The ratio $d^2/\epsilon s$, calculated from these constants for a particular piezoelectric material, is defined as K^2 , where K^2 is the coefficient of electromechanical coupling. As a consequence of conservation of energy, it can be shown that K is a number less than unity and that a fraction K^2 of applied energy (mechanical or electric) is stored in the other form (electric or mechanical). Since D and E are vectors and S and T are tensors, the piezoelectric equations are tensor equations and are equivalent to nine algebraic equations, describing three vector and six tensor components.

Materials that are appreciably piezoelectric are either crystals with anisotropic properties or ceramics with ferroelectric properties which can be given permanent charge polarization through dielectric hysteresis. Ferroelectric ceramics, principally barium titanate and lead zirconate titanate, are characterized by relative dielectric constants ranging from several hundred to several thousand, by coupling coefficients as high as 0.7, and by polycrystalline grain structure which will propagate acoustic waves with moderate attenuation at frequencies extending up to the low-megahertz range.

Single crystals are generally suited for much higher acoustic frequencies, and in quartz acoustic-wave propagation has been observed at 125 GHz. Quartz has low loss but a low coupling coefficient. Lithium niobate is a synthetic crystal, ferroelectric and highly piezoelectric; lithium tantalate is somewhat similar. The semiconductors cadmium sulfide and zinc oxide are moderately low in loss and show appreciable coupling.

Stress Waves in Solids

Acoustic waves propagate with low loss and high velocity (5000 m/s) in solids. Solids also have shear strength, whereas sound waves in gases and fluids are simple pressure waves, manifested as traveling disturbances measurable by pressure and longitudinal motion.

Sound waves in solids involve either longitudinal or transverse particle motion. The transverse waves may be propagation of simple shear strains or may involve bending in flexural waves. Since different modes of waves travel with different velocities, and since both reflections and mode changes can occur at material discontinuities, the general pattern of wave propagation in a bounded solid medium is quite complicated.

Bulk waves are longitudinal or transverse waves traveling through solids essentially without boundaries; e.g., the wavefronts extend over many wavelengths in all directions. A solid body supporting bulk waves undergoes motion and stress throughout its volume. A *surface wave* follows a smooth boundary plane, with elliptical particle motion which is greatest at the surface and drops off so rapidly with depth that almost all the energy is carried in a one-wavelength layer at the surface.

Ideally, the wave medium for surface-wave propagation is regarded as infinitely deep; practically if it is many wavelengths deep, its properties are equivalent. A surface wave following a surface free from forces is a Rayleigh wave; if an upper material with different elastic properties bounds the surface, the motion may be a Stonely wave.

Bulk-Wave Devices

Most acoustic amplifiers utilizing bulk waves have the components shown in Fig. 11.3.35. The input and output transducers are piezoelectric crystals or deposited thin layers of piezoelectric material, used for energy conversion at the terminals. The amplifier crystal is generally CdS, which is not only piezoelectric but also an *n*-type semiconductor. Electrodes are attached at the input and output surfaces of the CdS crystal, for bias current. Since the mobility of negative-charge carriers in CdS is only about 250 cm²/V·s, large bias fields are required to provide a drift velocity equal to acoustic velocity: in CdS, 4500 m/s for longitudinal waves and 1800 m/s for shear waves. The buffer rods shown in Fig. 11.3.35 are therefore added for electrical isolation of the bias supply. Furthermore, the transducers and amplifying crystal are cut in the desired orientation, to couple to either longitudinal or shear waves.

In the analysis of bulk-wave amplification the crystal properties are characterized by f_D = diffusion frequency = $\omega_p/2\pi$; f_C = dielectric relaxation, or conductivity frequency = $\omega_c/2\pi$; $\gamma = (1 - f)$ times the drift velocity divided by the acoustic phase velocity, where f is the fraction of space charge removed from the conduction band by trapping; k = coefficient of electromechanical coupling; and ω = radian frequency of maximum gain = $\sqrt{\omega_c \omega_d}$. Figure 11.3.36 shows the computed gain curves, using these constants, for four values of drift velocity. The frequency of maximum gain can be selected by control of crystal conductivity, which is

FIGURE 11.3.35 Typical structure for acoustic amplification measurements.

easily accomplished in CdS by application of light. The amount of gain, and to some extent the bandwidth, are controlled by the bias field.

Figure 11.3.37 shows characteristics specifically calculated for CdS with shear acoustic-wave amplification. Large bias voltages (800 to 1300 V/cm) are required, and extremely high gains are possible. Generally, heat dissipation owing to the power supplied by bias is so high (up to 13 W/cm³ at $\gamma = 0.76$) that only pulsed operation is feasible.

Surface-Wave Devices

The disadvantages in bulk-wave amplifiers, evidenced as excessive bias requirements, could be alleviated if materials with high mobility were available. However, the amplifier crystal must show low acoustic loss, high piezoelectric coupling, and high mobility; a suitable material combining these properties has not been found. Figure 11.3.38 shows an acoustic amplifier structure which operates with acoustic surface waves and provides charge carriers in a thin film of silicon placed adjacent to the insulating piezoelectric crystal. Coupling for the interaction takes place in the electric field across the very small gap between piezoelectric and semiconductor surfaces. Transducers are formed by metallic fingers, interlaced to provide signal field for piezoelectric coupling between adjacent fingers. This interdigital-array technique is flexible, providing means for complicated transducer patterns useful in signal processing.

FIGURE 11.3.36 Normalized plots of gain vs. frequency. Note symmetry of frequency response and effects of bias and critical frequency values.

The composite structure makes it possible to combine separate materials, one chosen for strong piezoelectric coupling and the other chosen for high mobility, to cooperatively produce interactive amplification, or attenuation, of acoustic waves propagating in the piezoelectric component. The variety of material combinations and structural modifications possible has given rise to extensive analysis and experimental development in many countries. Lithium niobate crystals have the strongest piezoelectric coupling

FIGURE 11.3.37 Gain vs. frequency for CdS shear-wave amplification at $f_D = 796$ MHz.

FIGURE 11.338 Structure of a surface-wave acoustic amplifier. (See Lakin and Shaw)

of materials acoustically suitable for high-frequency operation, and indium antimonide semiconductor films have the highest drift mobility. Since high-frequency performance requires extremely accurate control of narrow air gaps, amplifier structures employing surface waves that propagate along the interface between a piezoelectric crystal and a deposited semiconductor film have been developed.

Surface-acoustic-wave (SAW) devices, with interdigital transducers designed for wide-band or filter frequency-response characteristics, have values of signal insertion loss owing primarily to acoustic attenuation and to the conversion loss of the input and output transducers. One role of acoustic amplification can be to offset that basic insertion loss. This is illustrated in Fig. 11.3.39, which shows the gain characteristic for a Rayleigh surface-wave amplifier employing lithium niobate, separated by thin dielectric rails from a silicon-on-sapphire semiconductor film. Continuous operation with cw signals is facilitated by the surface-wave geometry, specifically by high-mobility semiconductor films backed by dielectric substrate heat sinks. Amplified signal power, carried by bunched charge carriers, flows in the semiconductor films, so the level of signal saturation is a function of film thickness, compounded by reduction of drift mobility at high temperature. A saturation level of 15 dBm, with cw signals at 340 MHz, has been observed using a 550-Å indium antimonide film 25 μm wide.

Typically, gain in a surface-wave amplifier can be as much as 100 dB in a crystal less than 1 cm long, operating with as much as 50 percent bandwidth at frequencies as high as several hundred megahertz. The amount and direction of gain are controlled by the bias field, in some cases in conjunction with incident optical illumination. The bandwidth and center frequency of the transducers are determined by the geometry of the interdigital arrays. Semiconductor films of silicon or indium antimonide operate at much lower values of bias field than are required in bulk-wave amplifiers and can be deposited on a dielectric substrate in narrow strips to permit parallel excitation at low voltage. The upper frequency limits are set by resolution of the photolithographic processes used to form the transducer fingers and by the ability to provide air gaps, in the Rayleigh wave configurations, of much less than a wavelength. Electron-beam lithography of interdigital arrays has been developed for high resolution, extending transducer technology to more than 3 GHz.

Surface-Acoustic-Wave-Amplifier Analysis

When the SAW amplifier evolved from its bulk wave counterpart, the amplification medium was piezoelectric semiconductor CdS [see White (1967)], and the gain expression was obtained by solving the field equations. Ingebrigtsen (1970 and Lakin and Shaw (1969) were the first ones to investigate the gain of the

FIGURE 11.3.39 Terminal gain of an air-gap Rayleigh wave amplifier. The semiconductor, Si, was segmented to reduce the required drift voltage. [After Lakin and Shaw (1969)]

separate-medium SAW amplifiers by using perturbation techniques. Finally, a general form, similar to the expressions derived by White (1962) for bulk wave amplifiers, is obtained by Kino and Reeder (1971) using normal mode theory. Hunsinger and Datta (1986) introduced the concept of capacitance perturbation into the transmission line model of SAW propagation. This technique has extensively simplified the analytical process. We have further utilized the transmission line model to derive a SAW amplifier gain expression, in which the effects of the passivation and the encapsulation layers are included [see Lin (1995)]. Because of the space limitation, we will present the simplified one-dimensional analysis; however, the result of the two-dimensional analysis for the SAW amplifier will be given.

