fig. 22.4. The discharge tube is filled with an inert gas and a metal vapor. The electrodes generate free electrons, which are accelerated by the electrical field existing in the discharge. These accelerated electrons collide with the gas atoms, resulting in both elastic and inelastic collisions depending on the electron kinetic energy. The basic processes inside the discharge tube are illustrated in Fig. 22.4. They are as follows [28]:

1. *Heat Generation.* When the kinetic energy of the electron is low, an elastic collision takes place and only a small part of

the electron energy is transferred to the gas atom. The result of this type of collisions is an increase in the gas temperature. In this case, the electrical energy is consumed to produce heat dissipation. However, this is also an important process because the discharge has to set in its optimum operating temperature.

2. *Gas Atom Excitation.* Some electrons can have a high kinetic energy so that the energy transferred in the collision is used to send an electron of the gas atom to a higher orbit. This state is unstable and the electron tends to recover its original level, emitting the absorbed energy in the form of electromagnetic radiation. This radiation is used to directly generate visible light or, in other case, ultraviolet radiation is first generated and then transformed into visible radiation by means of a phosphor coating existing in the inside wall of the discharge tube.

3. *Gas Atom Ionization.* In some cases, electrons have gained such high kinetic energy that during the collision with the gas atom, an electron belonging to the gas atom is freed, resulting in a positively charged ion and a free electron. This freed electron can play the same roles as those generated by the electrodes. This process is specially important during both discharge ignition and normal running because ionized atoms and electrons are necessary to maintain the electrical current through the lamp.

The number of free electrons in the discharge can increase rapidly due to continuing ionization, producing an unlimited current and finally a short circuit. This is illustrated in Fig. 22.5, which shows how the voltage–current characteristics of a gas discharge exhibits a negative differential resistance. Therefore, in order to limit the discharge current, the use of an auxiliary supply circuit is mandatory. This circuit is called *ballast*.

Focusing on discharge lamps, the complete stabilization process consists of two main phases:

1. *Breakdown Phase.* Most of the gases are very good insulators, and an electric discharge is only possible if a sufficient

FIGURE 22.4 Basic processes inside the discharge tube.

FIGURE 22.5   Voltage–current characteristics of a gas discharge.

as initial starting gas. Figure 22.6a shows a typical penning mixture constituted by neon with 0.1% of argon.

2. Warm-up Phase.   Once the lamp is ignited, the collisions between free electrons and atoms generate heat and discharge temperature increases until reaching the normal operation conditions. During this phase, the heat is used to evaporate the metal atoms existing in the discharge tube and the emitted electromagnetic radiation has the characteristics of a metal vapor discharge instead of an inert gas discharge. From the electrical point of view, the discharge warm-up phase shows initially low discharge voltage and high discharge current. As long as more and more metal atoms are evaporated, the discharge voltage increases and the discharge current decreases. Finally, an equilibrium is reached at steady-state operation with the normal values of voltage and current. The time constant of the warm-up phase strongly depends on the lamp type. It varies from seconds for fluorescent lamps to minutes for high-intensity discharge lamps. Figure 22.6b illustrates some discharge waveforms during the warm-up phase.

The basic elements used in lamps to generate radiation in the visible part of the spectrum are sodium and mercury. The former generates radiation directly within the visible part of the spectrum; the latter generates radiation mainly in the ultraviolet region, but this radiation can be easily transformed to visible radiation by means of a phosphor coating on the internal wall of the discharge tube. Besides the element used, a very important parameter related to the efficiency and richness of the emitted radiation is the discharge pressure. For the sodium and mercury elements, there exist two pressure values around

concentration of charged particles is present. Normally, a high voltage is used to provide electricity carriers and to initiate the discharge. The minimum voltage applied to initiate the discharge is called *starting voltage*. The starting voltage mainly depends on the type of gas, gas pressure, and distance between electrodes. Figure 22.6a represents the starting voltage as a function of the gas pressure multiplied by electrode distance, for different gases. These functions are known as Paschen curves.

Usually, auxiliary inert gases are used to decrease the starting voltage. Particularly, there exist some special inert gas mixtures presenting a very low starting voltage, which are called *Penning mixtures*. These penning mixtures are very often used

FIGURE 22.6   (a) Paschen curves for different inert gases and (b) stabilization curve of a discharge lamp.

which the luminous efficacy of the discharge is higher. The first is obtained at quite low pressures, about 1 Pa, and the second at higher pressures around 10^5 Pa (1 at). This is the reason why there exist two main types of discharge lamps:

1. *Low-Pressure Discharge Lamps.* This type of lamps operates with pressures around 1 Pa, and they feature low current density inside the discharge and low power/unit of discharge length. Therefore, these lamps present normally a quite large discharge volume with low power rating. Most representative examples are low-pressure mercury lamps, also known as fluorescent lamps and low-pressure sodium lamps.

2. *High-Pressure Discharge Lamps.* The operating pressure in this type of lamps is around 10^5 Pa and higher, in order to achieve a considerable increase in the luminous efficacy of the discharge. These lamps present a high current density in the discharge and a high power/discharge length ratio, thus showing much smaller discharge tubes. Examples of these lamps are high-pressure sodium lamps, high-pressure mercury lamps, and metal halide lamps.

Finally, to characterize the light produced by a discharge lamp, it is necessary to know two important concepts: the correlated color temperature (CCT) and the color rendering index (CRI).

The CCT is defined as the temperature of the blackbody radiator whose perceived color most closely resembles that of the discharge lamp. The color of an incandescent body changes from deep red to orange, yellow, and finally white as its temperature rises. Thus, a cool white fluorescent lamp has a CCT around 3500 K and it is perceived as a white source of light, whereas a high-pressure sodium lamp presents a CCT of about 2000 K and it appears as yellow.

The CRI of a light source is the effect that the source has on the color appearance of the objects under it, when compared with their appearance under a reference source of equal CCT. The measurement gives a value lower than 100, and the higher the CRI the better the color rendition. For example, daylight and incandescent lamps has a CRI equal to 100.

To conclude this introduction on the discharge lamps, some comments regarding the most important types of discharge lamps will be given. Table 22.1 provides some additional data on the different discharge lamps for comparison.

1. *Fluorescent Lamps.* These lamps belong to the category of low-pressure mercury vapor discharge lamps. The discharge generates two main lines at 185 and 253.7 nm and other weak lines in the visible range of the spectrum. A fluorescent powder on the inside wall of the discharge tube converts the ultraviolet radiation into visible radiation, resulting in a broadband spectral distribution and good color rendition. In these lamps, the optimum mercury vapor pressure (which gives the maximum luminous efficacy) is 0.8 Pa. For the tube diameters normally used, this pressure is reached at a wall temperature of about 40°C, not much higher than typical ambient temperature. The heat generated inside the discharge is sufficient to attain the required operating temperature without using an outer bulb. However, this structure causes a great variation of the lamp lumen output with the temperature, which is one important drawback of the fluorescent lamps. One solution to this problem is the addition of amalgams to stabilize the light output. This is specially used in compact fluorescent lamps.

2. *Low-Pressure Sodium Lamps.* These lamps are the most efficient source of light. The reason is the almost monochromatic radiation that they generate, with two main lines at 589 and 589.6 nm, very close to the maximum human eye sensitivity. Therefore, color rendition of these lamps is very poor; however contrasts are seen more clearly under this light. This is the reason for using these lamps in situations where the recognition of objects and contours is essential for safety, such as motorway bridges, tunnels, intersections, and so on. The optimum pressure for the low-pressure sodium discharge is about 0.4 Pa, which is attained in normal discharge tubes at a temperature of 260°C. An outer bulb is normally used to reach and maintain this temperature.

3. *High-Pressure Mercury Vapor Lamps.* The increase in the pressure of the mercury vapor produces a radiation richer in spectral lines, some of them are in the visible part of the spectrum (405, 436, 546, and 577/579 nm). This leads to an increase

TABLE 22.1 Comparison of different discharge lamps

Lamp	Wattage (W)	Luminous efficacy ($\mathrm{lm \cdot W^{-1}}$)	Life (h)	CCT (K)	CRI
Fluorescent	4–100	62	20,000	4200	62
Compact fluorescent	7–30	60–80	10,000	2700–5000	82
Low-pressure sodium	50–150	110–180	15,000	1800	<0
Mercury vapor	50–1000	40–70	24,000	4000–6000	15–50
Metal-halide	40–15,000	80–125	10,000	4000	65
HPS	35–1000	65–140	24,000	2000	22
HPS(Amalgam)	35–1000	45–85	10,000	2200	65

in the luminous efficacy, reaching values of 40–60 lm·W^{-1} at pressures 10^5–10^7 Pa (1–100 at). These lamps operate with unsaturated mercury vapor, which means that all the mercury in the discharge tube has evaporated and the number of mercury atoms/unit volume remains constant. Thus, the operation of this type of lamps is more independent of the temperature than most other discharge lamps. One drawback of these lamps is the lack of spectral lines in the long wavelengths (reds) of the spectrum, thus showing low CRI. An increase of the color rendition can be obtained by adding metal halide compounds into the discharge tube, in order to generate radiation all over the visible spectrum. These lamps are known as *metal halide lamps.*

4. *High-Pressure Sodium Lamps.* This is a very popular source of light due to its high luminous efficacy and long life. The increase in the sodium vapor pressure produces a very widening spectrum, with good color rendition compared with the low-pressure sodium lamps. This also leads to a lower luminous efficacy, but it is still higher than the other high-intensity discharge lamps. Some of these lamps also incorporate mercury in the form of sodium amalgam to increase the field strength of the discharge, thus decreasing the discharge current. A lower lamp current and a higher lamp voltage allow to reduce the size and cost of the ballast. However, the addition of sodium amalgam strongly reduces the life of the lamp.

22.1.3 Electromagnetic Ballasts

Electromagnetic ballasts are commonly used to stabilize the lamp at the required operating point by limiting the discharge current. The operating point of the lamp is given by the intersection of both lamp and ballast characteristics, as shown in Fig. 22.7. The ballast line is the characteristic that shows the variation of the lamp power versus lamp voltage for a constant line voltage, and it can be measured during the warm-up phase of the lamp. The lamp line is the characteristic that gives the variation of the lamp power as a function of the lamp voltage for different line voltages, and it can be measured by varying the line voltage. Some lamps, such as high-pressure sodium, exhibit a great variation of lamp voltage with changes in the lamp wattage. Because of this characterstic, trapezoids have been established that define maximum and minimum permissible lamp wattage versus lamp voltage for purposes of ballast design, as shown in Fig. 22.7.

Figure 22.8 shows basic electromagnetic ballast used to supply low- and high-pressure lamps at line frequencies (50–60 Hz). Figure 22.8a illustrates the typical circuit used to supply fluorescent lamps with preheating electrodes, which basically uses a series inductor to limit the current through the discharge. Initially, the glow switch is closed and the short circuit current flows through the circuit, heating the electrodes.
FIGURE 22.7   Lamp and ballast characteristics.

A fraction of a second later, the glow switch is opened and the energy stored in the ballast inductor causes a voltage spike between the lamp electrodes (about 800 V), which finally produces the discharge breakdown. Once ignited, the lamp voltage is lower than the line voltage and the glow switch remains open during the normal lamp operation. Typical glow switches are based on two bimetal strips inside a small tube filled with an inert gas. An external capacitor of about 10 nF is used to enhance the glow-switch operation and also to reduce radio interference during lamp starting. Finally, in this type of inductive ballasts, a capacitor placed across the line input is mandatory to achieve a reasonable value of the input power factor.

Starting voltages of high-pressure discharge lamps are normally higher than low-pressure discharge lamps and can range from 2500 V for a lamp at room temperature to 30–40 kV to reignite a hot lamp. Thus, the simple ignition system based on the glow switch is no longer applicable for these lamps. Figures 22.8b and c show two typical arrangements to supply high-intensity discharge lamps. A series inductor is also used to limit the lamp current at steady-state operation, but autotransformers are used to attain higher voltage spikes for lamp ignition. For higher line voltages and short distances between starter and lamp, the inductor ballast can be used as ignition transformer as shown in Fig. 22.8b. In other cases, a separate igniting transformer is needed to provide higher voltage spikes and to avoid the effect of parasitic capacitance of connection cables (Fig. 22.8c).

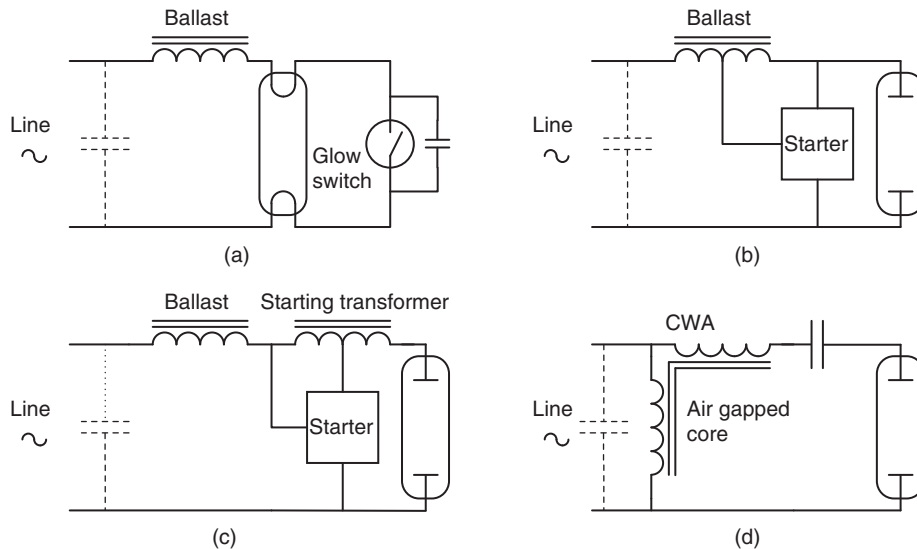
The inductive ballast provides low lamp-power regulation against line voltage variation and therefore it is only recommended in those installations with low voltage fluctuations. When a good lamp power regulation is necessary, the circuit shown in Fig. 22.8d is normally used. This circuit is commonly named as constant wattage autotransformer (CWA) and incorporates a capacitor in series with the lamp to limit the discharge current. Compared with the normal


FIGURE 22.8 Typical electromagnetic ballast used to supply discharge lamps at low frequency.

inductive ballast, the CWA also exhibits higher input power factor, lower line extinguishing voltage, and lower line starting currents.

The main advantage of electromagnetic ballasts is their simplicity, which in turn provides low cost and high reliability. However, since they operate at line frequencies, typically 50–60 Hz, they also feature high size and weight. Other important drawbacks of electromagnetic ballasts are as follows:

- Low efficiency especially for those ballasts featuring good lamp-power regulation against line voltage variation.
- Low reliability for ignition and reignition. If the voltage spike is not well located within the line period, the ignition of the lamp can fail.
- Difficult to control the lamp luminous flux (dimming).
- Lamp operating point changes due to lamp aging process, thus reducing lamp life.
- Low input power factor and high harmonic distortion. Large capacitors are needed across the line input to increase power factor.
- Over-current risk due to ballast saturation caused by rectifying effect of some discharge lamps, specially at the end of their life.
- *Flickering* and *stroboscopic effect* due to low frequency supply. The energy radiated by the lamp is a function of the instantaneous input power. Therefore, when supplied from an ac line, an instantaneous variation of the light output occurs, which is called *flicker*. For a line frequency of 60 Hz, the resulting light frequency is 120 Hz. This variation is too fast for the human eye, but when rapidly moving objects are viewed under these lamps, the objects seem to move slowly or even halted. This is called *stroboscopic effect*, and it can be very dangerous in

industrial environments. A flicker index is defined with values from 0 to 1.0 [1]. The higher the flicker index the higher is the possibilities of noticeable stroboscopic effect.
- Unsuitable for dc applications (emergency lighting, automobile lighting, etc.).

22.2 High Frequency Supply of Discharge Lamps

22.2.1 General Block Diagram of Electronic Ballasts

Figure 22.9 shows the general block diagram of a typical electronic ballast. The main stages are the following:

- *EMI Filter*. This filter is mandatory for commercial electronic ballast. Usually, it consists of two coupled inductors and a capacitor. The input filter is used to attenuate the electromagnetic interference (EMI) generated by the high frequency stages of the ballasts. It also protects the ballast against possible line transients.
- *AC–DC Converter*. This stage is used to generate a dc voltage level from the ac line. Normally, a full-bridge diode rectifier followed by a filter capacitor is used. However, this simple rectifier provides low input power factor and poor voltage regulation. In order to obtain a higher power factor and a regulated bus voltage, active converters can be used as expounded later in this chapter.
- *DC–AC Inverter and High-Frequency Ballast*. These stages are used to supply the lamp at high frequency. The inverter generates a high-frequency waveform, and the
FIGURE 22.9 Block diagram of a typical electronic ballast.

ballast is used to limit the current through the discharge. Both inductors and capacitors can be used to perform this function, with the advantage of low size and weight, because they operate at high frequencies.

- **Starting Circuit.** In most electronic ballast, specially those for low-pressure discharge lamps, the high-frequency ballast is used to both ignite the lamp and limit the lamp current at steady state. Therefore, no extra starting circuit is necessary. However, when supplying high-pressure discharge lamps, the starting voltages are quite higher and separate ignition circuits are needed, specially if hot reignition is pursued.

- **Control and Protection Circuit.** This stage includes the main oscillator, error amplifiers to regulate lamp current or power, output over-voltage protection, timers to control the ignition times, over-current protection, lamp failure protection, etc. It can vary from very simple circuits, those used in self-oscillating ballasts, to very complicated ones, which sometimes include a microprocessor-based control circuit.

There are several important topics when designing electronic ballasts:

- **Operating Frequency.** The operating frequency should be high in order to take benefit of the lower size and weight of the reactive elements used to stabilize the discharge. Usually, the operating frequency should be higher than 20 kHz to avoid audible frequencies, which can produce annoying noises. On the other hand, a higher frequency produces higher switching losses and the practical limit of the switching frequency is about 100 kHz when using MOSFET switches. It is also important to avoid frequencies in the range 30–40 kHz because these frequencies are normally used in IR remote controls and could generate some kind of interference.

- **Lamp Current Waveform.** In order to attain the maximum lamp life, it is important to drive the lamp with symmetrical alternating currents, thus making use of both the lamp electrodes alternately. Also, an important parameter is the *lamp current crest factor* (CF), which is the ratio of the peak value to the rms value of the lamp current. In case of electronic ballasts, the ratio of the peak value of the low-frequency-modulated envelope to the rms value should be used. The higher the CF the lower the lamp life. The ideal situation is to supply the lamp with a pure sinusoidal waveform. Usually, a CF lower than 1.7 is recommended to avoid early aging of the lamp [31].

- **Lamp Starting Procedure.** This is a very important issue when developing commercially available electronic ballasts. The reason is that the life of the lamp greatly depends on how well the lamp starting is performed, specially for hot-cathode fluorescent lamps. During the starting process, electrodes must be warmed up to the emission temperature, about 800°C, and no high voltage should be applied until their temperature is sufficiently high, thus avoiding sputtering damage. Once the electrodes reach the emission temperature, the starting voltage can be applied to ignite the lamp. For lamps with cold cathodes, the starting voltage must be applied rapidly to prevent harmful glow discharge and cathode sputtering. In any case, starting voltage must be limited to the minimum value to ignite the lamp, since higher voltages could provide undesirable starting conditions that would reduce the life of the lamp.

- **Dimming.** This is an important feature, which allows the ballast to control lamp power and thereby lighting output. Usually the switching frequency is used in solid-state ballasts as a control parameter to provide dimming capability. Variations in frequency affect the high-frequency ballast impedance and allow to change the discharge current. For example, if an inductor is used as high-frequency ballast, a frequency increase yields an increase in the ballast impedance, thus decreasing lamp current. Dimming should be carried out smoothly, avoiding abrupt changes in lamp power when passing from one level to another. In an eventual power cutoff, the lamp

should be restarted at maximum lighting level and then slowly reduced to the required output level.

- *Acoustic Resonance*. The HID lamps exhibit an unstable operation when they are supplied at high frequency. At certain operating frequencies, the arc fluctuates and becomes unstable, which can be observed as a high flicker due to important changes in the lamp power and thus in the lighting output. This can be explained by the dependence of the damping of acoustic waves on the plasma composition and pressure. More information about this topic can be found in [2]. The avoidance of acoustic resonance is mandatory to implement commercial electronic ballasts. This can be performed by selecting the operating frequency in a range free of acoustic resonances, typically below 1 kHz and over 100 kHz. Other methods are frequency modulation, square wave operation, and sine-wave superposed with the third harmonic frequency [3, 4].

22.2.2 Classification of Electronic Ballast Topologies

Typical topologies used to supply discharge lamps at high frequency can be classified into two main groups: nonresonant ballasts and resonant ballasts.

22.2.2.1 Nonresonant Ballasts

These topologies are usually obtained by removing the output diode of dc-to-dc converters, in order to supply alternating current to the lamp. Current mode control is normally employed to limit the discharge lamp current. The lamp is supplied with a square current waveform, which can exhibit a dc level in some cases. A small capacitor is used to initially ignite the lamp, but its effect at steady-state operation can be neglected.

Examples of nonresonant electronic ballasts are shown in Fig. 22.10. Figures 22.10a and 22.10b illustrate a boost-based and a flyback-based ballast, respectively. Other topologies, which can supply symmetric alternating current through the

lamp, are shown in Fig. 22.10c (symmetric boost) and 22.10d (push–pull).

These topologies present several drawbacks such as high-voltage spikes across the switch, which necessitates the use of high-voltage transistors, and high switching losses due to hard switching, which gives low efficiency specially for high powers. Besides, since the ideal situation is the lamp being supplied with a sine wave, these circuits produce an early aging of the lamp. To conclude, typical applications of these topologies are portable and emergency equipments, in which lamp power is low and the number of ignitions during its life is not very high. Some applications of these circuits can be found in [5–8].

22.2.2.2 Resonant Ballasts

These ballasts use a resonant tank circuit to supply the lamp. The resonant tank filters the high-order harmonics, thus obtaining a sine current waveform through the lamp. Resonant ballasts can be classified into two categories:

A. Current-fed Resonant Ballasts

These ballasts are supplied with a dc current source, usually obtained by means of a choke inductor in series with the input dc voltage source. The dc current is transformed into an alternating square current waveform by switching power transistors. Typical topologies of this type of ballasts are shown in Fig. 22.11.

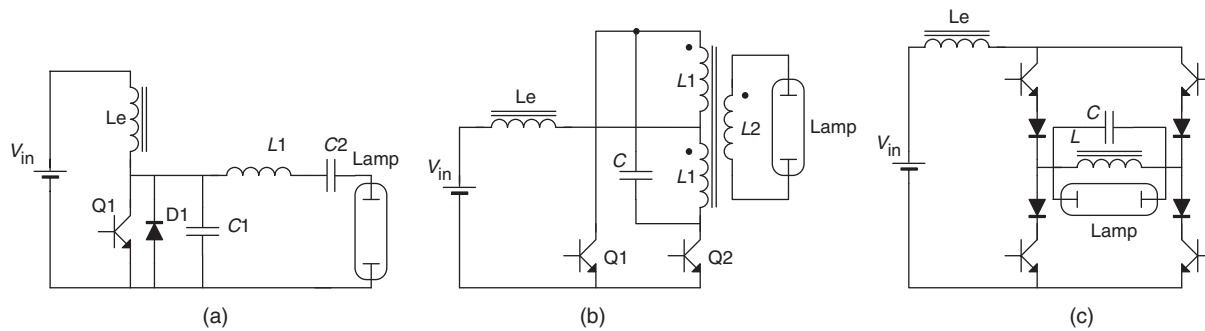
The topology shown in Fig. 22.11a corresponds to a class E inverter. Inductor Le is used to obtain a dc input current with low current ripple. This current supplies the resonant tank through the power switch formed by Q1–D1. The resonant tank used in this topology can vary from one ballast to another; the circuit shown in Fig. 22.11a is the one, which is normally used. The main advantage of this topology is that zero voltage switching (ZVS) can be attained in the power switch, thus reducing the switching losses and making possible the operation at very high frequencies, which can reach several megahertz. This allows to drastically reduce the size and weight of the ballast. However, the adjustment of the circuit parameters to obtain the optimum operation results is quite difficult, specially for mass production. Another important drawback is
FIGURE 22.10 Nonresonant electronic ballasts.


FIGURE 22.11 Two typical current-fed resonant inverters: (a) class E inverter; (b) current-fed push–pull inverter; and (c) current-fed full-bridge resonant inverter.

the high voltage stress across the switch, which can reach values of three times the dc input voltage. For these reasons, the main applications of this circuit are battery-supplied ballasts with low input voltage and low lamp power, as those used in emergency lighting and portable equipment. Typical power range of this ballast varies from 5 to 30 W. Applications of this circuit can be found in [9, 10].

Another typical topology in this group is the current-fed push–pull inverter shown in Fig. 22.11b. In this circuit, a dc input current is obtained by means of choke inductor Le. Transistors are operated with a 50% duty cycle, thus providing a current square wave, which supplies the current-fed parallel resonant circuit formed by the mutual inductance of the transformer and capacitor *C*. This circuit has the advantage of being relatively easy to implement in a self-oscillating configuration, avoiding the use of extra control circuits and thereby reducing the cost. Also, ZVS can be obtained in the power switches. However, the switches also present a high voltage stress, about three times the dc input voltage, which makes this topology unsuitable for power line applications. This circuit is also normally used in battery-operated applications in a self-oscillating arrangement. The typical power range is 4–100 W. Applications based on this circuit can be found in [11, 12].

Finally, Fig. 22.11c shows a current fed full-bridge resonant inverter, which can be used for higher power rating. Also, this circuit allows to control the output power at constant frequency by switching the devices of the same leg simultaneously, generating a quasi-square current wave through the resonant tank [13].

B. Voltage-fed Resonant Ballasts

At present, electronic ballast manufactures mostly use voltage-fed resonant ballasts, specially for applications supplied from the ac mains. The circuit is fed from a dc voltage source, normally obtained by line voltage rectifying. A square wave voltage waveform is then obtained by switching the transistors with a 50% duty cycle, and is used to feed a series resonant circuit. This resonant tank filters the high/order harmonics and supplies the lamp with a sine current waveform. One

advantage of the voltage-fed series resonant circuit is that the starting voltage can be easily obtained without using extra ignition capacitors by operating close to resonant tank frequency. Figure 22.12 shows electrical diagrams of typical voltage-fed resonant ballasts.

The voltage-fed version of the push–pull inverter is illustrated in Fig. 22.12a. This inverter includes a transformer, which can be used to step up or down the input voltage in order to obtain an adequate rms value of the output square wave voltage. This not only provides higher design flexibility but also increases the cost. One disadvantage is that the voltage across transistors is twice the input voltage, which can be quite high for line applications. Therefore, this inverter is normally used for low-voltage applications. Another important drawback of this voltage-fed inverter is that any asymmetry in the two primary windings (different number of turns) or in the switching times of power transistors would provide an undesirable dc level in the transformer magnetic flux, which in turn could saturate the core or decrease the efficiency due to the circulation of dc currents.

Figures 22.12b and 22.12c illustrate two possible arrangements for the voltage-fed half-bridge resonant inverter. The former is normally referred as asymmetric half-bridge, and it uses one of the resonant tank capacitors (*C*1 in the figure) to block the dc voltage level of the square wave generated by the bridge. This means that capacitor *C*1 will exhibit a dc level equal to half the dc input voltage superimposed to its normal alternating voltage. A transformer can also be used in this inverter to step up or down the input voltage to the required level for each application. In this case, the use of the series capacitor *C*1 prevents any dc current from circulating through the primary winding, thus avoiding transformer saturation. This topology is widely used by ballast manufacturers to supply fluorescent lamps, especially in the self-oscillating version, which allows to drastically reduce the cost. When supplying hot-cathode fluorescent lamps, the parallel capacitor *C*2 is normally placed across two electrodes, as shown in Fig. 22.12b, in order to provide a preheating current for the electrodes and achieve soft ignition. Figure 22.12c shows other version of the
FIGURE 22.12   Typical voltage-fed resonant inverters: (a) push–pull; (b)–(c) half-bridge; and (d) full-bridge.

half-bridge topology, using two bulk capacitors to provide a floating voltage level equal to half the input voltage. In this case, capacitor $C1$ is no longer used to block a dc voltage, thus showing lower voltage stress.

Finally, for the high power range (>200 W), the full-bridge topology shown in Fig. 22.12d is normally used. The transistors of each half-bridge are operated with a 50% duty cycle, and their switching signals are phase-shifted by 180°. Thus, when switches Q1 and Q2 are activated, direct voltage V_{in} is applied to the resonant tank; when switches Q3 and Q4 are activated, the reverse voltage $-V_{in}$ is obtained across the resonant circuit. One of the advantages of this circuit is that the switching signals of the two branches can be phase-shifted by angles between 0 and 180°, thus controlling the rms voltage applied to the resonant tank ranging from 0 to V_{in}. This provides an additional parameter to control the output power at constant frequency, which is useful to implement dimming ballast.

22.3 Discharge Lamp Modeling

The low frequency of the mains is not an adequate power source for supplying discharge lamps. At these low frequencies, electrons and ionized atoms have enough time to recombine at each current reversal. For this reason, the discharge must be reignited twice within each line period. Figure 22.13a illustrates the current and voltage waveforms and the *I–V* characteristics of a 150-W HPS lamp operated with an inductive ballast at

50 Hz. As can be seen, the reignition voltage spike is nearly 50% higher than the normal discharge voltage, which is constant during the rest of the half-cycle.

When lamps are operated at higher frequencies (above 5 kHz), electrons and ions do not have enough time to recombine. Therefore, charge carrier density is sufficiently high at each current reversal and no extra power is needed to reignite the lamp. The result is an increase in the luminous flux compared with that at low frequencies, which is especially high for fluorescent lamps (10–15%).

Figure 22.13b shows the lamp waveforms and *I–V* characteristics for the same 150-W HPS when supplied at 50 kHz. It also shows how the reignition voltage spikes dissapear, and the lamp behaviour is nearly resistive.

Figure 22.14 illustrates how the voltage waveforms change in a fluorescent lamp when increasing the supply frequency. As can be seen, at a frequency of 1 kHz, the voltage is already nearly sinusoidal and the lamp exhibits a resistive property.

Therefore, a resistor can be used to model the lamp at high frequencies for ballast design purposes. However, most lamp manufactures provide only lamp data for operating at low frequencies, where the lamp acts as a square wave voltage source. Table 22.2 shows the low-frequency electric data of different discharge lamps provided by the manufacturer and the measured values at high frequency for the same lamps. As can be seen, a power factor close to unity is obtained at high frequency.

The equivalent lamp resistance at high frequencies can be easily estimated from the low-frequency data. Lamp power at
FIGURE 22.13   150-W HPS lamp waveforms and $I - V$ characteristics at: (a) 50 Hz and (b) 50 kHz.

FIGURE 22.14   Voltage waveforms for a 36-W linear fluorescent lamp supplied through a resistive ballast at nominal power and different operating frequencies. Vertical scale: 100 V/DIV.

any operating frequency can be expressed as follows:

$$P_{LA} = V_{LA} \, I_{LA} \, FP_{LA} \qquad (22.2)$$

where V_{LA} and I_{LA} are the rms values of lamp voltage and current, and FP_{LA} is the lamp power factor.

At line frequencies, the lamp power factor is low (typically 0.8), due to the high distortion in the lamp voltage waveform. However, at high frequencies the lamp power factor reaches nearly 1.0. Then, lamp voltage and current at high frequency ($V_{LA,hf}$, $I_{LA,hf}$) can be estimated from the following equation:

$$I_{LA,hf} \, V_{LA,hf} = P_{LA} \qquad (22.3)$$

where P_{LA} is the nominal lamp power provided by the manufacturer.

As can be seen in Table 22.2, fluorescent lamps tend to maintain nearly the same rms current at low and high frequency, whereas high-pressure discharge lamps tend to maintain nearly the same rms voltage. Based on these assumptions, the equivalent lamp resistance at high frequency estimated from the low frequency values is shown in Table 22.3.

TABLE 22.2 Electric data of different discharge lamps

Lamp*	Manufacturer @ 50 Hz				Measured @ H.F.			
	V (V_{rms})	I (A_{rms})	P (W)	PF	V (V_{rms})	I (A_{rms})	P (W)	PF
Fluorescent (TLD-36 W)	103	0.44	36	0.79	83.2	0.46	36	0.94
Compact fluorescent (PLC-26 W)	105	0.31	26	0.80	82	0.32	26	0.99
Low-pressure sodium (SOX-55 W)	109	0.59	55	0.86	75	0.76	56	0.98

*Lamps aged for 100 h.

TABLE 22.3 Estimated electric data of discharge lamps at high frequency

Lamp	$V_{LA,hf}$	$I_{LA,hf}$	$R_{LA,hf}$
Fluorescent lamps	$P_{LA}/I_{LA,lf}$	$I_{LA,lf}$	$P_{LA}/I_{LA,lf}^2$
High-pressure lamps	$V_{LA,lf}$	$P_{LA}/V_{LA,lf}$	$V_{LA,lf}^2/P_{LA}$

Low-pressure sodium lamps neither maintain voltage nor current constant at high frequency, and they also exhibit an equivalent resistance quite dependent on the frequency. Therefore, their equivalent resistance can only be obtained by laboratory testing.

Note that the values given in Table 22.3 are only an approximation to the real value, which should be obtained by measurement at the laboratory. This can be used as the first starting point in the design of the electronic ballast, but final adjustments should be made at the laboratory.

Another important issue is that the lamp equivalent resistance is strongly dependent on power delivered to the lamp, which is specially important for designing electronic ballasts with dimming feature. The characteristic lamp resistance versus lamp power is different for each discharge lamp type and must be obtained by laboratory testing. One of the best possibilities to fit the lamp resistance versus power characteristic is the hyperbolic approximation. For example, Mader and Horn propose in [14] the following simple approximation:

$$R_{LA}(P_{LA}) = \frac{V_0^2}{P_{LA} + P_0} \tag{22.4}$$

where R_{LA} is the equivalent lamp resistance, P_{LA} is the average lamp power, and V_0 and P_0 are two parameters which depend on each lamp. This characteristic has been plotted in Fig. 22.15 for a particular lamp with $V_0 = 100$ V and $P_0 = 1$ W.

This model can be implemented very easily in circuit simulation programs, such as SPICE-based programs. Figure 22.16 shows the electric circuit and the description used to model the
FIGURE 22.15 Lamp resistance versus lamp power characteristic.

characteristic of lamp in a SPICE-based simulation program. The voltage-controlled voltage source EL is used to model the resistive property of the lamp. The voltage source Vs is used to measure the lamp current, so that the instantaneous and average lamp current can be calculated; for this reason, its voltage value is equal to zero. GP is a voltage-controlled current source used to calculate the instantaneous lamp power, which is then filtered by RP and CP in order to obtain the averaged lamp power. Finally, the hyperbolic relationship between the lamp resistance and power is implemented by means of the voltage-controlled voltage source EK. The time constant $\tau = RP \cdot CP$ is related to the ionization constant of the discharge.

Figure 22.17 illustrates some simulation results at low frequency when the lamp is supplied from a sinusoidal voltage source and stabilized with an inductive ballast.

The Mader–Horn model can also be used at high frequencies, which makes the lamp resistive. The equivalent lamp resistance at high frequency will also exhibit a hyperbolic variation with the averaged lamp power and with a time constant given by τ. This model is then useful to simulate electronic ballast with dimming feature.

FIGURE 22.17 (a) Example of simulation with an inductive ballast at low frequency; (b) operating waveforms; and (c) lamp *I–V* characteristics.

Discharge lamp modeling has become an important subject, since its results are very useful to optimize the electronic ballast performance. Some improvements on the Mader–Horn model and other interesting models can be found in the literature [14–16].

22.4 Resonant Inverters for Electronic Ballasts

Most modern domestic and industrial electronic ballasts use resonant inverters to supply discharge lamps. They can be implemented in two basic ways: current-fed resonant inverters and voltage-fed resonant inverters.

22.4.1 Current-fed Resonant Inverters

One of the most popular topologies belonging to this category is the current-fed push–pull resonant inverter, previously shown in Fig. 22.11. For this reason, this inverter will be studied here to illustrate the operation of the current-fed resonant ballasts.

The current-fed push–pull inverter uses an input choke to obtain a dc input current with low current ripple. This current is alternatively conducted by the switches so that a parallel
FIGURE 22.18 (a) Equivalent circuit of a current-fed parallel resonant inverter and (b) operating waveforms.

resonant tank can be supplied with a current square wave. Figure 22.18 shows the equivalent circuit and the operating waveforms of a current-fed parallel resonant inverter.