If we define the surface potential ϕ of a SAW as the voltage V and select the current I to satisfy the power P of the SAW such that $P = VI^*$, then the familiar relationships for a transmission line can be used to describe SAW propagation:

$$V_a = \frac{1}{\sqrt{LC}} \quad C = \frac{1}{Z_a V_a} \quad (11)$$

where L and C are the distributed inductance and capacitance, both defined by the Mason model, and $V_a = \omega/k$ is the acoustic wave velocity. Z_a , the characteristic impedance of the propagating SAW, is defined as

$$Z_a = \frac{\phi_a \phi_a^*}{2P} \quad (12)$$

where ϕ_a is the electric potential generated by the SAW and P is the total power of that wave. If a layer of charge is placed above the surface of the SAW propagation path, separated by h (see Figs. 11.3.40 and

FIGURE 11.3.40 Monolithic acoustic surface-wave amplifier. [After Coldren and Kino (1971)]

11.3.41), it is equivalent to have an additional capacitance ΔC on the transmission line, which can be defined as

$$\Delta C = -\frac{\rho_s W}{\phi_{ah}} \tag{13}$$

where ρ_s = induced surface charge

W = beam width

ϕ_{ah} = acoustic potential value at $y = h$, where the charge is located

FIGURE 11.3.41 Analytical model: (a) two-dimensional semiconductor layer, and (b) simplified one-dimensional.

Because of ΔC , V_a will change accordingly (assume that the SAW propagates as $e^{j(\omega t - kz)}$):

$$\frac{\Delta V_a}{V_a} = -\frac{\Delta k}{k} = -\frac{1}{2} \frac{\Delta C}{C} \quad (14)$$

The imaginary part of Δk ($\Delta k = \beta + j\alpha$) is the gain of the SAW amplifier, which can be found by combining Eqs. (11), (12), and (14) is

$$\alpha = k \operatorname{Im} \left(\frac{\Delta k}{k} \right) = \frac{k}{2} \operatorname{Im} \left(\frac{\Delta C}{C} \right) = \frac{k}{2} \operatorname{Im} (\Delta C Z_a V_a) \quad (15)$$

In the following, ΔC and Z_a are to be derived. For a very thin semiconductor layer, a good approximation is to consider the charge layer infinitesimally thin. Thus, one-dimensional analysis, such as the model in Fig. 11.3.41*b*, can be employed.

In order to express ρ_s in terms of ϕ_{ah} , we start from the current equation and the continuity equation for the charge layer of the semiconductor:

$$\frac{\partial J_z}{\partial z} + \frac{\partial \rho}{\partial t} = 0 \quad J_z = \sigma E_z - D_n \frac{\partial \rho}{\partial z} \quad (16)$$

where J_z = current density

$E_z = -\partial(\phi_a + \phi_c)/\partial z = jk(\phi_a + \phi_c)$ the electrical field

σ = conductivity of the semiconductor

D_n = diffusion coefficient of the electron carriers

ρ = bulk charge density

ϕ_c = potential induced by the charge layer. Then we have (at $y = h$)

$$\rho = \frac{-\phi_{ah}}{\frac{\phi_{ch}}{\rho} + \frac{D_n}{\sigma} + j \frac{V_a}{\sigma k}} \quad (17)$$

For a very thin semiconductor layer, ρ_s can be approximated with ρd (d is the thickness of the layer). The above equation leads to

$$\rho_s = \frac{-\phi_{ah}}{\frac{\phi_{ch}}{\rho_s} + \frac{1}{\sigma d} \left(D_n + j \frac{V_a}{k} \right)} \quad (18)$$

First, we need to find ϕ_{ch}/ρ_s . To simplify the analysis, we assume that the thin semiconductor layer is right on the piezoelectric substrate, i.e., $h \rightarrow 0$, and there is no encapsulation layer, $\epsilon_d \rightarrow \epsilon_0$. Then

$$\phi_{ch} = \begin{cases} A e^{-ky}, & y \geq 0 \\ D e^{ky}, & y < 0 \end{cases} \quad (19)$$

where the decay factor is k because the potential must satisfy the Laplace equation. With the following boundary conditions:

$$\begin{aligned} \phi_{ch}(y = 0^+) &= \phi_{ch}(y = 0^-) \\ -\epsilon_0 \frac{\partial \phi_{ch}}{\partial y}(y = 0^+) + \epsilon_p \frac{\partial \phi_{ch}}{\partial y}(y = 0^-) &= \rho_s \end{aligned} \quad (20)$$

we obtain

$$\frac{\phi_{ch}}{\rho_s} = \frac{1}{k(\epsilon_0 + \epsilon_p)} \quad (21)$$

Therefore,

$$\Delta C = -\frac{\rho_s W}{\phi_{ah}} = \frac{k(\epsilon_0 + \epsilon_p)W}{1 + \frac{(\epsilon_0 + \epsilon_p)}{\sigma d}(kD_n + jV_a)} \quad (22)$$

Now we proceed to find Z_a in terms of the electromechanical coupling coefficient K^2 . By definition,

$$\begin{aligned} \frac{K^2}{2} &= \frac{\Delta k}{k} \Big|_{\substack{\sigma=\infty \\ h=0}} = \frac{1}{2} \frac{\Delta C}{C} \Big|_{\substack{\sigma=\infty \\ h=0}} = \frac{1}{2} Z_a V_a \Delta C \Big|_{\substack{\sigma=\infty \\ h=0}} \\ &= \frac{1}{2} k(\epsilon_0 + \epsilon_p) W Z_a V_a = \frac{1}{2} (\epsilon_0 + \epsilon_p) W \omega Z_a \end{aligned} \quad (23)$$

Therefore,

$$Z_a = \frac{K^2}{(\epsilon_0 + \epsilon_p) W \omega} \quad (24)$$

Substituting Z_a and ΔC into Eq. (15)

$$\alpha = -\frac{K^2}{2} \frac{\frac{k\sigma d V_a}{\epsilon_0 + \epsilon_p}}{\left(\frac{k\sigma d}{\epsilon_0 + \epsilon_p} + kD_n \right)^2 + V_a^2} \quad (25)$$

Taking the applied electrical field E_0 into account, the current density in Eq. (16) and the charge density in Eq. (17) become

$$J_z = \sigma E_z + \rho \mu E_0 - D_n \frac{\partial \rho}{\partial z} \quad \rho = \frac{-\phi_{ah}}{\frac{\phi_{ch}}{\rho} + \frac{D_n}{\sigma} + j \frac{V_a - \mu E_0}{\sigma k}} \quad (26)$$

where μE_0 gives the carrier drift velocity. It is clear that the gain is analogous to Eq. (25) except that the term V_a should be replaced with $V_a - \mu E_0$,

$$\alpha_{\text{SAW}} = -\frac{K^2}{2} \frac{\frac{\sigma(dk)}{\epsilon_0 + \epsilon_p} (V_a - \mu E_0)}{(V_a - \mu E_0)^2 + \left[\frac{\sigma(dk)}{(\epsilon_0 + \epsilon_p)k} + kD_n \right]^2} \quad (27)$$

The gain for bulk acoustic wave amplifier can be expressed as

$$\alpha_{\text{BAW}} = -\frac{K^2}{2} \frac{\frac{\sigma}{\epsilon_p}(V_a - \mu E_0)}{(V_a - \mu E_0)^2 + \left(\frac{\sigma}{\epsilon_p k} + kD_n\right)^2} \quad (28)$$

Obviously, σ in the bulk wave amplifier has been replaced by $\sigma(kd)$ in the SAW amplifier because of the thin-film form semiconductor material.

In order to explain the approximate experimental linear relationship between gain and drift field illustrated by Fig. 11.3.39, the gain expression [Eq. (27)] can be further simplified. For InSb/LiNbO₃ SAW amplifier, σd is typically about $45 \times 10^{-6} \text{S}/\square$, and $\epsilon_p = 50\epsilon_0 \approx 4.5 \times 10^{-12} \text{F}/\text{cm}$, so that $\sigma d(\epsilon_0 + \epsilon_p) \gg kD_n$ and $V_0 - \mu E_0$. Thus, by dropping the negligible terms, we have

$$\alpha \approx \frac{K^2}{2} (\mu E_0 - V_a) \frac{\epsilon_p k}{\sigma d} \quad (29)$$

This is essentially the electronic gain equation given by Kotelyanski et al. (1978).

In the above derivation, we have assumed that $kd \ll 1$ and d is much smaller than the semiconductor's Debye length, which can be written as $(D_n \epsilon_s / \sigma)^{1/2} = 1/\zeta$. The assumptions imply that the potential and charge distribution inside the semiconductor is homogeneous along the y axis. To remove those restrictions and cover more general cases, the variation in y direction must be considered, i.e., analytical model Fig. 11.3.41a must be used.

A thicker semiconductor layer affects the SAW amplifier gain in two ways. First, the decay of acoustic potential in the semiconductor from the $y = h$ surface will become significant. The induced charge and the associated potential will decay accordingly, although at different rates. Therefore a field owing to the charge gradient in the y -direction will appear. The boundary condition now must be matched by the total potential from each side.

The second factor is the charge per unit area, which is needed in order to find ΔC . ρ_s is no longer ρd . It has to be calculated by the integration $\int \rho dy$.

The modification [see Lin (1995)] leads to

$$\alpha = -\frac{K^2}{2} \frac{\frac{\sigma \tanh(kd)(V_a - \mu E_0)}{\epsilon_h + \epsilon_p} \frac{e^{-2kh}}{F^2}}{\left[\frac{\sigma \tanh(kd)}{k(\epsilon_h + \epsilon_p)} + \zeta D_n \frac{\tanh(kd)}{\tanh(\zeta d)} \right]^2 + (V_a - \mu E_0)^2} \quad (30)$$

where

$$F = \frac{1}{2} \left[\left(\frac{\epsilon_d - 1}{\epsilon_h} \right) \frac{\epsilon_h - \epsilon_p}{\epsilon_h + \epsilon_p} e^{-2kh} + \left(\frac{\epsilon_d + 1}{\epsilon_h} \right) \right] \quad (31)$$

If $\epsilon_d = \epsilon_h$, $F = 1$.