The input current can be expressed as a Fourier series in the following way:

$$i_s(t) = \sum_{n=1,3,5...} I_{S,n} \sin n\omega t = \sum_{n=1,3,5...} \frac{4I_S}{n\pi} \sin n\omega t \quad (22.5)$$

$I_{S,n}$ being the peak value of each current harmonic and I_S the DC input current of the inverter. The output voltage for each current harmonic is obtained by multiplying the input current $I_{S,n}$ by the equivalent parallel impedance $Z_{E,n}$, which is given below:

$$V_{0,n} = I_{S,n}Z_{E,n} = I_{S,n}\frac{1}{1/R + jn\omega C - j(1/n\omega L)} \quad (22.6)$$

Usually, normalized values are employed in order to provide more general results. Then, the output voltage can be expressed as follows:

$$V_{0,n} = I_{S,n}Z_B\frac{1}{1/Q + jn\Omega - j(1/n\Omega)} \quad (22.7)$$

where Z_B is the base impedance of the resonant tank, Q is the normalized load, Ω is the normalized frequency, and ω_0 is the natural frequency of the resonant circuit, given by

$$Z_B = \sqrt{L/C} \quad Q = R/Z_B \quad \Omega = \omega/\omega_0 = \omega\sqrt{LC} \quad \omega_0 = 1/\sqrt{LC} \quad (22.8)$$

From Eq. (22.7), the peak output voltage $V_{0,n}$ and phase angle φ_n can be obtained for each harmonic as follows:

$$V_{0,n} = I_{S,n}Z_B\frac{1}{\sqrt{1/Q^2 + (n\Omega - 1/n\Omega)^2}} \quad (22.9)$$

$$\varphi_n = -\tan^{-1} Q(n\Omega - 1/n\Omega) \quad (22.10)$$

The total harmonic distortion (THD) of the output voltage can be calculated as follows:

$$THD(\%) = \frac{\sqrt{\sum_{n=3,5,7...} V_{0,n}^2}}{V_{0,1}} \cdot 100 \quad (22.11)$$

Based on these equations, the analysis and design of the current-fed resonant inverter can be performed. Normally, the circuit operates close to the natural frequency ω_0 and the effect of the high frequency harmonics can be neglected. To probe this, Fig. 22.19a obtained by plotting Eq. (22.11) illustrates the THD of the output voltage as a function of the normalized load and frequency. As can be seen, for values of Q higher than 1 and for operation close to the natural frequency ($\Omega = 1$), the THD is low, which means that the output voltage is nearly a sinusoidal waveform. However, for low values of Q, the output voltage tends to be a square waveform and the THD tends to the value of about 48%, corresponding to the THD of a square waveform. Figure 22.19b illustrates the normalized output voltage for the fundamental component.

As stated previously, when used as lamp ballast, the current-fed parallel resonant inverter operates at the natural frequency of the resonant tank to both ignite the lamp and limit the current at normal running. Neglecting the effect of high-order harmonics, the rms output voltage is given by the fundamental component and can be obtained using $\Omega = 1$ in Eq. (22.9) as follows:

$$V_{0(rms)} \approx V_{0,1(rms)} = I_{S,1(rms)}Z_BQ = \frac{4I_SR}{\pi\sqrt{2}} \quad (22.12)$$

In a current-fed resonant inverter, the dc input current I_S is supplied from a dc voltage source V_{in} with a series choke, as stated previously. Then, the dc input current can be obtained, assuming 100% efficiency, by equaling input and output power as follows:

$$P_{in} = V_{in}I_S = \frac{V_{0(rms)}^2}{R} \quad (22.13)$$
FIGURE 22.19   Characteristics of the current-fed parallel resonant inverter: (a) THD and (b) fundamental output voltage.

and then

$$I_S = \frac{V_{0(\text{rms})}^2}{V_{\text{in}} R} \tag{22.14}$$

Using Eq. (22.14) in Eq. (22.12) and solving for the output voltage

$$V_{0(\text{rms})} = \frac{\pi\sqrt{2}}{4} V_{\text{in}} = 1.1 V_{\text{in}} \tag{22.15}$$

As can be seen, when operating at the natural frequency, the rms output voltage is independent of the resonant tank load. The peak output voltage is equal to $\pi V_{\text{in}}/2$. This value is directly related to the peak voltage stress in the switches. For a full-bridge topology, as shown in Fig. 22.11c, this value is equal to the switch voltage stress. However, for the current-fed push–pull inverter, the voltage stress is twice this value, which is πV_{in}, due to the presence of the transformer. This gives a very high voltage stress for the switches in this topology, which is the reason why the current-fed push–pull is mainly used to implement low input voltage ballasts.

On the other hand, lamp starting voltage can vary from 5 to 10 times the lamp voltage in normal discharge mode. This makes difficult the use of the current-fed parallel resonant inverter at constant frequency to both ignite the lamp and supply it at steady state, since the output voltage is independent of the resonant tank load.

One solution to this problem is to ignite the lamp at the resonant tank natural frequency and then change the frequency to decrease the output voltage and output current to the normal running values of the lamp. This solution makes necessary the use of extra circuitry to control the frequency, normally in closed loop to avoid lamp instabilities, which increase the ballast cost.

Another solution, very often used in low-cost ballasts, is to design the parallel resonant tank to ignite the lamp and limit the lamp current in discharge mode by using an additional reactive element in series with the lamp. Normally a capacitor is used to limit the lamp current in order to minimize the cost of the ballast. This solution is used in combination with the self-oscillating technique, which assures the operation at a constant frequency equal to the natural frequency of the resonant tank. Figure 22.20a illustrates this circuit. Normally, the effect of the series capacitor is neglected and the resonant tank is assumed to act as a sinusoidal voltage source during both ignition and normal operation, as shown in Fig. 22.20b. The high lamp starting voltage is obtained by means of a step-up transformer, which is the reason why typically a push–pull topology is used. If V_{in} is the dc input voltage and V_{ig} is the lamp ignition voltage, then the necessary transformer turn ratio is given by the following expression:

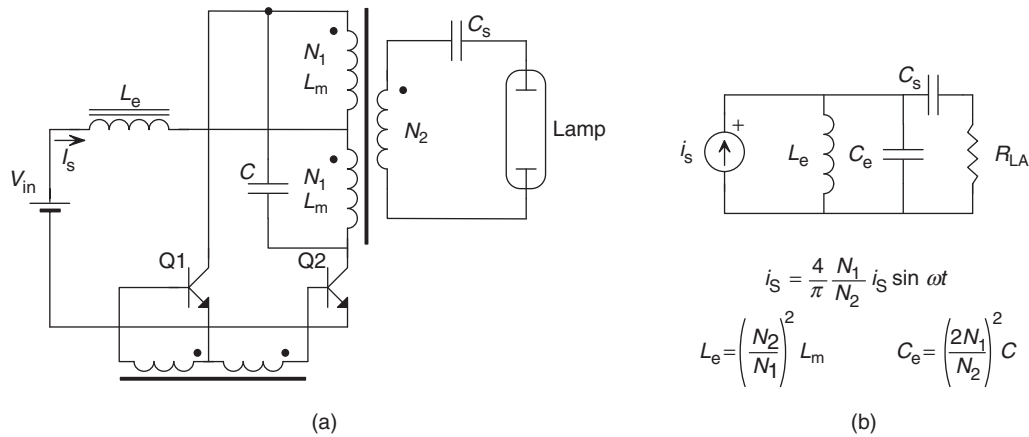
$$\frac{N_2}{N_1} = \frac{V_{\text{ig}}}{\pi V_{\text{in}}/2} \tag{22.16}$$
FIGURE 22.20   (a) Typical parallel resonant circuit used to supply discharge lamps and (b) equivalent circuit.


FIGURE 22.21   (a) Self-oscillating current-fed push–pull electronic ballast and (b) equivalent circuit.

The rms lamp current in discharge mode can be approximated as follows:

$$I_{LA} = \frac{1.1(N_2/N_1)V_{in}}{\sqrt{R^2 + (1/2\pi f C_S)^2}} \qquad (22.17)$$

where R is the equivalent resistance of the lamp. From Eq. (22.17), the necessary value of the series capacitor C_S, used to limit the lamp current to the nominal value I_{LA}, can be easily obtained.

Finally, Figs. 22.21a and b illustrate a typical ballast based on a current-fed resonant inverter and its equivalent circuit, respectively.

22.4.2 Voltage-fed Resonant Inverters

Some voltage-fed resonant inverters used to supply discharge lamps were previously shown in Fig. 22.12. Basically, they use two or more switches to generate a square voltage waveform. The different topologies are mainly given by the type of resonant tank used to filter this voltage waveform. There are three typical resonant tanks; their equivalent circuits are shown in Fig. 22.22. These circuits are the series-loaded resonant tank (Fig. 22.22a), the parallel-loaded resonant tank (Fig. 22.22b),

and the series–parallel-loaded resonant tank (Fig. 22.22c). The typical operating waveforms are shown in Fig. 22.22d.

Similar to the current-fed resonant inverter, the input voltage can be expressed as a Fourier series in the following way:

$$v_s(t) = \sum_{n=1,3,5...} V_{S,n} \sin n\omega t = \sum_{n=1,3,5...} \frac{4V_S}{n\pi} \sin n\omega t \quad (22.18)$$

$V_{S,n}$ being the peak value of each voltage harmonic and V_S the dc input voltage of the inverter. The same methodology as that used to analyze the current-fed resonant inverter will be used here to study the property of the three basic voltage-fed resonant inverters.

22.4.2.1 Series-Loaded Resonant Circuit

The output voltage corresponding to the n-order harmonic is easily obtained as follows:

$$V_{0,n} = V_{S,n} \frac{1}{\sqrt{1 + \frac{1}{Q_S^2}\left(n\Omega - \frac{1}{n\Omega}\right)^2}} \qquad (22.19)$$
FIGURE 22.22   (a–c) Equivalent circuits of voltage-fed resonant inverters and (d) typical operating waveforms.
FIGURE 22.23 Characteristics of series-loaded resonant inverter: (a) THD and (b) fundamental output voltage.

where Q_S and Ω are the normalized load and switching frequency given by the following expressions:

$$Q_S = R/Z_B = R\,(L/C_S)^{-1/2} \quad \Omega = \omega/\omega_0 = \omega\sqrt{LC_S} \quad (22.20)$$

Figure 22.23a shows the THD of the series-loaded circuit and Fig. 22.23b shows the fundamental output voltage, which is normally considered for design purposes.

In this circuit, the input and output currents are equal and can be calculated by dividing the output voltage by the load impedance. This current is also circulating through the inverter switches and therefore represents an important parameter for the design. Another important parameter is the phase angle of the input current, which defines the type of commutations in the inverter switches. For the fundamental harmonic, the phase angle of the current circulating through the resonant tank can be calculated as follows:

$$\varphi = -\tan^{-1}\frac{\Omega - 1/\Omega}{Q_S} \quad (22.21)$$

At the natural frequency (ω_0), the input voltage and current will be in phase, which means that there is no reactive energy handled by the circuit and all the input energy is transferred to the load at steady-state operation. For frequencies higher than ω_0, the current is lagged and some reactive energy will be handled. In this case the inverter switches will present zero voltage switching (ZVS) [17]. For frequencies lower than ω_0, the current is in advance and also some reactive energy will be handled. In this case, the inverter switches will present zero current switching (ZCS).

As can be seen in Fig. 22.23a, the THD is lower for the lower values of the normalized load and for frequencies close to the natural frequency of the resonant tank. For the higher values of

Q_S, the THD tends to the value corresponding to a square wave. The output voltage is always lower than the input voltage, and for frequencies around the natural frequency, the circuit acts as a voltage source, especially for the high values of Q_S. This means that the lamp cannot be ignited and supplied in discharge mode, maintaining a constant switching frequency. This property is similar to that encountered for the current-fed resonant inverter. The use of step-up transformers is mandatory to achieve lamp ignition, especially for the low input voltages. In order to maintain the operating frequency constant, a series element will be necessary to limit the lamp current at normal discharge operation. A capacitor can also be used as expounded in the previous section. In summary, this circuit is mainly used in high input voltage and low-current applications, and it is not very frequently used to implement electronic ballasts.

22.4.2.2 Parallel-loaded Resonant Circuit

In this circuit, the output voltage corresponding to the *n*-order harmonic is given by the following expression:

$$V_{0,n} = V_{S,n}\frac{1}{\sqrt{\dfrac{n^2\Omega^2}{Q_P^2} + \left(n^2\Omega^2 - 1\right)^2}} \quad (22.22)$$

where

$$Q_P = R/Z_B = R\,(L/C_P)^{-1/2} \quad \Omega = \omega/\omega_0 = \omega\sqrt{LC_P} \quad (22.23)$$

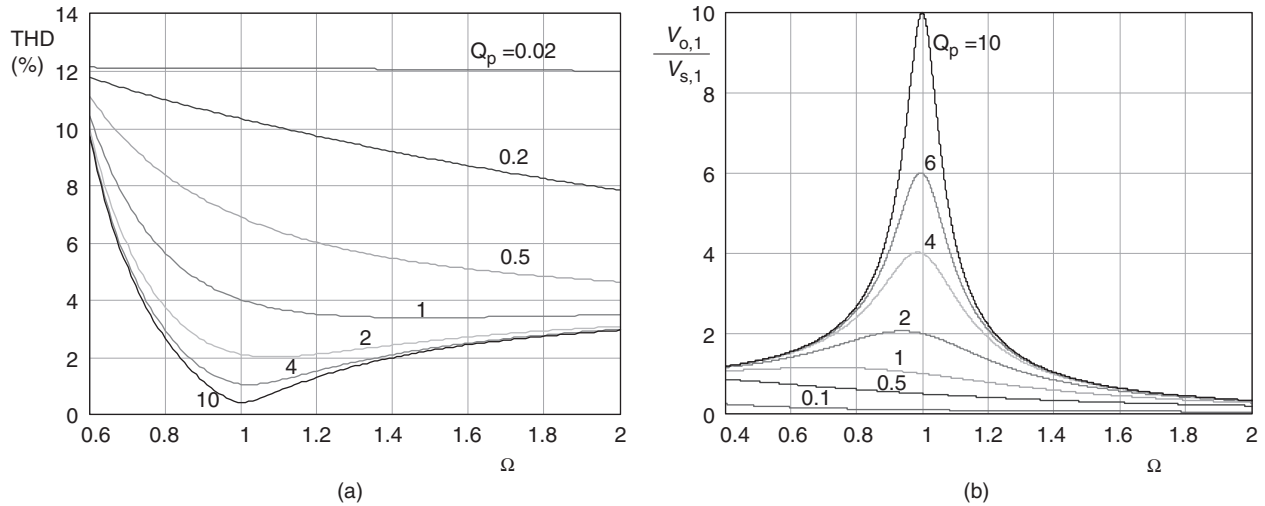
The THD and fundamental output voltage are shown in Fig. 22.24. This circuit has characteristics very much useful to implement electronic ballasts than the series-loaded resonant


FIGURE 22.24   Characteristics of parallel-loaded resonant inverter: (a) THD and (b) fundamental output voltage.

circuit. First, the THD of the output voltage around the natural frequency is in general quite lower than that of the series circuit. For the lower values of Q_P, the THD tends to a value of 12%, which corresponds to the THD of a triangular wave. As a result, the lamp voltage and current waveforms will be very similar to a sine wave, which is an adequate waveform to supply the lamp. Second, the frequency response of the output voltage (Fig. 22.24b) makes it possible to both ignite the lamp and limit the lamp current at steady state, maintaining a constant operating frequency. During ignition, the lamp shows a very high impedance, thus giving a high value of Q_P. Under these conditions, the parallel circuit can generate a very high output voltage, provided that the operating frequency is close to the natural frequency. Once the lamp is ignited, the normalized load Q_P decreases and the circuit can limit the lamp current without changing the operating frequency. In fact, the parallel circuit operating close to the natural frequency acts as a current source for the load, as will be shown later. This is adequate to supply discharge lamps because it assures a good discharge stability, avoiding the lamp being easily extinguished by transitory power fluctuations.

The maximum value of the voltage gain shown in Fig. 22.24 can be calculated to be equal to $Q_P/\sqrt{1 - 1/4Q_P^2}$, and it appears at a frequency $\Omega_m = \sqrt{1 - 1/2Q_P^2}$. This means that a maximum is only present if Q_P is greater than $1/\sqrt{2} \approx 0.71$. For the higher values of Q_P, the maximum gain can be approximated to Q_P and the frequency of maximum gain can be approximated to the natural frequency ω_0.

The input current of the parallel resonant circuit is another important parameter to calculate the current handled by the inverter switches. Since the operating frequency is normally around resonance, only the fundamental component

is considered. The value of this fundamental current and its phase angle can be obtained as follows:

$$I_{S,1} = \frac{V_{S,1}}{Z_B} \sqrt{\frac{1 + Q_P^2 \Omega^2}{\Omega^2 + Q_P^2(\Omega^2 - 1^2)}} \qquad (22.24)$$

$$\varphi = \tan^{-1} \frac{-1}{\Omega Q_P} - \tan^{-1} Q_P \left(\Omega - \frac{1}{\Omega} \right) \qquad (22.25)$$

The condition for the input voltage being in phase with the input current can be obtained by equaling Eq. (22.25) to zero. This gives a value of the normalized frequency, which is $\Omega_{\varphi=0} = \sqrt{1 - 1/Q_P^2}$. For a frequency greater than that value, the input current will lag the input voltage and the inverter switches will present zero voltage switching. For frequencies lower than that value, the current will be in advance and zero current switching is obtained. The output voltage gain at that frequency is equal to Q_P.

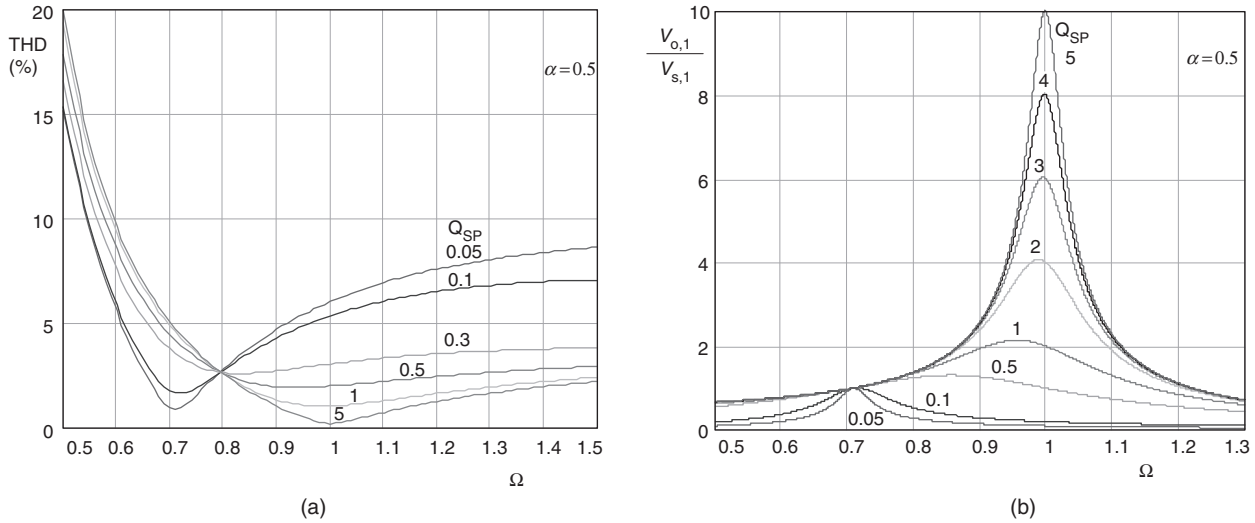
Finally, it is very interesting to study the characteristic of this circuit for frequencies close to the natural frequency ω_0 ($\Omega = 1$), since this is the normal region selected to operate for ballast applications. At this frequency, the output voltage gain is equal to Q_P and then the output current will be $V_{S,1}/Z_B$. This means that when operated at the natural frequency, the parallel circuit acts as a current source, whose value only depends on the input voltage. At the natural frequency, the input current is equal to $V_{S,1}\sqrt{1 + Q_P^2}/Z_B$ and the phase angle is equal to $\tan^{-1}(-1/Q_P)$. The circuit is always inductive, with ZVS, and the phase angle decreases when Q_P increases, which means that less reactive energy is handled by the circuit.


FIGURE 22.25 Characteristics of series–parallel-loaded resonant inverter: (a) THD and (b) fundamental output voltage.

22.4.2.3 Series–Parallel-Loaded Resonant Circuit

This circuit is also very widely used to implement electronic ballasts. The fundamental output voltage is given by the following expression:

$$V_{0,1} = V_{S,1} \frac{1}{\sqrt{\frac{1}{Q_{SP}^2}\left(\Omega - \frac{1-\alpha}{\Omega}\right)^2 + \frac{1}{\alpha^2}\left(\Omega^2 - 1\right)^2}} \qquad (22.26)$$

where

$$Q_{SP} = R/Z_B = R\left(L/C_E\right)^{-1/2} \quad \Omega = \omega/\omega_o = \omega\sqrt{LC_E}$$

$$\alpha = C_E/C_P = 1 - C_E/C_S \qquad (22.27)$$

and $C_E = C_S C_P/(C_S + C_P)$ is the series equivalent of the two capacitors present in this resonant circuit.

The fundamental input current and its phase angle are the following:

$$I_{S,1} = \frac{V_{S,1}}{Z_B}\left[\frac{1 + \left(\Omega^2 Q_{SP}^2/\alpha^2\right)}{\left(\Omega - (1-\alpha/\Omega)\right)^2 + \left(Q_{SP}^2/\alpha^2\right)\left(\Omega^2 - 1\right)^2}\right]^{1/2} \qquad (22.28)$$

$$\varphi = \begin{cases} \tan^{-1}\frac{-\alpha}{Q_{SP}\,\Omega} - \tan^{-1}\left(\frac{Q_{SP}}{\alpha}\frac{\Omega^2 - 1}{\Omega - ((1-\alpha)/\Omega)}\right) + 180° \\ \qquad \text{if} \quad \Omega < \Omega_C = \sqrt{1-\alpha} \\ \tan^{-1}\frac{-\alpha}{Q_{SP}\,\Omega} - \tan^{-1}\left(\frac{Q_{SP}}{\alpha}\frac{\Omega^2 - 1}{\Omega - ((1-\alpha)/\Omega)}\right) \\ \qquad \text{if} \quad \Omega \geq \Omega_C = \sqrt{1-\alpha} \end{cases} \qquad (22.29)$$

Figure 22.25 shows the characteristics corresponding to the THD of the output voltage and the fundamental output voltage

for $\alpha = 0.5$. As can be seen, the THD is also very low around the natural frequency, especially for the higher values of the normalized load Q_{SP}. Regarding the output voltage, this circuit acts as a parallel circuit around the natural frequency ω_0, with a maximum gain voltage of about Q_{SP}/α. Around the natural frequency of the series circuit given by L and C_S, $\omega_{0S} = \omega_0\sqrt{1-\alpha}$, the circuit acts as a series-loaded circuit with a maximum voltage gain equal to unity.

The series–parallel circuit can also be used to both ignite and supply the lamp at constant frequency, since it also acts as a current source at the natural frequency. Besides, this circuit allows to limit the ignition voltage by means of the factor α, thus avoiding sputtering damage of lamp electrodes. Also, the series capacitor can be used to block any dc component of the inverter square output voltage, as that existing in the asymmetric half-bridge. In summary, the series–parallel circuit combines the best features of the series-loaded and the parallel-loaded, and this is the reason why it is used widely to implement electronic ballasts.

When operated at frequency ω_0, the output voltage gain is equal to Q_{SP}/α, and then the circuit acts as a current source equal to $V_{S,1}/\alpha Z_B$, which is independent of the load. As stated previously, this current source behaviour is adequate to supply discharge lamps because it allows the lamp current to be limited all the time. The input current phase angle at this frequency is equal to $\tan^{-1}(-\alpha/Q_{SP})$, and the input current always lags the input voltage, thus showing ZVS operation.

Finally, the condition to have input current in phase with the input voltage can be obtained by equaling Eq. (22.27) to zero. This gives the following value:

$$Q_{SP,\varphi=0} = \frac{\alpha}{\Omega}\sqrt{\frac{\Omega^2 - (1-\alpha)}{(1-\Omega^2)}} \qquad (22.30)$$

Equation (22.30) defines the borderline between the ZVS and the ZCS modes. The output voltage gain in this borderline can be obtained by using Eq. (22.30) in Eq. (22.26), and it is equal to $\alpha/\sqrt{\alpha(1-\Omega^2)}$.

22.4.3 Design Issues

The design methodology of a resonant inverter for discharge lamp supply can be very different depending on the lamp type and characteristics, inverter topology, design goals, etc. Some guidelines, especially focused for supplying fluorescent lamps with voltage-fed resonant inverters are presented in this section to illustrate the basic design methodology.

A typical starting process for a hot-cathode fluorescent lamp is shown in Fig. 22.26. Initially, lamp electrodes are heated up to the emission temperature. During this phase, the inverter should assure a voltage applied to the lamp not high enough to produce sputtering damage in lamp electrodes, thus avoiding premature aging of the lamp. Once electrodes reach the emission temperature, the lamp can be ignited by applying the necessary starting voltage. Following this procedure, a soft starting is achieved and a long lamp life is assured.

The best method to perform this soft starting is to control the inverter switching frequency, so that the lamp voltage and current are always under control. During the heating process, the operating frequency is adjusted to a value above the natural frequency of the resonant tank. In this way, the heating current can be adjusted to the necessary value, maintaining a lamp voltage quite lower than the starting voltage. Since normally MOSFET or bipolar transistors are used, the operation over the natural frequency is preferable because they provide ZVS, and the slow parasitic diodes existing in these transistors can be used. After a short period of time, the switching frequency is reduced until the starting voltage is obtained, and then the lamp is ignited. Normally, the final operating point at steady-state operation is adjusted to be at a switching frequency equal to the natural frequency, so that a very stable operation for the lamp is assured.

Figure 22.27a shows a fluorescent lamp supplied using a series–parallel resonant tank. The input data for the design are normally the fundamental input voltage V_S, the switching frequency in normal discharge operation (running) f_S, the lamp voltage and current at high frequency V_{LA}, I_{LA}, the electrode heating current I_H, the maximum lamp voltage during heating process V_H, and the lamp starting voltage V_{IG}.

The equivalent circuit during the heating and ignition phase is shown in Fig. 22.27b. The current circulating in this circuit is the electrode heating current, which can be calculated by using $Q_{SP}=\infty$ in Eq. (22.24)

$$I_H = \frac{V_S/Z_B}{\Omega - 1/\Omega} \tag{22.31}$$

where the electrode resistance has been neglected for simplicity. For a given heating current I_H, the necessary switching frequency is obtained from Eq. (22.31) as follows:

$$\Omega_H = \frac{V_S}{2Z_B I_H} + \sqrt{1 + \left(\frac{V_S}{2Z_B I_H}\right)^2} \tag{22.32}$$

Regarding the heating voltage, it can be calculated from Eq. (22.26) using $Q_{SP}=\infty$, and the following value is obtained:

$$V_H = \frac{\alpha V_S}{\Omega_H^2 - 1} \tag{22.33}$$
FIGURE 22.26   Typical starting process of discharge lamps.
FIGURE 22.27   (a) Fluorescent lamp supplied with a series–parallel circuit; (b) equivalent circuit during heating and ignition; and (c) equivalent circuit during normal discharge mode.

The frequency at which the starting voltage is achieved can also be obtained using $Q_{SP} = \infty$ in Eq. (22.26), giving the following value:

$$\Omega_{IG} = \sqrt{1 + \alpha \frac{V_S}{V_{IG}}} \qquad (22.34)$$

Once the lamp is ignited, the new operation circuit is shown in Fig. 22.27c. Normally, the switching frequency is selected to be very close to the natural frequency, and the circuit characteristics can be obtained by using $\Omega = 1$. Thus, as stated previously, the circuit acts as a current source of the following value:

$$I_{LA} = \frac{V_S}{\alpha Z_B} \qquad (22.35)$$

From this equation, the impedance Z_B needed to provide a lamp current equal to I_{LA} is easily obtained

$$Z_B = \frac{V_S}{\alpha I_{LA}} \qquad (22.36)$$

Using Eqs. (22.31)–(22.36), the design procedure can be performed as follows:

Step 1 Steady-state operation. Choose a value for the factor α; normally a value of 0.8–0.9 will be adequate for most applications. From Eq. (22.36), calculate the value of Z_B for the resonant tank. Since the natural frequency is equal to the switching frequency, the reactive elements of the resonant tank can be calculated as follows:

$$L = \frac{Z_B}{2\pi f_S} \quad C_P = \frac{1}{2\pi f_S \alpha Z_B} \quad C_S = \frac{1}{2\pi f_S (1-\alpha) Z_B} \quad (22.37)$$

Step 2 Heating phase. From Eq. (22.32), calculate the switching frequency for a given heating current I_H. Then, calculate the value of the heating voltage V_H from Eq. (22.33).

Step 3 Check if the heating voltage is lower than the maximum value allowed to avoid electrode sputtering. If the voltage is too high, choose a lower value of α and repeat steps 1 and 2. Also, the maximum heating frequency can be limited to avoid excessive frequency variation. The lower the α the lower is the frequency variation from heating to ignition, since the output voltage characteristics are narrower for the lower values of α.

The described procedure to achieve lamp soft ignition requires the use of a voltage-controlled oscillator to control the switching frequency. This can increase the cost of the ballast. A similar soft ignition can be achieved using the resonant circuit shown in Fig. 22.28. This circuit is very often used in self-oscillating ballasts, where the switches are driven from the resonant current using a current transformer [18].
FIGURE 22.28   Resonant circuit using a PTC resistor.

In the circuit shown in Fig. 22.28, the PTC is initially cold and capacitor C_{P1} is practically short-circuited by the PTC. The resonant tank under these conditions is formed by $L-C_S-C_{P2}$, which can be designed to heat the lamp electrodes with a heating voltage low enough to avoid lamp cold ignition. Since the PTC is also heated by the circulating current, after a certain period of time, it reaches the threshold temperature and trips. At this moment, the new resonant tank is formed by L, C_S, and the series equivalent of C_{P1} and C_{P2}. This circuit can be designed to generate the necessary ignition voltage and to supply the lamp in normal discharge mode. Once the lamp is ignited, the PTC maintains its high impedance since the dominant parallel capacitor in this phase is C_{P1} (usually $C_{P1} \ll C_{P2}$).

22.5 High-Power Factor Electronic Ballasts

As commented in a previous section, when electronic ballasts are supplied from the ac line, an ac–dc stage is necessary to provide the dc input voltage of the resonant inverter (see Fig. 22.9). Since the introduction of harmonic regulations, as IEC 1000-3-2, the use of a full-bridge diode rectifier followed by a filter capacitor is no longer applicable for this stage due to the high harmonic content of the input current. Therefore, the use of an ac–dc stage showing a high input power factor (PF) and a low total harmonic distortion (THD) of the input current is mandatory. The inclusion of this stage can significantly increase the cost of the complete ballast, and therefore the search for low-cost high-power factor electronic ballasts is presently an important field of research.

Figure 22.29a shows a first possibility to increase the input power factor of the ballast by removing the filter capacitor across the diode rectifier. However, since there are no low-frequency storage elements inside the resonant inverter, the output power instantaneously follows the input power, thus producing an annoying light flicker. Besides, the resulting lamp current crest factor is very high, which considerably decreases lamp life.

In order to avoid flicker and increase lamp current crest factor, continuous power must be delivered to the lamp. This can only be accomplished by using a PFC stage with a low-frequency storage element. This solution is shown in
FIGURE 22.29 High power factor ballasts.

Fig. 22.29b, where capacitor C_0 is used as energy storage element. The main drawback of this solution is that the input power is handled by the two stages, which reduces the efficiency of the complete electronic ballast.

22.5.1 Harmonic Limiting Standards

The standards IEC 1000-3-2 and EN 61000-3-2 [19] are the most popular regulations regarding the harmonic pollution produced by electronic equipment connected to the mains. These standards are a new version of the previous IEC 555-2 regulation, and they are applicable to the equipment with less than 16 A/phase and supplied from low voltage lines of 220/380 V, 230/400 V, and 240/415 V at 50 or 60 Hz. Limits for equipment supplied from voltages lower than 220 V have not yet been established.

This regulation divides the electrical equipment in several classes from class A to class D. Class C is especially for lighting equipment, including dimming devices; the harmonic limits for this class are shown in Table 22.4. As shown in Table 22.4, this regulation establishes a maximum amplitude for each input harmonic as a percentage of the fundamental harmonic component. The harmonic content established in Table 22.4 is quite restrictive, which means that the input current wave must be quite similar to a pure sine wave. For example, for a typical input power factor equal to 0.9, the THD calculated from Table 22.1 is only 32%.

TABLE 22.4   IEC 1000-3-2. Harmonic limits for class c equipment

Harmonic order n	Maximum permissible harmonic current expressed as a percentage of the input current at the fundamental frequency (%)
2	2
3	30 λ*
5	10
7	7
9	5
$11 \leq n \leq 39$ (odd harmonics only)	3

*λ is the circuit power factor.

22.5.2 Passive Solutions

A first possibility to increase the ballast power factor and to decrease the harmonic content of the input current is the use of passive solutions. Figure 22.30 shows two typical passive solutions, which can be used to improve the input power factor of electronic ballasts.

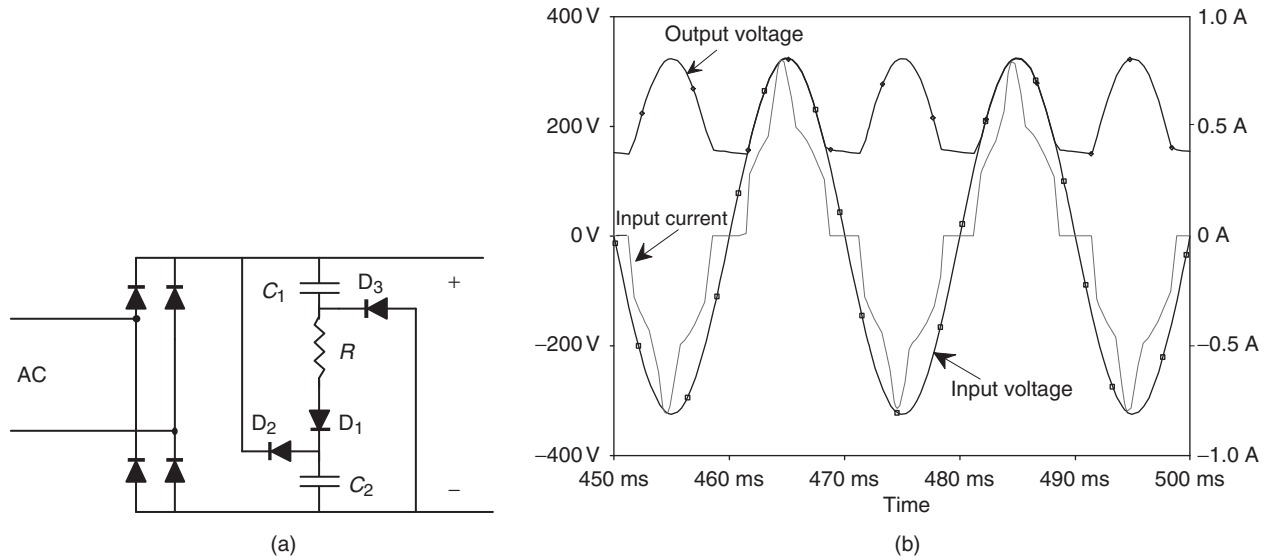
Figure 22.30a shows the most common passive solution based on a filter inductor L. Using a large inductance L a square input current can be obtained, with an input power factor of 0.9 and a THD of about 48%. However a square input waveform does not satisfy the IEC 1000-3-2 requirements and then it is not a suitable solution. The addition of capacitor C across
FIGURE 22.30 Passive circuits to improve input power factor (a) LC filter and (b) tuned LC filter.


FIGURE 22.31 Valley-fill circuit: (a) electric diagram and (b) waveforms.

the ac terminals can increase the power factor up to 0.95, but still the standard requirements are difficult to fulfill.

A simple variation of this circuit is shown in Fig. 22.30b, where a parallel circuit tuned to the third harmonic of the line frequency is used to improve the shape of the line current. The input power factor obtained with this circuit can be close to unity.

A third possible solution, known as valley-fill circuit, is shown in Fig. 22.31a. The typical filter capacitor following the diode rectifier is split into two different capacitors that are alternately charged using three extra diodes. The addition of a small series resistor improves the power factor by about two points, maintaining a low cost for the circuit. An inductor in place of the resistor can also be used to improve the power factor but with a higher cost penalty. Figure 22.31b shows the output voltage and input current of the valley-fill circuit. The main disadvantage of this circuit is the high ripple of the output voltage, which produces lamp power and luminous flux fluctuation and high lamp current crest factor.

Passive solutions are reliable, rugged, and cheap. However, the size and weight of these solutions are high and their design

to fulfill the IEC 1000-3-2 requirements is usually difficult. Therefore, they are normally applied in the lower power range.

22.5.3 Active Solutions

Active circuits are most popular solutions to implement high-power-factor electronic ballasts. They use controlled switches to correct the input power factor and in some cases to include galvanic isolation via high-frequency transformers. Active circuits normally used in electronic ballasts operate at a switching frequency well above the line frequency and over the audible range.

Some typical active circuits used in electronic ballasts are shown in Fig. 22.32. Buck–boost and flyback converters shown in Figs. 22.32a and 22.32b, respectively, can be operated in discontinuous conduction mode (DCM) with constant frequency and constant duty cycle in order to obtain an input power factor close to unity [20].

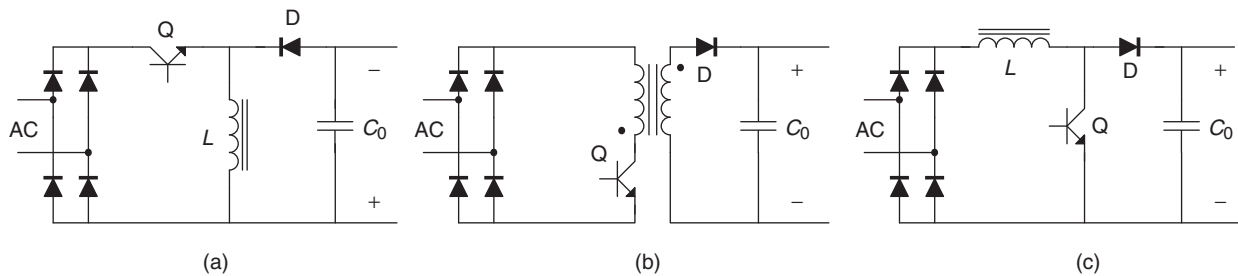
Figure 22.32c shows the boost converter, which is one of the most popular active circuits used to correct the input power factor of electronic ballasts [21–23]. If the boost converter


FIGURE 22.32 Power factor correction circuits for ballasts: (a) buck–boost; (b) flyback; and (c) boost.

is operated in DCM, an input power factor close to unity is obtained, provided that the output voltage is about twice the peak input voltage [21]. The main disadvantage of DCM operation, when compared with the CCM mode, is the high distortion of the input current (due to the discontinuous high-frequency current) and the higher current and voltage stresses in the switches. Therefore, the DCM operation is only used for the lower power range.

For the medium power range, the operation of the boost converter at the DCM–CCM borderline is preferred. In this solution, the on-time of the controlled switch is maintained constant within the whole line period and the switching frequency is adjusted to allow the input current to reach zero at the end of the switching period. The typical control circuit used and the input current waveform are shown in Figs. 22.33a and 22.33b, respectively. The inductor current is sensed using a resistor in series with the switch, and the peak inductor current is programmed to follow a sine wave using a multiplier. A comparator is employed to detect the zero-crossing of the inductor current in order to activate the switch. Most IC manufacturers provide a commercial version of this circuit to be used for electronic ballast applications.

The boost circuit operating with borderline control provides a continuous input current, which is easier to filter. Besides, it presents low switch turn-on losses and low recovery losses in the output diode. The main disadvantages are the variable switching frequency and the high output voltage, which must be higher than the peak line voltage.

For the higher power range, the boost converter can be operated in continuous conduction mode (CCM) to correct the input power factor. The input current in this scheme is continuous with very low distortion and easy to filter. The current stress in the switch is also lower, which means that more power can be handled maintaining a good efficiency. The normal efficiency obtained with a boost circuit operating either in the DCM–CCM borderline or in CCM can be as high as 95%.

22.6 Applications

Electronic ballasts are widely used in lighting applications, such as portable lighting, emergency lighting, automotive applications, home lighting, industrial lighting, and so on. They provide low volume and size, making it possible to reduce the luminaire size as well, which is a very interesting new trend in lighting design.

22.6.1 Portable Lighting

In this application, a battery is used as power source and then a low input voltage is available to supply the lamp. Examples are hand lanterns and backlightings for laptop computers. Typical input voltages in these applications range from 1.5 to 48 V. Therefore, a step-up converter is necessary to supply the discharge lamp, and then electronic ballasts are the only suitable solution. Since the converter is supplied from a battery, the efficiency of the ballast should be as high as possible in order to optimize the use of the battery energy, thus increasing the operation time of the portable lighting. Typical topologies used are the class E inverter and the push–pull resonant inverter, obtaining efficiencies up to 95%.

22.6.2 Emergency Lighting

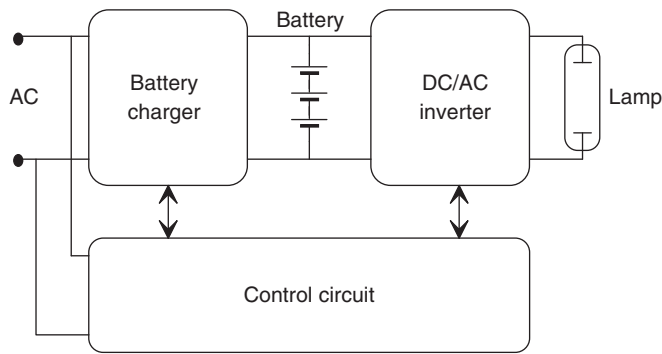
Emergency lightings are used to provide a minimum lighting level in case of a main supply cut-off. Batteries are employed to store energy from the mains and to supply the lamp in case of a main supply failure. A typical block diagram is shown in Fig. 22.34. An ac–dc converter is used as a battery
FIGURE 22.33 (a) Boost power factor corrector with borderline control and (b) input current waveform.


FIGURE 22.34 Block diagram of an emergency lighting.

FIGURE 22.35 Block diagram of a microprocessor-based lighting.

charger to store energy during normal line operation. A control circuit continuously measures the line voltage and activates the inverter in case of a main supply failure. Normally a minimum operating time of one hour is required for the system in emergency state. Thus, the use of high efficient electronic ballasts is mandatory to reduce the battery size and cost. Typical topologies used include class E inverters, push–pull resonant inverters, and half-bridge resonant inverters. Fluorescent lamps are mainly used in emergency ballasts, but high intensity discharge lamps, such as metal-halide lamps or high-pressure sodium lamps, are also used in some special applications.

22.6.3 Automotive Lighting

Electronic ballasts are used in automotive applications such as automobiles, buses, trains, and aircrafts. Normally, a low-voltage dc bus is available to supply the lamps. These applications are similar to portable and emergency lightings previously commented. In modern aircrafts, a 120/208-V, 400-Hz, 3-phase electrical system is also available and can be employed for lighting. Fluorescent lamps are typically used for automotive indoor lighting, whereas high-intensity discharge lamps are preferred in the exterior lighting; for example, in automobile headlights.

22.6.4 Home and Industrial Lighting

Electronic ballasts, especially for fluorescent lamps, are also very often used in home and industrial applications. The higher efficiency of fluorescent lamps supplied at high frequency provides an interesting energy saving when compared with incandescent lamps. A typical application is the use of compact fluorescent lamps with the electronic ballast inside the lamp base, which can directly substitute an incandescent lamp reducing the energy consumption four or five times. A self-oscillating half-bridge inverter is typically used in these energy saving lamps, since it allows to reduce the size and cost. The power of these lamps is normally below 25 W.
Other applications for higher power include more developed ballasts based on a power factor correction stage followed by a resonant inverter. Hot-cathode fluorescent lamps are mostly used in these electronic ballasts. Also, with the development of modern HID lamps such as metal halide lamps and very high-pressure sodium lamps (both showing very good color rendition), the use of HID lamps is being more and more frequent in home, commercial, and industrial lighting.

22.6.5 Microprocessor-Based Lighting

The use of microprocessors in combination with electronic ballasts is very interesting from the point of view of energy saving [24–26]. The inclusion of microprocessor circuits allows to incorporate control strategies for dimming, such as scheduling, task tuning, daylighting, and so on [27]. Using these strategies, the achieved energy saving can be as high as 35–40%. Another advantage of using microprocessors is the possibility of detecting lamp failure or bad operation, thus increasing the reliability and decreasing the maintenance cost of the installation. Most advanced electronic ballasts can include a communication stage to send and receive information regarding the state of the lighting to or from a central control unit. In some cases, communications can be performed via power line, thus reducing the installation costs. Figure 22.35 shows the block diagram of a microprocessor-based electronic ballast.

Power Supplies

Y. M. Lai, Ph.D.

Department of Electronic and Information Engineering, The Hong Kong Polytechnic University, Hong Kong

23.1 Introduction

Power supplies are used in most electrical equipment. Their applications cut across a wide spectrum of product types, ranging from consumer appliances to industrial utilities, from milliwatts to megawatts, from hand-held tools to satellite communications.

By definition, a power supply is a device which converts the output from an ac power line to a steady dc output or multiple outputs. The ac voltage is first rectified to provide a pulsating dc, and then filtered to produce a smooth voltage. Finally, the voltage is regulated to produce a constant output level despite variations in the ac line voltage or circuit loading. Figure 23.1 illustrates the process of rectification, filtering, and regulation in a dc power supply. The transformer, rectifier, and filtering circuits are discussed in other chapters. In this chapter, we will concentrate on the operation and characteristics of the regulator stage of a dc power supply.

In general, the regulator stage of a dc power supply consists of a feedback circuit, a stable reference voltage, and a control circuit to drive a pass element (a solid-state device such as transistor, MOSFET, etc.). The regulation is done by sensing variations appearing at the output of the dc power supply. A control signal is produced to drive the pass element to cancel any variation. As a result, the output of the dc power supply is maintained essentially constant. In a transistor regulator, the pass element is a transistor, which can be operated in its active region or as a switch, to regulate the output voltage. When the transistor operates at any point in its active region, the regulator is referred to as a *linear voltage regulator*. When the transistor operates only at cutoff and at saturation, the circuit is referred to as a *switching regulator*.

Linear voltage regulators can be further classified as either series or shunt types. In a series regulator, the pass transistor is connected in series with the load as shown in Fig. 23.2. Regulation is achieved by sensing a portion of the output voltage through the voltage divider network R_1 and R_2, and comparing this voltage with the reference voltage V_{REF} to produce a resulting error signal that is used to control the conduction of the pass transistor. This way, the voltage drop across the pass transistor is varied and the output voltage delivered to the load circuit is essentially maintained constant.

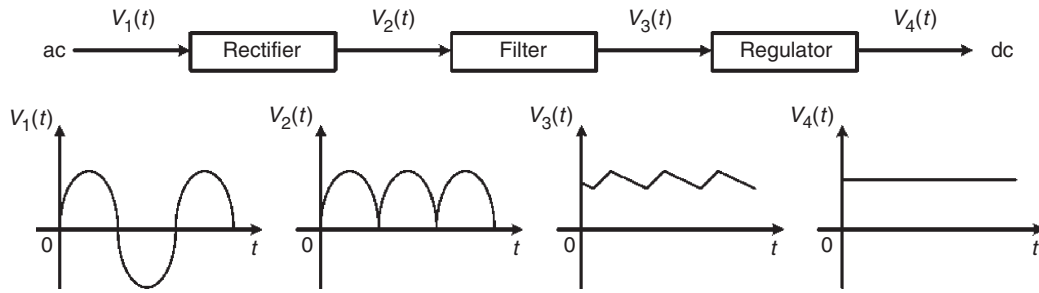
In the shunt regulator shown in Fig. 23.3, the pass transistor is connected in parallel with the load, and a voltage-dropping


FIGURE 23.1   Block diagram of a dc power supply.
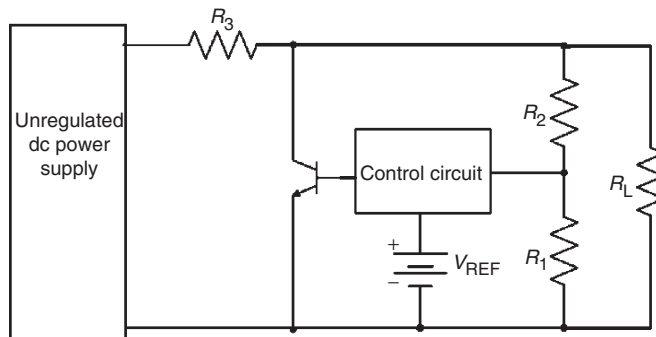
FIGURE 23.2   A linear series voltage regulator.
FIGURE 23.4   A simplified form of a switching regulator.


FIGURE 23.3   A linear shunt voltage regulator.

shows a switching regulator in a simplified form. The high-frequency switch converts the unregulated dc voltage from one level to another dc level at an adjustable duty cycle. The output of the dc supply is regulated by means of a feedback control that employs a pulse-width-modulator (PWM) controller, where the control voltage is used to adjust the duty cycle of the switch.

Both linear and switching regulators are capable of performing the same function of converting an unregulated input into a regulated output. However, these two types of regulators have significant differences in properties and performances. In designing power supplies, the choice of using certain type of regulator in a particular design is significantly based on the cost and performance of the regulator itself. In order to use the more appropriate regulator type in the design, it is necessary to understand the requirements of the application and select the type of regulator that best satisfies those requirements. Advantages and disadvantages of linear regulators, as compared to switching regulators, are given below:

resistor R_3 is connected in series with the load. Regulation is achieved by controlling the current conduction of the pass transistor such that the current through R_3 remains essentially constant. This way, the current through the pass transistor is varied and the voltage across the load remains constant.

As opposed to linear voltage regulators, switching regulators employ solid-state devices, which operate as switches: either completely *on* or completely *off*, to perform power conversion. Because the switching devices are not required to operate in their active regions, switching regulators enjoy a much lower power loss than those of linear voltage regulators. Figure 23.4

1. Linear regulators exhibit efficiency of 20–60%, whereas switching regulators have a much higher efficiency, typically 70–95%.
2. Linear regulators can only be used as a step-down regulator, whereas switching regulators can be used in both step-up and step-down operations.

3. Linear regulators require a mains-frequency transformer for off-the-line operation. Therefore, they are heavy and bulky. On the other hand, switching regulators use high-frequency transformers and can therefore be small in size.
4. Linear regulators generate little or no electrical noise at their outputs, whereas switching regulators may produce considerable noise if they are not properly designed.
5. Linear regulators are more suitable for applications of less than 20 W, whereas switching regulators are more suitable for large power applications.

In this chapter, we will examine the circuit operation, characteristics, and applications of linear and switching regulators. In Section 23.2, we will look at the basic circuits and properties of linear series voltage regulators. Some current-limiting techniques will be explained. In Section 23.3, linear shunt regulators will be covered. The important characteristics and uses of linear Integrated Circuit (IC) regulators will be discussed in Section 23.4. Finally, the operation and characteristics of switching regulators will be discussed in Section 23.5. Important design guidelines for switching regulators will also be given in this section.

23.2 Linear Series Voltage Regulator

A zener diode regulator can maintain a fairly constant voltage across a load resistor. It can be used to improve the voltage regulation and reduce the ripple in a power supply. However, the regulation is poor and the efficiency is low because of the non-zero resistance in the zener diode. To improve the regulation and efficiency of the regulator, we have to limit the zener current to a smaller value. This can be accomplished by using an amplifier in series with the load as shown in Fig. 23.5. The effect of this amplifier is to limit the variation of the current I_D through the zener diode D_z. This circuit is known

as a linear series voltage regulator because the transistor is in series with the load.

Because of the current-amplifying property of the transistor, I_D is reduced by a factor of $(\beta + 1)$, where β is the dc current gain of the transistor. Hence there is a small voltage drop across the diode resistance and the zener diode approximates an ideal voltage source. The output voltage V_o of the regulator is

$$V_o = V_z + V_{BE} \tag{23.1}$$

where V_z is the zener voltage and V_{BE} is the base-to-emitter voltage of the transistor. The change in output voltage is

$$\Delta V_o = \Delta V_z + \Delta V_{BE}$$
$$= \Delta I_D r_d + \Delta I_L r_e \tag{23.2}$$

where r_d is the dynamic resistance of the zener diode and r_e is the output resistance of the transistor. Assume that V_i and V_z are constant. With $\Delta I_D \approx \Delta I_L/(\beta + 1)$, the change in output voltage is then

$$\Delta V_o \approx \Delta I_L r_e \tag{23.3}$$

If V_i is not constant, then the current I will change with the input voltage. In calculating the change in output voltage, this current change must be absorbed by the zener diode.

In designing linear series voltage regulators, it is imperative that the series transistor must work within the rated Safe Operation Area (SOA) and be protected from excess heat dissipation because of current overload. The emitter-to-collector voltage V_{CE} of Q_1 is given by

$$V_{CE} = V_i - V_o \tag{23.4}$$

Thus, with specified output voltage, the maximum allowable V_{CE} for a given Q_1 is determined by the maximum input
FIGURE 23.5   Basic circuit of a linear series regulator.

voltage to the regulator. The power dissipated by Q_1 can be approximated by

$$P_{Q1} \approx (V_i - V_o)I_L \qquad (23.5)$$

Consequently, the maximum allowable power dissipated in Q_1 is determined by the combination of the input voltage V_i and the load current I_L of the regulator. For a low output voltage and a high loading current regulator, the power dissipated in the series transistor is about 50% of the power delivered to the output.

In many high-current high-voltage regulator circuits, it is necessary to use a Darlington-connected transistor pair so that the voltage, current, and power ratings of the series element are not exceeded. The method is shown in Fig. 23.6. An additional desirable feature of this circuit is that the reference diode dissipation can be reduced greatly. The maximum base current I_{B1} is then $I_L/(\beta_1 + 1)(\beta_2 + 1)$, where β_1 and β_2 are the dc current gain of Q_1 and Q_2 respectively. This current is usually of the order of less than 1 mA. Consequently, a low-power reference diode can be used.

23.2.1 Regulating Control

The series regulators shown in Figs. 23.5 and 23.6 do not have feedback loop. Although they provide satisfactory performance for many applications, their output resistances and ripples cannot be reduced. Figure 23.7 shows an improved form of the series regulator, in which negative feedback is employed to improve the performance. In this circuit, transistors Q_3 and Q_4 form a single-ended differential amplifier, and the gain of this amplifier is established by R_6. Here D_z is a stable zener diode reference, biased by R_4. For higher accuracy, D_z can be replaced by an IC reference such as REF series from Burr-Brown. Resistors R_1 and R_2 form a voltage divider

for output voltage sensing. Finally, transistors Q_1 and Q_2 form a Darlington pair output stage. The operation of the regulator can be explained as follows. When Q_1 and Q_2 are on, the output voltage increases, and hence the voltage V_A at the base of Q_3 also increases. During this time, Q_3 is off and Q_4 is on. When V_A reaches a level that is equal to the reference voltage V_{REF} at the base of Q_4, the base-emitter junction of Q_3 becomes forward-biased. Some Q_1 base current will divert into the collector of Q_3. If the output voltage V_o starts to rise above V_{REF}, Q_3 conduction increases to further decrease the conduction of Q_1 and Q_2, which will in turn maintain output voltage regulation. Figure 23.8 shows another improved series regulator that uses an operational amplifier to control the conduction of the pass transistor.

One of the problems in the design of linear series voltage regulators is the high-power dissipation in the pass transistors. If an excess load current is drawn, the pass transistor can be quickly damaged or destroyed. In fact, under short-circuit conditions, the voltage across Q_2 in Fig. 23.7, will be the input voltage V_i, and the current through Q_2 will be greater than the rated full-load output current. This current will cause Q_1 to exceed its rated SOA unless the current is reduced. In the next section, some current-limiting techniques will be presented to overcome this problem.

23.2.2 Current Limiting and Overload Protection

In some series voltage regulators, overloading causes permanent damage to the pass transistors. The pass transistors must be kept from excessive power dissipation under current overloads or short circuit conditions. A current-limiting mechanism must be used to keep the current through the transistors at a safe value as determined by the power rating of the transistors. The mechanism must be able to respond quickly to protect the transistor and yet permit the regulator to
FIGURE 23.6 A linear series regulator with Darlington-connected amplifier.
FIGURE 23.7   An improved form of discrete component series regulator.
FIGURE 23.8   An improved form of op-amp series regulator.

return to normal operation as soon as the overload condition is removed. One of the current-limiting techniques to prevent current overload, called the constant current-limiting method, is shown in Fig. 23.9(a). Current limiting is achieved by the combined action of the components shown inside the dashed line. The voltage developed across the current-limit resistor R_3 and the base-to-emitter voltage of current-limit transistor Q_3 is proportional to the circuit output current I_L. During current overload, I_L reaches a predetermined maximum value that is set by the value of R_3 to cause Q_3 to conduct. As Q_3 starts to conduct, Q_3 shunts a portion of the Q_1 base current. This action, in turn, decreases and limits I_L to a maximum value $I_{L(max)}$. Since the base-to-emitter voltage V_{BE} of Q_3 cannot exceed above 0.7 V, the voltage across R_3 is held at this value

and $I_{L(max)}$ is limited to

$$I_{L(max)} = \frac{0.7 \text{ V}}{R_3} \tag{23.6}$$

Consequently, the value of the short-circuit current is selected by adjusting the value of R_3. The voltage–current characteristic of this circuit is shown in Fig. 23.9(b).

In many high-current regulators, foldback current limiting is always used to protect against excessive current. This technique is similar to the constant current-limiting method, except that as the output voltage is reduced as a result of load impedance moving toward zero, the load current is also reduced. Therefore, a series voltage regulator that includes
FIGURE 23.9   Series regulator with constant current limiting: (a) circuit and (b) voltage–current characteristic.

a foldback current-limiting circuit has the voltage–current characteristic shown in Fig. 23.10. The basic idea of foldback current limiting, with reference to Fig. 23.11, can be explained as follows. The foldback current-limiting circuit (in dashed outline) is similar to the constant current-limiting circuit, with the exception of resistors R_5 and R_6. At low output current, the current-limit transistor Q_3 is cutoff.

A voltage proportional to the output current I_L is developed across the current-limit resistor R_3. This voltage is applied to
FIGURE 23.10   Voltage–current characteristic of foldback current-limit.

the base of Q_3 through the divider network R_5 and R_6. At the point of transition into current-limit, any further increase in I_L will increase the voltage across R_3 and hence across R_5, and Q_3 will progressively be turned on. As Q_1 conducts, it shunts a portion of the Q_1 base current. This action, in turn, causes the output voltage to fall. As the output voltage falls, the voltage across R_6 decreases and the current in R_6 also decreases, and more current is shunted into the base of Q_3. Hence, the current required in R_3 to maintain the conduction state of Q_3 is also decreased. Consequently, as the load resistance is reduced, the output voltage and current fall, and the current-limit point decreases toward a minimum when the output voltage is short-circuited. In summary, any regulator using foldback current limiting can have peak load current up to $I_{L(max)}$. But when the output becomes shorted, the current drops to a lower value to prevent overheating of the series transistors.

23.3 Linear Shunt Voltage Regulator

The second type of linear voltage regulator is the shunt regulator. In the basic circuit shown in Fig. 23.12, the pass transistor
FIGURE 23.11 Series regulator with foldback current limiting.
FIGURE 23.12 Basic circuit of a linear shunt regulator.

Q_1 is connected in parallel with the load. A voltage-dropping resistor R_3 is in series with this parallel network. The operation of the circuit is similar to that of the series regulator, except that regulation is achieved by controlling the current through Q_1. The operation of the circuit can be explained as follows. When the output voltage tries to increase because of a change in load resistance, the voltage at the non-inverting terminal of the operational amplifier also increases. This voltage is compared with a reference voltage and the resulting difference voltage causes Q_1 conduction to increase. With constant V_i and V_o, I_L will decrease and V_o will remain constant. The opposite action occurs when V_o tries to decrease. The voltage appearing at the base of Q_1 causes its conduction to decrease.

This action offsets the attempted decrease in V_o and maintains it at an almost constant level.

Analytically, the current flowing in R_3 is

$$I_{R3} = I_{Q1} + I_L \tag{23.7}$$

and

$$I_{R3} = \frac{V_i - V_o}{R_3} \tag{23.8}$$

With I_L and V_o constant, a change in V_i will cause a change in I_{Q1}.

$$\Delta I_{Q1} = \frac{\Delta V_i}{R_3} \tag{23.9}$$

With V_i and V_o constant,

$$\Delta I_{Q1} = -\Delta I_L \tag{23.10}$$

Equation (23.10) shows that if I_{Q1} increases, I_L decreases, and vice versa. Although shunt regulators are not as efficient as series regulators for most applications, they have the advantage of greater simplicity. This topology offers inherently short-circuit protection. If the output is shorted, the load current is limited by the series resistor R_3 and is given by

$$I_{L(max)} = \frac{V_i}{R_3} \tag{23.11}$$

The power dissipated by Q_1 can be approximated by

$$P_{Q1} \approx V_o I_C$$
$$= V_o(I_{R3} - I_L) \tag{23.12}$$

For a low value of I_L, the power dissipated in Q_1 is large and the efficiency of the regulator may drop to 10% under this condition.

To improve the power handling of the shunt transistor, one or more transistors connected in the common-emitter configuration in parallel with the load can be employed, as shown in Fig. 23.13.

23.4 Integrated Circuit Voltage Regulators

The linear series and shunt voltage regulators presented in the previous sections have been developed by various solid-state device manufacturers and are available in integrated circuit (IC) form. Like discrete voltage regulators, linear IC voltage regulators maintain an output voltage at a constant value despite variations in load and input voltage.

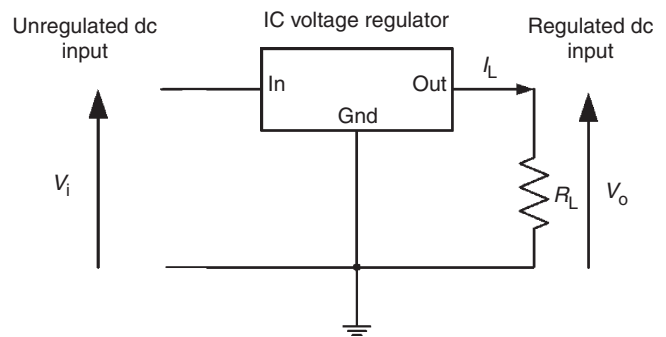
In general, linear IC voltage regulators are three-terminal devices that provide regulation of a fixed positive voltage, a fixed negative voltage, or an adjustable set voltage. The basic connection of a three-terminal IC voltage regulator to a load is shown in Fig. 23.14. The IC regulator has an unregulated input voltage V_i applied to the input terminals, a regulated voltage V_o at the output, and a ground connected to the third terminal. Depending on the selected IC regulator, the circuit can be operated with load currents ranging from milliamperes to tens of amperes and output power from milliwatts to tens


FIGURE 23.14 Basic connection of a three-terminal IC voltage regulator.

FIGURE 23.13 Linear shunt regulator with two transistors as shunt element.

of watts. Note that the internal construction of IC voltage regulators may be somewhat more complex and different from that previously described for discrete voltage regulator circuits. However, the external operation is much the same. In this section, some typical linear IC regulators are presented and their applications are also given.

23.4.1 Fixed Positive and Negative Linear Voltage Regulators

The 78XX series of regulators provide fixed regulated voltages from 5 to 24 V. The last two digits of the IC part number denote the output voltage of the device. For example, a 7824 IC regulator produces a +24 V regulated voltage at the output. The standard configuration of a 78XX fixed positive voltage regulator is shown in Fig. 23.15. The input capacitor C_1 acts as a line filter to prevent unwanted variations in the input line, and the output capacitor C_2 is used to filter the high-frequency noise that may appear at the output. In order to ensure proper operation, the input voltage of the regulator must be at least 2 V above the output voltage. Table 23.1 shows the minimum and maximum input voltages of the 78XX series fixed positive voltage regulator.

The 79XX series voltage regulator is identical to the 78XX series except that it provides negative regulated voltages instead
FIGURE 23.15 The 78XX series fixed positive voltage regulator.

23.4.2 Adjustable Positive and Negative Linear Voltage Regulators

The IC voltage regulators are also available in circuit configurations that allow the user to set the output voltage to a desired regulated value. The LM317 adjustable positive voltage regulator, for example, is capable of supplying an output current of more than 1.5 A over an output voltage range of 1.2–37 V. Figure 23.17 shows how the output voltage of an LM317 can be adjusted by using two external resistors R_1 and R_2. The capacitors C_1 and C_2 have the same function as those in the fixed linear voltage regulator.

As indicated in Fig. 23.17, the LM317 has a constant 1.25 V reference voltage, V_{REF}, across the output and the adjustment terminals. This constant reference voltage produces a constant current through R_1 regardless of the value of R_2. The output voltage V_o is given by

$$V_o = V_{REF}\left(1 + \frac{R_2}{R_1}\right) + I_{adj}R_2 \qquad (23.13)$$
FIGURE 23.17 The LM317 adjustable positive voltage regulator.
FIGURE 23.18 The LM337 adjustable negative voltage regulator.

where I_{adj} is a constant current into the adjustment terminal and has a value of approximately 50 μA for the LM317. As can be seen from Eq. (23.13), with fixed R_1, V_o can be adjusted by varying R_2.

The LM337 adjustable voltage regulator is similar to the LM317 except that it provides negative regulated voltages instead of positive ones. Figure 23.18 shows the standard configuration of a LM337 voltage regulator. The output voltage can be adjusted from −1.2 to −37 V, depending on the external resistors R_1 and R_2.

23.4.3 Applications of Linear IC Voltage Regulators

Most IC regulators are limited to an output current of 2.5 A. If the output current of an IC regulator exceeds its maximum allowable limit, its internal pass transistor will dissipate an amount of energy more than it can tolerate. As a result, the regulator will be shutdown.

For applications that require more than the maximum allowable current limit of a regulator, an external pass transistor can be used to increase the output current. Figure 23.19 illustrates such a configuration. This circuit has the capability of producing higher current to the load, but still preserving the thermal shutdown and short-circuit protection of the IC regulator.

A constant current-limiting scheme, as discussed in Section 23.2.2, is implemented by using the transistor Q_2 and the resistor R_2 to protect the external pass transistor Q_1 from excessive current under current-overload or short-circuit conditions. The value of the external current-sensing resistor R_1 determines the value of current at which Q_1 begins to conduct. As long as the current is less than the value set by R_1, the transistor Q_1 is off, and the regulator operates normally as shown in Fig. 23.15. But when the load current I_L starts to increase, the voltage across R_1 also increases. This turns on the external transistor Q_1 and conducts the excess current. The value of R_1 is determined by

$$R_1 = \frac{0.7\,\text{V}}{I_{max}} \qquad (23.14)$$

where I_{max} is the maximum current that the voltage regulator can handle internally.

23.5 Switching Regulators

The linear series and shunt regulators have control transistors that are operating in their linear active regions. Regulation is achieved by varying the conduction of the transistors to
FIGURE 23.19 A 78XX series regulator with an external pass transistor.

maintain the output voltage at a desirable level. The switching regulator is different in that the control transistor operates as a switch, either in cutoff or saturation region. Regulation is achieved by adjusting the on-time of the control transistor. In this mode of operation, the control transistor does not dissipate as much power as that in the linear types. Therefore, switching voltage regulators have a much higher efficiency and can provide greater load currents at low voltage than linear regulators.

Unlike their linear counterparts, switching regulators can be implemented by many different topologies such as forward and flyback. In order to select an appropriate topology for an application, it is necessary to understand the merits and drawbacks of each topology and the requirements of the application. Basically, most topologies can work for various applications. Therefore, we have to determine from the factors such as cost, performances, and application that make one topology more desirable than the others. However, no matter which topology we decide to use, the basic building blocks of an off-the-line switching power supply are the same, as depicted in Fig. 23.1.

In this section, some popular switching regulator topologies, namely flyback, forward, half-bridge, and full-bridge topologies, are presented. Their basic operation is described, and the critical waveforms are shown and explained. The merits, drawbacks, and application areas of each topology are discussed. Finally, the control circuitry and PWM of the regulators will also be discussed.

23.5.1 Single-ended Isolated Flyback Regulators

An isolated flyback regulator consists of four main circuit elements: a power switch, a rectifier diode, a transformer, and a filter capacitor. The power switch, which can be either a power transistor or a MOSFET, is used to control the flow of energy in the circuit. A transformer is placed between the input source and the power switch to provide DC isolation between the input and the output circuits. In addition to being an energy storage element, the transformer also performs a stepping up or down function for the regulator. The rectifier diode and filter capacitor form an energy transfer mechanism to supply energy to maintain the output voltage of the supply. Note that there are two distinct operating modes for flyback regulators: *continuous* and *discontinuous*. However, both modes have an identical circuit. It is only the transformer magnetizing current that determines the operating mode of the regulator. Figure 23.20(a) shows a simplified isolated flyback regulator. The associated steady-state waveforms, resulting from a discontinuous-mode operation, is shown in Fig. 23.20(b). As shown in the figure, the voltage regulation of the regulator is achieved by a control circuit, which controls the conduction period or duty cycle of the switch, to keep the output voltage at a constant level. For clarity, the schematics and operation of the control circuit will be discussed in a separate section.

23.5.1.1 Discontinuous-mode Flyback Regulators

Under steady-state conditions, the operation of the regulator can be explained as follows. When the power switch Q_1 is on, the primary current I_p starts to build up and stores energy in the primary winding. Because of the opposite-polarity arrangement between the input and output windings of the transformer, the rectifier diode D_R is reverse-biased. In this period of time, there is no energy transferred from the input to the load R_L. The output voltage is supported by the load current I_L, which is supplied from the output filter capacitor C_F. When Q_1 is turned off, the polarity of the windings reverses as a result of the fact that I_p cannot change instantaneously. This causes D_R to turn on. Now D_R is conducting, charging the output capacitor C_F and delivering current to R_L. This charging action ends at the point where all the magnetic energy stored in the secondary winding during the first half-cycle is emptied. At this point, D_R will cease to conduct and R_L absorbs energy just from C_F until Q_1 is switched on again.

During the Q_1 on-time, the voltage across the primary winding of the transformer is V_i. The current in the primary winding I_p increases linearly and is given by

$$I_p = \frac{V_i t_{on}}{L_p} \tag{23.15}$$

where L_p is the primary magnetizing inductance. At the end of the on-time, the primary current reaches a value equal to $I_{p(pk)}$ and is given by

$$I_{p(pk)} = \frac{V_i D T}{L_p} \tag{23.16}$$

where D is the duty cycle and T is the switching period. Now when Q_1 turns off, the magnetizing current in the transformer forces the reversal of polarities on the windings. At the instant of turn off, the amplitude of the secondary current $I_{s(pk)}$ is

$$I_{s(pk)} = \left(\frac{N_p}{N_s}\right) I_{p(pk)} \tag{23.17}$$

This current decreases linearly at the rate of

$$\frac{dI_s}{dt} = \frac{V_o}{L_s} \tag{23.18}$$

where L_s is the secondary magnetizing inductance.

In the discontinuous-mode operation, $I_{s(pk)}$ will decrease linearly to zero before the start of the next cycle. Since the energy transfer from the source to the output takes place only in the first half cycle, the power drawn from V_i is then

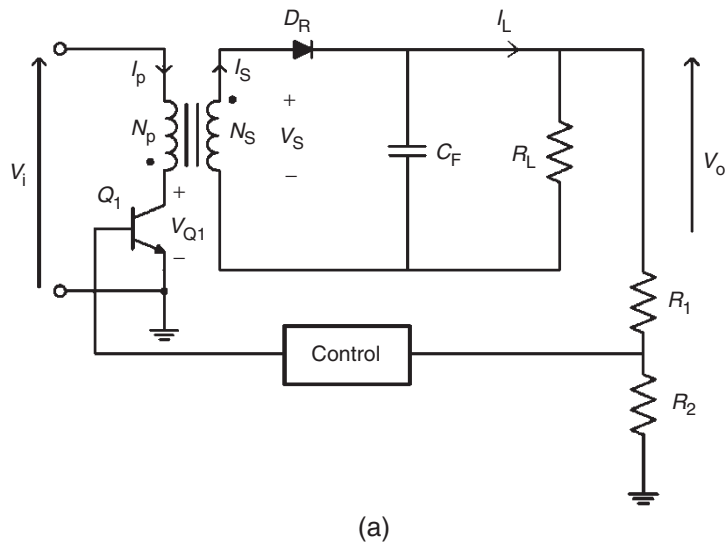
$$P_{in} = \frac{L_p I_p^2}{2T} \tag{23.19}$$


FIGURE 23.20   A simplified isolated flyback regulator: (a) circuit and (b) the associated waveforms.