Equation (55) is derived in Wang and Lin (1996). Equation (30) reduces to Eq. (27), when the semiconductor thickness d is extremely thin such that both $kd \ll 1$ and $\zeta d \ll 1$.

MAGNETIC AMPLIFIERS

Harold W. Lord

Static Magnetic Amplifiers

Static magnetic amplifiers can be divided into two classes, identified by the terms saturable reactor and self-saturating magnetic amplifier. A *saturable reactor* is an adjustable inductor in which the current-versus-voltage

relationship is adjusted by control magnetomotive forces applied to the core. A *magnetic amplifier* is a device using saturable reactors either alone or in combination with other circuit elements to secure amplification or control. A *simple magnetic amplifier* is a magnetic amplifier consisting only of saturable reactors. The abbreviation SR is used in this section to denote a *saturable reactor* and/or simple magnetic amplifier.

A self-saturating magnetic amplifier is a magnetic amplifier in which half-wave rectifying circuit elements are connected in series with the output windings of saturable reactors. It has been shown that saturable reactors can be considered to have negative feedback. Half-wave rectifiers in series with the load windings will block this intrinsic feedback. A self-saturating magnetic amplifier is therefore a parallel-connected saturable reactor with blocked intrinsic feedback. This latter term avoids the term self-saturation, which, although extensively used, does not have a sound physical basis. The abbreviation MA is used here to denote this type of high-performance magnetic amplifier.

Saturable-Reactor (SR) Amplifiers

The SR can be considered to have a very high impedance throughout one part (the *exciting interval*) of the half cycle of alternating supply voltage and to abruptly change to a low impedance throughout the remainder of the half cycle (the *saturation interval*). The phase angle at which the impedance changes is controlled by a direct current. This is the type of operation obtained when the core material of the SR has a highly rectangular hysteresis loop. Two types of operation, representing limiting cases, are discussed here, namely, *free even-harmonic currents* and *suppressed even-harmonic currents*. Intermediate cases are very complex, but use of one or the other of the two extremes is sufficiently accurate for most practical applications.

The present treatment is limited to resistive loads, the most usual type for SR applications. [See Storm (1955), for inductive dc loads and Wilson (1952), for inductive ac loads]. The basic principles of operation of SRs and MAs are given in more detail in Shea (1968).

Series-Connected SR Amplifiers

Basically, an SR circuit consists of the equivalent of two identical single-phase transformers. Figure 11.3.42 shows two transformers, SR_A and SR_B , interconnected to form a rudimentary series-connected SR circuit.

The two series-connected SR windings in series with the load are called *gate windings*, and the other two series-connected windings are called *control windings*. Note, from the dots that indicate relative polarity, that the gate windings are connected in series additive and the control windings are connected in series subtractive. By reason of these connections, the fundamental power frequency and all *odd* harmonics thereof will not appear across the total of the two control windings but any *even* harmonic induced in one control winding will be additive with respect to a corresponding even harmonic induced in the other control winding.

For this connection, SR_A and SR_B are normally so designed that each gate winding will accommodate one-half the alternating voltage of the supply without producing a peak flux density in the core that exceeds the knee of the magnetization curve, assuming no direct current is flowing in the control winding. Under these conditions,

if SR_A is identical with SR_B , one-half of the supply voltage appears across each gate winding, and the net voltage induced in the control circuit is zero. The two SRs operate as transformers over the entire portion of each half cycle.

When a direct current is supplied to the control circuit, each SR will have a saturation interval during a part of each cycle, SR_A during half cycles of one polarity and SR_B during half cycles of the opposite polarity. The ratio of the saturation interval to the exciting interval can be controlled by varying the direct current in the control winding.

When an SR core has a saturation interval during part of half cycles of one polarity, and there is a load or other impedance in series with the gate winding, even-harmonic voltages are induced in all other windings on that core. In the series connection, one SR gate winding can be the

FIGURE 11.3.42 Series-connected SR amplifier.

series impedance for the SR, and large even-harmonic voltages will appear across the individual gate windings and control windings when direct current flows in the control windings. The amount of even-harmonic current which flows in the control circuit of Fig. 11.3.42 will depend on the impedance of the control circuit to the harmonic voltages. If the control-circuit impedance between terminals Y_1 and Y_1' is low with respect to the induced harmonic voltages of the control windings (usually referred to as a *relatively low* control-circuit impedance), the harmonic currents can flow freely in this circuit, and the SR circuit is identified by the term *free even-harmonic currents*. If the control-circuit impedance is high with respect to the induced harmonic voltages (a *relatively high* control-circuit impedance), the harmonic-current flow is suppressed and the SR circuit is identified by the term *suppressed even-harmonic currents*.

If R_C in Fig. 11.3.42 is relatively low and the source impedance of the dc control current is low, the circuit is of the free even-harmonic-currents type and the two SRs are tightly coupled together by the control circuit. If one SR is in its saturation interval, it will reflect a low impedance to the gate winding of the other SR, even though it is then operating in its exciting interval. Thus, during the saturation interval of any core, transformer action causes both gate windings to have low impedances and current can flow from the ac source to the load, with correspondingly high harmonic circulating currents in the control circuit. When both cores are in their exciting intervals, only the low core-exciting current can flow and the current circulating in the control circuit is substantially zero.

If the exciting current is so low as to be negligible, and if N_G are the turns in each gate winding, N_C are the turns in each control winding, I_G is the rectified average of the load current, and I_C is the average value of the control current, then applying the law of equal ampere-turns for transformers provides the following expression for the circuit in Fig. 11.3.42: $I_C N_C = I_G N_G$. This is the law of equal ampere-turns for the series-connected SR with resistive load. It applies to operation in the so-called *proportional region*, the upper limit of this region being that point in the control characteristic where the load current is limited solely by the load circuit resistance. Figure 11.3.43 shows the gate-current circuit and control-circuit current at one operating point in the proportional region. An increase in control current causes a decrease in the angle α , thereby increasing I_L , the rectified average of the current to the load.

Parallel-Connected SR Amplifiers

Figure 11.3.44 shows the circuit diagram for the parallel-connected SR. Each gate winding is connected directly between the ac supply and the load resistance, thus providing two parallel paths through the SR. There is therefore a low-impedance path for the free flow of even-harmonic currents, even though the impedance of the control circuit happens to be relatively high. As a result, the parallel-connected SR is always of the *free flow of even-harmonic-currents* type, the cores operate in the same manner as described in the previous paragraph, and the waveshapes of currents to the *load* are as shown in Fig. 11.3.43. However, the gate winding currents are different, as shown in Fig. 11.3.45.

FIGURE 11.3.43 Currents in circuit of Fig. 11.3.42, for free even-harmonic-current conditions: (a) gate current; (b) control-circuit current.

FIGURE 11.3.44 Parallel-connected SR amplifier.

FIGURE 11.345 Currents in the circuit of Fig. 11.344 for free even-harmonic-current conditions: (a) load current; (b) components of load current in SR_A gate winding; (c) same in SR_B ; (d) control-circuit current; (e) gate-current in SR_A ; (f) same in SR_B .

It is obvious from Fig. 11.345 that $I'_L = -I_L/2$. Since, except for the low-excitation requirements for the core, the net ampere-turns acting on the core must be zero during the exciting interval, then $I'_L N_G + I_C N_C = 0$. Using the above equation to eliminate I'_L , the result is $I_C N_C = I_L N_G/2$. Figure 11.346 shows the control characteristic of saturable core amplifiers applicable both to free and suppressed even-harmonic modes of operation.

FIGURE 11.346 Control characteristic of SR amplifier applying both to free and suppressed even-harmonic conditions.

FIGURE 11.347 Idealized operating hysteresis loops for suppressed even-harmonic-current condition.

Series-Connected SR Circuit with Suppressed Even Harmonics

This circuit is usually analyzed by assuming operation into a short circuit and the control current from a current source. Figure 11.347 shows idealized operating minor hysteresis loops for this circuit, and Fig. 11.348 shows pertinent current and voltage waveshapes lettered to correspond to Fig. 11.347. Note that this current supplies a square wave of current to the load so long as it is operating in the proportional region. Energy is interchanged between the power-supply circuit and the control circuit so as to accomplish this type of operation. If a large inductor is used to maintain substantially ripple-free current in the control circuit, the energy

interchanged between the supply voltage and control circuit is alternately stored in, and given up by, the control-circuit inductor.

Gain and Speed of Response of SRs

It is obvious from the generalized control characteristic that the current gain is directly proportional to the ratio of the control winding turns to the gate winding turns. Thus $I_1/I_c = N_c/N_g$. If R_c is the control-circuit resistance and R_L is the load resistance, the power gain GP is $N_c^2 R_L^2 / N_g^2 R_c^2$.

The response time of saturable reactors is the combination of the time constants of the control circuit and of the gate-winding circuit. Expressed in terms of the number of cycles of the supply frequency, the time constant of the control winding of a series-connected SR is $\tau_c = R_c N_c^2 / 4 R_L N_g^2$ cycles. If the SR is operating under-excited, a transportation lag may cause an additional delay in response.

High-Performance Magnetic Amplifier (MA)

If a rectifier is placed in series with each gate winding of a parallel-connected SR and the rectifiers are poled to provide an ac output, it becomes a type of high-gain MA circuit called the *doubler circuit*. When this is done,

FIGURE 11.348 Series-connected suppressed even-harmonic condition: (a) control-circuit current; (b) applied input voltage; (c) gate winding and load current; (d) voltage across series-connected control coils.

the law of equal ampere-turns no longer applies, and the transfer characteristic is mainly determined by the magnetic properties of the SR cores. The design of an MA therefore requires more core-materials data than are required for SRs in simple magnetic amplifier circuits. The text of this section assumes that the designer has the required magnetic-core-materials data on hand, since such data are readily available from the manufacturers of cores for use in high-performance MAs.