Substituting Eq. (23.15) into Eq. (23.19), we have

$$P_{\text{in}} = \frac{(V_i t_{\text{on}})^2}{2TL_p} \qquad (23.20)$$

The output power P_o may be written as

$$
\begin{aligned}
P_o &= \eta P_{\text{in}} \\
&= \frac{\eta (V_i t_{\text{on}})^2}{2TL_p} = \frac{V_o^2}{R_L}
\end{aligned}
\qquad (23.21)
$$

where η is the efficiency of the regulator. Then, from Eq. (23.21), the output voltage V_o is related to the input voltage V_i by

$$V_o = V_i D \sqrt{\frac{\eta R_L T}{2L_p}} \qquad (23.22)$$

Since the collector voltage V_{Q1} of Q_1 is maximum when V_i is maximum, the maximum collector voltage $V_{Q1(\text{max})}$, as shown in the Fig. 23.20(b), is given by

$$V_{Q1(\text{max})} = V_{i(\text{max})} + \left(\frac{N_p}{N_s}\right) V_o \qquad (23.23)$$

The primary peak current $I_{p(pk)}$ can be found in terms of P_o by combining Eq. (23.16) and Eq. (23.21) and then eliminating L_p as

$$
\begin{aligned}
I_{p(pk)} &= \frac{2V_o^2}{\eta V_i D R_L} \\
&= \frac{2P_o}{\eta V_i D}
\end{aligned}
\qquad (23.24)
$$

The maximum collector current $I_{C(\text{max})}$ of the power switch Q_1 at turn on is

$$
\begin{aligned}
I_{C(\text{max})} &= I_{p(pk)} \\
&= \frac{2P_o}{\eta V_i D}
\end{aligned}
\qquad (23.25)
$$

As can be seen from Eq. (23.21), V_o will be maintained constant by keeping the product $V_i t_{\text{on}}$ constant. Since maximum on-time $t_{\text{on(max)}}$ occurs at minimum supply voltage $V_{i(\text{min})}$, the maximum allowable duty cycle for the discontinuous-mode can be found from Eq. (23.22) as

$$D_{\text{max}} = \frac{V_o}{V_{i(\text{min})}} \sqrt{\frac{2L_p}{\eta R_L T}} \qquad (23.26)$$

and V_o at D_{max} is then

$$V_o = V_{i(\text{min})} D_{\text{max}} \sqrt{\frac{\eta R_L T}{2L_p}} \qquad (23.27)$$

23.5.1.2 Continuous-mode Flyback Regulators

In the continuous-mode operation, the power switch is turned on before all the magnetic energy stored in the secondary winding empties itself. The primary and secondary current waveforms have a characteristic appearance as shown in Fig. 23.21. This mode produces a higher power capability without increasing the peak currents. During the on-time, the primary current I_p rises linearly from its initial value $I_p(0)$ and is given by

$$I_p = I_p(0) + \frac{V_i t_{\text{on}}}{L_p} \qquad (23.28)$$
FIGURE 23.21 The primary and secondary winding currents of a flyback regulator operated in the continuous-mode.

At the end of the on-time, the primary current reaches a value equal to $I_{p(pk)}$ and is given by

$$I_{p(pk)} = I_p(0) + \frac{V_i DT}{L_p} \quad (23.29)$$

In general, $I_p(0) \gg V_i DT/L_p$; thus, Eq. (23.29) can be written as

$$I_{p(pk)} \approx I_p(0) \quad (23.30)$$

The secondary current I_s at the instant of turn off is given by

$$I_{s(pk)} = \left(\frac{N_p}{N_s}\right) I_{p(pk)}$$

$$= \left(\frac{N_p}{N_s}\right) \left(I_p(0) + \frac{V_i DT}{L_p}\right) \quad (23.31)$$

$$\approx \left(\frac{N_p}{N_s}\right) I_p(0)$$

This current decreases linearly at the rate of

$$\frac{dI_s}{dt} = \frac{V_o}{L_s} \quad (23.32)$$

The output power P_o is equal to V_o times the time-average of the secondary current pulses and is given by

$$P_o = V_o I_s \frac{T - t_{on}}{T}$$

$$\approx V_o I_{s(pk)} \frac{T - t_{on}}{T} \quad (23.33)$$

or

$$I_{s(pk)} = \frac{P_o}{V_o(1 - t_{on}/T)} \quad (23.34)$$

For an efficiency of η, the input power P_{in} is

$$P_{in} = \frac{P_o}{\eta}$$

$$= V_i I_p \frac{t_{on}}{T} \quad (23.35)$$

$$\approx V_i I_{p(pk)} \frac{t_{on}}{T}$$

or

$$I_{p(pk)} = \frac{P_o}{\eta V_i (t_{on}/T)} \quad (23.36)$$

Combining Eqs. (23.31), (23.34), and (23.36) and solving for V_o, we have

$$V_o = \left(\frac{N_s}{N_p}\right) \frac{\eta V_i D}{1 - D} \quad (23.37)$$

The output voltage at D_{max} is then

$$V_o = \left(\frac{N_s}{N_p}\right) \frac{\eta V_{i(min)} D_{max}}{1 - D_{max}} \quad (23.38)$$

The maximum collector current $I_{C(max)}$ for the continuous-mode is then given by

$$I_{C(max)} = I_{p(pk)}$$

$$= \frac{P_o}{\eta V_i D_{max}} \quad (23.39)$$

The maximum collector voltage of Q_1 is the same as that in the discontinuous-mode and is given by

$$V_{Q1(max)} = V_{i(max)} + \left(\frac{N_p}{N_s}\right) V_o \quad (23.40)$$

The maximum allowable duty cycle for the continuous-mode can be found from Eqs. (23.38) and is given by

$$D_{max} = \frac{1}{1 + \left(\frac{N_s}{N_p}\right) \frac{\eta V_{i(min)}}{V_o}} \quad (23.41)$$

At the transition from the discontinuous-mode to continuous-mode (or from continuous-mode to discontinuous-mode), the relationships in Eqs. (23.27) and (23.38) must hold. Thus, equating these two equations, we have

$$V_{i(min)} D_{max} \sqrt{\frac{\eta R_L T}{2 L_p}} = \frac{N_s}{N_p} \frac{D_{max}}{1 - D_{max}} \eta V_{i(min)} \quad (23.42)$$

Solving this equation for L_p to give the critical inductance $L_{p(limit)}$, at which the transition occurs, we have

$$L_{p(limit)} = \frac{1}{2\eta} T R_L \left[(1 - D_{max}) \frac{N_p}{N_s}\right]^2$$

$$= \frac{1}{2\eta} T \frac{V_o^2}{P_o} \left[(1 - D_{max}) \frac{N_p}{N_s}\right]^2 \quad (23.43)$$

Replacing V_o with Eq. (23.38) and solving for $L_{p(limit)}$, we have

$$L_{p(limit)} = \frac{1}{2} \eta T \frac{D_{max}^2 V_{i(min)}^2}{P_o} \quad (23.44)$$

Then, for a given D_{max}, input, and output quantities, the inductance value $L_{p(limit)}$ in Eq. (23.44) determines the mode

of operation for the regulator. If $L_p < L_{p(limit)}$, then the circuit is operated in the discontinuous-mode. Otherwise, if $L_P > L_{p(limit)}$, the circuit is operated in the continuous-mode.

In designing flyback regulators, regardless of their operating modes, the power switch must be able to handle the peak collector voltage at turn off and the peak collector currents at turn on as shown in Eqs. (23.23), (23.25), (23.39), and (23.40). The flyback transformer, because of its unidirectional use of the *B–H* curve, has to be designed so that it will not be driven into saturation. To avoid saturation, the transformer needs a relatively large core with an air gap in it.

Although the continuous and discontinuous modes have an identical circuit, their operating properties differ significantly. As opposed to the discontinuous-mode, the continuous-mode can provide higher power capability without increasing the peak current $I_{p(pk)}$. It means that, for the same output power, the peak currents in the discontinuous-mode are much higher than those operated in the continuous-mode. As a result, a higher current rating and, therefore, a more expensive power transistor is needed. Moreover, the higher secondary peak currents in the discontinuous-mode will have a larger transient spike at the instant of turn off. However, despite all these problems, the discontinuous-mode is still much more widely used than its continuous-mode counterpart. There are two main reasons. First, the inherently smaller magnetizing inductance gives the discontinuous-mode a quicker response and a lower transient output voltage spike to sudden changes in load current or input voltage. Second, the continuous-mode has a right-half-plane zero in its transfer function, which makes the feedback control circuit more difficult to design.

The flyback configuration is mostly used in applications with output power below 100 W. It is widely used for high output voltages at relatively low power. The essential attractions of this configuration are its simplicity and low cost.

Since no output filter inductor is required for the secondary, there is a significant saving in cost and space, especially for multiple output power supplies. Since there is no output filter inductor, the flyback exhibits high ripple currents in the transformer and at the output. Thus, for higher power applications, the flyback becomes an unsuitable choice. In practice, a small *LC* filter is added after the filter capacitor C_F in order to suppress high-frequency switching noise spikes.

As mentioned previously, the collector voltage of the power transistor must be able to sustain a voltage as defined in Eq. (23.23). In cases where the voltage is too high for the transistor to handle, the double-ended flyback regulator shown in Fig. 23.22 may be used. The regulator uses two transistors that are switched on or off simultaneously. The diodes D_{R1} and D_{R2} are used to restrict the maximum collector voltage to V_i. Therefore, the transistors with a lower voltage rating can be used in the circuit.

23.5.2 Single-ended Isolated Forward Regulators

Although the general appearance of an isolated forward regulator resembles that of its flyback counterpart, their operations are different. The key difference is that the dot on the secondary winding of the transformer is so arranged that the output diode is forward-biased when the voltage across the primary is positive, that is, when the transistor is *on*. Energy is thus not stored in the primary inductance as it was for the flyback. The transformer acts strictly as a transformer. An inductive energy storage element is required at the output for proper and efficient energy transfer.

Unlike the flyback, the forward regulator is very suitable for working in the continuous-mode. In the discontinuous-mode, the forward regulator is more difficult to control because of a
FIGURE 23.22 A double-ended flyback regulator.

double-pole at the output filter. Thus, it is not as much used as the continuous-mode. In view of it, only the continuous-mode will be discussed here.

Figure 23.23 shows a simplified isolated forward regulator and the associated steady-state waveforms for the continuous-mode operation. Again for clarity, the details of the control circuit are omitted from the figure. Under steady-state condition, the operation of the regulator can be explained as follows. When the power switch Q_1 turns on, the primary current I_p starts to build up and stores energy in the primary winding. Because of the same polarity arrangement of the primary and secondary windings, this energy is forward-transferred to the secondary and onto the $L_1 C_F$ filter and the load R_L through the rectifier diode D_{R2}, which is forward-biased. When Q_1 turns off, the polarity of the transformer winding voltage reverses. This causes D_{R2}, to turn off and D_{R1}, and D_{R3}, to turn on. Now D_{R3}, is conducting and delivering energy to R_L through the inductor L_1. During this period, the diode D_{R1}, and the tertiary winding provide a path for the magnetizing current returning to the input.

When the transistor Q_1 is turned on, the voltage across the primary winding is V_i. The secondary winding current is reflected into the primary, and the reaction current I_p, as shown in Fig. 23.24, is given by

$$I_p = \frac{N_s}{N_p} I_s \qquad (23.45)$$

The magnetizing current in the primary has a magnitude of I_{mag} and is given by

$$I_{mag} = \frac{V_i t_{on}}{L_p} \qquad (23.46)$$

The total primary current I_p' is then

$$I_p' = I_p + I_{mag}$$
$$= \frac{N_s}{N_p} I_s + \frac{V_i t_{on}}{L_p} \qquad (23.47)$$

The voltage developed across the secondary winding V_s is

$$V_s = \frac{N_s}{N_p} V_i \qquad (23.48)$$

Neglecting diode voltage drops and losses, the voltage across the output inductor is $V_s - V_o$. The current in L_1 increases linearly at the rate of

$$I_{L1} = \frac{(V_s - V_o)t_{on}}{L_1} \qquad (23.49)$$

At the end of the on-time, the total primary current reaches a peak value equal to $I_{p(pk)}'$ and is given by

$$I_{p(pk)}' = I_p'(0) + \frac{V_i DT}{L_p} \qquad (23.50)$$

The output inductor current I_{L1} is

$$I_{L1(pk)} = I_{L1}(0) + \frac{(V_s - V_o)DT}{L_1} \qquad (23.51)$$

At the instant of turn on, the amplitude of the secondary current has a value of $I_{s(pk)}$ and is given by

$$I_{s(pk)} = \left(\frac{N_p}{N_s}\right) I_{p(pk)}'$$
$$= \left(\frac{N_p}{N_s}\right) \left[I_p'(0) + \frac{V_i DT}{L_p}\right] \qquad (23.52)$$

During the off-time, the current I_{L1} in the output inductor is equal to the current I_{DR3} in the rectifier diode D_{R3} and both decrease linearly at the rate of

$$\frac{dI_{L1}}{dt} = \frac{dI_{DR3}}{dt}$$
$$= \frac{V_o}{L_1} \qquad (23.53)$$

The output voltage V_o can be found from the time integral of the secondary winding voltage over a time equal to DT of the switch Q_1. Thus, we have

$$V_o = \frac{1}{T} \int_0^{DT} \frac{N_s}{N_p} V_i dt$$
$$= \frac{N_s}{N_p} V_i D \qquad (23.54)$$

The maximum collector current $I_{C(max)}$ at turn on is equal to $I_{p(pk)}'$ and is given by

$$I_{C(max)} = I_{p(pk)}'$$
$$= \left(\frac{N_s}{N_p}\right) \left[I_p'(0) + \frac{V_i DT}{L_p}\right] \qquad (23.55)$$

The maximum collector voltage $V_{Q1(max)}$ at turn-off is equal to the maximum input voltage $V_{i(max)}$ plus the maximum voltage $V_{r(max)}$ across the tertiary winding and is given by

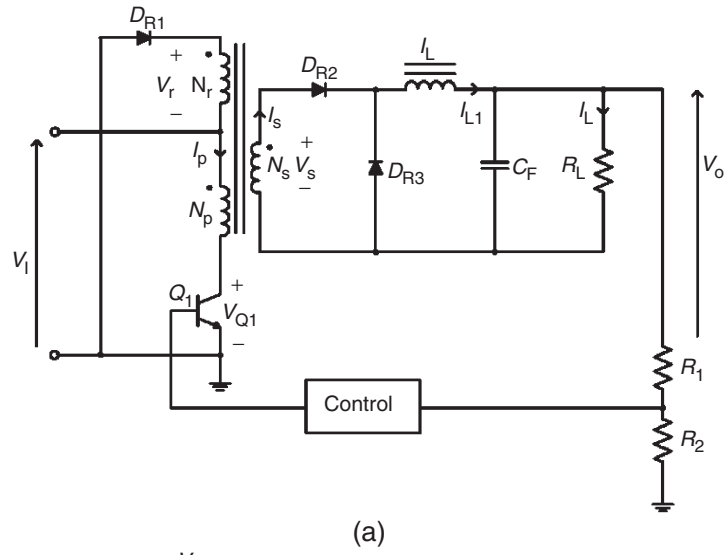
$$V_{Q1(max)} = V_{i(max)} + V_{r(max)}$$
$$= V_{i(max)} \left(1 + \frac{N_p}{N_r}\right) \qquad (23.56)$$


FIGURE 23.23   A simplified isolated forward regulator: (a) circuit and (b) the associated waveforms.
FIGURE 23.24   The current components in the primary winding.

The maximum duty cycle for the forward regulator operated in the continuous-mode can be determined by equating the time integral of the input voltage when Q_1 is on and the clamping voltage V_r when Q_1 is off.

$$\int_0^{DT} V_i\,dt = \int_{DT}^{T} V_r\,dt \tag{23.57}$$

which leads to

$$V_i DT = V_r(1-D)T \tag{23.58}$$

Grouping the D terms in Eq. (23.58) and replacing V_r/V_i with N_r/N_p, we have

$$D_{max} = \frac{1}{1 + N_r/N_p} \tag{23.59}$$

Thus, the maximum duty cycle depends on the turn ratio between the demagnetizing winding and the primary one.

In designing forward regulators, the duty cycle must be kept below the maximum duty cycle D_{max} to avoid saturating the transformer. It should also be noted that the transformer magnetizing current must be reset to zero at the end of each cycle. Failure to do so will drive the transformer into saturation, which can cause damage to the transistor. There are many ways of implementing the resetting function. In the circuit shown in Fig. 23.23(a), a tertiary winding is added to the transformer so that the magnetizing current will return to the input source V_i when the transistor turns off. The primary current always starts at the same value under the steady state condition.

Unlike flyback regulators, forward regulators require a minimum load at the output. Otherwise, excess output voltage will be produced. One commonly used method to avoid this situation is to attach a small load resistance at the output terminals. Of course, with such an arrangement, a certain amount of power will be lost in the resistor.

Because forward regulators do not store energy in their transformers, for the same output power level the transformer can be made smaller than for the flyback type. The output current is reasonably constant owing to the action of the output inductor and the flywheel diode; as a result, the output filter capacitor can be made smaller and its ripple current rating can be much lower than that required for the flybacks.

The forward regulator is widely used with output power below 200 W, though it can be easily constructed with a much higher output power. The limitation comes from the capability of the power transistor to handle the voltage and current stresses if the output power were to increase. In this case, a configuration with more than one transistor can be used to share the burden. Figure 23.25 shows a double-ended forward regulator. Like the double-ended flyback counterpart, the circuit uses two transistors which are switched on and off simultaneously. The diodes are used to restrict the maximum collector voltage to V_i. Therefore, the transistors with low voltage rating can be used in the circuit.

23.5.3 Half-bridge Regulators

The half-bridge regulator is another form of an isolated forward regulator. When the voltage on the power transistor in the single-ended forward regulator becomes too high, the half-bridge regulator is used to reduce the stress on the transistor. In a half-bridge regulator, the voltage stress imposed on the power transistors is subject to only the input voltage and is only half of that in a forward regulator. Thus, the output power of a half-bridge is double to that of a forward regulator for the same semiconductor devices and magnetic core.

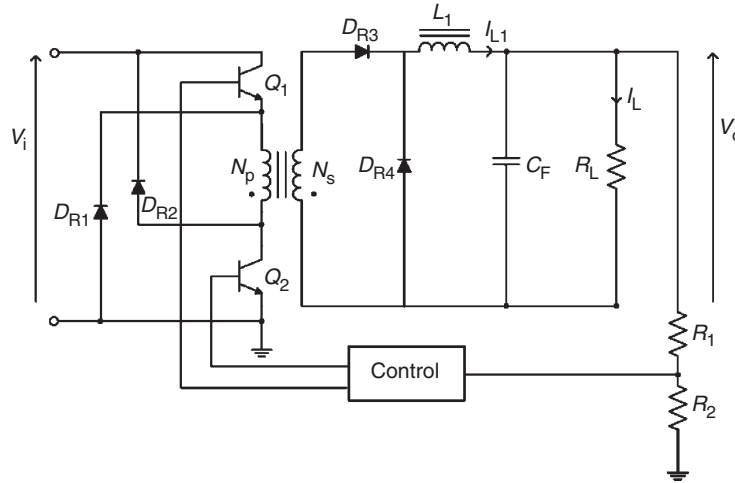
Figure 23.26 shows the basic configuration of a half-bridge regulator and the associated steady state waveforms. As seen in Fig. 23.26(a), the half-bridge regulator can be viewed as two back-to-back forward regulators, fed by the same input voltage, each delivering power to the load at each alternate half cycle. The capacitors C_1 and C_2 are placed between the input and ground terminals. As such, the voltage across the primary winding is always half the input voltage. The power switches Q_1 and Q_2 are switched on and off alternatively to produce a square-wave ac at the input of the transformer.


FIGURE 23.25 Double-ended forward regulator.

This square-wave is either stepped down or up by the isolation transformer and then rectified by the diodes D_{R1} and D_{R2}. Subsequently, the rectified voltage is filtered to produce the output voltage V_o.

Under steady state condition, the operation of the regulator can be explained as follows. When Q_1 is on and Q_2 off, D_{R1} conducts and D_{R2} is reverse-biased. The primary voltage V_p is $V_i/2$. The primary current I_p starts to build up and stores energy in the primary winding. This energy is forward-transferred to the secondary and onto the $L_1 C$ filter and the load R_L, through the rectifier diode D_{R1}. During the time interval Δ, when both Q_1 and Q_2 are off, D_{R1} and D_{R2} are forced to conduct to carry the magnetizing current that resulted in the interval during which Q_1 is turned on. The inductor current I_{L1} in this interval is equal to the sum of the currents in D_{R1} and D_{R2}. This interval terminates at half of the switching period T, when Q_2 is turned on. When Q_2 is on and Q_1 off, D_{R1} is reverse-biased and D_{R2} conducts. The primary voltage V_p is now $-V_i/2$. The circuit operates in a likewise manner as during the first half cycle.

With Q_1 on, the voltage across the secondary winding is

$$V_{s1} = \frac{N_{s1}}{N_p}\left(\frac{V_i}{2}\right) \qquad (23.60)$$

Neglecting diode voltage drops and losses, the voltage across the output inductor is then given by

$$V_{L1} = \frac{N_{s1}}{N_p}\left(\frac{V_i}{2}\right) - V_o \qquad (23.61)$$

In this interval, the inductor current I_{L1} increases linearly at the rate of

$$
\begin{aligned}
\frac{dI_{L1}}{dt} &= \frac{V_{L1}}{L_1} \\
&= \frac{1}{L_1}\left[\frac{N_{s1}}{N_p}\left(\frac{V_i}{2}\right) - V_o\right]
\end{aligned}
\qquad (23.62)
$$

At the end of Q_1 on-time, I_{L1} reaches a value which is given by

$$I_{L1(pk)} = I_{L1}(0) + \frac{1}{L_1}\left[\frac{N_{s1}}{N_p}\left(\frac{V_i}{2}\right) - V_o\right]DT \qquad (23.63)$$

During the interval Δ, I_{L1} is equal to the sum of the rectifier diode currents. Assuming the two secondary windings are identical, I_{L1} is given by

$$I_{L1} = 2I_{DR1} = 2I_{DR2} \qquad (23.64)$$

This current decreases linearly at the rate of

$$\frac{dI_{L1}}{dt} = \frac{V_o}{L_1} \qquad (23.65)$$

The next half cycle repeats with Q_2 on and for the interval Δ. The output voltage can be found from the time integral of the inductor voltage over a time equal to T. Thus, we have

$$V_o = 2 \times \frac{1}{T}\left[\int_0^{DT}\left(\frac{N_{s1}}{N_p}\left(\frac{V_i}{2}\right) - V_o\right)dt + \int_{T/2}^{T/2+DT} -V_o dt\right] \qquad (23.66)$$
FIGURE 23.26   A simplified half-bridge regulator: (a) circuit and (b) the associated waveforms.

Note that the multiplier of 2 appears in Eq. (23.66) because of the two alternate half cycles. Solving Eq. (23.66) for V_o, we have

$$V_o = \frac{N_{s1}}{N_p} V_i D \qquad (23.67)$$

The output power P_o is given by

$$
\begin{aligned}
P_o &= V_o I_L \\
&= \eta P_{in} \qquad (23.68) \\
&= \eta \frac{V_i I_{p(avg)} D}{2}
\end{aligned}
$$

or

$$I_{p(avg)} = \frac{2 P_o}{\eta V_i D} \qquad (23.69)$$

where $I_{p(avg)}$ has the value of the primary current at the center of the rising or falling ramp. Assuming the reaction current I_p' reflected from the secondary is much greater than the magnetizing current, then the maximum collector currents for Q_1 and Q_2 are given by

$$
\begin{aligned}
I_{C(max)} &= I_{p(avg)} \\
&= \frac{2 P_o}{\eta V_i D_{max}} \qquad (23.70)
\end{aligned}
$$

As mentioned, the maximum collector voltages for Q_1 and Q_2 at turn off are given by

$$V_{C(max)} = V_{i(max)} \qquad (23.71)$$

In designing half-bridge regulators, the maximum duty cycle can never be greater than 50%. When both the transistors are switched on simultaneously, the input voltage is short-circuited to ground. The series capacitors C_1 and C_2 provide a dc bias to balance the volt–second integrals of the two switching intervals. Hence, any mismatch in devices would not easily saturate the core. However, if such a situation arises, a small coupling capacitor can be inserted in series with the primary winding. A dc bias voltage proportional to the volt–second imbalance is developed across the coupling capacitor. This balances the volt–second integrals of the two switching intervals.

One problem in using half-bridge regulators is related to the design of the drivers for the power switches. Specifically, the emitter of Q_1 is not at ground level, but is at a high ac level. The driver must therefore be referenced to this ac level. Typically, transformer-coupled drivers are used to drive both switches, thus solving the grounding problem and allowing the controller to be isolated from the drivers.

The half-bridge regulator is widely used for medium-power applications. Because of its core-balancing feature, the half-bridge becomes the predominant choice for output power ranging from 200 to 400 W. Since the half-bridge is more complex, for application below 200 W, the flyback or forward regulator is considered to be a better choice and more cost-effective. Above 400 W, the primary and switch currents of the half-bridge become very high. Thus, it becomes unsuitable.

23.5.4 Full-bridge Regulators

The full-bridge regulator is yet another form of isolated forward regulator. Its performance is improved over that of the half-bridge regulator because of the reduced peak collector current. The two series capacitors that appeared in half-bridge circuits are now replaced by another pair of transistors of the same type. In each switching interval, two of the switches are turned on and off simultaneously such that the full input voltage appears at the primary winding. The primary and the switch currents are only half that of the half-bridge for the same power level. Thus, the maximum output power of this topology is twice that of the half-bridge.

Figure 23.27 shows the basic configuration of a full-bridge regulator and the associated steady-state waveforms. Four power switches are required in the circuit. The power switches Q_1 and Q_4 turn on and off simultaneously in one of the half cycles. Q_2 and Q_3 also turn on and off simultaneously in the other half cycle, but with opposite phase as Q_1 and Q_4. This produces a square-wave ac with a value of $\pm V_i$ at the primary winding of the transformer. Like the half-bridge, this voltage is stepped down, rectified, and then filtered to produce a dc output voltage. The capacitor C_1 is used to balance the volt-second integrals of the two switching intervals and prevent the transformer from being driven into saturation.

Under steady-state conditions, the operation of the full-bridge is similar to that of the half-bridge. When Q_1 and Q_4 turn on, the voltage across the secondary winding is

$$V_{s1} = \frac{N_{s1}}{N_p} V_i \qquad (23.72)$$

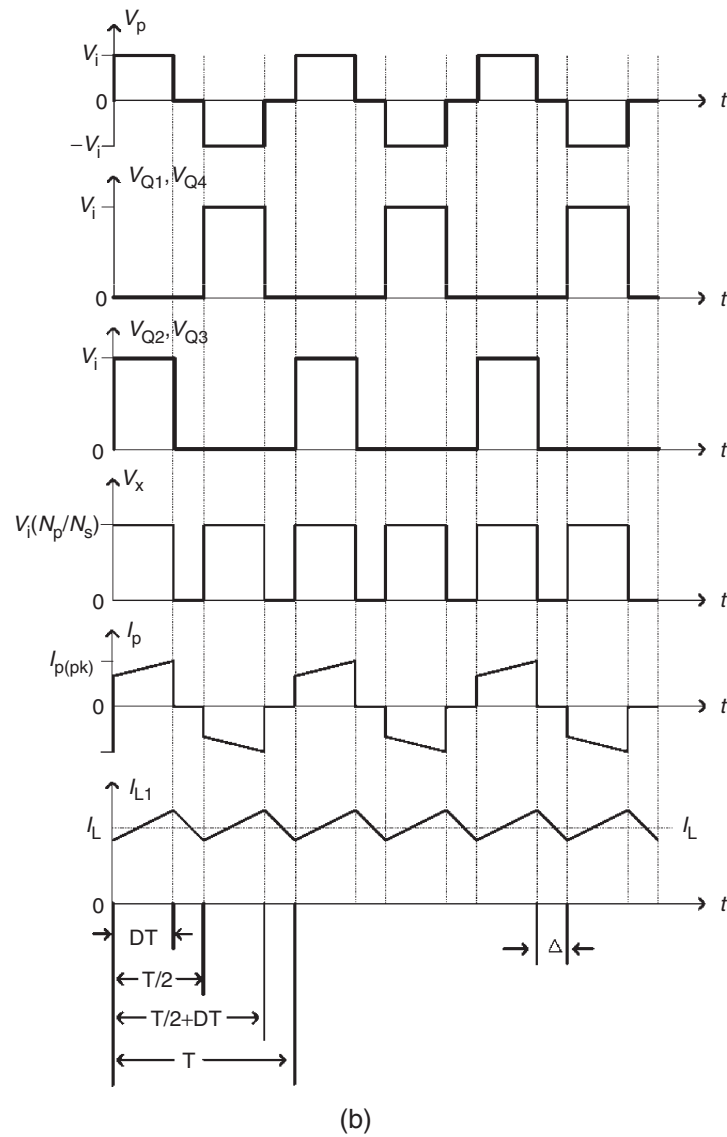
Neglecting diode voltage drops and losses, the voltage across the output inductor is then given by

$$V_{L1} = \frac{N_{s1}}{N_p} V_i - V_o \qquad (23.73)$$

In this interval, the inductor current I_{L1} increases linearly at the rate of

$$
\begin{aligned}
\frac{dI_{L1}}{dt} &= \frac{V_{L1}}{L_1} \\
&= \frac{1}{L_1}\left[\frac{N_{s1}}{N_p} V_i - V_o \right] \qquad (23.74)
\end{aligned}
$$

(a)

(b)


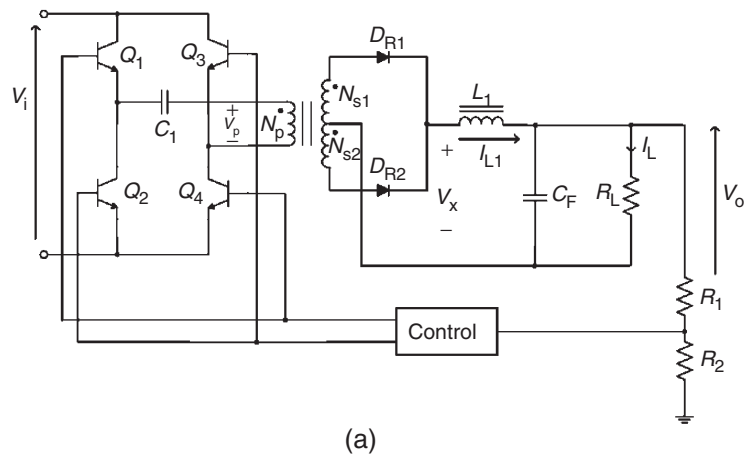


FIGURE 23.27   A simplified full-bridge regulator: (a) circuit and (b) the associated waveforms.

At the end of Q_1 and Q_4 on-time, I_{L1} reaches a value which is given by

$$I_{L1(pk)} = I_{L1}(0) + \frac{1}{L_1}\left[\frac{N_{s1}}{N_p}V_i - V_o\right]DT \qquad (23.75)$$

During the interval Δ, I_{L1} decreases linearly at the rate of

$$\frac{dI_{L1}}{dt} = \frac{V_o}{L_1} \qquad (23.76)$$

The next half cycle repeats with Q_2 and Q_3 on and the circuit operates in a similar manner as in the first half cycle.

Again, as in the half-bridge, the output voltage can be found from the time integral of the inductor voltage over a time equal to T. Thus, we have

$$V_o = 2 \times \frac{1}{T}\left[\int_0^{DT}\left(\frac{N_{s1}}{N_p}V_i - V_o\right)dt + \int_{T/2}^{T/2+DT} -V_o dt\right] \qquad (23.77)$$

Solving Eq. (23.77) for V_o, we have

$$V_o = \frac{N_{s1}}{N_p}2V_i D \qquad (23.78)$$

The output power P_o is given by

$$P_o = \eta P_{in}$$
$$= \eta V_i I_{p(avg)} D \qquad (23.79)$$

or

$$I_{p(avg)} = \frac{P_o}{\eta V_i D} \qquad (23.80)$$

where $I_{p(avg)}$ has the same definition as in the half-bridge case.

Comparing Eq. (23.80) with Eq. (23.69), we see that the output power of a full-bridge is twice that of a half-bridge with same input voltage and current. The maximum collector currents for Q_1, Q_2, Q_3, and Q_4 are given by

$$I_{C(max)} = I_{p(avg)}$$
$$= \frac{P_o}{\eta V_i D_{max}} \qquad (23.81)$$

Comparing Eq. (23.81) with Eq. (23.70), for the same output power, the maximum collector current is only half that of the half-bridge.

As mentioned, the maximum collector voltage for Q_1 and Q_2 at turn off is given by

$$V_{C(max)} = V_{i(max)} \qquad (23.82)$$

The design of the full-bridge is similar to that of the half-bridge. The only difference is the use of four power switches instead of two in the full-bridge. Therefore, additional drivers are required by adding two more secondary windings in the pulse transformer of the driving circuit.

For high power applications ranging from several hundred to thousand kilowatts, the full-bridge regulator is an inevitable choice. It has the most efficient use of magnetic core and semiconductor switches. The full-bridge is complex and therefore expensive to build, and is only justified for high-power applications, typically over 500 W.

23.5.5 Control Circuits and Pulse-width Modulation

In previous subsections, we presented several popular voltage regulators that may be used in a switching mode power supply. This section discusses the control circuits that regulate the output voltage of a switching regulator by constantly adjusting the conduction period t_{on} or duty cycle d of the power switch. Such adjustment is called *pulse-width modulation* (PWM).

The duty cycle is defined as the fraction of the period during which the switch is on, i.e.

$$d = \frac{t_{on}}{T}$$
$$= \frac{t_{on}}{t_{on} + t_{off}} \qquad (23.83)$$

where T is the switching period, i.e. $t_{off} = T - t_{on}$. By adjusting either t_{on} or t_{off}, or both, d can be modulated. Thus, PWM controlled regulators can operate at variable frequency as well as fixed frequency.

Among all types of PWM controllers, the fixed frequency controller is by far the most popular choice. There are two main reasons for their popularity. First, low-cost fixed-frequency PWM IC controllers have been developed by various solid-state device manufacturers, and most of these IC controllers have all the features that are needed to build a PWM switching power supply using a minimum number of components. Second, because of their fixed-frequency nature, fixed-frequency controllers do not have the problem of unpredictable noise spectrum associated with variable frequency controllers. This makes EMI control much easier.

There are two types of fixed-frequency PWM controllers, namely, *the voltage-mode controller* and the *current-mode controller*. In its simplified form, a voltage-mode controller

consists of four main functional components: an adjustable clock for setting the switching frequency, an output voltage error amplifier for detecting deviation of the output from the nominal value, a ramp generator for providing a sawtooth signal that is synchronized to the clock, and a comparator that compares the output error signal with the sawtooth signal. The output of the comparator is the signal that drives the controlled switch. Figure 23.28 shows a simplified PWM voltage-mode controlled forward regulator operating at fixed frequency and its associated driving signal waveform. As shown, the duration of the on-time t_{on} is determined by the time between the reset of the ramp generator and the intersection of the error voltage with the positive-going ramp signal.

The error voltage v_e is given by

$$v_e = \left(1 + \frac{Z_2}{Z_1}\right) V_{REF} - \frac{Z_2}{Z_1} v_2 \qquad (23.84)$$

From Eq. (23.84), the small-signal term can be separated from the dc operating point by

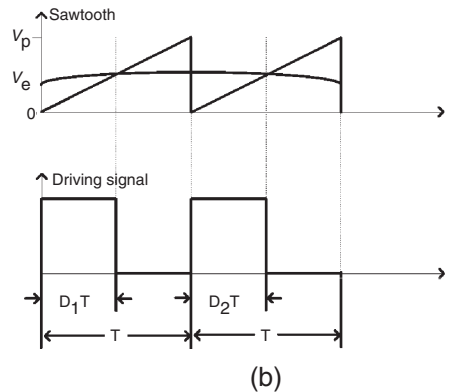
$$\Delta v_e = -\frac{Z_2}{Z_1} \Delta v_2 \qquad (23.85)$$

The dc operating point is given by

$$V_e = \left(1 + \frac{Z_2}{Z_1}\right) V_{REF} - \frac{Z_2}{Z_1} V_2 \qquad (23.86)$$

Inspecting the waveform of the sawtooth and the error voltage shows that the duty cycle is related to the error voltage by

$$d = \frac{v_e}{V_p} \qquad (23.87)$$

where V_p is the peak voltage of the sawtooth.


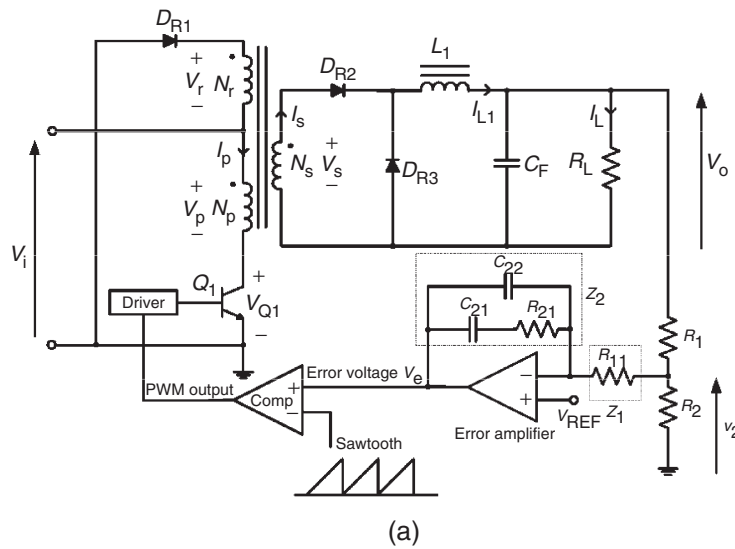


FIGURE 23.28 A simplified voltage-mode controlled forward regulator: (a) circuit and (b) the associated driving signal waveform.

Hence, the small-signal duty cycle is related to the small-signal error voltage by

$$\Delta d = \frac{\Delta v_e}{V_p} \qquad (23.88)$$

The operation of the fixed-frequency voltage-mode controller can be explained as follows. When the output is lower than the nominal dc value, a high error voltage is produced. This means that Δv_e is positive. Hence, Δd is positive. The duty cycle is increased to cause a subsequent increase in output voltage. The feedback dynamics (stability and transient response) is determined by the operational amplifier circuit that consists of Z_1 and Z_2. Some of the popular voltage-mode control ICs are SG1524/25/26/27, TL494/5, and MC34060/63.

The current-mode control makes use of the current information in a regulator to achieve output voltage regulation. In its simplest form, current-mode control consists of an inner loop that samples the inductance current value and turns the switches off as soon as the current reaches a certain value set by the outer voltage loop. In this way, the current-mode control achieves faster response than the voltage mode. There are two types of fixed-frequency PWM current-mode control, namely, the *peak current-mode control* and the *average current-mode control*.

In the peak current-mode control, no sawtooth generator is needed. In fact, the inductance current waveform is itself a sawtooth. The voltage analog of the current may be provided by a small resistance, or by a current transformer. Also, in practice, the switch current is used since only the positive-going portion of the inductance current waveform is required. Figure 23.29 shows a peak current-mode controlled flyback regulator.

In Fig. 23.29, the regulator operates at fixed frequency. Turn on is synchronized with the clock pulse, and turn off is determined by the instant at which the input current equals the error voltage V_e.

Because of its inherent peak current-limiting capability, the peak current-mode control can enhance reliability of power switches. The dynamic performance is improved because of the use of the additional current information. One main disadvantage of the peak current-mode control is that it is extremely susceptible to noise, since the current ramp is usually small compared to the reference signal. A second disadvantage is its inherent instability property at duty cycle exceeding 50%, which results in sub-harmonic oscillation. Typically, a compensating ramp is required at the comparator input to eliminate this instability. The third disadvantage is that it has a non-ideal loop response because of the use of the peak, instead of the average current sensing.

Figure 23.30 shows an average current-mode controlled flyback regulator. In the circuit, a PWM modulator (instead

(a)

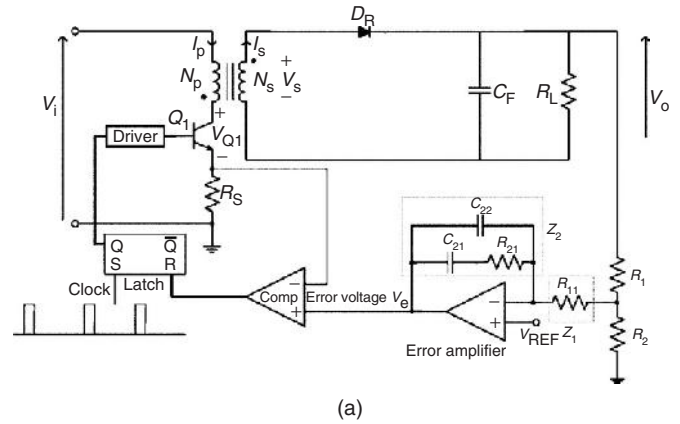
(b)


FIGURE 23.29 A simplified peak current-mode controlled flyback regulator: (a) circuit and (b) the associated waveforms.

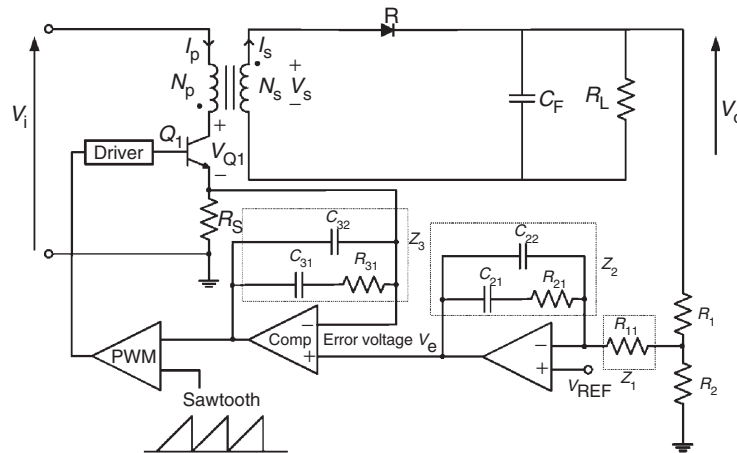
of a clocked SR latch in the peak current-mode control) is employed to compare the current error to an externally generated sawtooth signal to formulate the desired control signal. The main advantages of this method over the peak current-control are that it has excellent noise immunity property; it is stable at duty cycle exceeding 50%; and it provides good tracking of average current. However, since there are three compensation networks (Z_1, Z_2, and Z_3), the analysis


FIGURE 23.30 A simplified average current-mode controlled flyback regulator: (a) circuit and (b) the associated waveforms.

and optimal design of these networks are non-trivial. This is a major obstacle for adopting the average current mode control.

It should be noted that current-mode control is particularly effective for the flyback and boost-type regulators that have an inherent right-half-plane zero. Current-mode control effectively reduces the system to first-order by forcing the inductor current to be related to the output voltage, thus achieving faster response. In the case of the buck-type regulator, current-mode control presents no significant advantage because the current information can be derived from the output voltage, and hence faster response can still be achieved with a proper feedback network. Some of the popular current-mode control ICs are UC3840/2, UC3825, MC34129, and MC34065.

Wisconsin-Milwaukee, 3200
North Cramer Street, Milwaukee
Wisconsin, USA*

24.1 Introduction

Power distortions such as power interruptions, voltage sags and swells, voltage spikes, and voltage harmonics can cause severe impacts on sensitive loads in the electrical systems. Uninterruptible power supply (UPS) systems are used to provide uninterrupted, reliable, and high quality power for these sensitive loads. Applications of UPS systems include medical facilities, life supporting systems, data storage and computer systems, emergency equipment, telecommunications, industrial processing, and on-line management systems [1–3]. The UPS systems are especially required in places where power outages and fluctuations occur frequently. A UPS provides a backup power circuitry to supply vital systems when a power outage occurs. In situations where short time power fluctuations or disturbed voltage occur, a UPS provides constant power to keep the important loads running. During extended power failures, a UPS provides backup power to keep the systems running long enough so that they can be gracefully powered down.

Most of the UPS systems also suppress line transients and harmonic disturbances. Generally, an ideal UPS should be able to simultaneously deliver uninterrupted power and provide the necessary power conditioning for the particular power application. Therefore, an ideal UPS should have the following features: regulated sinusoidal output voltage with low total harmonic distortion (THD) independent from the changes in the input voltage or in the load, on-line operation that means zero

transition time from normal to back-up mode and vice versa, low THD sinusoidal input current and unity power factor, high reliability, high efficiency, low EMI and acoustic noise, electric isolation, low maintenance, low cost, weight, and size. Obviously, there is not a single configuration that can provide all of these features. Different configurations of UPS systems emphasize on some of the features mentioned above. Classifications of UPS systems are described in Section 24.2.

24.2 Classifications

24.2.1 Standby UPS

This configuration of UPS system is also known as "off-line UPS" or "line-preferred UPS" [4, 5]. Figure 24.1 shows the configuration of a typical standby UPS system. It consists of an AC/DC converter, a battery bank, a DC/AC inverter, and a static switch. A passive low pass filter may also be used at the output of the UPS or inverter to remove the switching frequency from the output voltage. The static switch is on during the normal mode of operation. Therefore, load is supplied from the AC line directly without any power conditioning. At the same time, the AC/DC rectifier charges the battery set. This converter is rated at a much lower power rating than the power demand of the load. When a power outage occurs or the primary power is out of a given preset tolerance, the static switch is opened and the DC/AC inverter provides power to
FIGURE 24.1 Configuration of a typical standby UPS system.

tion of the load from the AC line, no output voltage regulation, long switching time, poor performance with non-linear loads, and no line conditioning are the main disadvantages of this configuration.

Different configurations of AC/DC rectifiers such as linear or switching may be used in this system. To reduce the cost, a simple diode-bridge rectifier with a capacitor at the front end is used. A full-bridge or half-bridge full controlled converter is also used to charge the battery bank. Two typical topologies for a single-phase UPS system are shown in Fig. 24.2. The full controlled topologies can provide power factor correction (PFC) to meet the corresponding standards. To optimize the charging process, the charging cycle is divided into "constant current" and "constant voltage" modes. In the constant current mode, the converter injects a constant current into the battery till the battery is charged up to about 95% of its capacity. After this mode, the constant voltage mode starts that applies a constant voltage on the battery. In this mode, the input current of the battery declines exponentially until it is fully charged.

the load from the battery set for the duration of the preset backup time or till the AC line is back again. This inverter is rated at 100% of the load power demand. It is connected in parallel to the load and stays standby during the normal mode of operation. The transition time from the AC line to DC/AC inverter is usually about one quarter of the line cycle, which is enough for most of the applications such as personal computers. The main advantages of this topology are simple design, low cost, and small size. On the other hand, lack of real isola-

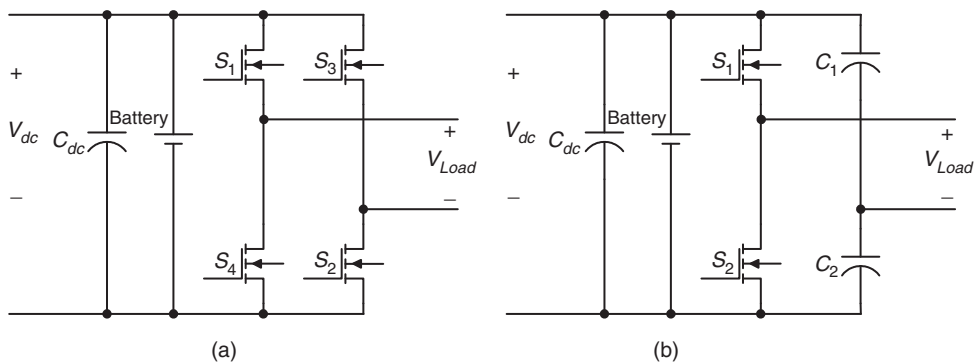
The purpose of the DC/AC inverter is to provide high quality AC power to the load when the static switch is opened. A full- or half-bridge topology is used for this inverter. Figure 24.3 shows two simple single-phase topologies for the DC/AC inverter.
FIGURE 24.2 Two simple topologies of AC/DC rectifier: (a) full-bridge diode rectifier and (b) full-bridge full controlled topology.


FIGURE 24.3 Two simple single-phase topologies for the DC/AC inverter: (a) full-bridge and (b) half-bridge.
FIGURE 24.4   Typical configuration of ferroresonant standby UPS system.

In some topologies of standby UPS systems, an isolating transformer is used at the output stage of the UPS. This topology is called ferroresonant standby UPS system. The transformer also acts as a low pass filter that cancels out switching frequency from the output voltage of the DC/AC inverter. On the other hand, the transformer stores electromagnetic energy in the core and acts as a buffer when a power outage occurs. For a short time, the transformer provides power to the load and protects sensitive equipment from being affected during the transfer time from the input AC to the UPS. Figure 24.4 shows the configuration of a ferroresonant standby UPS system. Since the transformer is bulky and expensive, this configuration is more appropriate for high power applications.

24.2.2 On-line UPS System

Similar to standby UPS systems, on-line UPS systems also consist of a rectifier/charger, a battery set, an inverter, and a static switch (bypass). Other names for this configuration are "true UPS," "inverter preferred UPS," and "double-conversion UPS" [6, 7]. Figure 24.5 shows the block diagram of a typical on-line UPS. The rectifier/charger continuously supplies power to the DC bus. The power rating of this converter must be designed appropriately to supply power to the load and charge the battery bank at the same time. The batteries are rated in order to supply full power to the load during the backup time. The duration of this time varies in different applications. The inverter is rated at 100% of the load power since it must supply the load during the normal mode of operation as well as during the backup time. It is connected in series with the load; hence, there is no transfer time associated with the transition from normal mode to stored energy mode. This is the main advantage of on-line UPS systems. The static switch provides redundancy of the power source in the case of UPS malfunction or overloading. The AC line and load voltages must be in phase in order to use the static switch. This can be achieved easily by a phase-locked loop control. During the normal mode of operation, the power to the load is continuously supplied via the rectifier/charger and inverter. In fact, a double conversion from AC to DC and then from DC to AC takes place. This configuration of the UPS allows good power conditioning. The AC/DC converter charges the battery set and also supplies power to the load via the inverter. Therefore, it has the highest power rating in this topology, thereby increasing
FIGURE 24.5   Block diagram of an on-line UPS system.
FIGURE 24.6 Configuration of a three-phase on-line UPS system.

the cost. When the AC input voltage is outside the preset tolerance, the inverter and battery maintain continuity of power to the load. The duration of this mode is the duration of preset UPS backup time or till the AC line returns within the preset tolerance.

The main advantages of on-line UPS are very wide tolerance to the input voltage variation and very precise regulations of output voltage. In addition, there is no transfer time during the transition from normal to stored energy modes. It is also possible to regulate or change the output frequency [8]. The main disadvantages of this topology are low power factor, high THD at the input, and low efficiency. The input current is distorted by the rectifier unless an extra PFC circuit is added; but, this adds to the cost of the UPS system [9].

As mentioned for the standby UPS system, different topologies are employed for the AC/DC rectifier and DC/AC inverter. Unlike standby UPS system, in this system, these converters provide power to the load continuously. Therefore, more care should be given to the quality of the input current and output voltage as well as the efficiency of the system. Figure 24.6 shows the configuration of a three-phase on-line UPS system. The proper switching method such as PWM is employed for the AC/DC rectifier to minimize the input current harmonics and provide regulated DC bus voltage. A low pass filter at the output of the system removes the switching frequency from the output voltage.

24.2.3 Line-interactive UPS

Line-interactive UPS systems consist of a static switch, a series inductor, a bi-directional converter, and a battery bank. An optional passive filter can be added at the output of the bi-directional converter or at the input side of the load. A line-interactive UPS can operate either as an on-line UPS or as an off-line UPS. For an off-line line-interactive UPS, the series inductor is not required. However, most of the line-interactive UPS systems operate on-line in order to either improve the

power factor of the load or regulate the output voltage for the load. When the AC line is within the preset tolerance, it feeds the load directly. The AC/DC converter is connected in parallel with the load and charges the battery. This converter may also be used to improve the power factor of the system and compensate the load current harmonics. [10, 11]. Typical configuration of a line-interactive UPS is shown in Fig. 24.7.

When a power outage occurs or input voltage falls outside the preset tolerance, the system goes to bypass mode. In this mode, the bi-directional converter operates as a DC/AC inverter and supplies power to the load from the battery set. The static switch disconnects the AC line in order to prevent back feed from the inverter. The main advantages of the line-interactive UPS systems are simple design and, as a result, high reliability and lower cost compared to the on-line UPS systems. They also have good harmonic suppression for the input current. Since this is a single stage conversion topology, the efficiency is higher than on-line UPS system. The main disadvantage is the lack of effective isolation of the load from the AC line. Employing a transformer in the output can eliminate this; but, it will add to the cost, size, and weight of the UPS system. Furthermore, the output voltage conditioning is not good because the inverter is not connected in series with the load. In addition, since the AC line supplies the load directly during the normal mode of operation, there is no possibility for regulation of the output frequency.

24.2.4 Universal UPS

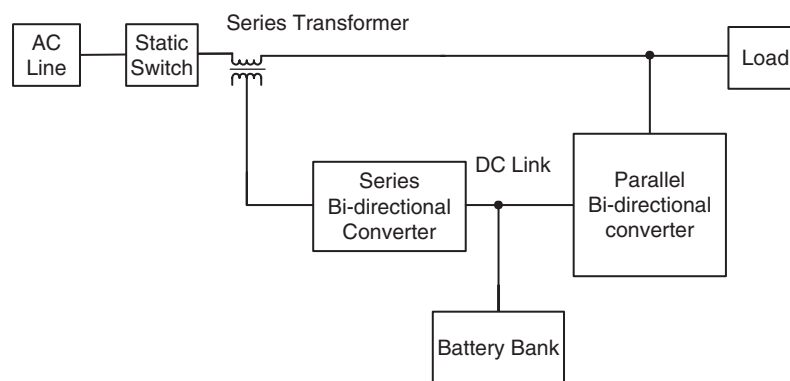
This type of UPS is also called "series-parallel" or "delta conversion." Its topology is derived from unified power quality conditioner (UPQC) topology and combines the advantages of both on-line and line-interactive UPS systems [12, 13]. It can achieve unity power factor, precise regulation of the output voltage, and high efficiency simultaneously. Its configuration is shown in Fig. 24.8. It consists of two bi-directional converters connected to a common battery set, static switch, and
FIGURE 24.7   A typical configuration of a line-interactive UPS system.


FIGURE 24.8   Block diagram of a universal UPS system.

a series transformer. The series bi-directional converter is rated at about 20% of the output power of the UPS system and it is connected via a transformer in series with the AC line. The second bi-directional converter is the usual inverter for a line-interactive UPS connected in parallel to the load and rated at 100% of the output power.

When the input voltage is in the acceptable range, the system is in the bypass mode. In this mode, parallel converter deals with current-based distortions. It mitigates load current harmonics and improves input power factor. At the same time, it charges the battery pack. Series converter deals with voltage-based distortions. It cancels input voltage harmonics and compensates voltage sags and swells. Most of the power is supplied directly from the AC line to the load. Only a small percentage of the input power is absorbed by parallel converter. This power is used to compensate the differences between input and reference voltages and to charge the battery pack. On the other hand, when the input voltage shuts down, the static switch separates the source and the load and the system goes to backup mode. In this situation, the parallel inverter acts as a DC/AC inverter and supplies power to the load. Since a large portion of the power flows without any conversion from

the AC line to the load, the efficiency is higher than that of an on-line UPS system. Having eliminated the main drawback of double-conversion UPS systems, the universal UPS topology appears to be a strong competitor of on-line UPS systems in many applications. Figure 24.9 shows the topology of a three-phase universal UPS system.

24.2.5 Rotary UPS

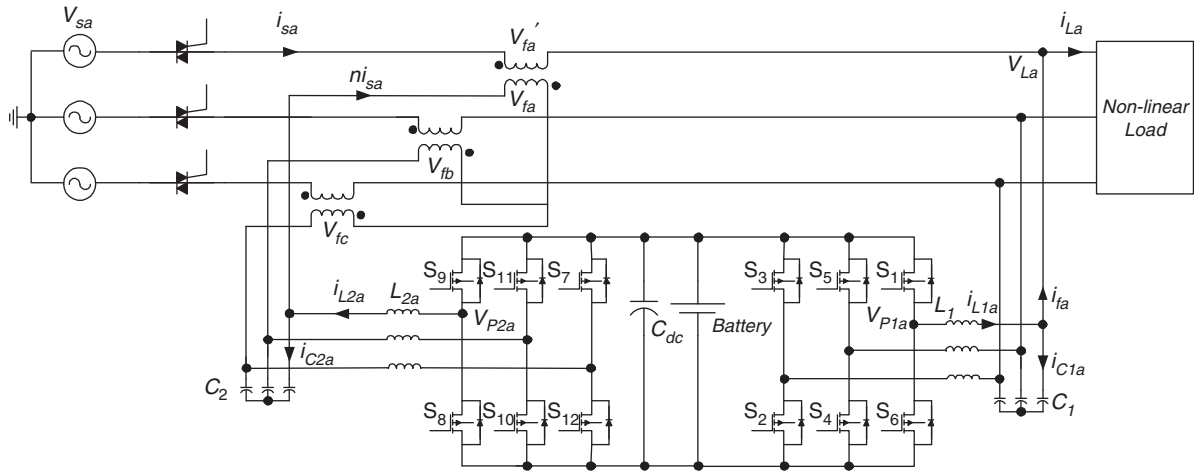
Rotary UPS systems use the stored kinetic energy in the electrical machines to provide power to the load when a power outage occurs. There are different configurations for rotary UPS systems. The simplest topology consists of an AC motor and an AC generator, which are mechanically coupled. A flywheel is also used on the shaft of the machines to store more kinetic energy in the system. In normal operation, the input AC line provides power to the AC motor and this AC motor drives the AC generator. The configuration of this system is shown in Fig. 24.10a. In backup mode, the kinetic energy stored in the motor, flywheel, and generator is converted to electric power and supplies the load. This simple topology is designed to provide short time backup power to the


FIGURE 24.9   A universal UPS topology based on two three-leg bi-directional converters.
FIGURE 24.10   Different configuration of rotary UPS systems: (a) motor–generator set; (b) rotary UPS with battery backup; and (c) rotary UPS with standby diesel/natural gas engine.

load (typically less than 2 s) in case of power interruption. In another configuration of rotary UPS system which is shown in Fig. 24.10b, an AC motor, a DC machine, an AC generator, and a battery bank are used. During the normal mode of operation, the AC line supplies the AC motor, which drives the DC machine. The DC machine drives the AC generator, which supplies the load. During the backup mode of operation, the battery bank supplies the DC machine, which, in turn, drives the AC generator and the AC generator supplies the load. This system can provide long time backup power to

the load depending on the capacity of the battery set. These two rotary UPS systems are much more reliable than the static UPS systems and provide complete electrical isolation between the load and input AC line. Yet, they require more maintenance and have much bigger size and weight. Therefore, they are usually used for high power applications [14, 15]. The configuration of a standby rotary UPS system is shown in Fig. 24.10c. This system does not provide electrical isolation between the load and input AC. There is also a transition delay for switching from main AC to backup AC generator. However, it can provide power to the load as long as needed.

24.2.6 Hybrid Static/Rotary UPS

Hybrid static/rotary UPS systems combine the main features of both static and rotary UPS systems. They have low output impedance, high reliability, excellent frequency stability, and low maintenance requirements [6]. Typical configurations of hybrid static/rotary UPS are depicted in Fig. 24.11. They are usually used in high power applications. In the system shown in Fig. 24.11a, during normal operation, the input AC power feeds the AC motor. The power is provided to the load from the AC generator, which is driven by the AC motor. In
FIGURE 24.11   Three configurations of hybrid rotary-static UPS systems: (a) motor–generator set with battery backup; (b) motor–generator set with power conditioning at input side; and (c) battery-less hybrid UPS system.

case of low input power quality or power interruption, the bidirectional AC/DC converter acts as an inverter and feeds the AC motor from battery pack. Configuration of a hybrid UPS system with power conditioning at the input is shown in Fig. 24.11b. Figure 24.11c shows the configuration of a more complicated hybrid UPS system. This system has three operation modes. In normal operation, the load is directly supplied by the main AC input and the AC motor is rotated at no-load. In the case of short power interruption, main breaker and generator breaker are opened and the inverter breaker is closed. The DC/AC inverter provides power to the load from the kinetic energy stored in the AC machine. If power is not restored in the short-term, the diesel engine is turned on, which provides power to the load through the AC generator. In this mode, the main breaker and inverter breaker remain open. One of the advantages of this topology is operation without a battery set to minimize cost, space, and required maintenance. The second advantage is avoiding double power conversion in long-term power interruption.

24.2.7 Comparison of UPS Configurations

Table 24.1 below provides the comparison between characteristics of different types of UPS systems.

24.3 Performance Evaluation

There are four criteria for evaluating the performance of a UPS system: quality of output voltage, input PFC and current harmonic cancellation, transition time, and efficiency. The quality of output voltage is the most important factor. The output voltage of a UPS system should be sinusoidal with low THD in different loading conditions even with non-linear loads. The control system should have small transient responses to provide appropriate line conditioning in different loading profiles. Typically, rotary UPS systems, which employ an AC generator at the load side, have better output voltage quality than static UPS systems. In these systems, there is no converter switching frequency present at the output voltage. Among the static

UPS systems, on-line UPS configuration provides better output voltage quality. In this system, output voltage is provided by a DC/AC inverter regardless of input voltage quality. Usually, a pulse width modulation (PWM) method is used to regulate the output voltage. This kind of UPS should be designed to have minimum switching frequency at the output and provide pure sinusoidal voltage at different loading conditions. Followed by on-line UPS system are universal and line-interactive configurations. In universal topology, during normal mode of operation, the series converter provides voltage conditioning and regulates output voltage. In the backup mode, the parallel converter provides the load with sinusoidal voltage. In the line-interactive topology, during normal operation mode, input voltage directly supplies the load and no voltage conditioning is provided. In the backup mode, the DC/AC inverter provides the load with sinusoidal voltage.

The second criterion is transition time from normal mode of operation to stored energy mode. On-line rotary and static UPS systems have superior performance in this regard. The output voltage is always provided by the output generator or output DC/AC inverter and there is no transition time between operation modes of the systems. However, some of the rotary and hybrid configurations shown in Figs. 24.10 and 24.11 can only provide power to the load for a limited time. This time is determined by the amount of kinetic energy stored in the mechanical system. The transfer time in universal and line-interactive topologies depends on the time necessary for converting the power flow from the battery bank through the inverter to the load. Improved performance is achieved by choosing the DC bus capacitor voltage at the battery side to be slightly higher than the floating voltage of the batteries. Therefore, when the AC line fails, it is not necessary to sense the failure because the DC bus voltage will immediately fall under the floating voltage of the batteries and the power flow will naturally turn to the load. For off-line UPS systems, the transfer time is the longest. It depends upon the speed of sensing the failure of the AC line and starting the inverter.

The next important factor is the input power factor and the ability of the system to provide conditioning for load power. Universal UPS system has better performance followed

TABLE 24.1 Performance comparison of different configurations of UPS systems

Parameter	On-line	Line interactive	Off-line	Universal	Rotary	Hybrid
Surge protection	Excellent	Good	Good	Good	Excellent	Excellent
Transition time	Excellent	Good	Poor	Good	Excellent	Excellent
Line conditioning	Poor	Good	Poor	Excellent	Good	Good
Backup duration	Depends on battery	Depends on battery	Depends on battery	Depends on battery	Typically 0.1–0.5 s	Depends on battery
Efficiency	Low around 80%	High up to 95%	High	High up to 95%	High typically above 85%	High typically around 95%
Input/Output isolation	Poor	Poor	Poor	Poor	Perfect	Perfect
Cost	High	Medium-high	Low	High	Very high	Very high

by line-interactive and on-line UPS in this regard. During normal mode of operation, the parallel converter acts as an active filter and compensates reactive current and current harmonics generated by the load. In the line-interactive system, the bi-directional AC/DC converter performs this task. In an on-line UPS system, an additional system must be added to improve PFC and mitigate current harmonics.

The last criterion for performance evaluation is efficiency. To emphasize this factor, it should be noted that losses in UPS systems represent about 5–12% of all the energy consumed in data centers. Efficiency in rotary and hybrid configurations depends on the topology of the system but typically for low power application due to mechanical loss in the motor and generator, the efficiency is not very high. Among the static UPS systems, on-line UPS system has the poorest efficiency due to double conversion. Line-interactive and universal topologies provide higher efficiencies since most of the power directly flows from the input AC to the load during normal operation.

24.4 Applications

The UPS systems have wide applications in a variety of industries. Their common applications range from small power rating for personal computer systems to medium power rating for medical facilities, life supporting systems, data storage, and emergency equipment and high power rating for telecommunications, industrial processing, and on-line management systems. Different considerations should be taken into account for these applications. For emergency systems and lighting, the UPS should support the system for at least 90 minutes. Except for emergency systems, the UPS is designed to provide backup power to sensitive loads for 15–20 minutes. After this time, if the power is not restored, the system will be gracefully shut down. If a longer backup period is considered, a larger battery with higher cost and space is required. For process equipment and high power applications, some UPS systems are designed to provide enough time for the secondary power sources such as diesel generators to start up.

For industrial applications, it should be noted that UPS systems add to the complexity of the electrical system. They also add installation and ongoing maintenance costs. They may also add non-linearity to the system, decrease the efficiency, and deteriorate the input PFC mechanism. The power rating of the UPS should be appropriately selected considering the existing load and future extensions. For many applications, input voltage surges and spikes cause more damage than power outages. For these systems, another device instead of UPS can be utilized. Load characteristics should also be considered in UPS selection. For motor loads, the inrush current, which is sometimes 2.5 times of the rated current, should be considered. A good UPS for the motor loads is the one with higher transient overloads. For non-linear loads such as switching power supplies, the input current is not sinusoidal. Therefore, the instantaneous current is higher than the RMS current. This high instantaneous current should be considered in UPS selection.

For a power distribution network, two different approaches are taken to support sensitive loads. In a distributed approach, which is more suitable for highly proliferated loads such as medical equipment, data processing, and telecommunications many separate UPS units operate in parallel to supply critical loads. UPS units are placed flexibly in the system to form a critical load network. A typical on-line distributed UPS system is shown in Fig. 24.12. High flexibility and redundancy are the main advantages of distributed systems. Individual load increase can be supported by adding more UPS systems. Consideration for future extension can also be delayed until the loads are added. On the other side, this method has some disadvantages. The load sharing between different UPS units is a difficult task. Complicated digital control methods and communication between units are required to perform optimal load sharing. The second disadvantage is that the monitoring of the whole system is difficult and requires specially trained staff.

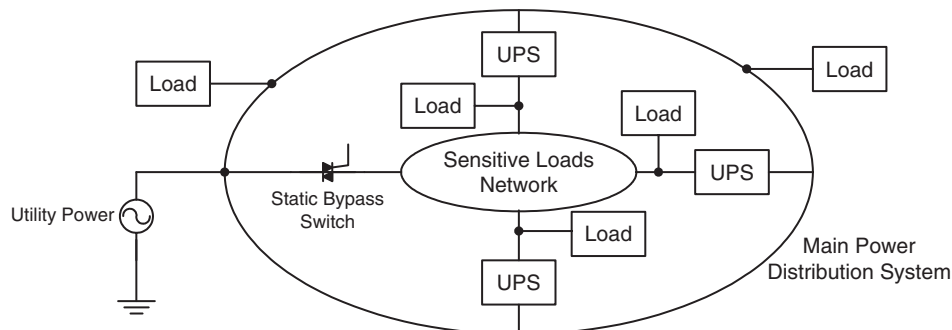
The other method to support distributed loads is to use a large UPS unit to supply all the critical loads in a centralized approach. This approach is more desirable for industrial and


FIGURE 24.12 Typical configuration of a distributed UPS network.

utility applications. The advantage of this method is easier maintenance and troubleshooting. The disadvantages on the other side are lack of redundancy and high installation cost. In addition, consideration for system expansion should be taken into account when the original UPS unit is selected.

24.5 Control Techniques

The main task of the control system in a UPS unit is to minimize the output voltage total harmonic distortion in different loading profiles. In addition, it should provide the proper mechanism to recharge the battery set and maintain high input power factor and low total input current harmonic distortion. Other factors considered for a good control technique are nearly zero steady-state inverter output voltage error, good voltage regulation, robustness, fast transient response, and protection of the inverter against overload under linear/non-linear loads.

The most common switching technique is Sinusoidal PWM. This method can be utilized for both single-phase and three-phase systems. The advantage of this method is low output voltage harmonic and robustness. This strategy uses a single feedback loop to provide well-regulated output voltage with low THD. The feedback control can be continuous or discontinuous. Analog techniques are used in continuous approach. The sinusoidal PWM (SPWM) can be of natural sampling type, average type, or instantaneous type [17, 18].

In natural sampling type, the peak value of the output voltage is detected and compared with a reference voltage in order to obtain the error, which is used to control the reference to the modulator. The average approach is basically the same; but, the sensed voltage is converted to an average value and after that, is compared with a reference signal. These approaches control only the amplitude of the output voltage and are good only at high frequencies. In an instantaneous voltage feedback SPWM control, the output voltage is continuously compared with the reference signal improving the dynamic performance of the UPS inverter.

A typical block diagram of a three-phase DC/AC inverter for UPS systems and SPWM switching control technique is shown in Fig. 24.13. The disadvantage of this method is lack of flexibility for non-linear loads. Other programmed PWM techniques such as selective harmonic elimination, minimum THD, minimum loss, minimum current ripple, and reduced acoustic noise may be used for the inverter.

Better performance even with non-linear and step-changing loads can be achieved by multiple control loop strategies [19]. As shown in Fig. 24.14, there are two control loops: an outer and an inner. The outer control loop uses the output voltage as a feedback signal, which is compared with a reference signal. The error is compensated by a PI-integrator to achieve stable output voltage under steady-state operation. This error is also used as a reference signal for the inner current regulator loop, which uses the inductor or the capacitor output filter current as the feedback signal. The minor current loop

(a)

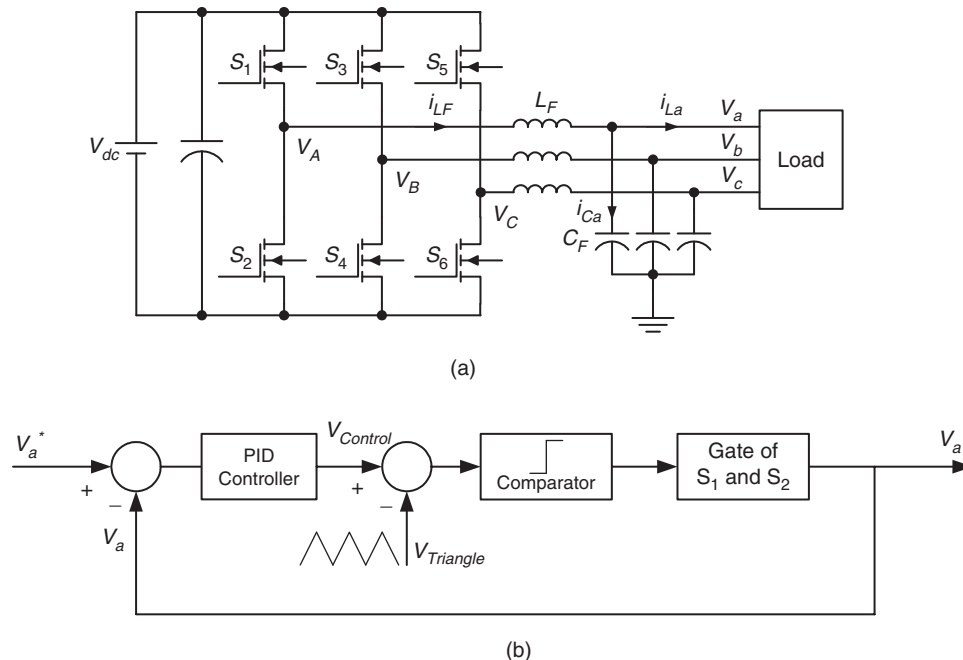
(b)


FIGURE 24.13 (a) Configuration of a three-phase DC/AC inverter for UPS systems and (b) simple voltage controller using PWM technique.
FIGURE 24.14 Typical current and voltage control loops for UPS inverter.

ensures fast dynamic responses enabling good performance with non-linear or step-changing loads. The basic current regulators employed as minor current loop are: hysteresis regulators, sinusoidal PWM regulator, and predictive regulators. In a typical hysteresis regulator, the reference signal is compared with the feedback signal. The sign and predetermined amplitude of the error determine the output of the modulator. The duration between two successive levels is determined by the slope of the reference signal. The output voltage tracks the reference signal within the upper and lower boundary levels. This hysteresis control has fast transient response; but, the switching frequency varies widely [20].

In SPWM control technique, the output voltage feedback is compared with a sine reference signal and the error voltage is compensated by a PI-regulator to produce the current reference. The current through the inductor or the capacitor is sensed and compared with the reference signal. After being compensated by a PI-regulator, the error signal is compared with a triangular waveform to generate SPWM signal for switching control. The SPWM current control has a constant switching frequency and also provides fast dynamic responses. In predictive current control method, the switching instants are determined by suitable error boundaries. When the current vector touches the boundary line, the next switching state vector is determined by prediction and optimization in order to minimize the error. Predictive current control requires a good knowledge of the load parameters. All these current regulators are typically used as an inner loop to regulate the current in the filter inductor. The current reference for the current regulator is obtained by summing together the error in an outer voltage loop with the actual load current to yield the rated output voltage.