Descriptions of the operation of MAs require several terms which are defined here for reference.

Firing. In a magnetic amplifier, the transition from the unsaturated to the saturated state of the saturable reactor during the conducting or gating alternation. Firing is also used as an adjective modifying phase or time to designate when the firing occurs.

Gate angle (firing angle). The angle at which the gate impedance changes from a high to a low value.

Gating. The function or operation of a saturable reactor or magnetic amplifier that causes it, during the first

portion of the conducting alternation of the ac supply voltage, to block substantially all the supply voltage from the load and during a later portion allows substantially all the supply voltage to appear across the load. The "gate" is said to be virtually closed before firing and substantially open after firing.

Reset, degree of. The reset flux level expressed as a percentage or fraction of the reset flux level required to just prevent firing of the reactor in the subsequent gating alternation under given conditions.

Reset flux level. The difference in saturable-reactor core flux level between the saturation level and the level attained at the end of the resetting alternation.

Resetting (presetting). The action of changing saturable-reactor core flux level to a controlled ultimate reset level, which determines the gating action of the reactor during the subsequent gating alternation. The terms resetting and presetting are synonymous in common usage.

Resetting half cycle. The half cycle of the MA ac supply voltage at which resetting of the saturable reactor may take place.

FIGURE 11.3.49 Half-wave MA circuit.

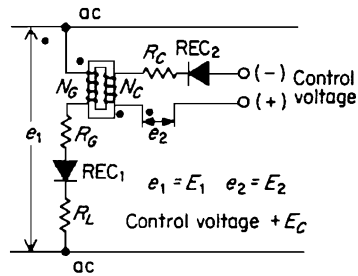

FIGURE 11.3.50 Voltage-controlled MA circuit.

Half-Wave MA Circuits

Figure 11.3.49 shows a half-wave MA circuit with control from a source of controllable direct current. Figure 11.3.50 shows a half-wave MA circuit with control from a controllable source of direct voltage. The following sequence of operation is the same for both circuits and is described in connection with Fig. 11.3.51.

1. During the gating half cycle (diode REC or REC₁ conducting) the core flux increases toward a saturation level (3') from some reset flux level (0) and the current to the load R_L is very low.
2. When saturation of the SR occurs at 2', firing occurs and current flows to the load for the rest of the gating half cycle, leaving the core flux at 4'.
3. During the resetting half cycle (diode REC or REC₁ blocking) the SR core is reset from 4' through 5' to a value of reset flux level corresponding to B' and 0.

The waveshape of the current to the load is the same for both circuits, being a portion of one polarity of sine wave (phase-controlled half-wave). The two types of control circuits differ as follows:

FIGURE 11.3.51 Major and operating minor dynamic hysteresis loops for circuit of Fig. 11.3.49.

1. The curve on the reset portion of the hysteresis loop between 4' and 0 is as shown in Fig. 11.3.51 for the current control type of control circuit (Fig. 11.3.49), but for the circuit of Fig. 11.3.50, the resetting portion of the curve in the region 5' is not a vertical line and may coincide with the outer major hysteresis loop for a substantial portion of the resetting period.
2. The output of the circuit of Fig. 11.3.49 is a maximum for zero dc control current, but for Fig. 11.3.50 the output is a minimum for zero dc control voltage.

The operation of a half-wave MA can be summarized as follows: (1) During the gating half cycle, the core acts to withhold current from the load for a portion of each half cycle, the length of the withholding period being determined by the degree of reset of core flux provided during the immediately preceding resetting half cycle. (2) During the resetting half cycle, the degree of reset can be controlled by varying the amount of direct current of proper polarity in the control winding, or by varying the amount of average voltage of proper polarity applied to the control winding. (3) The amount of current and power required to reset the core is primarily a function of the excitation requirements of the core and bears no direct relationship to the power delivered to the load.

FIGURE 11.3.52 Full-wave ac-output MA circuit with high-impedance control circuit.

FIGURE 11.3.53 Full-wave bridge MA circuit with inductive load.

Full-Wave MA Circuits

Two half-wave MA circuits can be combined to provide either full-wave ac output (Fig. 11.3.52) or full-wave dc output (Fig. 11.3.53). During the gating half cycle, all gate windings act in the same manner as described for the half-wave MA circuit. Because of an interaction of the common load resistor voltage with the availability of inverse voltage across a rectifier during its resetting half cycle, each half-wave part of Fig. 11.3.52 cannot be assumed to operate independently of its mate. The differences in control characteristics are shown by Fig. 11.3.54, where curve A applies to the circuit of Fig. 11.3.49 and curve B applies to the circuit of Fig. 11.3.52.

Equations for MA Design

For SRs in simple MA circuits, since the ampere-turn balance rules apply, their design is so similar to transformer design that ordinary transformer design procedures are applicable. For SRs in MA circuits, the gate windings must carry rms load currents that are related to the ac and dc load currents in the same manner that rectifier transformer secondary rms currents are related to the load current. Gate windings must be able to withstand a full half cycle of ac supply voltage, without saturation, for a total flux swing from $-B\mu_m$ to $+B\mu_m$, where $B\mu_m$ is the flux density at which the permeability of the core material is a maximum. In the cgs system of units:

Maximum ac supply voltage, rms: $E_e = 4.44N_G B\mu_m A f \times 10^{-8}$, where N_G is gate winding turns, A is core area, and f is supply frequency.

Maximum load current for firing angle $\alpha = 0^\circ$ (rectified average): $I_{LM} = E_e / 1.11(R_G + R_L)$, where R_G is total gate winding resistance, including diode drops, and R_L is the effective load resistance.

For current-controlled MA circuits the following equations apply:

Minimum load current ($\alpha = 180^\circ$): $I_{LX} = 2I_X = 2H_{csf}l / 0.4\pi N_G$, where I_X = exciting current (A) of one SR core. H_{csf} = sine flux coercive force of the core material (Oe) and l = mean length of magnetic circuit of one core.

Control current for upper end of control current: $I_C = H_C l / 0.4\pi N_C$, where H_C = dc coercive force of the core material.

Control current for minimum load-current point: $I_C = H_{csf} l / 0.4\pi N_C$. Ampere-turn gain $G_{AT} = (I_{LM} / 2I_X) \pi$.

Time constant $\tau_C = 0.9\pi E_e R N_C^2 / 4f I_X R_C N_G^2$ seconds, where R_C is the control circuit resistance and assuming $\alpha = 90^\circ$. This equation does not take into account a transportation or any underexcited effects which increase the delay time.

Power gain $G_p = G_{AT}^2 (N_C / N_G)^2 (R_L / R_C)$, where k_f = form factor (ratio of rms to average values). If only average values are used, k_f is unity. At $\alpha = 90^\circ$, dynamic power gain $G_D = G_p / \tau_C = \pi f I_{LM} R_L I_X (R_G + R_L)$ per second.

FIGURE 11.3.54 MA circuit control characteristics: (A) half-wave circuit; (B) full-wave ac-output circuit.

FIGURE 11.3.55 Three-legged SR core-and-coil configuration.

FIGURE 11.3.56 Four-legged SR core-and-coil configuration.

For voltage-controlled MA circuits, the following equations apply to Fig. 11.3.50:

AC bias voltage $E_2 > E_1 N_C / N_G$ and of indicated relative polarities. A value of $E_2 = 1.2 E_1 N_C / N_G$ is usually adequate. Since the dc control voltage E_C acts to inhibit the resetting effect of E_2 , a firing angle $\alpha = 0^\circ$ occurs when $E_C \geq \sqrt{2} E_2$.

A single-stage amplifier has a half-cycle transport lag and no other time delay unless the resetting is inhibited by common-load interactions with other half-wave-amplifier elements.

Maximum average load current $I_{LM} = 0.9 E_1 / (R_G + R_L)$.

Minimum average load current $I_{LX} = I_X = H_{csf} / 0.4 \pi N_G$.

The calculation of the power gain of voltage-controlled MA circuits largely depends on the control circuit. The dc control voltage of Fig. 11.3.50 actually must *absorb* power from the ac bias circuit during much of its control range. Assuming that $E_2 = 1.2 E_1 N_C / N_G$ and a resistor R'_C is connected across the control source, which has a drop of $0.2 E_2$ at cutoff, then $R'_C = 0.24 E_1 N_C^2 / N_{GX}^2$. The maximum dc control voltage is then $1.2 \sqrt{2} E_1 N_C / N_G$.

When the dc control voltage, $E_C > 2 E_2$, rectifier REC_2 is blocking all the time, and so the only load on the control source is R'_C . Therefore the maximum power from the control source $P_C = E_C^2 / R'_C = 5 \sqrt{2} E_1 I_X$.

The maximum power output is $P_0 = I_{LM}^2 R_L (0.9 E_1)^2 / (R_G + R_L)^2$.

The power gain is then $G_p = P_0 / P_C$ if the gain is assumed to be linear over most of the control characteristic. This can also be written $G_p = I_{LM}^2 G_p - I_{LM}^2 R_L / 5 \sqrt{2} E_1 I_X$.

Core Configurations

Figures 11.3.55 and 11.3.56 show two coil-and-core configurations commonly used for SRs. The best core-and-coil geometry for the SRs and MAs is the toroid-shaped core with the gate winding uniformly wound over the full 360° of the core. Full-wave operation requires two such cores. After winding a gate winding on each core of a matched pair, the two cores and coils can be stacked together coaxially and the required control coils wound over the stack. The gate coils are so connected into the load circuit that no fundamental or odd-harmonic voltage is induced in the control windings.