With the increase of speed and reliability of digital processors and a decrease in their cost, digital processors have been facing an enormous growth of popularity in control applications in the past few years. Many digital and discrete control techniques such as dead-beat control [21], dissipativity-based control [22], sliding-mode control [23], space vector-based control [24], and multiple-feedback loop [25] have been developed using digital signal processors (DSP).

In this section, fundamental analysis of a dead-beat control method is explained for the three-phase UPS configuration

shown in Fig. 24.13a. The state space equations of one phase of this system in the continuous time-domain are as follows.

$$C_F \frac{dV_a}{dt} = i_{LF} - i_{La} \tag{24.1}$$

$$L_F \frac{di_{LF}}{dt} = V_A - V_a \tag{24.2}$$

Considering V_a and i_{LF} as state variables, the state space equation of the system is as follows:

$$\begin{bmatrix} V_a \\ i_{LF} \end{bmatrix}^{\bullet} = \begin{bmatrix} 0 & 1/C_F \\ -1/L_F & 0 \end{bmatrix} \begin{bmatrix} V_a \\ i_{LF} \end{bmatrix} + \begin{bmatrix} 0 \\ 1/L_F \end{bmatrix} V_A + \begin{bmatrix} -1/C_F \\ 0 \end{bmatrix} i_{La} \tag{24.3}$$

These continuous time-domain state space equations are converted to the discontinuous time domain with a sampling period of T_s [26].

$$\begin{bmatrix} V_a(k+1) \\ i_{LF}(k+1) \end{bmatrix} = \begin{bmatrix} \cos \omega_0 T_s & \dfrac{\sin \omega_0 T_s}{\omega_0 C_F} \\ -\dfrac{\sin \omega_0 T_s}{\omega_0 L_F} & \cos \omega_0 T_s \end{bmatrix} \begin{bmatrix} V_a(k) \\ i_{LF}(k) \end{bmatrix}$$
$$+ \begin{bmatrix} 1 - \cos \omega_0 T_s \\ \dfrac{1}{\omega_{02} L_F} \sin \omega_0 T_s \end{bmatrix} V_A(k)$$
$$+ \begin{bmatrix} -\dfrac{1}{\omega_0 C_F} \sin \omega_0 T_s \\ 1 - \cos \omega_0 T_s \end{bmatrix} i_{La}(k) \tag{24.4}$$

Where ω_0 is the angular resonance frequency of L_F and C_F. The sampling frequency of the system is always considered much higher than the resonance frequency of L_F and C_F. With this assumption, Eq. (24.4) is simplified to Eq. (24.5). This conversion is valid for almost $f_s \geq 20f_0$.

$$\begin{bmatrix} V_a(k+1) \\ i_{LF}(k+1) \end{bmatrix} = \begin{bmatrix} 1 & T_s/C_F \\ -T_s/L_F & 1 \end{bmatrix} \begin{bmatrix} V_a(k) \\ i_{LF}(k) \end{bmatrix}$$
$$+ \begin{bmatrix} 0 \\ T_s/L_F \end{bmatrix} V_A(k) + \begin{bmatrix} -T_s/C_F \\ 0 \end{bmatrix} i_{La}(k) \tag{24.5}$$

The current equation according to Eq. (24.5) is given by:

$$i_{LF}(k+1) = i_{LF}(k) + \frac{T_s}{L_F}[V_A(k) - V_a(k)] \qquad (24.6)$$

Alternatively, this equation can be achieved by converting Eq. (24.2) from a differential equation to a difference equation. The same suggestion of $f_s \geq 20f_0$ has to be made for this conversion as well. If V_a and i_{LF}^* are considered constant over the next switching period, the output voltage of the inverter, which corrects the error of i_{LF} after two sampling periods, is described by:

$$V_A(k+1) = V_a(k+1) + \frac{L_F}{T_s}[i_{LF}^*(k+1) - i_{LF}(k+1)] \qquad (24.7)$$

A linear estimation of $V_a(k+1)$ can be achieved from previous values:

$$V_a(k+1) = V_a(k) + [V_a(k) - V_a(k-1)] = 2V_a(k) - V_a(k-1) \qquad (24.8)$$

By substituting Eqs. (24.8) and (24.10) in Eq. (24.9) and updating reference current for i_{LF} in every two sampling periods, the dead-beat digital control for series converter is described by:

$$V_A(k+1) = \frac{L_F}{T_s}[i_{LF}^*(k) - i_{LF}(k)] - V_A(k) + 3V_a(k) - V_a(k-1) \qquad (24.9)$$

Equation (24.9) ensures that the current error between i_{LF} and i_{LF}^* at time $k+2$ goes to zero with a delay of two sampling periods. Avoiding interaction between voltage and current control loops, load voltage, V_a, is sampled at half of the current sampling frequency. The voltage equation according to Eq. (24.5) is as follows.

$$V_a(k+1) = V_a(k) + \frac{T_s}{C_F}i_{CF}(k) \qquad (24.10)$$

$$V_a(k+2) = V_a(k+1) + \frac{T_s}{C_F}i_{CF}(k+1)$$

$$= V_a(k) + \frac{T_s}{C_F}i_{CF}(k) + \frac{T_s}{C_F}i_{CF}(k+1) \qquad (24.11)$$

As current control is suggested to be dead-beat with a delay of two sampling periods, capacitor current at time k and $(k+1)$ are given by:

$$i_{CF}(k) = i_{CF}^*(k-2), i_{CF}(k+1) = i_{CF}^*(k-1) \qquad (24.12)$$

Substituting Eq. (24.12) in Eq. (24.11) and updating the reference current at each of the two sampling periods, $V_a(k+2)$ is given by:

$$V_a(k+2) = V_a(k) + \frac{2T_s}{C_F}i_{CF}^*(k-2) \qquad (24.13)$$

The current of i_{CF}^* at time k which corrects the voltage error of V_a at time $k+4$ is as follows.

$$i_{CF}^*(k) = \frac{C_F}{2T_s}[V_a^*(k) - V_a(k)] - i_{CF}^*(k-2) \qquad (24.14)$$

A block diagram of the implementation of voltage and current control of the inverter is shown in Fig. 24.15. Block diagram of the current and voltage controller for the inverter is also shown in Fig. 24.16. Voltage regulator is a pure dead-beat controller with a delay of two sampling periods including the consumed time for calculation. G_1 is the time delay needed for calculations and analog to digital conversions. G_2 is the time delay caused by the PWM inverter and G_3 is the transfer function of the low pass filter. Current regulator is also considered as a pure delay. The output voltage of the inverter follows its reference with four sampling periods of delay. In practice, the dynamics of the current regulator is not a pure delay and shows some deviation from the dead-beat controller.

24.6 Energy Storage Devices

In this section, three dominant energy storage devices for the existing and future UPS systems are described. These energy storage devices are battery, flywheel, and fuel cell.

24.6.1 Battery

Battery is the energy storage component of current static UPS systems. It determines the capacity and run-time of the UPS.
FIGURE 24.15 Implementation of the current and voltage control for the inverter shown in Figure 24.13a.
FIGURE 24.16   Block diagram of the current and voltage controller for the inverter shown in Figure 24.13a.

For small units, it is the size of battery that determines the size of the UPS. Different types of batteries are used in UPS systems but the most commonly used types are lead-acid, nickel–cadmium, and lithium ion. The lead acid batteries used in this application are the same as the ones used in the cars. However, there is one small difference. Car batteries generate electricity by the reaction of sulfuric acid on lead plates that are drowned under the liquid. These types of battery cells are not suitable for UPS applications because there is a chance of acid spillage from them. In addition, during the charging process, they release hydrogen that is explosive and dangerous in a closed environment. Lead acid batteries used in UPS systems are a special kind called sealed or valve-regulated. The nickel–cadmium batteries are another popular type of batteries used in UPS systems. They usually provide higher energy and power density compared to lead-acid batteries. The nominal voltage of nickel–cadmium cells is 1.2 V, which is smaller than 1.5 V of lead-acid batteries. However, the cell voltage variation throughout different charge levels is less than lead-acid batteries. These batteries also have less series resistance and can provide higher surge currents. Lithium-ion batteries have much higher energy density. This kind of battery can be molded into different shapes. They have a nominal voltage of 4.2 V. The main disadvantage of lithium-ion battery is that they lose their capacity from the time of manufacturing regardless of their charge level and conditions of use. Table 24.2 shows a comparison between different kinds of batteries for UPS application.

The traditional method of charging batteries is to apply constant current and constant voltage in two consecutive periods. Constant current is applied at the beginning of a typical full-charge cycle, when the battery voltage is low. When the battery voltage rises to a specified limit, the charger switches to constant voltage and continues in that mode until the charging current declines to nearly zero. At that time, the battery is fully charged. During the constant-voltage phase, the current drops exponentially due to the sum of battery resistance and any resistance in series with the battery (much like charging a capacitor through a resistor). Because current drops exponentially, a complete, full charge takes a long time.

24.6.2 Flywheel

Flywheel is simply a mechanical mass that is placed on the shaft of a motor–generator set and stores mechanical energy in the form of kinetic energy. When the electrical power is required, this kinetic energy is converted to electricity by the generator coupled with the flywheel. Flywheels are the oldest type of energy storage devices. The advantages of flywheel energy storage systems are high efficiency, high energy and power density, and long life. On the other hand, flywheels are more expensive and require more space than batteries and fuel cells. There are also some safety concerns about flywheels rotating at high speeds.

24.6.3 Fuel Cell

Due to high efficiency and low emissions, fuel cell systems have been gaining popularity in recent years. A fuel cell uses hydrogen as fuel and produces electricity, heat, and water from the reaction between hydrogen and oxygen. Each cell consists of an electrolyte and two electrodes as anode and cathode. Figure 24.17 shows the configuration of a typical fuel cell system. There are different kinds of fuel cell system depending on the types of electrolyte and hydrogen sources. Some fuel cell systems have an on-board fuel reformer and generate hydrogen from natural gas, methanol, and other hydrocarbons. Recent technology development in this field has made fuel cells a more reliable and cost-effective alternative for batteries. Fuel cells currently have a variety of applications in automotive, electric utility, and portable power industries. Table 24.3 provides a comparison between the most popular types of fuel cells.

TABLE 24.2   A comparison between different types of batteries for UPS systems

Battery type	Energy density (WH/kg)	Power density (W/kg)	Commercial availability
Lead-acid	35	300	Very mature and readily available
Nickel–cadmium	40	200	Mature and available
Lithium-ion	120	180	Available
Nickel hydride	70	200	Available
Zinc-air	350	60–225	Research stage
Aluminum-air	400	10	Research stage
Sodium chloride	110	150	Available
Sodium sulfur	170	260	Available
Zinc bromine	70	100	Available

TABLE 24.3 A comparison between different types of fuel cell system

Fuel cell type	Applications	Advantages	Disadvantages
Proton exchange membrane (PEM)	• Electric utility • Portable power • Automotive	• Solid electrolyte reduces corrosion and management problems • Low temperature • Quick start-up	• Expensive catalysts • High sensitivity to fuel impurities
Alkaline (AFC)	• Military • Space	• High performance	• Expensive removal of CO_2 from fuel and air streams required
Phosphoric acid (PAFC)	• Electric utility • Automotive	• Up to 85% efficiency in cogeneration of electricity and heat • Can use impure H_2 as fuel	• Expensive catalysts • Low power • Large size/weight
Molten carbonate (MCFC)	• Electric utility	• High efficiency • Fuel flexibility • Can use a variety of catalysts	• High temperature enhances corrosion and breakdown of cell components
Solid oxide fuel cell (SOFC)	• Electric utility	• High efficiency • Fuel flexibility • Can use a variety of catalysts • Solid electrolyte reduces corrosion and management problems • Low temperature • Quick start-up	• High temperature enhances the breakdown of cell components
Direct alcohol fuel cell (DAFC)	• Automotive • Portable power	• Compactness • High energy density	• Lower efficiency • Alcohol passing between electrodes without reacting
FIGURE 24.17 Configuration of a typical fuel cell system.

25.1 Introduction

The modern automobile has an extensive electrical system consisting of a large number of electrical, electromechanical, and electronic loads that are central to vehicle operation, passenger safety, and comfort. Power electronics is playing an increasingly important role in automotive electrical systems – conditioning the power generated by the alternator, processing it appropriately for the vehicle electrical loads, and controlling the operation of these loads. Furthermore, power electronics is an enabling technology for a wide range of future loads with new features and functions. Such loads include electromagnetic engine valves, active suspension, controlled lighting, and electric propulsion.

This chapter discusses the application and design of power electronics in automobiles. Section 25.2 provides an overview

of the architecture of the present automotive electrical power system. The next section, Section 25.3, describes the environmental factors, such as voltage ranges, EMI/EMC requirements, and temperature, which strongly influence the design of automotive power electronics. Section 25.4 discusses a number of electrical functions that are enabled by power electronics, while Section 25.5 addresses load control via multiplexed remote switching architectures that can be implemented with power electronic switching. Section 25.6 considers the application of power electronics in automotive electromechanical energy conversion, including power generation. Section 25.7 describes the potential evolution of automotive electrical systems towards high- and dual-voltage systems, and provides an overview of the likely requirements of power electronics in such systems. Finally, the application of power electronics in electric and hybrid electric vehicles is addressed in Section 25.8.
FIGURE 25.1   The 12-V point-to-point automotive electrical power system.

25.2 The Present Automotive Electrical Power System

Present-day automobiles can have over 200 individual electrical loads, with average power requirements in excess of 800 W. These include such functions as the headlamps, tail lamps, cabin lamps, starter, fuel pump, wiper, blower fan, fuel injector, transmission shift solenoids, horn, cigar lighter, seat heaters, engine control unit, cruise control, radio, and spark ignition. To power these loads, present day internal combustion engine (ICE) automobiles use an electrical power system similar to the one shown in Fig. 25.1. Power is generated by an engine-driven three-phase wound-field synchronous machine – a Lundell (claw-pole) alternator [1, 2]. The ac voltage of this machine is rectified and the dc output regulated to about 14 V by an electronic regulator that controls the field current of the machine. The alternator provides power to the loads and charges a 12 V lead-acid battery. The battery provides the high power needed by such loads as the starter, and supplies power when the engine is not running or when the demand for electrical power exceeds the output power of the alternator. The battery also acts as a large capacitor and smoothes out the system voltage.

Power is distributed to the loads via fuses and point-to-point wiring. The fuses, located in one or more fuseboxes, protect the wires against overheating and fire in the case of a short. Most of the loads are controlled directly by manually actuated mechanical switches. These primary switches are located in areas in easy reach of either the driver or the passengers, such as the dashboard, door panels, and the ceiling. Some of the heavy loads, such as the starter, are switched indirectly via electromechanical relays.

25.3 System Environment

The challenging electrical and environmental conditions found in the modern automobile have a strong impact on the design of automotive power electronic equipment. Important factors affecting the design of electronics for this application include static and transient voltage ranges, electromagnetic interference and compatibility requirements (EMI/EMC), mechanical vibration and shock, and temperature and other environmental conditions. This section briefly describes some of the factors that most strongly affect the design of power electronics for automotive applications. For more detailed guidelines on the design of electronics for automotive applications, the reader is referred to [1, 3–16] and the documents cited therein, from which much of the information presented here is drawn.

25.3.1 Static Voltage Ranges

In most present-day automobiles, a Lundell-type alternator provides dc electrical power with a lead-acid battery for energy storage and buffering. The nominal battery voltage is 12.6 V, which the alternator regulates to 14.2 V when the engine is on in order to maintain a high state of charge on the battery. In practice, the regulation voltage is adjusted for temperature to match the battery characteristics. For example, in [1], a 25°C regulation voltage of 14.5 V is specified with a −10 mV/°C adjustment. Under normal operating conditions, the bus voltage will be maintained in the range of 11–16 V [3]. Safety-critical equipment is typically expected to be operable even under battery discharge down to 9 V, and equipment operating during starting may see a bus voltage as low as 4.5–6 V under certain conditions.

In addition to the normal operating voltage range, a wider range of conditions is sometimes considered in the design of automotive electronics [3]. One possible condition is reverse-polarity battery installation, resulting in a bus voltage of approximately −12 V. Another static overvoltage condition can occur during jump starting from a 24-V system such as on a tow truck. Other static overvoltage conditions can occur due to failure of the alternator voltage regulator. This can result in a bus voltage as high as 18 V, followed by battery electrolyte boil-off and a subsequent unregulated bus voltage as high as 130 V. Typically, it is not practical to design the electronics for operation under such an extreme fault condition, but it should be noted that such conditions can occur. Table 25.1 summarizes the range of static voltages that can be expected in the automotive electrical system.

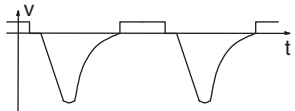
TABLE 25.1 Static voltage range for the automotive electrical system [3]

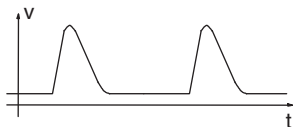
Static voltage condition	Voltage
Nominal voltage with engine on	14.2 V
Nominal voltage with engine off	12.6 V
Maximum normal operating voltage	16 V
Minimum normal operating voltage	9 V
Minimum voltage during starting	4.5 V
Jump start voltage	24 V
Reverse battery voltage	−12 V
Maximum voltage with alternator regulator failure followed by battery failure	130 V

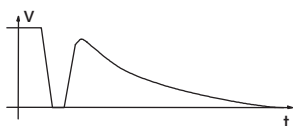
25.3.2 Transients and Electromagnetic Immunity

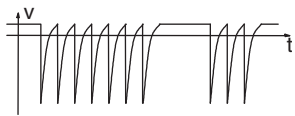
Power electronic circuits designed for automotive applications must exhibit electromagnetic compatibility, i.e. the conducted and radiated emissions generated by the circuit must not interfere with other equipment on board the vehicle, and the circuit must exhibit immunity to radiated and conducted disturbances. The Society of Automotive Engineers (SAE) has laid out standards and recommended practices for the electromagnetic compatibility of automotive electronics in a set of technical reports [4]. These reports are listed in Table 25.2. Here we will focus on two of the basic requirements of automotive power electronics: immunity to power lead transients and limitation of conducted emissions.

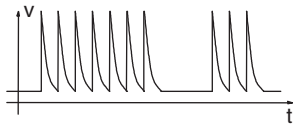
A major consideration in the design of an automotive power electronic system is its immunity to the transients that can appear on its power leads. A number of transient sources exist in the vehicle [5] and procedures for validating immunity to these transients have been established in documents such as

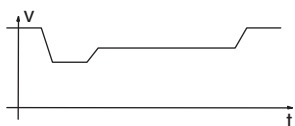
SAE J1113/11 [4, 6] and DIN 40389 [1]. Table 25.3 illustrates the transient test pulses specified in SAE J1113/11. Each test pulse corresponds to a different type of transient. The vehicle manufacturer determines which test pulses apply to a specific device.


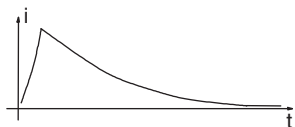












Transients occur when inductive loads such as solenoids, motors, and clutches are turned on and off. The transients can be especially severe when the bus is disconnected from the battery, as is the case for the accessory loads when the ignition is switched off. Test pulse 1 in Table 25.3 simulates the transient generated when an inductive load is disconnected from the battery and the device under test remains in parallel with it. When the inductive load is a dc motor, it may briefly act as a generator after disconnection. This transient is simulated by test pulse 2b. Test pulse 2a models the transient when current in an inductive element in series with the device under test is interrupted. Test pulses 3a and 3b model switching spikes that appear on the bus during normal operation. Test pulse 4 models the voltage transient that occurs on starting.

Perhaps the best-known electrical disturbance is the so-called load dump transient that occurs when the alternator load current drops sharply and the battery is unable to properly buffer the change. This can occur when the battery becomes disconnected while drawing a large amount of current. To understand why a major transient can occur under this situation, consider that the Lundell-alternator has a very large leakage reactance. The high commutating reactance interacting with the diode rectifier results in a high degree of load regulation, necessitating the use of a large back emf to source rated current at high speed [7]. Back voltages as high as 120 V may be needed to generate rated current into a 14 V output at top speed. Analytical modeling of such systems is addressed in [8]. Two effects occur when the load on the alternator suddenly steps down. First, as the machine current drops, the energy

TABLE 25.2 SAE J1113 electromagnetic compatibility technical reports

SAE specification	Type	Description
SAE J1113/1	Standard	Electromagnetic compatability measurement procedures and limits, 60 Hz–18 GHz
SAE J1113/2	Standard	Conducted immunity, 30 Hz–250 kHz
SAE J1113/3	Standard	Conducted immunity, direct injection of RF power, 250 kHz–500 MHz
SAE J1113/4	Standard	Conducted immunity, bulk current injection method
SAE J1113/11	Standard	Conducted immunity to power lead transients
SAE J1113/12	Recommended practice	Electrical interference by conduction and coupling – coupling clamp
SAE J1113/13	Recommended practice	Immunity to electrostatic discharge
SAE J1113/21	Information report	Electrical disturbances by narrowband radiated electromagnetic energy – component test methods
SAE J1113/22	Standard	Immunity to radiated magnetic fields from power lines
SAE J1113/23	Recommended practice	Immunity to radiated electromagnetic fields, 10 kHz–200 MHz, strip line method
SAE J1113/24		Immunity to radiated electromagnetic fields, 10 kHz–200 MHz, TEM cell method
SAE J1113/25	Standard	Immunity to radiated electromagnetic fields, 10 kHz–500 MHz, tri-plate line method
SAE J1113/26	Recommended practice	Immunity to ac power line electric fields
SAE J1113/27	Recommended practice	Immunity to radiated electromagnetic fields, reverberation method
SAE J1113/41	Standard	Radiated and conducted emissions, 150 kHz–1000 MHz
SAE J1113/42	Standard	Conducted transient emissions

TABLE 25.3   Transient pulse waveforms specified in SAE J1113/11

Pulse	Shape	Maximum excursion	Source impedance	Duration and repetition rate
1		−100 V	10 Ω	$T_{pulse} = 2$ ms 0.5 s $< T_{rep} < 5$ s
2a		100 V	10 Ω	$T_{pulse} = 50$ μs 0.5 s $< T_{rep} < 5$ s
2b		10 V	0.5–3 Ω	$T_{pulse} \geq 200$ ms
3a		−150 V	50 Ω	$T_{pulse} = 100$ ns $T_{rep} = 100$ μs
3b		100 V	50 Ω	$T_{pulse} = 100$ ns $T_{rep} = 100$ μs
4		−7 V	0.01 Ω	$T_{pulse} \leq 20$ s
5		84 A	0.6 Ω	$\tau = 115$ ms $T_{pulse} \sim 4\tau$

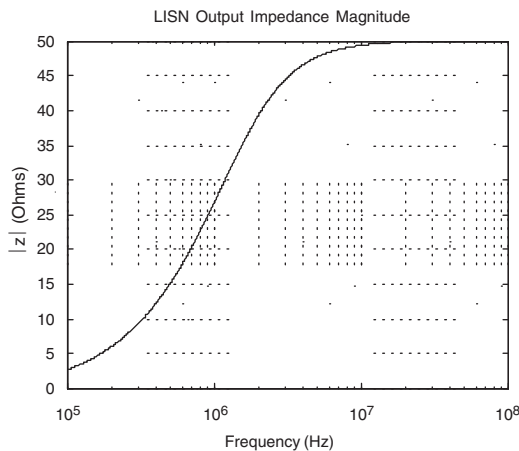
in the alternator leakage reactances is immediately delivered to the alternator output, causing a voltage spike. The peak voltage reached depends on the electrical system impedance, and may be limited by suppression devices. Second, once the alternator current is reduced, the voltage drops across the leakage (commutating) reactances are reduced, and a much larger fraction of the machine back-emf is impressed across the dc output. The proper output voltage is only re-established as the voltage regulator reduces the field current appropriately. With conventional regulator circuits, this takes place on the time scale of the field winding time constant (typically 100 ms), and results in a major transient event. In systems without centralized

protection, a load dump can generate a transient with a peak voltage in excess of 100 V lasting hundreds of milliseconds. Test pulse 5 in Table 25.3 (expressed as a current waveform in parallel with an output resistance) is designed to simulate such a load-dump transient; other load-dump tests are even more severe [1, 3].

25.3.3 Electromagnetic Interference

Strict limits also exist for the amount of electromagnetic interference (EMI) that an automotive electronic component can generate. Limits for both conducted and radiated emissions are

specified in SAE standards J1113/41 and J1113/42 [4, 9, 10]. Here we will consider the conducted EMI specifications for power leads, since they directly impact the design of EMI filters for automotive power electronics. Meeting the conducted specifications is a major step towards achieving overall compliance.

The conducted EMI specifications in SAE J1113/41 limit the ripple that an electronic circuit can inject onto the voltage bus over the frequency range from 150 KHz to 108 MHz. The amount of ripple injected by a circuit usually depends on the bus impedance. To eliminate any variability due to this, EMI compliance testing is done using a line impedance stabilization network (LISN) between the bus and the device under test, as illustrated in Fig. 25.2. The LISN is also sometimes referred to as an artificial mains network (AN). Essentially, the LISN ensures that the equipment under test receives the proper dc voltage and current levels and also sees a controlled impedance for the ripple frequencies of interest. Figure 25.3 shows the magnitude of the LISN output impedance for a low-impedance input source; the effective impedance is 50 Ω over most of the frequency range of interest. The 50-Ω termination impedance of the LISN is typically provided by the measurement equipment. The EMI specifications are stated in terms of the allowable voltage ripple (in dB μV) appearing across the 50-Ω LISN resistance as a function of frequency.


There are a wide range of other technical considerations for EMI testing, including the arrangement of the equipment over a ground plane and the types and settings of the measuring devices. One characteristic to consider is that the EMI measurements are done across frequency with a spectrum analyzer having a prespecified receiver bandwidth (RBW). For frequencies between 150 kHz and 30 MHz, the receiver bandwidth is 9 kHz, resulting in spectral components within 9 kHz of one another being lumped together for purposes of the test. A full test procedure is defined in the SAE specifications, beginning with narrowband measurements and moving to wideband measurements if necessary. Figure 25.4 illustrates the narrowband conducted EMI limits for power leads in SAE J1113/41. It is interesting to note that for the commonly used Class 5 limits, the allowable ripple current into the LISN at 150 kHz is less than 100 μA!

As seen in the previous section, the transient disturbances generated by electrical and electronic equipment are an important consideration in automotive applications. Because power electronic circuits typically contain switches and magnetic elements, they are potential sources for such transients, especially when powered from the switched ignition line. SAE J1113/42 specifies methods for testing and evaluating the transients generated by automotive electrical components, and proposes transient waveform limits for different severity levels. The equipment under test is set up in a configuration similar to that in Fig. 25.2, but with a switching device on one side or the other of the LISN, depending on the application. The equipment under test is then evaluated for transient behavior at turn on, turn off, and across its operating range. The voltage transients at the input of the equipment are measured and

FIGURE 25.2 Conducted EMI test set up with LISN. $L_{LISN} = 5\,\mu\text{H}$, $C_{LISN} = 0.1\,\mu\text{F}$, and $R_{LISN} = 50\,\Omega$.

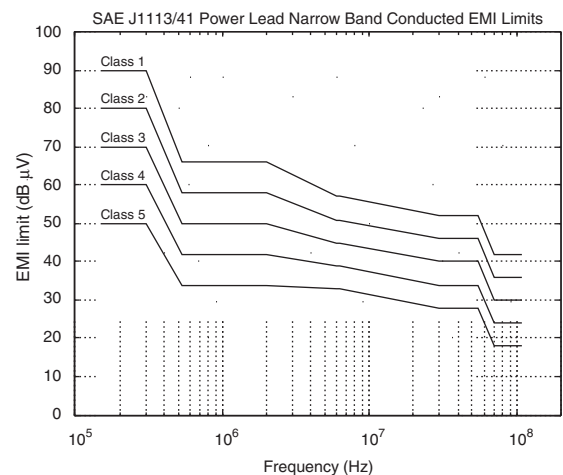
FIGURE 25.3 The LISN output impedance magnitude for a low impedance input source.


FIGURE 25.4 SAE J1113/41 narrowband conducted EMI limits for power leads. The specification covers the frequency range from 150 kHz to 108 MHz.

evaluated with respect to magnitude, duration, and rise and fall times. Specific limits for such transients are specified by the vehicle manufacturer, but SAE J1113/42 proposes a representative set of limits for four different transient severity levels.

Due to the tight conducted emissions limits, input EMI filter design is an important consideration in automotive power electronics. Single or multistage low-pass filters are typically used to attenuate converter ripple to acceptable levels [11–13]. When designing such filters, the parasitic behavior of the filter components, such as capacitor equivalent series resistance and inductance, and suitable filter damping are important considerations [14]. One must also ensure that the filter design yields acceptable transients at switch on and off, and does not result in undesired dynamic interactions with the power circuit [13]. Attention to appropriate filter design, coupled with proper circuit layout, grounding, and shielding goes a long way towards meeting electromagnetic interference specifications [14].

25.3.4 Environmental Considerations

The automobile is a very challenging environment for electronics. Environmental factors influencing the design of automotive electronics include temperature, humidity, mechanical shock, vibration, immersion, salt spray, and exposure to sand, gravel, oil, and other chemicals. In 1978, the SAE developed a recommended practice for electronic equipment design to address these environmental considerations [3, 4]. This document, SAE J1211, provides quantitative information about the automotive environment to aid the designer in developing environmental design goals for electronic equipment. Here, we briefly summarize a few of the most important factors affecting the design of power electronics for automotive applications. For more detailed guidelines, the reader is referred to [3] and the documents cited therein.

Perhaps the most challenging environmental characteristic is the extreme range of temperatures that can occur in the automobile. Table 25.4 summarizes some of the temperature extremes listed in SAE J1211 for different locations in the automobile. Ambient temperatures as low as −40°C may be found during operation, and storage temperatures as low as −50°C may be found for components shipped in unheated aircraft. Maximum ambient temperatures vary widely depending on vehicle location, even for small differences in position. Because ambient temperature has a strong impact on the design of a power electronic system it is important to work closely with the vehicle manufacturer to establish temperature specifications for a particular application. For equipment that is air-cooled, one must also consider that the equipment may be operated at altitudes up to 12,000 feet above sea level. This results in low ambient pressure (down to 9 psia), which can reduce the heat transfer efficiency [3]. For equipment utilizing the radiator-cooling loop, maximum coolant temperatures in the range of 105–120°C at a pressure of 1.4 bar are possible [15].

TABLE 25.4 Automotive temperature extremes by location [3]

Vehicle location	Min temp. (°C)	Max temp. (°C)
Exterior	−40	85
Chassis		
Isolated	−40	85
Near heat source	−40	121
Drive train high temperature location	−40	177
Interior		
Floor	−40	85
Rear deck	−40	104
Instrument panel	−40	85
Instrument panel top	−40	177
Trunk	−40	85
Under hood		
Near radiator support structure	−40	100
Intake manifold	−40	121
Near alternator	−40	131
Exhaust manifold	−40	649
Dash panel (normal)	−40	121
Dash panel (extreme)	−40	141

In addition to the temperature extremes in the automobile, thermal cycling and shock are also important considerations due to their effect on component reliability. Thermal cycling refers to the cumulative effects of many transitions between temperature extremes, while thermal shock refers to rapid transitions between temperature extremes, as may happen when a component operating at high temperature is suddenly cooled by water splash. The damaging effects of thermal cycling and shock include failures caused by thermal expansion mismatches between materials. Test methods have been developed which are designed to expose such weaknesses [3, 16]. The thermal environment in the automobile, including the temperature extremes, cycling, and shock, are challenging issues that must be addressed in the design of automotive power electronics.

A number of other important environmental factors exist in the automobile. Humidity levels as high as 98% at 38°C can exist in some areas of the automobile, and frost can occur in situations where the temperature drops rapidly. Salt atmosphere, spray, water splash, and immersion are also important factors for exterior, chassis, and underhood components. Failure mechanisms resulting from these factors include corrosion and circuit bridging. Dust, sand, and gravel bombardment can also be significant effects depending on equipment location. Mechanical vibration and shock are also important considerations in the design of automotive power electronic equipment. Details about the effects of these environmental factors, sample recorded data, and recommended test procedures can be found in [3].

25.4 Functions Enabled by Power Electronics

Over the past 20 years, power electronics has played a major role in the introduction of new functions such as the antilock breaking system (ABS), traction control, and active suspension, as well as the electrification of existing functions such as the engine-cooling fan, in the automobile. This trend is expected to continue, as a large number of new features being considered for introduction into automobiles require power electronics. This section discusses some of the new functions that have been enabled by power electronics, and some existing ones that benefit from it.

25.4.1 High Intensity Discharge Lamps

High intensity discharge (HID) lamps have started to appear in automobiles as low-beam headlights and fog lights. The HID lamps offer higher luminous efficacy, higher reliability, longer life, and greater styling flexibility than the traditional halogen lamps [17, 18]. The luminous efficacy of an HID lamp is over three times that of a halogen lamp and its life is about 2000 hours, compared to 300–700 hours for a halogen lamp. Therefore, HID lamps provide substantially higher road illumination while consuming the same amount of electrical power and, in most cases, should last the life of the automobile. The HID lamps also produce a whiter light than halogen lamps since their color spectrum is closer to that of the sun.

High intensity discharge lamps do not have a filament. Instead, light is generated by discharging an arc through a pressurized mixture of mercury, xenon, and vaporized metal halides – mercury produces most of the light, the metal halides determine the color spectrum, and xenon helps reduce the start-up time of the lamp [17, 19]. Unlike halogen lamps that can be powered directly from the 12-V electrical system, HID lamps require power electronic ballasts for their operation. Initially, a high voltage pulse of 10–30 kV is needed to ignite the arc between the electrodes and a voltage of about 85 V is needed to sustain the arc [4.3]. Figure 25.5 shows a simplified power electronic circuit that can be used to start and drive an HID lamp. A step-up dc–dc converter is used to boost the

voltage from 12 V to the voltage needed for the steady-state operation of the HID lamp. Any dc–dc converter that can step up the voltage, such as the boost or flyback converter, can be used for this application. An H-bridge is then used to create the ac voltage that drives the lamp in steady state. The circuit to initiate the arc can be as simple as a circuit that provides an inductive voltage kick, as shown in Fig. 25.5.

25.4.2 Pulse-width Modulated Incandescent Lighting

Future automobiles may utilize a 42 V electrical system in place of today's 14 V electrical system (see Section 25.7). Because HID lamps are driven through a power electronic ballast, HID lighting systems operable from a 42 V bus can be easily developed. However, the high cost of HID lighting – as much as an order of magnitude more expensive than incandescent lighting – largely limits its usefulness to headlight applications. Incandescent lamps compatible with 42 V systems can also be implemented. However, because a much longer, thinner filament must be employed at the higher voltage, lamp lifetime suffers greatly. An alternative to this approach is to use pulse-width modulation to operate 12 V incandescent lamps from a 42 V bus [20].

In a pulse-width modulated (PWM) lighting system, a semiconductor switch is modulated to apply a periodic pulsed voltage to the lamp filament. Because of its resistive nature, the power delivered to the filament depends on the rms of the applied voltage waveform. The thermal mass of the system filters the power pulsations so that the filament temperature and light production are similar to that generated by a dc voltage with the same rms value. The PWM frequency is selected low enough to avoid lamp mechanical resonances and the need for EMI filtering, while being high enough to limit visible flicker; PWM frequencies in the range of 90–250 Hz are typical [20].

Ideally, a 11.1% duty ratio is needed to generate 14 V rms across a lamp from a 42 V nominal voltage source. In practice, deviations from this duty ratio are needed to adjust for input voltage variations and device drops. In some proposed systems, multiple lamps are operated within a single lighting module with phase staggered (interleaved) PWM waveforms to reduce the input rms current of the module.
FIGURE 25.5 Simplified power electronic circuit for an HID lamp ballast.

Another issue with PWM lighting relates to startup. Even with operation from a 12 V dc source, incandescent lamps have an inrush current that is 6–8 times higher than the steady-state value, because of how filament resistance changes with temperature; this inrush impacts lamp durability. The additional increase in peak inrush current due to operating from a 42 V source can be sufficient to cause destruction of the filament, even when using conventional PWM soft-start techniques (a ramping up of duty ratio). Means for limiting the peak inrush current – such as operating the controlling MOSFET in current limiting mode during startup – are needed to make practical use of PWM lighting control.