CHAPTER 11.4

OPERATIONAL AMPLIFIERS

Samuel M. Korzekwa, Joseph P. Hesler, Clayton R. Roberts

DIRECT-COUPLED AMPLIFIERS

Samuel M. Korzekwa

A direct-coupled amplifier has frequency response that starts at zero frequency (dc) and extends to some specified upper limit. To obtain the zero-frequency capability, such amplifiers are normally direct-coupled throughout; i.e., they do not use capacitive or transformer coupling (except for auxiliary higher-frequency compensation or signal transmission).

The primary sources of error of a direct-coupled amplifier are initial offset, drift, and gain variations, errors usually dependent on temperature, aging, and so forth. The gain-variation problem can be minimized by feedback gain-stabilization techniques, but offset and drift errors are usually not handled so effectively by feedback techniques. A bias shift or drift error cannot be distinguished from a signal response because their output responses are identical. Various techniques are available to minimize this drift problem, and several different methods may be used in an amplifier.

One method of minimizing drift is to use a balanced topology, as in differential amplifiers, whereby the drift errors tend to cancel out. A more complicated but effective method is the modulated-carrier-amplifier approach: the signal is first converted into a carrier signal, amplified using an ac-coupled amplifier, and then demodulated to a baseband signal. The function performed by the modulated-carrier amplifier is identical with that of a direct-coupled amplifier, but the signal processing technique differs.

An example of a direct-coupled transistor amplifier is illustrated in Fig. 11.4.1. The primary signal path, shown in heavy lines, directly couples the input signal to the amplifier output. This configuration also provides gain and bias stabilization via the direct-coupled R_3 feedback path. Usually the low-frequency amplifier voltage gain is primarily determined via the R_1 and R_3 components, while the function of the C_1 capacitor and R_6 resistor is to provide high-frequency compensation or stabilization. Sources of error for this topology include the initial V_{BE} offset of the Q_1 input transistor and the subsequent drift caused by the temperature dependence of this offset.

Differential Amplifiers

A differential amplifier is a dual-input amplifier that amplifies the difference between its two signal inputs. This amplifier may have an output that is single-ended (one output) or it may have a differential output.

The differential amplifier eliminates or greatly minimizes many common sources of error. The drift problem encountered in direct-coupled amplifiers can be handled more effectively by the differential approach. A second major advantage of a differential amplifier is its ability to reject common-mode signals, i.e., unwanted signals present at both of the amplifier inputs or other common points. Common-mode performance is usually a critical requirement of instrumentation amplifiers.

FIGURE 11.4.1 Direct-coupled transistor amplifier.

The basic circuit commonly used in differential amplifiers is shown in Fig. 11.4.2. Such differential pairs can be constructed using separate devices or in integrated-circuit form. The integrated package yields additional advantages since the parameter differences between the units of the integral differential pair are usually much less than if separate devices are used. Thus the units of such integral pairs tend to track differentially more closely, even though their individual parameters may vary in absolute value. Also, many of the passive components in the integrated amplifiers track better. Figure 11.4.3 shows a typical differential transistor amplifier. For further detailed information, including analysis procedures, design techniques, and application data, refer to the literature.

Chopper (Modulated-Carrier) Amplifiers

The chopper amplifier performs the function of a direct-coupled amplifier by using a carrier frequency and an ac-coupled amplifier. The modulated-carrier approach is used specifically to minimize drift and offset types of errors.

FIGURE 11.4.2 Differential amplifier pair.

Although this approach is often more complex to implement, the performance improvement makes this technique desirable for applications demanding low-drift performance.

Figure 11.4.4 shows the block diagram of a modulated-carrier amplifier. While the input and output signals are decoupled, the interstage coupling between the modulator, amplifier, and demodulator may be either a capacitor or a transformer.

Since modulator and demodulator are usually operated synchronously, the carrier delay must be maintained at acceptable levels. Low-pass filters are generally included in the modulator and demodulator. The choice of carrier frequency depends on the application. Typical examples of low-frequency carriers are 60 and 400 Hz. Carrier frequencies above 10 kHz are also feasible. Since

the chopper and demodulator generate noise at their carrier frequency and its harmonics, the carrier frequency should normally be chosen above the baseband frequency range of interest. Early chopper modulators and demodulators were mechanical devices, but modern types employ solid-state electronics.

A variation of the modulated-carrier technique uses the chopper-stabilized approach illustrated in Fig. 11.4.5, which includes an additional parallel ac-coupled high-frequency signal path. The two signal paths

FIGURE 11.4.3 Two-stage differential amplifier with common-mode feedback.

FIGURE 11.4.4 Modulated-carrier (chopper) amplifier.

FIGURE 11.4.5 Chopper-stabilized amplifier.

have gains and bandwidths tailored to a crossover frequency; e.g., when the high-frequency signal path becomes dominant, the modulated-carrier signal path ceases to contribute to the sum total. This variation offers the low-drift advantages of the carrier-modulated system with much higher bandwidth.

Operational Amplifiers

An operational amplifier is intended to realize specific signal processing functions. For example, the same operational amplifier (depending on the externally added components) can be used as an integrating amplifier, a differentiating amplifier, an active filter, or an oscillator, among others. Applications of operational amplifiers also include such functions as impedance transformers, regulators, and signal conditioning. They are versatile building blocks that can also be used in nonlinear applications to realize functions such as logarithmic amplifiers, comparators, ideal rectifiers, and so forth.

The early application of operational amplifiers was largely in the area of analog computations. The requirements placed on the amplifiers were severe, and the cost was high. Currently, however, these high-performance functions are available at low cost and are widely used.

An operational amplifier can be either direct-coupled or ac-coupled. Most operational amplifiers have differential inputs and consequently realize common-mode rejection; however, many operational amplifiers are single-ended. Their power capability covers a wide range, and they can function as a power driver. The open-loop bandwidth can range from below 1 kHz up to the megahertz range. Voltage gain can be designed from unity to above 100,000.

To design or use the many excellent models now available commercially, it is necessary to understand the attributes and limitations of these versatile building blocks. The reader is referred to the literature and, of course, to the data sheets and applications literature of individual suppliers of op amps.

Application of Operational Amplifiers

Figure 11.4.6 shows the block diagram for an operational amplifier with associated external elements. A_1 represents the transfer function of the amplifier, either current gain or voltage gain, which is generally frequency-

FIGURE 11.4.6 Operational amplifier A_1 with external impedances which determine its functional application.

dependent. Z_i and Z_f are the primary elements that normally determine the closed-loop transfer function for this operational amplifier. The indicated Z_{in} and Z_l are equivalent summing node and load impedances, respectively, which are usually factored into the error terms of the composite transfer function. All the elements are general impedances that may be real or complex. Thus the simplified transfer function of this operational amplifier can be written

$$e_o/e_i \approx -Z_f/Z_i \tag{1}$$

The error terms of the complete transfer function equation are not shown in Eq. (1); however, the complete equation with error terms can be readily derived or obtained from the literature. Thus, if the required constraints are adhered to, Eq. (1) can be used to generate various transfer functions, as illustrated in the examples given below.

Integrating Amplifier. An example of an integrating amplifier is shown in Fig. 11.4.7. Assume that the external-component values are as indicated and that the A_1 amplifier is a widely used commercial integrated circuit op amp. Using Laplace transform notation, the integrator transfer function becomes

$$(e_o/e_i)S = (-)1/RCs \tag{2}$$

FIGURE 11.4.7 Operational amplifier used for integration: (a) basic schematic; (b) frequency response.

Using the component values specified in the figure, the integrator transfer function can then be written

$$(e_o/e_i)S = (-)5000/S \tag{3}$$

An alternative frequency-domain representation of the above integrator transfer function can also be used.

$$(e_o/e_i)f = (-)800/jf \tag{4}$$

The closed- and open-loop frequency responses of this operational integrator amplifier are illustrated in Fig. 11.4.7b.

The frequency range of application depends primarily on the accuracy desired. In this example, 1 Hz to 10 kHz frequency is considered a realistic range of operation. For very low frequencies the error tends to increase because of inadequate excess gain within the operational amplifier, whereas for high frequencies the closed-loop gain becomes low and drift and offset errors may then become important.

Differentiating Amplifier. An example of a differentiating amplifier is shown in Fig. 11.4.8. The following simplified closed-loop equations are applicable:

$$(e_o/e_i)S \approx (-)RCS \tag{5}$$

$$(e_o/e_i)S \approx (-)0.165S \tag{6}$$

$$(e_o/e_i)f \approx (-)jf \tag{7}$$

FIGURE 11.4.8 Operational amplifier used for differentiation: (a) basic schematic; (b) frequency response.

The frequency responses of this operational amplifier differentiator are shown in Fig. 11.4.8*b*. The open-loop response of the operational amplifier of Fig. 11.4.7 is used, and the differentiator closed-loop response is superimposed onto it.

The frequency range of this operational amplifier differentiator depends primarily on the closed-loop differentiation accuracy required. The difference between open- and closed-loop transfer functions (usually referred to as *excess gain*) can be used to predict the accuracy of the function being generated. A realistic frequency range is from 0.01 to 100 Hz. At very low frequencies the closed-loop gain becomes very small, and consequently errors such as drift and offset may become critical. At high frequencies the accuracy degrades, and ultimately an integration function is generated rather than the differentiation function intended.

Servo Amplifiers

The function of a servo amplifier, one of the principal components in a control feedback system, is to amplify the input (usually low-level) error signals and to provide rated drive power to the load (the servo actuator). Servo amplifiers can be dc- or ac-operated, and can be linear or nonlinear.