While PWM incandescent lighting technology is still in the early stages of development, it offers a number of promising advantages in future 42 V vehicles. These include low-cost adaptation of incandescent lighting to high-voltage systems, control of lighting intensity independent of bus voltage, the ability to implement multiple intensities, flashing, dimming, etc. through PWM control, and the potential improvement of lamp durability through more precise inrush and operating control [20].

25.4.3 Piezoelectric Ultrasonic Actuators

Piezoelectric ultrasonic motors are being considered as actuators for window lifts, seat positioning, and head restraints in automobiles [21, 22]. These motors work on the principle of converting piezoelectrically induced ultrasonic vibrations in an elastic body into unidirectional motion of a moving part. Unidirectional motion is achieved by allowing the vibrating body to make contact with the moving part only during a half-cycle of its oscillation, and power is transferred from the vibrating body to the moving part through frictional contact. Ultrasonic motors have a number of attractive features, including high-torque density, large holding torque even without input power, low speed without gears, quiet operation, no magnetic fields, and high dynamics [21, 23]. These characteristics make ultrasonic motors an attractive alternative to electromagnetic motors for low-power high-torque applications.

Various types of ultrasonic motors have been developed. However, because of its compact design, the traveling wave type is the most popular ultrasonic motor [24]. Figure 25.6a shows the basic structure of such a motor. It consists of a metal stator and rotor, which are pushed against each other by a spring. The rotor is coated with a special lining material to increase friction and reduce wear at the contacting surfaces. A layer of piezoelectric material, such as lead zirconate titanate (PZT), is bonded to the underside of the stator. Silver electrodes are printed on both sides of the piezoceramic ring. The top electrode is segmented and the piezoceramic is polarized as shown in Fig. 25.6b. The number of segments is twice the order of the excited vibration mode.
FIGURE 25.6 (a) Basic structure of a traveling wave piezoelectric ultrasonic motor and (b) structure of the piezoceramic ring and electrode for a four-wavelength motor. Arrows indicate direction of polarization. Dashed lines indicate segments etched in the electrode for poling but electrically connected during motor operation.

When a positive voltage is applied between terminals A and C, the downwards poled segment elongates and the upwards poled segments contract. This causes the stator to undulate, waving down at the elongated section and up at the contracted one. When the polarity of the voltage is inverted, the undulations are also inverted. Hence, when an ac voltage is applied a flexural standing wave is created in the stator. To get a large wave amplitude, the stator is driven at the resonance frequency of the flexural mode. An ac voltage between terminals B and C similarly produces another standing wave. However, because of the spacer segments in the piezoceramic ring, the second standing wave is 90° spatially out of phase from the first one. If the two standing waves are excited by ac voltages that are out of phase in time by 90°, a traveling wave is generated. As the traveling wave passes through a point along the neutral plane, that points simply exhibits axial (z-axis) motion. However, off-neutral plane points also have an azimuthal (ϕ-axis) component of motion. This azimuthal motion of the surface points propels the rotor. Ultrasonic motors require a power electronic drive. A power electronic circuit suitable for driving an ultrasonic motor is shown in Fig. 25.7. The two H-bridges are controlled to generate waveforms that are 90° out of phase with each other.

25.4.4 Electromechanical Engine Valves

Electromagnetic actuators are finding increasing application in automotive systems. These actuators are more desirable than the other types of actuators, such as the hydraulic and pneumatic actuators, because they can be more easily controlled by a microprocessor to provide more precise control. An application of electromagnetic actuators that is of particular interest is the replacement of the camshaft and tappet valve assembly
FIGURE 25.7   Drive circuit for an ultrasonic motor.
FIGURE 25.8   Power electronic circuits for driving solenoids.

by electromechanically driven engine valves [25]. The opening and closing of the intake and exhaust valves can be controlled to achieve optimum engine performance and improved fuel economy over a wide range of conditions determined by variables such as the speed, load, altitude, and temperature. The present cam system provides a valve profile that can give optimum engine performance and improved fuel economy only under certain conditions.

Two power electronic circuits suitable for driving the solenoids for valve actuation are shown in Fig. 25.8. The circuit of Fig. 25.8a is suitable for solenoids that require unidirectional currents through their coils, while the circuit of Fig. 25.8b is suitable for solenoids that require bidirectional currents through their coils.

25.4.5 Electric Air Conditioner

It is desirable to replace some of the engine-driven functions of a vehicle with electrically driven counterparts. The benefits of driving these functions electrically include the elimination of belts and pulleys, improved design and control due to independence from engine speed, and resulting increased efficiency and improved fuel economy. Furthermore, there is the opportunity for operation of the function in the engine-off condition.

The air conditioner is an example of an engine-driven function that could benefit from electrification. The engine drives the compressor of the air conditioner. Consequently, the speed of the compressor varies over a wide range and the compressor has to be over-sized to provide the desired performance at engine idle. Also, since the compressor speed is dependent on

the engine speed, excessive cooling occurs at highway speeds requiring the cool air to be blended with the hot air to keep the temperature at the desired level. Furthermore, shaft seals and rubber hoses can lead to the loss of refrigerant (CFC) and pose an environmental challenge.

In an electric air conditioner, an electric motor is used to drive the compressor [26]. The motor is usually a three-phase brushless dc motor driven by a three-phase MOSFET bridge. The speed of the compressor in an electric air conditioner is independent of the engine speed. As a result, the compressor does not have to be over-sized and excessive cooling does not occur. Also, shaft seals and hoses can be replaced with a hermetically sealed system. Another benefit of an electric air conditioner is the flexibility in its location, since it does not have to be driven by the engine.

25.4.6 Electric and Electrohydraulic Power Steering Systems

The hydraulic power steering system of a vehicle is another example of an engine-driven accessory. This system can be replaced with an electric power steering (EPS) system in which a brushless dc motor is used to provide the steering power assist [27]. The electric power steering system is more efficient than the hydraulic power steering system because, unlike the engine-driven hydraulic steering pump, which is driven by the engine all the time, the motor operates only on demand. Another system that can replace the hydraulic power steering system is the electrohydraulic power steering (EHPS) system. In this case, a brushless dc motor and inverter can be employed to drive the hydraulic steering pump. The ability of the EPHS system to drive the pump only on demand leads to energy savings of as much as 80% as compared with the conventional hydraulic system. Challenges in implementing EPS and EPHS systems include meeting the required levels of cost and reliability for this critical vehicle subsystem.

25.4.7 Motor Speed Control

Some of the motors used in a vehicle require variable speed control. Consider, as an example, the blower motor used to provide air flow to the passenger compartment. This motor is typically a permanent magnet dc motor with a squirrel-cage fan. The speed of the motor is usually controlled by varying the resistance connected in series with the motor winding. This method of speed control leads to a significant power loss. A low-loss method of speed control employs semiconductor devices as shown in Fig. 25.9. In this case, the speed of the motor is controlled via PWM – that is, by switching the MOSFET on and off with different duty-ratios for different speed settings. An input filter is needed to reduce the EMI generated by the switching of the MOSFET. This method of speed control is equivalent to supplying power to the motor
FIGURE 25.9 Low-loss circuit to control the speed of a motor.

through a variable-output dc-to-dc converter. The converter is located close to the motor and no filter is required between the converter output and motor winding.

Another low-loss method that can be used to control the speed of a motor employs a three-phase brushless dc motor. The speed in this case is controlled by controlling the MOSFETs in the dc-to-three-phase-ac converter that drives the motor.

25.5 Multiplexed Load Control

Another emerging application of power electronics in automobiles is in the area of load control. In the conventional point-to-point wiring architecture, most of the loads are controlled directly by the primary mechanical switches, as shown in Fig. 25.1. In a point-to-point wiring architecture, each load has a dedicated wire connecting it to the fuse box via the primary switch. Consequently, fairly heavy wires have to be routed all over the vehicle, as illustrated in Fig. 25.10a. The situation is made worse when multiple switches control the same load, as is the case with power windows and power door locks. The complete harness of a 1994 C-class Mercedes-Benz that uses point-to-point wiring has about 1000 wires, with a total length of 2 km, over 300 connectors and weighs 36 kg. The process of assembling the wiring harness is difficult and time consuming, leading to high labor costs. Retrofitting, fault tracing, and repairing are time consuming and expensive. The bulky harness also places constraints on the vehicle body design, and the large number of connectors compromise system reliability.

An alternative wiring technique is to control the loads remotely and multiplex the control signals over a communication bus, as shown in Fig. 25.10b and c. A control message is sent on the communication bus to switch a particular load on or off. This allows more flexibility in the layout of the power cables and could allow the pre-assembly of the harness to be more automated. Furthermore, with communication between the remote switches, it is practical to have a power management system than can turn off non-essential loads when there is a power shortage. One possibility is to group the remote switches into strategically located distribution boxes, as shown in Fig. 25.10b. A power and a communication bus connect the distribution boxes. Another possibility is to integrate the remote switches with the load, i.e. point-of-load switching,

as shown in Fig. 25.10c. In Fig. 25.10b the transceivers are also built into the distribution boxes, while in Fig. 25.10c each load and primary switch has an integrated transceiver. The point-of-load switching topology is attractive because of its simplicity, but raises cost and fusing challenges.

Multiplexed remote switching architectures have been under consideration since at least the early 1970s, when Ziomek investigated their application to various electrical subsystems [28]. The initial interest was dampened by cost and reliability concerns and the non-availability of appropriate remote switches. However, advances in semiconductor technology and rapid growth in the automotive electrical system revived interest in multiplexed architectures. The SAE Multiplexing Standards Committee has partitioned automotive communications into three classes: Class A for low data-rate (1–10 kbit/s) communication for the control of body functions, such as headlamps, windshield wipers, and power windows, Class B for medium data-rate (10–100 kbit/s) parametric data exchange, and Class C for high data-rate (1 Mbit/s) real-time communication between safety critical functions, such as between ABS sensors and brake actuators [29]. Although load control is categorized as Class A, lack of any widely accepted Class A communication protocols has lead to the application of Class B and Class C communication IC's to load control. Class B has received the most attention due to the California Air Resources Board mandated requirement for on-board diagnostics (OBD II) and a large number of competing protocols, including the French vehicle-area network (VAN), the ISO 9141 and the SAE J1850, have been developed [30]. Of these, the SAE J1850 is the most popular in the US. Another popular protocol is the controller area network (CAN) developed by Bosch [31]. Although designed for Class C with bit rates up to 1 Mbit/s, it is being applied for Class A and Class B applications due to the availability of inexpensive CAN ICs from a large number of semiconductor manufacturers.

Remote switching systems require remote power switches. An ideal remote switch must have a low on-state voltage, be easy to drive from a micro-controller, and incorporate current sensing. A low on-state voltage helps minimize the heatsinking requirements, while current sensing is needed for the circuit protection function to be incorporated into the switch. To withstand the harsh automotive environment the switch must also be rugged. Furthermore, if PWM control is required for the load, the switch must have short turn-on and turn-off times and a high cycle-life. The traditional means of remotely switching loads in an automobile is via electromechanical relays. Although relays offer the lowest voltage drop per unit cost, they require large drive current, are relatively large, are difficult to integrate with logic, and are not suitable for PWM applications [32–34]. Therefore, their use will be limited to very high current, non-PWM applications. The power levels of the individual loads in the automobile are too low for IGBTs and MCTs to be competitive. Bipolar transistors are
FIGURE 25.10   Alternative control strategies illustrated for a simple automotive electrical system with six loads (L1-6) and six primary switches (S1-6): (a) conventional direct switching architecture with a single fusebox (F1); (b) multiplexed remote switching architecture, with remote switches and transceivers in three distribution boxes (D1-3); and (c) multiplexed point-of-load switching with electronics integrated into the loads and the primary switches.

also not very attractive because they are harder to drive than a MOS-gated device. Because of its fast switching speed, low voltage drop, relative immunity to thermal runaway, low drive requirements, and ease of integration with logic, the power MOSFET is the most attractive candidate for remote switching. Smart-power MOSFET devices with integrated logic interface and circuit protection have recently become available. Use of these devices for power electronic control of individual loads has become economically competitive in some subsystems, and may be expected to become more so with the advent of higher voltage electrical systems.

The benefits of remote switching electrical distribution systems have been demonstrated by Furuichi *et al.* [35]. The multiplexed architecture they implemented had 10 remote units (two power units with fuses, power drivers and signal inputs, five load control units with power drivers and signal inputs but no fuses, and three signal input units with only signal inputs). To increase system reliability, each power unit was connected to the battery via independently fused power cables. Although wiring cost decreased, the authors report an increase in overall system cost due to the additional cost of the remote units. Intel's CAN ICs with data rates of 20 kbit/s were used

TABLE 25.5 Comparison of a multiplexed and the conventional system, as reported by Furuichi *et al.* for a compact vehicle [35]. In the multiplexed system, the function of nine electronic control units (ECUs) was integrated into the remote units

	Point-to-point	Multiplexed	Change (%)
Harness weight (kg)	14.0	9.8	−30
ECU weight (kg)	1.2	0.0	N/A
Remote unit weight (kg)	0.0	3.5	N/A
Total weight (kg)	15.2	13.3	−12.5
Number of wires	743	580	−21.9
Number of terminals	1195	915	−23.4
Number of splices	295	246	−16.6
Length of wire (m)	809	619	−23.5

for the transmission and reception of control signals over an unshielded twisted-pair ring bus. Intelligent power MOSFETs were used as the remote switches and fusing was done with mini-fuses. The results of their work are shown in Table 25.5. Although weight of the wiring harness was reduced by 30%, the total system weight decreased by only 12.5% due to the added weight of the remote units.

25.6 Electromechanical Power Conversion

Power is generated in the automobile by an electrical machine driven by the engine. In the early days of the automobile, the electrical load was small and a dc generator was used for this purpose. As the electrical loads grew, the dc generator could not meet the growing demand of electrical power and was displaced by a three-phase alternator and diode rectifier. Continuously increasing power and performance requirements are driving further evolution in automotive power generation and control, and are motivating the introduction of power electronics and improved electrical machines in automobiles. In addition to high-power alternators, future applications of electromechanical power conversion may include integrated starter/alternators and propulsion systems. This section describes some of the machine and power electronic technologies that are useful for meeting the increasing challenges in the automobile.

25.6.1 The Lundell Alternator

The Lundell, or claw-pole, alternator is a three-phase wound-field synchronous machine that is almost universally used for power generation in present-day vehicles [1]. As illustrated in Fig. 25.11, the rotor is made of a pair of stamped pole pieces ("claw poles") fixed around a cylindrical field coil. The field winding is driven from the stator via a pair of slip rings and
brushes, and causes the two pole pieces to become opposing magnetic poles. A full-bridge diode rectifier is traditionally used at the machine output, and a fan mounted on the rotor is typically used to cool the whole assembly.

The dc output voltage of the alternator system is regulated by controlling the field current. A switching field regulator applies a pulse width modulated voltage across the field. The steady-state field current is determined by the field-winding resistance and the average voltage applied by the regulator. Changes in the field current occur with an L/R field-winding time constant in the order of 100 ms or more. This long field-winding time constant and a large stator leakage reactance are characteristic of this type of alternator and tend to dominate its performance.

The alternator is driven by means of a belt, and is designed to operate over a wide speed ratio of about 10:1, though much of its operating lifetime is spent within a narrower 3:1 or 4:1 range. The gearing ratio provided by the belt is a design variable for the alternator; an alternator mechanical speed range from 1800 to 18,000 rpm for a 12-pole machine is typical.

A simple electrical model for the Lundell alternator is shown in Fig. 25.12. The armature of the alternator is modeled as a Y-connected set of leakage inductances L_s and back voltages v_{sa}, v_{sb}, and v_{sc}. The fundamental electrical frequency ω of
FIGURE 25.12 A simple Lundell alternator model.

the back-emfs is one-half of the product of the number of machine poles p and the mechanical speed ω_m. The magnitude of the back-emfs is proportional to the electrical frequency and the field current. For the sinusoidal case, the line-to-neutral voltage back-emf magnitude can be calculated as:

$$V_s = k\omega i_f \tag{25.1}$$

where k is the machine constant and i_f is the field current. The diode bridge feeds a constant voltage V_o representing the battery and other loads. This simple model captures many of the important characteristics of the Lundell alternator, while remaining analytically tractable. Other effects, such as stator resistance, mutual coupling, magnetic saturation, and waveform harmonic content, can be incorporated into this model at the expense of simplicity. The constant-voltage battery load on the alternator makes the analysis of this system different from the classic case of a diode rectifier with a current-source load. Nevertheless, with reasonable approximations, the behavior of this system can be described analytically [8]. Using the results presented in [8], alternator output power vs operating point can be calculated as:

$$P_o = \frac{3V_o\sqrt{V_s^2 - (4V_o^2/\pi^2)}}{\pi\omega L_s} \tag{25.2}$$

where V_o is the output voltage, V_s is the back-emf magnitude, ω is the electrical frequency, and L_s is the armature leakage inductance. Extensions of Eq. (25.2) that also include the effect of the stator resistance are given in [8].

As can be inferred from Eq. (25.2), alternator output power varies with speed, and is maximized when the back-emf magnitude of the machine is substantially larger than the output voltage. In a typical Lundell alternator, back voltages in excess of 80 V may be necessary to source-rated current into a 14 V output at high speed. Furthermore, as can be seen from Eq. (25.2), the armature leakage reactance limits the output power capability of the alternator. These characteristics are a result of the fact that significant voltage drops occur across the leakage reactances when current is drawn from the machine. These drops increase with speed and current, and cause the alternator to exhibit significant drop in output voltage with increasing current. Thus, an appropriate dc-side model for a Lundell alternator is a large open-circuit voltage (related to the back-emf magnitude) in series with a large current- and speed-dependent output impedance. This characteristic, coupled with the long field time constant, is the source of the undesirable load-dump transient characteristic of the Lundell alternator. In this transient, the large open-circuit voltage is transiently impressed across the alternator output when the load is suddenly reduced.

The efficiency of the conventional Lundell alternator is relatively poor. Typical efficiency values are in the order of 40–60%, depending on the operating point [1, 36, 37]. At low and medium speeds, losses tend to be dominated by stator copper losses. Iron losses become dominant only at very high speeds [1].

25.6.2 Advanced Lundell Alternator Design Techniques

The conventional diode-rectified Lundell alternator, though inefficient, has so far met vehicle electrical power requirements in a cost-effective manner. However, continuing increase in electrical power demand and growing interest in improved fuel economy is pushing the limits of conventional Lundell alternator technology. This section describes some established and emerging technologies that can be used to improve the performance of the Lundell alternator.

25.6.2.1 Third-harmonic Booster Diodes

One widely used approach for improving the high-speed output power capability of Lundell alternators is the introduction of third-harmonic booster diodes [1]. In this technique, the neutral point of the Y-connected stator winding is coupled to the output via a fourth diode leg, as illustrated in Fig. 25.13. While the fundamental components of the line-to-neutral back voltages are displaced by 120° in phase, any third-harmonic components will be exactly in phase. As a result, third-harmonic energy can be drawn from the alternator and transferred to the output by inducing and rectifying common-mode third-harmonic currents through the three windings. The booster diodes provide a means for achieving this. At high speed, the combination of the third-harmonic voltages at the main rectifier bridge (at nodes a, b, and c in Fig. 25.13), combined with the third-harmonic of the back voltages are large enough to forward bias the booster diodes and deliver third-harmonic energy to the output. In systems with significant (e.g. 10%) third-harmonic voltage content, up to 10% additional output power can be delivered at high speed. Additional power is not achieved at low speed, or in cases where the third-harmonic of the back voltage is small.

25.6.2.2 Lundell Alternator with Permanent Magnets

The structure of the rotor of the claw-pole alternator is such that the leakage flux is high. This reduces the output current capability of the alternator. The leakage flux can be reduced by placing permanent magnets on the pole faces or in the spaces between the adjacent poles of the rotor. This modification allows the alternator to deliver more output current. Placing the magnets in the spaces between adjacent poles is a better approach because it is simpler to implement and leads to a higher output current at engine idle [38].
FIGURE 25.13   Lundell alternator with booster diodes.

25.6.2.3 Twin-rotor Lundell Alternator

The maximum power capability of the Lundell alternator is limited in part by the limit on its length-to-diameter ratio imposed by mechanical stresses on the stamped pole pieces. This prevents the Lundell alternator from being arbitrarily scaled up in size. The power capability of conventional designs is probably limited to 3 kW, which is likely to be unacceptable in the foreseeable future [39]. One way to retain the cost-effectiveness of the claw-pole alternator while achieving higher output power is to place two claw-pole rotors back-to-back on a common shaft inside a common stator [40]. This effectively increases the length of the claw-pole alternator without changing its diameter. This design allows higher power alternators to be built while retaining most of the cost benefits of the claw-pole design.

25.6.2.4 Power Electronic Control

Another approach for improving the output power and efficiency of the Lundell alternator is through the use

of more sophisticated power electronics. Power electronics technology offers tremendous value in this application. For example, replacing the conventional diode rectifier with a switched-mode rectifier provides an additional degree of design and control freedom, and allows substantially higher levels of power and efficiency to be attained from a given machine. One such design is shown in Fig. 25.14. It employs a simple switched-mode rectifier along with a special load-matching control technique to achieve dramatic improvement in alternator output power, efficiency, and transient performance [37]. The switched-mode rectifier provides improved control without the cost and complexity of a full active converter bridge. By controlling the duty ratio of the switched-mode rectifier based on available signals such as alternator speed, the alternator output power characteristic Eq. (25.2) can be altered and improved, particularly for speeds above idle [37]. Improvements in average power capability of a factor of two and average efficiency improvements on the order of 20% are possible with this technology. Furthermore, the
FIGURE 25.14   Lundell alternator with a switched-mode rectifier.

switched-mode rectifier can be employed to achieve greatly improved load-dump transient control.

25.6.3 Alternative Machines and Power Electronics

The demand for increased alternator power levels, efficiency, and performance also motivates the consideration of alternative electrical machines, power electronics, and design approaches. While no alternative machine has yet displaced the Lundell alternator in production vehicles, primarily due to cost considerations, some potential candidates are reviewed in this section. These include machines that are mounted directly on the engine rather than driven from a belt. These direct-driven machines become important as power levels rise. This section also addresses the more general case of the combined starter/alternators. While the use of a single machine to do both starting and generation functions is clearly possible, a separate (transient-rated) dc machine is presently used for starting. This is because the large mismatch in starting and generating requirements has made the combined starter/alternator approach unattractive. However, as alternator power ratings increase, the mismatch is reduced, and a single starter/alternator system becomes more practical. A combined system has the potential to eliminate the need for a separate flywheel, starter, solenoid switch, and pinion engaging drive. It also has the potential to allow regenerative braking and "light hybrid" operation, and to provide idle-stop capability (i.e. the ability to turn off the engine when the vehicle is stopped and seamlessly restart when the vehicle needs to move) for reduced fuel consumption. A move to this more sophisticated approach relies upon advanced electrical machines and power electronics.

25.6.3.1 Synchronous Machine with a Cylindrical Wound Rotor

The claw-pole rotor can be replaced with a cylindrical rotor to achieve better coupling between the stator and rotor.

The cylindrical rotor is made from steel laminations and the field winding is placed in the rotor slots. The cylindrical rotor is similar to the armature of a dc machine except that the connection of the field winding to the external circuit is made through slip rings instead of a commutator. The cylindrical rotor structure leads to quiet operation and increased output power and efficiency. Unlike the claw-pole alternator, the length of the machine can be increased to get higher output power at a higher efficiency. The efficiency is higher since the effect of the end windings on the machine performance is less in a machine with a long length. It is also possible to build the machine with a salient-pole rotor instead of a cylindrical rotor. However, a machine with a salient-pole rotor is likely to produce more noise than a machine with a cylindrical rotor.

A machine with a cylindrical wound rotor has similar power electronics and control options as a claw-pole machine. If generation-only operation is required, a diode bridge and field current control is sufficient to regulate the output voltage. Better performance can be achieved by using a switched-mode rectifier in conjunction with field control [37]. If motoring operation is desired (e.g. for starting), or even better performance is desired, a full-bridge (active-switch) converter can be used, as shown in Fig. 25.15. Since this is a synchronous machine, some form of rotor position sensing or estimation is typically necessary. The full-bridge converter allows maximum performance and flexibility but carries a significant cost penalty.

25.6.3.2 Induction Machine

The stator of a three-phase induction machine is similar to that of a three-phase synchronous machine. The rotor is either a squirrel-cage or wound rotor. The machine with the squirrel-cage rotor is simpler in construction and more robust than the machine with a wound rotor in which the three-phase rotor winding is brought outside the rotor through slip rings. The rotor is cylindrical and is constructed from steel laminations. It is also possible to use a solid rotor instead of a laminated rotor. However, a solid rotor leads to higher losses as compared with a laminated rotor. The losses in a solid rotor can be
FIGURE 25.15 Model of an alternator with full-bridge converter.

reduced by cutting slots in the rotor surface, filling the stator slot openings with magnetic wedges to reduce the field ripple, and placing a copper cage on the rotor.

An induction machine requires a source that can provide the leading reactive power to magnetize the airgap. This means that a three-phase induction generator cannot supply power to a load through a three-phase diode bridge. Capacitor supply of the reactive energy is impractical because of the wide operating speed range. In the most general case (in which both motoring and generating operation can be achieved) a three-phase active bridge can be used. If only generating operation is desired, the power to the load can be supplied through a three-phase diode bridge and the reactive power can be obtained from a small three-phase active bridge provided for this purpose. This design requires a large number of devices and complex control.

25.6.3.3 Reluctance Machines

The switched reluctance machine is a doubly salient machine. Both the stator and rotor of the machine are made from steel laminations to reduce the iron losses. Only the stator carries windings; the rotor is constructed of steel laminations with a salient shape. The structure of a three-phase switched reluctance machine with six stator poles and four rotor poles is shown in Fig. 25.16a. A winding placed on diametrically opposite stator poles forms a phase winding. When a phase of the machine is excited, a pair of rotor poles tends to align with the excited stator poles to provide a path of minimum reluctance. If the rotor is moving towards alignment with the excited pair of stator poles, then the machine develops a positive torque and acts as a motor. If the rotor is moving away from the excited pair of stator poles, then the machine develops a negative torque and acts as a generator. The advantages of the switched reluctance machine include simple construction, fault-tolerant power electronic circuit, high reliability, unidirectional phase currents, and low cost. The drawbacks of the machine include high levels of torque ripple, vibration and acoustic noise, and a relatively high power electronics cost.

The synchronous reluctance machine is a singly salient machine. The stator of the machine is similar to that of a synchronous or induction machine. The rotor has a segmented structure with each segment consisting of a stack of axially laminated steel sheets sandwiched with a non-magnetic material. The structure of a four-pole synchronous reluctance machine is shown in Fig. 25.16b. A synchronous reluctance machine has less torque ripple, lower losses, and higher power density than a comparable switched reluctance machine. Inclusion of permanent magnets in the rotor structure allows both reluctance and magnet torque to be achieved. Such interior permanent magnet (IPM) machines can achieve very high performance and power density. When permanent magnets are included, however, careful attention must be paid to the effects of shutdown of the power electronics as an uncontrolled back-emf component will exist in this case [41].

The switched reluctance machine, like the induction machine, requires an external source to magnetize the airgap. Several circuits are available to excite the switched reluctance machine. A circuit that is suitable for the automotive application of this machine is shown in Fig. 25.17. A phase leg is needed for each stator phase of the machine. In this case, the switched reluctance machine obtains its excitation from the same bus that it generates into. Unlike the synchronous and induction machines in which the number of wires needed to connect the machines to the power converters is usually equal to the number of phases, the number of wires needed to connect the switched reluctance machine to a converter is equal to twice the number of phases. This is of no particular concern in a switched reluctance machine in which the power converter is integrated with the machine in the same housing. The synchronous reluctance machine also requires an external source to magnetize the airgap. The machine usually employs an active bridge similar to the one used with an induction machine for the desired power conversion. The machine can also employ the converters used with the switched reluctance machine. In this case, the currents through the stator windings are unidirectional. The relative complexity of the power electronics is a disadvantage of these machine types in the case where only generator operation is necessary.

25.6.3.4 Permanent Magnet and Hybrid Synchronous Machines

The permanent magnet synchronous machine designed with high-energy rare-earth magnets operates with high efficiency, high power density, low rotor inertia, and low acoustic noise. The excitation from the permanent magnets is fixed and, therefore, the regulation of the output voltage of the machine is not as straightforward as in a synchronous machine with a wound rotor. For generator operation, machines of this type can use switched-mode rectifiers to regulate the output voltage [42, 43]. The boost rectifier of Fig. 25.14 is one possible implementation of this approach. Alternatively, a diode rectifier followed by a dc/dc converter can be used to regulate the generator system output [44]. Another method proposed
FIGURE 25.16 Structures of: (a) switched reluctance and (b) synchronous reluctance machines. AA′ represents phase A winding.
FIGURE 25.17 Circuit for a switched reluctance machine.

for this type of system involves the use of tapped windings and two three-phase SCR bridges [45]. The taps on the phase windings are connected to one bridge, while full phase windings are connected to the other bridge. The bridge connected to the full phase windings is used to supply power to the dc bus at low engine speeds, while the converter connected to the taps is used at high speed. The use of a tapped winding and dual bridges helps the system cope with the wide speed range of the alternator and limit the losses associated with the pulsating output currents. In the case when both motoring and generating modes are desired, a full-bridge converter can be used. Again, as this is a synchronous machine, some form of position sensing or estimation is necessary. Also, in all of these systems the effects of failure of the power electronics must be carefully considered as there is no possibility of regulating the back voltages by field control.

Attempts to develop a simpler voltage regulation scheme for permanent magnet synchronous machines have led to a permanent magnet/wound-rotor hybrid synchronous machine in which the rotor consists of two parts: a part with permanent magnets and a part with a field winding [46]. The two parts are placed next to each other on a common shaft. The rotor with the field winding can employ claw-pole, salient-pole, or cylindrical structure. The field current generates a flux that is used to either aid or oppose the permanent magnet flux and regulate the output voltage of the machine. One possible failure mode of this approach that can lead to catastrophic failure is if the field winding breaks while the machine is operating at high speed. In this case, the generated output voltage will become large and uncontrolled. Some means of mechanically disconnecting the alternator at the input or electrically disconnecting it at the output may be necessary to limit the impact of this failure mode.

25.6.3.5 Axial-airgap Machines

The principle of operation of an axial-airgap, or axial-flux, machine is the same as that of a radial-airgap machine. An axial-airgap machine is characterized by a short axial length and large diameter. The structure of an axial-airgap permanent magnet machine with surface magnets is shown in

| Stator | Rotor |
| Magnets | Shaft |
FIGURE 25.18 Structure of an axial-airgap permanent magnet machine.

Fig. 25.18 [47]. The stator of the machine can be slotless or slotted. Two different magnetic circuit configurations are possible. In the NN configuration, the magnetic polarities in one pole pitch on both sides of stator are the same so that there are two main fluxes with symmetrical distribution through the stator. In this case, the conductors can be wound into two back-to-back stator slots to make one coil. The machine has a large stator yoke dimension because the flux passes through the yoke, but less copper loss because of short end windings. In the NS configuration, the magnetic polarities in one pole pitch on the opposite sides of stator are the opposite of each other so that there is only one main axial flux through the stator. In this case, the stator yoke dimension is small, but the end windings are long because the direction of current in the back-to-back stator slots is the same. The iron losses are small due to small yoke dimension and the copper losses are high because of long end windings. Heat removal is more challenging due to small stator dimensions. The structure shown in Fig. 25.18 is that of an axial-airgap permanent magnet machine with surface magnets. In an axial-airgap machine with interior permanent magnets, the magnets are embedded in the steel of the rotor.

The axial airgap versions of other types of machines, such as the induction and switched reluctance machines, are also possible. The structure of an axial-airgap induction machine

is similar to that of an axial-airgap permanent magnet machine except that windings are used instead of permanent magnets.

25.7 Dual/High Voltage Automotive Electrical Systems

The electrical system of a 1920s internal combustion engine (ICE) automobile had only a few loads: a starter, an ignition device, a horn, and some lamps [48]. The mean power consumption of these loads was less than 100 W. An engine-driven dc generator charged a 6 V lead-acid battery that provided electrical power. The power was distributed via point-to-point wiring, with most loads controlled directly by manually operated primary switches located within the reach of the driver. Only the starter was switched indirectly by an electromechanical relay. After the Second World War, the automotive electrical system started to grow rapidly in complexity and power consumption as additional features, including radios, multispeed windshield wipers, and power windows, were added. The introduction of higher compression engines stretched the 6-V system beyond its technological limits. The 8.5 to 1 compression ratio engines required 100–200% greater ignition voltages than the 6.4 to 1 engines. As a result, the primary side current of the ignition coil was doubled or tripled and the life of the distributor contacts was reduced to an unacceptable level. To overcome this problem, the battery voltage was increased to 12 V in the mid-1950s [49, 50].

Over the past four decades, the electrical power requirements of automobiles have increased even more rapidly. From a mere 400 W in 1955, the power rating of a luxury vehicle's generator has increased to over 1800 W [51, 52]. However, the electrical system of a modern automobile is architecturally identical to the 12-V point-to-point system of the 1950s. The only changes that have taken place have been at the component level, such as the replacement of the dc generator by a three-phase alternator-rectifier, the replacement of wound-field dc motors by permanent magnet ones, and an increased use of relays. The rapid growth in the electrical system is expected to continue due to environmental regulations, consumer demand for increased functionality, safety, security and comfort, and replacement of some mechanical actuators by electrical counterparts. The average electrical power requirement of a modern luxury vehicle is about 800 W. With the addition of such loads as electric power steering, engine-cooling fan, water pump, and electromechanical engine valves, the average power requirement could increase to 2.5 kW by 2005 [53]. The traditional solution of increasing the size of the alternator and the battery is not practical due to space limitations and fuel efficiency requirements. Furthermore, the peak power requirements of some of the anticipated loads – heated windshield (2.5 kW), heated catalyst (3 kW), electromechanical engine valves (2.4 kW at 3000 rpm), and active suspension

(12 kW) – cannot be met economically using the present architecture. These factors have motivated the development of new dual/high voltage electrical architectures that incorporate a higher-voltage bus in addition to the standard 14 V bus [39, 54–56]. A dual/high voltage approach allows an efficient supply of power to many loads which benefit from operating at a higher voltage, while retaining the 14 V bus for loads (such as lamps and electronics) which do not benefit from a higher voltage. High-voltage architectures that do not retain the 14 V bus are also possible, but will require a substantial investment in the design and production of new high-voltage components. This section describes some of the characteristics and preliminary specifications of the new dual/high voltage electrical system architectures. It also discusses some of the widely considered implementation approaches.

25.7.1 Trends Driving System Evolution

The conventional 12-V automotive electrical power system has many defects, including a widely varying steady-state system voltage and large transients, which force the electrical functions to be over-designed. However, these limitations alone have not been a strong enough driver for automotive companies to seriously evaluate advanced alternatives. Now a number of new factors are changing this situation. The most important of these are future load requirements that cannot be met by the present 12-V architecture.

25.7.1.1 Future Load Requirements

Table 25.6 gives a list of electrical loads expected to be introduced into automobiles in the next ten years [53]. Some of these loads (electrohydraulic power steering, electric engine fan, electric water pump, and electromechanical valves) will replace existing mechanically or hydraulically driven loads. The remaining are new loads introduced to either meet government mandates or satisfy customer needs.

TABLE 25.6 Electrical loads expected to be introduced into automobiles in the next decade [53]

Load	Peak power (W)	Average power (W)
Exhaust air pump	300	10
Electrohydraulic power steering	1000	150
Electric engine fan	800	150
Heated catalytic converter	3000	90
Electric water pump	300	150
Heated windshield	2500	120
Electromechanical engine valves (6 cylinders at 6000 rpm)	2400	800
Active suspension	12,000	360
Total		1830

The average electrical power requirement of a present-day automobile is in the range of 500–900 W depending on whether it is an entry-level or a luxury vehicle. When the loads of Table 25.6 are introduced, the average electrical power requirement will increase by 1.8 kW. Furthermore, if the air-conditioning (A/C) pump were to ever become electrically driven, the peak and average power demands would increase by an additional 3.5 kW and 1.5 kW, respectively. Distributing such high power at a relatively low voltage will result in unacceptably bulky wiring harnesses and large distribution losses. Since the alternator has to generate both the power consumed by the loads and the power dissipated in the distribution network, its output rating (and hence size and power consumption) will be greater than in an architecture with lower distribution losses. With the large premium attached to the size of the alternator (due to space constraints in the engine compartment), an architectural change in the distribution and generation systems is essential before many of the future loads can be introduced.

There is also an increasing disparity in the voltage requirements of future electrical loads. High pulse-power loads, such as the heated windshield and electrically heated catalytic converter, become feasible only at voltages greater than the current 14 V [57]. On the other hand, incandescent lamps and electronic control units (ECUs) will continue to require low voltages. For example, present day ECUs have linear regulators which convert the 14 V distribution voltage to the 5 V needed by the integrated circuits. The efficiency of these regulators is equal to the ratio of output to input voltage, i.e. 35%. Furthermore, the next generation of higher speed lower power consumption integrated circuits operate at 3.3 V, making the regulators more inefficient. This inefficiency also means that larger heat sinks are required to remove the heat from the ECUs.

25.7.1.2 Higher Fuel Efficiency

A secondary motivating factor for the introduction of a higher system voltage is the challenge of achieving higher fuel economy. The average fuel economy of present-day automobiles in the United States is in the vicinity of 30 miles per gallon (mpg). There is little market incentive for automobile manufacturers to increase the fuel economy of vehicles for the US market where the price of fuel is relatively low. The price of gasoline in the US ($1.70 per gallon) is less than the price of bottled water ($4.00 per gallon when bought by the quart). Although market forces have not been a driver for the development of fuel-efficient vehicles, a number of new incentives have emerged over the past few years. One of these is the fine imposed on the automakers by the US government if the average fuel economy of their fleet falls below the mandated standard. The mandated standard for cars has increased from 24 mpg in 1982 to its 1997 level of 27.5 mpg, and will continue to increase. In Europe, the German Automotive Industry Association (VDA)

plans to increase the average fleet fuel efficiency to 39.9 mpg by 2005 – compared to 31.4 mpg in 1990 [58].

Another driver behind the development of fuel-efficient vehicles is the partnership for a new generation of vehicles (PNGV). This ten-year research program, launched in September 1993, is a collaboration between the US Federal Government and the big three US automakers (General Motors, Ford, and DaimlerChrysler) that aims to strengthen national competitiveness in the automotive industry and reduce dependence on foreign oil. The PNGV has set a goal to develop an 80 mpg midsize vehicle by 2004 [59]. The German Automotive Industry Association is pursuing similar targets. The VDA has undertaken a pledge to introduce a 3 L/100 km (78 mpg) vehicle by the year 2000. This is complemented by the introduction of highly fuel-efficient vehicles (in excess of 50 mpg) in both the Japanese and American markets.

With the present alternator, 800 W of electrical power consumes 1.33 L of gasoline for every 100 km driven when the vehicle has an average speed of 33.7 km/h. This represents a 45% increase in fuel consumption for a 3 L/100 km vehicle. Hence, if future high fuel economy vehicles are going to have comfort, convenience, and safety features comparable to present-day vehicles, the efficiency of the electrical generation and distribution system will have to be substantially improved. Furthermore, as discussed in Section 25.8, one widely considered means of achieving high fuel economy is the use of a hybrid vehicle architecture. In practice, this approach necessitates the introduction of a higher voltage in the vehicle.

25.7.2 Voltage Specifications

A major issue when implementing a high or dual voltage system is the nominal voltage of the high-voltage bus, and the operating limits of both buses. While there are many possibilities, there is a growing consensus in the automotive industry for a nominal voltage of 42 V for the high-voltage bus (corresponding to a 36 V lead-acid storage battery) [39, 56, 60]. This voltage is gaining acceptance because it is as high as possible while remaining within acceptable safety limits for open wiring systems (once headroom is added for transients) and it provides substantial benefits in the power semiconductors and wiring harness [61]. Furthermore, this voltage is sufficient to implement starter/alternator systems and "light" hybrid vehicle designs [62, 63]. While no vehicles equipped at 42 V are in production at present, availability of 42 V components is rapidly increasing and 42 V equipped vehicles may be expected early in this decade.

The permissible static and transient voltage ranges in an electrical system are important design considerations for power electronic equipment. At present, no universally accepted specification exists for high or dual voltage automotive electrical systems. However, the preliminary specifications proposed by the European automotive working group, *Forum Bordnetz,* are under wide consideration by the

TABLE 25.7   Voltage limits for 14 and 42 V buses proposed in [56]

Voltage	Description	Value
$V_{42,OV-dyn}$	Maximum dynamic overvoltage on 42 V bus during fault conditions	55 V
$V_{42,OV-stat}$	Maximum static overvoltage on 42 V bus	52 V
$V_{42,E-max}$	Maximum operating voltage of 42 V bus while engine is running	43 V
$V_{42,E-nom}$	Nominal operating voltage of 42 V bus while engine is running	41.4 V
$V_{42,E-min}$	Minimum operating voltage of 42 V bus while engine is running	33 V
$V_{42,OP-min}$	Minimum operating, voltage on the 42 V bus. Also, lower limit operating voltage for all non-critical loads (i.e. loads not required for starting and safety)	33 V
$V_{42,FS}$	Failsafe minimum voltage: lower limit on operating voltage for all loads critical to starting and safety on the 42 V bus	25 V
$V_{14,OV-dyn}$	Maximum dynamic overvoltage on 14 V bus during fault conditions	20 V
$V_{14,OV-stat}$	Maximum static overvoltage on 14 V bus	16 V
$V_{14,E-max}$	Maximum operating voltage of 14 V bus while engine is running	14.3 V
$V_{14,E-nom}$	Nominal operating voltage of 14 V bus while engine is running	13.8 V
$V_{14,E-min}$	Minimum operating voltage of 14 V bus while engine is running	12 V
$V_{14,OP-min}$	Minimum operating voltage of 14 V bus. Also lower limit operating voltage for all non-critical loads	11 V
$V_{14,FS}$	Failsafe minimum voltage: lower limit on operating voltage for all critical loads on the 14 V bus	9 V

automotive industry [56]. These specifications, summarized in Table 25.7, impose tight static and transient limits on both the 42 and 14 V buses. The upper voltage limit on the 14 V bus is far lower than in the conventional 12-V system. The allowed upper limit on the 42 V bus is also proportionally tight. These strict limits facilitate the use of power semiconductor devices such as power MOSFETs and lower the cost of the protection circuitry needed in individual functions. However, they also require much more sophisticated means for limiting transients (such as load dump) than is found in conventional systems, which imposes a significant cost. Appropriate voltage range specifications for dual/high voltage electrical systems are thus a subject of ongoing investigation by vehicle manufacturers, and will likely continue to evolve for some time.

25.7.3 Dual-voltage Architectures

Conventional automotive electrical systems have a single alternator and battery. Dual-voltage electrical systems have two voltage buses and typically two batteries. Single-battery configurations are possible, but tend to be less cost effective [61]. A variety of different methods for generating and supplying energy to the two buses are under investigation in the automotive community. Many of these have power electronic circuits at their core. This section describes three dual-voltage electrical system architectures that have received broad attention. In all three cases the loads are assumed to be partitioned between the two buses with the starter and many of the other high-power loads on the 42 V bus and most of the lamps and electronics on the 14 V bus.

The dc/dc converter-based implementation of Fig. 25.19 is perhaps the most widely considered dual-voltage architecture.
FIGURE 25.19   Dual-voltage architecture based on a dc/dc converter.

In this implementation, an alternator and associated battery provide energy to one bus (typically the 42 V bus), while the other bus is supplied via a dc/dc converter. If a battery is used at the dc/dc converter output, the converter needs to be rated for slightly above average power. Otherwise, the converter needs to be rated a factor of two to three higher to meet peak power requirements [61]. The architecture of Fig. 25.19 has a number of advantages. The dc/dc converter provides high-bandwidth control of energy flow between the two buses, thus enabling better transient control on the 14 V bus than is available in present-day systems or in most other dual-voltage architectures. Furthermore, in systems with batteries on both buses, the dc/dc converter can be used to implement an energy management system so that generated energy is always put to best use. If the converter is bidirectional it can even be used to recharge the high-voltage (starter) battery from the low-voltage battery, thus providing a *self jump start* capability. The major challenge presented by this architecture is the implementation of dc/dc converters having the proper functionality within the tight cost constraints dictated by the automotive industry. Some aspects of design and optimization of converters for this application are addressed in [64].
FIGURE 25.20 Dual-voltage architecture based on a dual-wound alternator.

FIGURE 25.21 Model for a dual-wound alternator system. The two output voltages are regulated through field control and phase control. For a 42/14 V system, a winding ratio between the two stator windings of 2.5:1 is typical.

The dual-stator alternator architecture of Fig. 25.20 is also often considered for dual-voltage automotive electrical systems [65, 66]. In this case, an alternator with two armature windings is used along with two rectifiers to provide energy to the buses and their respective batteries. Control of the bus voltages is achieved via a combination of controlled rectification and field control. Typically, field control is used to regulate one output, while the other output is regulated using a controlled rectifier. Figure 25.21 shows one possible implementation of this architecture. It should be noted that to achieve sufficient output power and power steering from the dual-wound alternator, the winding ratio between the two outputs must be carefully selected. For 42/14 V systems, a winding ratio of 2.5:1 is typical [66]. Advantages of this electrical architecture include low cost. However, it does not provide the bidirectional energy control that is possible in the dc/dc converter architecture. Furthermore, there are substantial issues of cross-regulation and transient control with this architecture that remain to be fully explored.

In a third architecture, a single-output alternator with a dual-output rectifier is employed. This approach is shown schematically in Fig. 25.22. As with the dual-stator alternator configuration, this architecture has the potential for low cost. One widely considered implementation of the dual-rectified alternator is shown in Fig. 25.23 [65, 67–69]. Despite its simplicity, this implementation approach provides less functionality than the dc/dc converter-based architecture, generates substantial low-frequency ripple which must be filtered, and has serious output power and control limitations [66]. An alternative implementation, proposed in [37] and shown in Fig. 25.24, seems to overcome these limitations, and may potentially provide the same capabilities as the dc/dc converter-based architecture at lower cost. Clearly, this architecture has promise for dual-voltage electrical systems, but remains to be fully explored.

25.8 Electric and Hybrid Electric Vehicles

Battery-powered electric vehicles were first introduced over one hundred years ago, and continue to incite great public interest because they do not generate tailpipe emissions.
FIGURE 25.22 Dual-voltage architecture based on a dual-rectified alternator.

Nevertheless, the low energy storage density and the high cost of suitable batteries makes pure electric vehicles non-competitive with internal combustion engine vehicles in most applications. An alternative approach that is generating widespread attention is the hybrid electric vehicle (HEV). An HEV combines electrical propulsion with another energy source, such as an internal combustion engine, allowing the traditional range and performance limitations of pure electric vehicles to be overcome [70]. Alternative energy sources, such as fuel cells, are also possible in place of an internal combustion engine.

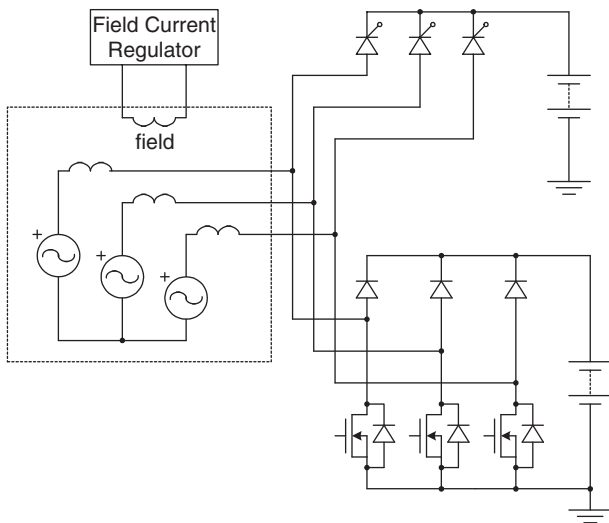
Hybrid electric vehicles can be classified as having either a parallel or series driveline configuration [71]. In a series HEV all of the propulsion force is produced from electricity; the engine is only used to drive a generator to produce electricity. In a parallel hybrid, propulsive force can come from either the
FIGURE 25.23 A dual-rectified alternator with a phase-controlled rectifier.


FIGURE 25.24 A dual-rectified alternator with a switched-mode rectifier.

engine or the electrical drive. In both cases, batteries or other electrical storage devices are used to buffer the instantaneous difference between the power needed for propulsion and that generated by the engine. The selection of a series or parallel driveline depends heavily on the performance requirements and mission of the vehicle.

In a series HEV, all power delivered to the wheels of the vehicle must be delivered through the electrical driveline. The electrical driveline components, including the batteries, power electronics, and machine(s), must all be rated for the *peak* traction power requirements, making these components relatively large and expensive if performance (e.g. acceleration) comparable to a conventional vehicle is to be achieved. To achieve the

required power levels, the electrical driveline must operate at hundreds of volts, necessitating the electrical subsystem to be sealed from access by the user. The engine, on the other hand, need only be rated to deliver the *average* power required by the vehicle, which is much lower. In a system that does not require utility recharge of the batteries (i.e. can drive indefinitely on fuel alone), the engine size is set by the power requirements of the vehicle at maximum cruising speed. If utility recharge of the batteries and a battery-limited driving range is acceptable, engine power requirements can be reduced even further. Because the engine does not provide tractive power, it can be designed to run at a single optimized condition, thus maximizing engine efficiency and minimizing emissions. Furthermore, the need for a transmission is eliminated and there is a great deal of flexibility in the engine placement.

In a parallel HEV, traction power is split between the engine and the electrical driveline. One possible approach is to utilize a single machine mounted on the engine crankshaft to provide starting capability along with electrical traction power and regeneration [72–75]. This approach can be replaced or complemented with other approaches, such as use of a power-splitting device such as a planetary gear set [70, 76], or using different propulsion and generation techniques on different sets of wheels [71, 77, 78]. In all parallel hybrid approaches, some form of transmission is needed to limit the required speed range of the engine. A wide range of divisions between engine size and electrical system size is possible in the parallel hybrid case, depending on structure. Depending on this split, the necessary electrical driveline system voltage may be as low as 42 V (which is safe for an open wiring system) or as high as 300 V. Also because the electrical subsystem, the internal combustion engine subsystem, or both may provide tractive power under different conditions, there exists a wide range of possible operating approaches for a parallel hybrid system. Consequently, the control strategy for a parallel hybrid tends to be substantially more complex than for a series hybrid.

One parallel hybrid approach that is receiving a lot of attention for near-term vehicles is a "light" or "mild" hybrid. In this case, a somewhat conventional vehicle driveline is complemented with a relatively small starter/alternator machine mounted on the crankshaft [62, 63, 72–75, 79]. The electrical drive power is typically below 10 kW average and 20 kW peak. The starter/alternator can be used to provide rapid, clean restart of the vehicle so that the engine can be turned off at idling conditions and seamlessly restarted. This so-called "stop and go" operation of the engine is valuable for fuel economy and emissions. The starter/alternator can also be used to implement regenerative braking, to provide engine torque smoothing (replacing the flywheel and allowing different engine configurations to be used) and to provide boost power for short-term acceleration. At the low-power end, such systems can be integrated directly into the open wiring configuration of a 42 V electrical system, simplifying the vehicle electrical architecture. System-level control remains

a major challenge in realizing the full benefits of such systems. Starter/alternator-based hybrids are expected to be a significant near-term application of power electronics and machines in automobiles.

25.9 Summary

Power electronics is playing an increasingly important role in automobiles. It is being used to enhance the output power capability and efficiency of the electrical power generation components. Power electronics is also an enabling technology for a wide range of new and improved functions that enhance vehicle performance, safety, and functionality.

The design of automotive power electronic systems is strongly influenced by the challenging electrical and environmental conditions found in automobiles. Important factors include the static and transient voltage ranges, electromagnetic interference and compatibility requirements, and temperature and other environmental conditions. Some of the most important design considerations for automotive power electronics were addressed in Section 25.3.

Section 25.4 described some of the vehicle functions that benefit from, or are enabled by, power electronics. These functions range from lighting to actuation and steering. Power electronic switches also play a central role in multiplexed electrical distribution systems. This role of power electronics was addressed in Section 25.5.

The rapid increase in electrical power demand in automobiles is motivating the introduction of new technologies for electrical power generation and control. Lundell alternators are presently used for power generation in automobiles, but are rapidly reaching their power limits. Section 25.6 reviewed the operating characteristics of the Lundell alternator. It also described several techniques for extending the power capabilities of this machine. To meet the growing demand for electrical power, alternative machine, and power electronic configurations may be necessary in the future. A number of candidate machine and power circuit configurations were reviewed in Section 25.6. Such configurations can also be applied towards the design of integrated starter/alternators and hybrid propulsion systems, as was discussed in Section 25.8.

The increasing electrical and electronic content of automobiles is beginning to stretch the capabilities of the conventional 12-V electrical system. Furthermore, there is a desire on the part of vehicle manufacturers to introduce new high-power loads, such as electromechanical engine valves, active suspension, and integrated starter/alternator. These are not likely to be practical within the present 12-V framework. These challenges are forcing the automotive industry to seriously consider high and dual voltage electrical systems. The ongoing developments in this area were reviewed in Section 25.7

The increasing electrical content of vehicles both underscores the need for power electronics and reflects the benefits of their introduction. It is safe to say that power electronics will continue to play an important role in the evolution of automobiles far into the future.

26.1 Introduction

Pulsed power (PP) can be considered as the science and technology of accumulating electrical energy over a relatively long period of time followed by the subsequent energy release in very short pulses, a single one or a controlled repetitive sequence, thus increasing the instantaneous peak power. An example is shown in Fig. 26.1, where a stored energy of 1 kJ can be discharged into a long pulse of 1 kW for 1 s or a short pulse of 1 GW for 1 μs, respectively, considering the ideal case of a lossless system.

Pulsed power is a technique primarily developed for radars, accelerators, and military applications, but with the potential for civil applications [1]. In fact, there is a growing variety of environmental, biomedical, commercial, and industrial applications that use positive and/or negative high-voltage (HV) repetitive pulses for enhancing the properties of a product or a technique [2]. These pulses may last anywhere from hundreds of picoseconds to tens of seconds, being released as a single shot or as a repetitive sequence up to several tens of thousands per second.

What makes PP so unique is the concept that one can deliver extremely high peak powers during short times without the demand for highly powerful energetic power sources, used in custom direct (dc) or alternating (ac) voltage systems.

Previously, this technology was dominated by vacuum or gas tubes (i.e., electronic valves) for switching the high powers needed for military and large plant physical applications [3]. With the technological advent of power semiconductors in the seventies and particularly modern power semiconductors in the nineties, it was possible to develop PP generators based on power semiconductors, still, lower power rated compared with the electronic valves, but largely rewarded by the higher energetic efficiency and flexibility together with compactness and cost effectiveness [4].

Nowadays, the applications of PP are driving the need for technological advances in medical, environment, biological, energetic and industrial applications. For example, in the reduction of pollution emissions from fossil fuels, in killing bacteria and organic pollutants, in melanoma cancer treatment, in molding metals sheets, and so on [5–9].

This chapter provides basic concepts and advanced know-how on the generation of repetitive HV pulses using state of the art power semiconductor technology. Apart from this introduction, in Section 26.2, "Power Semiconductors for Pulsed Power," the most common power semiconductors devices used in solid-state-based high-voltage generators are reviewed. In Section 26.3, "Load Types and Requirements," several types of pulsed power applications are presented, and the type of load requirements they present to the high-voltage modulators
FIGURE 26.1 Discharge of 1 kJ energy; (a) 1 kW during 1 s pulse, (b) 1 GW during 1 μs pulse.

are described. The most widespread semiconductor-based HV pulse modulator topologies are analyzed and discussed in terms of solid-state devices operation in Section 26.4, "Solid-State Pulsed Power topologies." Finally, the main conclusions about semiconductors use in high-voltage pulse generation are presented and the future trends on this technology are discussed in Section 26.5, "Conclusions and Future Trends."

26.2 Power Semiconductors for Pulsed Power

The demand for high-voltage modulators to generate repetitive high-voltage pulses with optimized performance and characteristics, based in solid-state technology, still needs enhancement of the Volt–Ampere capabilities and switching speed of modern power semiconductors.

Therefore, using power semiconductors in pulsed power is a matter of optimizing their use, going beyond the present semiconductor ratings and taking advantage of usually nonuseful phenomena or nonideal characteristics, such as controlled avalanche breakdown (for avalanche transistors), diode reverse recovery sharpness that can generate inductive high-voltage pulses, Zener capacitances, peak currents, and unusual very short-pulse behavior.

In the following subsections, the particular characteristics of power semiconductors enabling their use in pulsed power applications will be summarized, from the high-voltage diode through the latest silicon carbide (SiC) power junction field-effect transistors. To overcome power semiconductor's limited hold-off voltage and current ratings (Fig. 26.2), some techniques will be described, including series and parallel semiconductor arrangements, up to the cascode stacks.

26.2.1 High-Voltage PIN Diodes (SOS Diodes)

Figure 26.3a shows the simplified structure of a typical high-voltage, high-power diode with forward-bias carriers [10]. It has a heavily doped P^+ anode and N^+ substrate on which a lightly doped N^- (or near intrinsic, I) epitaxial layer, called drift region, is formed [11]. The drift region, usually not found in low-power diodes, has to contain the depletion layer of the reverse-biased high-voltage PIN diode, establishing the diode reverse breakdown (or hold-off) voltage rating (punch-through diodes).

PIN diodes turn-on requires removal of the depletion layer (the diode is reverse biased prior to turn-on). Removal of the stored depletion charge needs a certain current and time. Forward conduction is dominated by injected holes (conductivity modulation) in the drift region, which becomes a virtual P
FIGURE 26.2 Current maximum Volt–Ampere capabilities of high-power semiconductors (SCR, silicon-controlled rectifier; GTO, gate turn-off thyristor; GCT, gate-controlled thyristor; IGCT, integrated gate-commutated thyristor; IEGT, injection-enhanced gate transistor; IGBT, insulated gate bipolar transistor; MOSFET, metal-oxide semiconductor field-effect transistors).
FIGURE 26.3   (a) Forward-biased PIN diode; (b) $P^+PN^-N^+$ SOS diode structure and typical doping profile; and (c) SOS diode reverse blocking behavior.

region. The minority injected charge is positive if the diode is conducting, the forward current providing minority carriers at the rate they recombine.

To turn-off the PIN diode, the stored excess carriers, mostly in the drift region, must be discharged before the diode reverse biases, the minority charge becoming negative. Upon applying a reverse voltage U_R, the forward current will decrease at a rate of $di/dt \approx I_{RR}/t_{rr}$, (Fig. 26.3c), becoming negative to swept the excess carriers out of the drift region and charge the depletion capacitance C_{eqoff}. At constant U_R voltage applied in inductive circuits (L_S inductor), the diode reverse current rate is $di/dt \approx U_R/L_S$, reaching the value $I_{RR} = t_{rr}U_R/L_S$ at the reverse recovery time $t_{rr} = L_S I_{RR}/U_R$, being the reverse recovery charge $Q_{RR} = I_{RR}t_{rr}/2$.

In LC oscillating circuits (Fig. 26.4), the PIN diode may become reverse biased by a negative fast rising voltage with high peak value V_{RM}, which can be more than three times higher than the applied direct voltage U (Fig. 26.3c).

At high reverse voltages, the pulse energy must be limited to avoid the impact ionization current to destroy the diode by avalanche breakdown and excessive power dissipation. Therefore, PIN diodes should be used with very short pulses,

sharpening and increasing the voltage amplitude of the applied pulses.

Semiconductor Opening Switches (SOS) are modified PIN high-voltage diodes using a $P^+PN^-N^+$ structure with gradual doped P layer (Fig. 26.3b) [12]. They are optimized to exhibit relatively slow reverse recovery ($\Lambda t_{rr} \approx 50-100$ ns) but abrupt recovery (very fast reverse current decay) $(1 - \Lambda)t_{rr} \approx 5$ ns (Fig. 26.3c).

SOS characteristics depend not only on the pumping forward current (current density and very short time to avoid saturation) but also on the doping profile of the $P^+PN^-N^+$ structure. The reverse recovery of SOS diodes (e.g., their opening) should differ from PIN diodes, since current interruption ought to occur mostly in the narrower P doped layer, not in the drift layer. The SOS can switch high currents (kA) in nanosecond opening times, with automatic uniform distribution of reverse voltage (kV) in series-connected SOSs during current decay. Series stacks of up to 1000 SOSs can be deployed to obtain working voltages near the megavolt level, peak currents of several kiloampere, peak power of gigawatts, and average powers of tens of kilowatts.
FIGURE 26.4 SOS pulse generation using magnetic energy storage.

In a simplified circuit for SOS operation (Fig. 26.4), it is supposed that a rectangular prepulse with amplitude U and pulse length T_U is generated and applied to the SOS in series with an inductor L_S to charge the capacitor C_R.

During the positive part of the prepulse, the forward pumping period, the SOS diode is forward biased, and the inductor sinusoidal current rises to build up energy in the resonant $L_S C_R$ circuit and excess carriers in the diode, the capacitor C_R being charged to nearly $2U$. Neglecting losses, parasitic effects, and diode voltage drops, the peak forward current is $I_F \approx U/Z_R$, where $Z_R = \sqrt{L_S/C_R}$ is the characteristic impedance of the $L_S C_R$ resonant tank with oscillation frequency $\omega_R = \sqrt{L_S C_R}^{-1} = \pi/T_U$. Charging only occurs during the pulse length T_U. Neglecting the recombination decay time constant, the diode forward stored charge is nearly $2I_F/\omega_R$.

During the sinusoidal negative oscillation interval, the prepulse voltage is nearly zero and the inductor current goes negative. The SOS diode opens at nearly the C_R discharge peak current $I_{RR} \approx 2U/Z_R \approx 2I_F$, being the reverse recovery charge $Q_{RR} \approx I_{RR}/\omega_R$ nearly equal to the forward injected charge.

Supposing diode abrupt recovery and assuming energy conservation, the maximum v_p pulse voltage V_{RM} is dependent on the load capacitor C_Z and resistor R_Z, being $V_{RM} \approx I_{RR}(R_Z||Z_Z)$ for $C_R >> C_Z$, where R_Z is paralleled with $Z_Z = \sqrt{L_S/C_Z}$, the characteristic impedance of the second-order $L_S C_Z$ circuit with damping factor $\xi \approx Z_Z/(2R_Z)$ and natural frequency $\omega_Z \approx \sqrt{L_S C_Z}^{-1}$.

For near optimum energy transfer, damping slightly lower than the critical value should be used, the v_p pulse being roughly sinusoidal. Pulse forming networks or lines can be used to almost square it [12].

To obtain a near critical damped load ($0.7 < \xi < 1$), it must be $1.4\,R_Z < Z_Z < 2R_Z$. Then, from the required V_{RM} and I_{RR}, the Z_R value, it is $Z_R \approx 2U(R_Z||Z_Z)/V_{RM}$, being $L_S \approx Z_R/\omega_R$ and $C_R \approx 1/(Z_R\omega_R)$. From L_S and Z_Z, the load parallel capacitor C_Z, either added or stray capacitance or SOS C_{eqoff}, should be $C_Z \approx L_S/Z_Z^2$.

For a required V_{RM} in load resistor R_Z and capacitor C_Z, the SOS diode must withstand the forward current I_F, pumping time T_U, reverse voltage V_{RM}, reverse recovery current I_{RR}, and reverse recovery charge Q_{RR}.

High peak voltages V_{RM} and comparatively low values of I_{RR} need very low values of the load (spurious) parallel capacitance C_Z or higher values of I_{RR}.

EXAMPLE 26.1 Determine the circuit parameters of Fig. 26.4 to obtain a 30 ns 1 MV pulse in resistor $R_Z = 1\,k\Omega$ (1 MW peak) paralleled with C_Z capacitor, from a prepulse having $U = 300\,kV$ and pulse length T_U.

SOLUTION. The prepulse length should be $T_U \approx 30 \times 10^{-9} \times 10^6/(300 \times 10^3) \approx 100\,ns$. Then, from the above equations, it is obtained $\omega_R = \pi/T_U = \pi/(100 \times 10^{-9}) \approx 3.14 \times 10^7$, $Z_Z \approx 1.5R_Z \approx 1.5\,k\Omega$, $R_Z||Z_Z \approx 600\,\Omega$, $Z_R \approx 2U(R_Z||Z_Z)/V_{RM} \approx 2 \times 300 \times 10^3 \times 600/10^6 \approx 360\,\Omega$, $L_S \approx Z_R/\omega_R \approx 360/3.14 \times 10^7 \approx 11.4\,\mu H$, $C_R \approx 1/(Z_R\omega_R) \approx 1/(360 \times 3.14 \times 10^7) \approx 88\,pF$, and $C_Z \approx L_S/Z_Z^2 \approx 11.4 \times 10^{-6}/360^2 \approx 5.1\,pF$, which is a low value, considering stray capacitances, not to forget the SOS diode (or diode association) equivalent off-depletion capacitance C_{eqoff}. The SOS must withstand $I_F \approx U/Z_R \approx 300 \times 10^3/360 \approx 833\,A$, $I_{RR} \approx 2I_F \approx 1.67\,kA$, $V_{RM} \approx I_{RR}(R_Z||Z_Z) \approx 1667 \times 600 \approx 10^6\,V$, $Q_{RR} \approx I_{RR}/\omega_R \approx 1667/3.14 \times 10^7 \approx 53\,\mu C$, mean excess carrier (holes) lifetime (reciprocal of recombination decay) higher than $1\,\mu s$, and reverse recovery time $t_{rr} \approx \pi/(2\omega_R) \approx \pi\sqrt{L_S C_R}/2 \approx 50\,ns$, nearly half of the forward pumping time.

The pulse duration (settling time) is close to $T_p = \pi/(\xi\omega_Z) = \pi\sqrt{L_S C_Z}/\xi \approx 31\,ns$, being near the required 30 ns. Closer approximations for higher C_Z values require damping factors ξ toward 0.5, which increase SOS diode ratings (I_F, I_{RR}, and Q_{RR}), but allow the doubling of C_Z capacitances.

This SOS pulse generator multiplies the incoming prepulse amplitude by a factor slightly higher than three. Given the present capabilities of SOS diodes (nearly 1 kA and 1 kV), this 1 MV pulse modulator would require an array of some thousands SOS diodes arranged in series of few paralleled diodes. Oil isolation and cooling, complemented with water/air, are mandatory. Special care must be given to parasitic inductances and capacitances.

Other SOS devices use unique diffusion techniques to achieve ultrafast switching times, such as the Drift Step Recovery Device (DSRD), the Inverse Recovery Diode (IRD), and the Delayed Ionization Devices (DID). Each device is capable of producing pulses ranging from 1 to 10 kV, with rise times between 100 ps and 1 ns.

The PIN diode-based Silicon Avalanche Sharpener (SAS) is a sharpening device that shortens the pulse rise time. It works normally reverse biased, a slow rise time, and short reverse pulse being applied to the SAS in order to avalanche it. When avalanche breakdown of the SAS drift layer occurs, a very short rise time pulse is applied to the load. Avalanche breakdown does not destroy the SAS if the input pulse is short enough.

26.2.2 Metal Oxide Semiconductor Technology Transistors

26.2.2.1 Metal-Oxide Semiconductor Field-Effect Transistors (MOSFET)

MOSFETs are very fast unipolar-carrier enhancement-mode semiconductor devices controlled by the v_{GS} voltage applied at the gate-source terminals (Fig. 26.5a) [10, 11, 13]. Their speed is mostly due to the absence of carrier recombination since in N-type MOSFETs, the carriers are almost only electrons. MOSFET semiconductor structure forms a $N^+N^-PN^+$ shorted base-emitter bipolar transistor (Fig. 26.5a), which is often referred as behaving as an intrinsic antiparallel PIN diode (Fig. 26.5b).

The MOSFET has the capabilities for high-speed switching in the nanosecond or subnanosecond range [14, 15].

In pulsed power applications, MOSFETs should behave as ideal switches, being switched-on if v_{GS} exceeds the threshold value V_{GSth}, $v_{GS} > V_{GSth} + V_{DSon}$, with $V_{DSon} \approx R_{DSon}I_D$. The ON MOSFET behaves almost like a resistor R_{DSon}, with low value and positive temperature coefficient. The MOSFET opens (OFF state, $I_D \approx 0$) if $v_{GS} < V_{GSth}$, but usually the gate driver enforces $v_{GS} < 0$ with $v_{DS} > 0$. If $v_{DS} < 0$, then the intrin-

sic diode starts to conduct (the on voltage is V_{PINon}), which is seldom advantageous since the internal PIN diode is usually not optimized for low voltage drop or high-speed switching. In this case, it is better that the gate driver turns on the MOSFET channel in order to prevent the PIN diode conduction, if $-R_{DSon}I_D < V_{PINon}$.

The gate current after charging or discharging of gate stray capacitances is almost null, and therefore, needed gate power is very low. In pulsed power applications, fast switching is needed, therefore the circuits that drive the v_{GS} voltage must charge/discharge the MOSFET parasitic nonlinear capacitances considering the effects of device terminal inductances (Fig. 26.5c). The switching speed of existing MOSFETs is limited mainly by packaging (lead inductances) and drain, gate and source resistances together with intrinsic capacitances.

The switching times can be in the order of some nanoseconds or lower and are affected by the driver R_G value. Resistor R_G dampens the RLC series circuit that contains C_{GS}, C_{DG}, gate and source stray inductances L_S. The gate resistor can be sized adopting a suitable value for the damping factor of the RLC series circuit $\xi = R_G/(2Z_G)$, where $Z_G = \sqrt{L_S/C_G}$, where C_G is the equivalent gate capacitor, being $R_G \approx 1.4Z_G$ for $\xi = 0.7$.

(c)
FIGURE 26.5   (a) MOSFET structure showing the Drain-Source current path; (b) Electronic symbol including intrinsic diode; and (c) MOSFET model with parasitic components.

The equivalent gate capacitor C_G, can be known from the manufacturers datasheets ($C_{GS} = C_{iss} - C_{rss}$; $C_{DG} = C_{rss}$; and $C_{DS} = C_{oss} - C_{rss}$), giving $C_G \approx C_{GS} + C_{DG}(dv_{GD}/dv_{GS})$, while the gate and source stray inductances L_S can be estimated considering typical per unit values. For printed circuit boards (strip lines) or typical parallel wires, inductance L_S is usually given nearly by 10 nH/cm times the current path total length in centimeters (typical TO220 package of MOSFETs exhibits source terminal inductances of $l_S \approx 5$ nH). For twisted wire pairs or other low-inductance connections, the value can be lowered down to 3 nH/cm. The inductor estimation (and C_G nonlinear capacitor calculation) does not need to be very precise since they only affect R_G by their square root values.

EXAMPLE 26.2 Calculate the gate resistor for a MOSFET with $C_{GS} \approx 800$ pF and $C_{DG} \approx 40$ pF, operating at a drain voltage of 800 V, driven by $v_{GS} = 15$ V through a printed circuit strip-line of 5 cm total length.

SOLUTION. For the given strip-line length, it is obtained $L_S \approx 50$ nH. The gate capacitor is $C_G \approx C_{GS} + C_{DG}(dv_{GD}/dv_{GS}) \approx 10^{-12} \times [800 + 40 \times (800/15)] \approx 2.9$ nF. Therefore, the gate resistor is $R_G \approx 1.4\sqrt{L_S/C_G} \approx 5.8$ Ω. As C_{GS} and C_{DG} are nonlinear voltage-dependent capacitances, using $R_G << Z_G$ can establish gate-source overvoltages two to three times the applied v_{GS} voltage, which can disrupt the gate insulation oxide if they exceed the breakdown voltage V_{GSS}, destroying the MOSFET. To minimize the R_G value, for faster gate capacitor charging and switching, it is essential to strongly reduce the stray inductances (if $L_S \approx 0$, then $R_G \approx 0$).

Fast MOSFET drivers require low stray inductances and often must be based on avalanche transistors [12] (switching bipolar transistors optimized to operate near their collector emitter breakdown voltage V_B, but at limited current) or resonant circuits [13]. The avalanche transistors rapidly charge the capacitors C_{GS} and C_{DG}, by transferring capacitor charge from a capacitor reservoir C_a to C_{GS} and C_{DG} (Fig. 26.6a). Supposing charge continuity, the MOSFET gate voltage should be $V_{GS} \approx V_B C_a/(C_a + C_G)$. The Zener diode Z18V helps protect the gate oxide against disruption, but the Zener junction capacitance should be added to the above C_G value.

MOSFET switching behavior includes crossing the saturation zone (MOSFET active zone) where $i_D \approx K(v_{GS} - V_{GSth})^2$, being K a MOSFET structural parameter (see Chapter 4, "MOSFET," in this book). This effect can be worsened when switching pulsed power capacitive loads.

Switch-on t_{on} and Switch-off t_{off} times can be tailored using different resistive paths to turn-on (R_2) and to turn-off ($R_1||R_2$) (Fig. 26.6b) limiting the charging current and the drain voltage rise or fall rates, at the expense of increased switching losses.

Considering the on and off switching times (t_{on}, t_{off}), the dissipated switching power at the switching frequency f_S is $P_S = [(t_{on} + t_{off})V_{DS}I_D + C_{DS}V_{DS}^2]f_S/2$.