Direct-Coupled Servo Amplifiers. A direct-coupled servo amplifier can operate on dc error signals, i.e., zero frequency signals. The bandwidth of a dc servo amplifier is often quite large, and thus it has the capability of dynamic operation. In practice it is often operated in the dynamic mode, and the transient-response characterization is often used.

A servo amplifier is intended to drive or control its load to some prescribed reference level. It is the drift and offset errors associated with this control function that are the main concern in this dc mode of operation. Thus, if the actuator is positioned at its exact reference level, the amplifier should provide zero drive power. However, because of initial offsets or subsequent temperature or aging effects, the amplifier may still provide unwanted drive to the load. The usual solution is to minimize these problems by circuit design, e.g., tracking or balanced configurations, or by use of an intermediate-carrier modulated by the dc error input signals, subsequently demodulated for use as the direct-coupled drive to the actuator.

AC Servo Amplifiers. An ac servo amplifier operates at a selected fixed frequency and is consequently a carrier-system amplifier. The most commonly used carrier frequencies are 60 and 400 Hz, but ac servo systems can be designed to operate at almost any frequency compatible with the servo actuator used.

The principal advantage of ac servo amplifiers is that the previously discussed drift and offset problems present in dc servo amplifiers are virtually eliminated. Another advantage is that the prime power from the actuator now can be supplied directly from the line, for example, 60-Hz 115-V source.

For applications wherein the servo actuator or load is a servomotor, the load is often tuned to the carrier frequency via the addition of a capacitor in parallel with the motor. Note that the servomotor impedance is a function of the motor speed; however, the losses (usually resistive) change, whereas the parallel inductance remains virtually constant. Thus tuning the load causes it to become real (resistive), and consequently the efficiency of the amplifier output stage improves significantly.

The output stage of an ac servo amplifier is usually operated class B or AB and in a push-pull configuration to obtain the best possible drive efficiency. Figure 11.4.9 shows an example of a push-pull tuned-load ac servo amplifier.

Nonlinear Servo Amplifiers. This class of servo amplifier uses the load to filter the highly nonlinear drive signals resulting in improved drive efficiencies and higher realizable driver-power capabilities. The drivers essentially act as switches wherein the dissipation losses are low when the switches are either on or off. Since the loads or servo actuators are usually highly reactive, they can be advantageously used in this manner. The drive power can be readily derived from a dc source via a pulse-width-modulated scheme. In addition, an ac source of power can also be used via a phase-modulation technique. Some examples of high-power switching devices used for ac nonlinear servo amplifiers are thyratrons and silicon controlled rectifiers (SCRs).

FIGURE 11.4.9 Servo amplifier used as a motor drive.

OPERATIONAL AMPLIFIERS FOR ANALOG ARITHMETIC

Joseph P. Hesler

Analog Multiplier Circuits

Circuits used for analog multiplication fall into three categories: transconductance multipliers, averaging-type multipliers, and exponential multipliers.

Transconductance Multipliers

The most prominent type of transconductance multiplier uses the property of the bipolar transistor; i.e., its collector current and transconductance are linearly related. The balanced transistor differential amplifier used in these circuits offers good accuracy, wide bandwidth, and low cost.

FIGURE 11.4.10 Basic differential amplifier for analog multiplication.

In the differential amplifier as shown in Fig. 11.4.10, the collector currents I_{c1} and I_{c2} are functions of the differential input voltage $V_{b1} - V_{b2}$. It is assumed that the current transfer ratios of the two transistors (Q_1 and Q_2), the junction ambient temperatures, and the base-emitter junction saturation currents are the same, as is probable in integrated-circuit fabrication.

The diode equation governs the relationship between the transistor emitter currents I_{Ei} and the base-to-emitter voltage V_{BE1}

$$I_E = I_S \exp \left(\frac{V_{BE} q}{kT} - 1 \right)$$

FIGURE 11.4.11 Transfer curves on which analog multiplication is based.

where I_S = junction saturation current
 q = electron charge = 1.6×10^{19} C
 k = Boltzmann's constant = 1.38×10^{-23} W/s·K
 T = junction temperature (K)

The relationships of collector currents, shown graphically in Fig. 11.4.11 are

$$I_{c1} = \frac{\alpha_1 I_0}{1 + \exp [(V_{BE_2} - V_{BE_1})q/kT]} \quad I_{c2} = \frac{\alpha_2 I_0}{1 + \exp [(V_{BE_1} - V_{BE_2})q/kT]}$$

For zero differential input, $V_{BE_1} = V_{BE_2}$ and $\alpha_1 = \alpha_2$, and so

$$I_{c1} = I_{c2} = \alpha I_0 / 2$$

At zero input, $\Delta V_{BE} = 0$, the maximum single-ended transconductance occurs at

$$g_{m_{max}} = \alpha I_0 / (4kt/q)$$

For a differential output connection the maximum transconductance is twice this value. The linear range of transconductance extends over a differential input signal range of about 50 mV peak to peak at room temperature.

Linear multiplication occurs when one input varies the I_0 term and the other input is used to vary ΔV_{BE} .

$$\Delta I_c = g_m \Delta V_{BE} = \frac{\alpha I_0}{2kT/q} \Delta V_{BE}$$

FIGURE 11.4.12 Four-quadrant transconductance multiplier.

The linear range of input voltage can be extended by inserting resistance in series with each emitter. This increase in allowable signal is accompanied by a corresponding reduction in transconductance. For I_0 equal to 2 mA, the addition of 50 Ω in series with each emitter increases the linear input swing by a factor of 3 and reduces the transconductance to one-third. Optimization of the transconductance multiplier operation requires a trade-off between linearity and error sources because of offset voltages and thermal noise.

A typical four-quadrant multiplier using the differential amplifier as building blocks is shown in Fig. 11.4.12. This circuit is generally used with differential inputs to obtain maximum linearity and common-mode signal rejection.

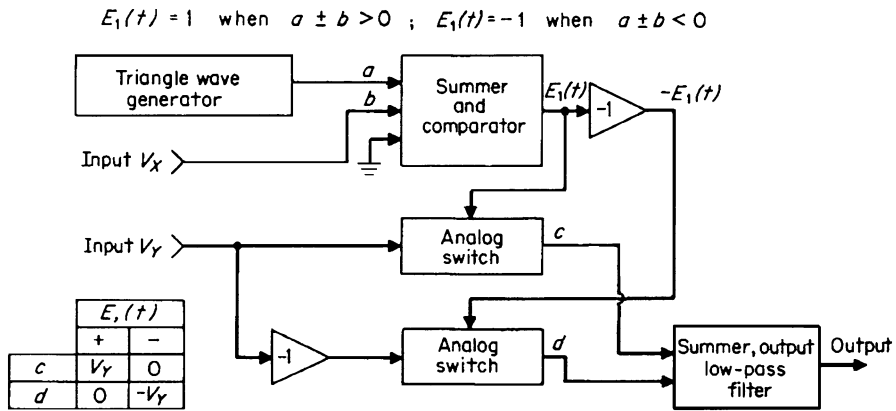

FIGURE 11.4.13 Block diagram of an averaging-type multiplier.

Averaging-Type Multipliers

Two types of averaging multipliers have found extensive use. The first type, the pulse height and width multiplier, uses one of the input variables to modulate the height or amplitude of a pulse train, while the pulse width is modulated with the other input variable. The pulse area, averaged over a suitable period, is proportional to the product of the input variables. High pulse rates permit short averaging intervals and fast response. These multipliers offer very good accuracy and stability but are more expensive than the transconductance multipliers. A block diagram of a typical pulse height and width averaging multiplier is shown in Fig. 11.4.13.

A second version of the averaging multiplier is the triangle averaging multiplier. In this type a high-frequency triangular waveform is generated and combined with the input variables to form an averaged output proportional to the product of the input signals. These multipliers are less accurate than the pulse height and width multipliers and are being displaced by transconductance multipliers.

A third type of averaging multiplier is the time-base multiplier. This approach uses a comparator to sense the time interval required for the integral of a reference input voltage to equal the amplitude of a sample of one input variable. During the same interval, 0 to T , the other input variable is integrated to produce an output V . This type of circuit can be built with a few components to provide moderate accuracy, 1 to 5 percent, at low cost.

Exponential Multipliers

The first electronic multipliers were of the exponential type. In these circuits, resistor-diode networks are designed to provide a current or voltage output approximating the square of the input. These multipliers are also called *quarter-square* multipliers based on the identity

$$XY = 1/4 [(X + Y)^2 - (X - Y)^2]$$

The piecewise-linear approximations to the squared response result in “lumpy” error characteristics. Also, the amount of circuitry required to compute the quarter-square algorithm is expensive. Although these multipliers are capable of good accuracy and bandwidth, they are becoming obsolete.

A second type of exponential multiplier uses logarithmic amplifiers, a summer, and an antilog amplifier to implement the relationship

$$XY = \text{antilog}_a (\log_a X + \log_a Y)$$

Semiconductor diodes are available with excellent logging characteristics over many decades of bias current. These diodes are used with operational amplifiers to realize the necessary functions. The circuits can provide

moderate to good accuracy (with thermal compensation) and good bandwidth. Applications are restricted by unipolar input requirements and differential drift because of thermal effects.

Multiplier Error Sources

Offset Error. There are two subclasses of offset error. The first is static offset caused by variances in component parameters such as saturation current I_s , in transistors and diodes. The second error is a result of drift in component parameters. While the initial static offset can be trimmed with external adjustments, the drift components must be compensated by introducing complementary temperature coefficients within the circuit. A common source of drift is local heating of diode junctions and resistive components having nonzero temperature coefficients.

Feedthrough Error. Feedthrough errors result from nonideal transfer characteristics. Two feedthrough error contributions can exist. The first, E_{FY} , is defined as the output owing to the input variable Y when the X input is zero. The second, E_{FX} , is the complementary function owing to an X input. Feedthrough errors may result in dc, fundamental, and harmonic components of the contributing input signal.

Gain and nonlinearity errors. Gain errors produce output deviations from the expected scale factor of the multipliers. Nonlinearity of the transfer functions of the multiplier can produce additional error contributions, as previously discussed. Gain is most apt to vary as a function of the combined input-signal values because the internal components are operated over a range of bias conditions.

In certain multiplier applications, required transient responses may overtax the bandwidth capabilities of the circuits. In these instances additional error terms may appear as a result of limited slew rate of the circuits and differential phase response between the input channels.

Squaring Circuits

Squaring circuits are readily implemented by introducing the variable to both inputs of a multiplier circuit. Alternatively, the resistor-diode squaring circuits used in exponential multipliers may be applied directly.

Dividing and Square-Root Circuits

Division and square-root functions can be implemented with basic multiplier circuits by altering the interconnections. A typical dividing-circuit connection is shown in Fig. 11.4.14. The multiplier output is fed back

FIGURE 11.4.14 Dividing circuit.

$$-\frac{Z}{R} + \frac{E_o^2}{KR} \approx 0$$

$$E_o^2 = KZ$$

$$E_o = \sqrt{KZ}$$

FIGURE 11.4.15 Square-root circuit.

through a summing amplifier to one of the multiplier inputs. The summing amplifier maintains an equivalence between the numerator Y and the multiplier output XE_0/K .

$$Y/R = -XE_0/KR \quad \text{or} \quad E_0 = -KY/X$$

Square-root circuits can be implemented in a similar method with another feedback connection involving a multiplier. In this instance, the output is used as each of the two multiplier-input variables, and the multiplier output is summed with the variable whose square root is desired. The square-root connection is shown in Fig. 11.4.15. The nonnegative input limitations should be stated for division and square-root connections.

LOW-NOISE OPERATIONAL AMPLIFIERS

Clayton R. Roberts

Low-Noise Op-Amp Design

The use of the standard operational-amplifier module or chip has grown into many areas of design because of its low cost, ease of design, and low number of supporting components. Some of the well-known basic amplifier uses are shown in Fig. 11.4.16. Low-noise amplifier developments have moved into the op-amp category for the same reasons. Applications in this area include microphone pre-amplifiers, threshold detectors, instrumentation amplifiers, and sensor amplifiers. Good low-noise op-amps are available, and understanding some of the basic design principles is helpful when using them.

There are many types of noise derived from a number of sources, but the types concerning amplifiers include $1/f$ or pink noise and thermal and other current- and voltage-associated effects within the amplifier. Pink noise is of concern at the very low end of the spectrum and involves dc amplifiers and some types of sensors. Generally the amplifier noise density can be expressed as follows:

$$A_v = \frac{e_o}{e_i} = \frac{R_2}{R_1}$$

$$A_v = \frac{e_o}{e_i} = \frac{R_1 + R_2}{R_1} \cdot \frac{R_4}{R_3 + R_4}$$

FIGURE 11.4.16 Basic operational-amplifier configurations.

$$E_n = G \sqrt{e_n^2 + (i_n R_{eq})^2 + e_t^2}$$

- where e_n = op-amp noise voltage
- i_n = op-amp current noise
- R_{eq} = equivalent input source resistance (including feedback network)
- e_t = thermal noise of source network (resistance)

and since

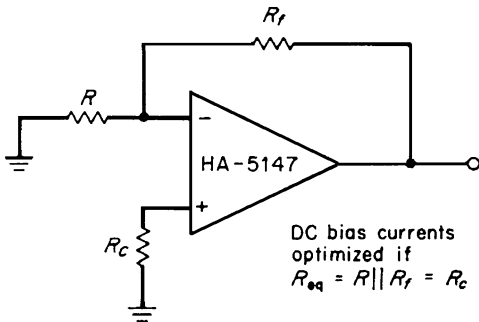

$$e_t = \sqrt{4KTR_{eq}}$$

where $K = 1.38 \times 10^{-23}$, $T = 300$ K, then

$$E_n = G \sqrt{e_n^2 + (i_n R_{eq})^2 + 4KTR_{eq}}$$

(a)

(b)

FIGURE 11.4.17 Simple op-amp configuration with and without bias.

FIGURE 11.4.18 Voltage and current noise characteristics of a commercially available op amp.

The R_{eq} can become a predominant influence in the noise of the amplifier. This resistance is the combination of the resistive component of the input to the amplifier and the feedback network. It is obvious that the input to the amplifier should be kept as low as possible without loading down the device the amplifier is attached to. Figure 11.4.17 shows the R_{eq} of the simple amplifier. When offset bias is added to the op amp, the thermal and current noise components must be added to the noise equation. Usually the bias resistance is equal to the R_{eq} making the noise density

$$E_n = G \sqrt{e_n^2 + 2(i_n R_{eq})^2 + 8KTR_{eq}}$$

The amplifier design should have bandwidth restrictions on it so that the band extent does not go beyond that which is necessary. When the amplifier design is the first stage of a larger amplifier and it becomes the noise determining circuit, the bandpass restrictions do not have to be repeated further on.

There is one other consideration regarding the R_{eq} and the source resistances. If truly low noise is desired, noncarbon resistors are needed in this part of the circuit. Metal film resistors are best. Wire-wound resistors are also a possibility, but not if high frequencies are involved. Carbon resistors have a larger “particle component” of noise beside the normal thermal noise.

Generally, the current noise i_n and voltage noise e_n remain relatively constant above 1 kHz and rise somewhat below 100 Hz, as shown in Fig. 11.4.18. If high values of R_{eq} or source resistances are necessary, op-amp selection is possible to reduce noise in parts of the spectrum. This is apparently a result of the biasing arrangement of different op amps with their input transistors ($e_n = f/\sqrt{i_c}$, $i_n = f\sqrt{i_c}$). With R_{eq} less than 1 k Ω , the thermal noise is expected to be low and the total noise is dominated by the voltage noise e_n .

POWER OPERATIONAL AMPLIFIERS

Clayton R. Roberts

Power Op Amps

The advent of the *power op amp* has provided us with another versatile design approach when high-current high-voltage drive requirements are needed. It is useful in motor drive circuits, deflection sweep circuits, many control functions, and high-quality audio amplifiers. Distortion levels below 0.05 percent can be achieved. In addition to the high-voltage high-current ratings the power op amps usually provide better matched components from internal control of the devices and laser trimming of the stages. Standard design approaches for op amps are used except for some considerations mentioned below. The definition of where the power op amp takes over from the standard op amp appears to be when the total supply voltage must be above 44 V and the delivered current is above 0.1 A.

Power Dissipation. In addition to the maximum voltage rating concerns, the power op-amp design must include operating temperature and dissipation values. Mounting of the device as well as the operating region of the parameters is a major design criterion. Figure 11.4.19 shows the effect of junction temperature of the power devices on failure rates as was derived from the base failure rate tables of MIL-HDBK-217C. Some power op-amp manufacturers design the cases so that they can be directly mounted to grounded heat sinks so that there is minimum thermal resistance to the sink. The required thermal resistance ϕ from a heat sink is calculated by the following:

$$\phi = (T_j - T_a) / P_{dis} - \phi_{JC}$$

where T_j = maximum junction temperature

T_a = maximum ambient temperature

P_{dis} = internal power dissipation

ϕ_{JC} = thermal resistance of the amplifier

Another heat-sink-design approach (Fig. 11.4.20) offers the approximate area required of a convection cooled surface.

The complexity of the power-dissipation calculation is very much dependent on the type of load that is being driven. Taking dc or instantaneous values of current and voltage, it may be expressed as

$$P_{dis} = (V_s - V_o)I_o + V_{ss}(I_q)$$

FIGURE 11.4.19 Failure rate (MTTF) vs. junction temperature.

FIGURE 11.4.20 Heat-sink area estimated for temperature rise and several values of power dissipation.

FIGURE 11.4.21 Safe operating curves for a power operational amplifier.

where V_s = one rail of the supply voltage
 V_o = output voltage
 I_o = output current
 V_{ss} = rail-to-rail supply voltage
 I_q = quiescent current

For sinusoidal waveforms the peak value of P_{dis} may be expressed as

$$P_{dis} = (V_s/2Z_l)[1 - \cos(60^\circ - \theta)]$$

where θ is the absolute value of the phase angle of Z_l and Z is the magnitude of the load impedance. This function is approximate.

Safe-operating-area (SOA) curves are supplied by some manufacturers to aid in limiting the power dissipation to within specifications. Figure 11.4.21 shows a curve for a commercial power op amp. The secondary breakdown region shown results from excess current densities in the base region of the output devices when high collector current occurs simultaneously with high collector-emitter voltage. These curves include all contributors to the dissipation problem. The three curves at the right-hand end of Fig. 11.4.21 are the limits of the short-pulse power applications for the SOA curve. Pulse width values of 0.5, 1.0, and 5.0 ms are indicated. Additional foldover or limiting current protection can be obtained when operating near the limits (rail) (refer to manufacturers product data).

Output Loads. Output loads can have reactance components involved even if they are designed to be resistive. With the higher currents present, and especially transients, reactive, or flyback (reversed polarity) voltages can exceed specified limits. Most power op amps have built-in diodes between the two rails and the output to help suppress such transients. By necessity these can handle limited current. Several manufacturers recommend external diodes be placed between the output of the op amp and each of the supplies. The back emf must be considered in the design (SOA curves). This is especially true with loads such as motors. Start-up and reverse conditions must be accounted for. Some types of loudspeaker circuits present a similar situation.

Circuit Layout. Lead inductance must be kept to a minimum. This is sometimes taken care of by use of a microstrip-type low-impedance line approach. Power-supply transients are reduced to a minimum by bypassing right at the op amp as well as at the supply terminals. With high currents involved, bypass capacitors must have low reactance leads and several times their normal values. With low-distortion amplifiers, deterioration

FIGURE 11.4.22 National Semiconductor LM12 power amplifier.

at the high-frequency end of the spectrum (higher distortion) can be the result of insufficient effective bypassing from the supply sources, but this is best taken care of by large short-lead bypasses at the device location. Ground loops and ground return interaction effects are also emphasized with the high-current devices. Input-output ground return coupling is to be avoided.

An audio power amplifier shown in Fig. 11.4.22 has some of the features indicated in a low-cost high-performance design. The LM12 (National Semiconductor) is a 150-W op amp capable of delivering that power to a 4- Ω load. The design includes Motorola MR752 diodes in its output to the rails. These diodes are capable of handling up to 400 A of surge current, 28 A average forward current, and a repetitive reverse voltage of 200 V. These specifications provide good protection against transients and back emf. The small capacitor in the feedback network aids in reducing the distortion at the high end of the spectrum and provides stability. The distortion is claimed to be about 0.01 percent. Good supply bypassing is obtained right at the device terminals. A central grounding point is used to avoid ground coupling of output to input. Thermal limiting, output current limiting, and over voltage shutdown is designed into the device. Note the parts count associated with circuit.

CHAPTER 11.5

HIGH-POWER AMPLIFIERS

Richard W. French, Clayton R. Roberts

THERMAL CONSIDERATIONS

A problem common to all high-power amplifier and oscillator equipment is removal of the excess thermal energy produced in the active devices and other circuit components so that operating temperatures consistent with reliable performance can be maintained. Available cooling methods are radiation, natural convection, forced convection, liquid, evaporative, and conduction. Radiation and evaporative cooling depend for suitable operation on a rather high temperature for the device being cooled and are thus generally restricted to use with vacuum tubes. The remaining methods are suitable for use in both solid-state and vacuum-tube systems.

HIGH-POWER BROADCAST-SERVICE AMPLIFIERS

Transmitters for amplitude modulation broadcast service may employ high-level (plate) modulation or low-level (grid or screen) modulation of the output stage or modulation of an intermediate stage, followed by linear amplification in the following stage(s). Generally, the last approach is used in very-high-power transmitters, because of the difficulty and expense in designing and building a modulation transformer to handle the high audio modulating power required. High-level modulation has been used in AM transmitters up to at least 250 kW carrier power with a modulator output power requirement of 125 kW. By a unique design in which the positive terminal of the modulator plate supply is grounded, and autotransformer is used as the modulation transformer, with a significant reduction in size and cost.

CLASS B LINEAR RF AMPLIFIERS

The conventional means for achieving linear amplification of an AM signal is the class B rf amplifier circuit, often referred to simply as a *linear amplifier*. The plate efficiency, plate dissipation, and output power are highly dependent on the drive level. It is convenient, therefore, to define a *drive ratio* or normalized drive level k .

$$k = E_{pm}/E_{bb}$$

where E_{bb} is the dc plate supply voltage and E_{pm} is the peak ac plate signal voltage.

Class B amplifiers using transistors can approach the theoretical maximum collector efficiency of $\pi/4$, or 78.54 percent, as a consequence of the very low collector saturation voltage of transistors, which gives a correspondingly high value for K .

HIGH-EFFICIENCY POWER AMPLIFIERS

The plate efficiency at carrier level in a practical linear amplifier circuit is about 33 percent, while that of a high-level (plate) modulated stage is 65 to 80 percent. When the efficiency of the modulator is taken into account, the net efficiency of the high-level modulated stage is still higher than that of the linear amplifier, since the output power level of the modulator is at most one-third of the total output power of the modulated stage.

Because of the difficulty and expense involved in the design and manufacture of very large modulation transformers and chokes, several linear amplifier circuits having much greater efficiency than the class B amplifier while amplifying an AM waveform have been developed. Low-level modulation can be employed, and the need for the large, expensive modulator components is circumvented.

Such high-efficiency amplifier circuits include the Chireix outphasing modulated amplifier, the Dome high-efficiency modulated amplifier, the Doherty high-efficiency amplifier, and the Terman-Woodyard high-efficiency modulated amplifier.

INDUCTION HEATING CIRCUITS

Induction heating is achieved by placing a coil carrying alternating current adjacent to a metal workpiece so that the magnetic flux produced by the current in the coil induces a voltage in the workpiece, which produces the necessary current flow.

Power sources for induction heating, in addition to direct use of commercial power, include spark-gap converters, motor-generator sets, vacuum-tube oscillators, and inverters. Motor-generator sets generally provide outputs from 1 kW to more than 1 MW and from 1 to 10 kHz. Spark-gap converters are generally used for the frequency range from 20 to 400 kHz and provide output power levels up to 20 kW. Vacuum-tube oscillators operate at frequencies from 3 kHz to several MHz and provide output levels from less than 1 kW to hundreds of kilowatts. Inverters using mercury-arc tubes have been used up to about 3 kHz. Solid-state inverters operate at frequencies up to about 10 kHz and at power levels of several megawatts. These solid-state inverters generally employ thyristors (silicon controlled rectifiers) and are replacing motor-generator sets and mercury-arc inverters.

DIELECTRIC HEATING

Whereas induction heating is used to heat materials which are electrical conductors, dielectric heating is used to heat nonconductors or dielectric materials. The basic arrangement for a dielectric heating system is that of a capacitor in which the material to be heated forms the dielectric or insulator. The heat generated in the material is proportional to the loss factor, which is the product of the dielectric constant and the power factor. Because the power factor of most dielectric materials is quite low at low frequencies, the range of frequencies employed for dielectric heating is higher than for induction heating, extending from a few megahertz to a few gigahertz.

The power generated in a material is given by

$$P = 141AV^2 f \frac{K \cos \phi}{t} \times 10^{-6} \quad (\text{W})$$

where V = voltage across material (V)

f = frequency of power source (MHz)

A = area of material (in²)

K = dielectric constant

t = material thickness (in)

$\cos \phi$ = power factor of dielectric material

The voltage that can be applied to a particular material is limited by the insulation properties of the material at the required process temperature. The frequency that can be used is limited by voltage standing waves

on the electrodes, which will be appreciable when the electrode dimensions are comparable with one-eighth wavelength (10 percent voltage variation).

TRANSISTORS IN HIGH-POWER AMPLIFIERS

Many high-power amplifier circuits can be implemented by using solid-state power devices. Bipolar transistors have been successfully applied in induction heaters, sonar transmitters, and broadcast transmitters. The sonar transmitters have employed class B, class C, and the so-called class D power amplifier circuits. In the class D circuit the active device is used as an on-off switch, and output power variations are achieved by pulse-width modulation or supply-voltage control. A tuned load or one incorporating a low-pass filter is used with the class D amplifier.

Power MOSFETs are advantageous compared with bipolar transistors in a number of applications. These include HF and VHF transmitters, high-speed power switching, and certain audio or low-frequency amplifiers.

The power MOSFET is a majority carrier device (contrast with a minority carrier device for the bipolar transistor). The input drive circuit requires current to supply the parasitic capacitances only. There is no minority carrier storage time or secondary breakdown. Switching time is usually much less than that of the bipolar transistor of the same die. The power MOSFET device uses a gate voltage-controlled circuit and requires very little current to maintain it in its OFF, ON, or an intermediate state. The ON resistance (r_{DS}) can vary from less than 0.5Ω to several ohms depending on the device selected. There is a trade-off between high-breakdown drain-source voltage and low ON-resistance. For a given die size the ON-resistance varies as follows:

$$r_{DS} = K(V_{DS})^2$$

where K is a constant related to the die and V_{DS} is the maximum breakdown voltage between drain and source. A typical drain current (I_D)-drain-source voltage (V_{DS}) transfer characteristic curve of a TMOS power MOSFET is shown in Fig. 11.5.1. The ON-resistance r_{DS} is, of course, a function of the conduction state of the device and does have a threshold value depending on the gate voltage which controls the conduction (see Fig. 11.5.2). Also, if the design is dependent on the r_{DS} value, one must keep in mind a potential shortcoming which is its variation with temperature. Figure 11.5.3 shows this function with a Motorola MTM8N15. Temperature coefficients are provided as a function of I_D with a number of device data sheets. Switching speeds of this device are not influenced by temperature.

Considerations for Broadcast Transmitters. There are some advantages to using the power FET in this type of application through the VHF spectrum. The power FET offers stability in the drive circuit as well as its own transfer characteristics. With the bipolar transistor there is a dependent relationship between the collector current i_C and the current gain β . If the drive level is decreased, causing the i_C to decrease, the β will increase and can cause instability in an amplifier. The input impedance can also change as the drive level is changed. Both of these factors can become a stability design problem. The input and output impedances of the

FIGURE 11.5.4 Power amplifier for Nautel broadcast transmitter.

device are reasonably independent of drive. The input impedance is somewhat higher in magnitude and more capacitive than bipolar devices, allowing simpler matching circuits to be used.

There are a number of approaches used in transmitter design. Which one to use depends on the number of modulation and carrier uses. Usually, a slightly positive (adjustable) bias is required on the gate unless strictly class C is needed. The amplifier design can be made to withstand high VSWR conditions in the output without damage. This is accomplished by selection of the device so that maximum rated drain-source voltage ($V_{(BR)DSS}$) is not exceeded. Likewise, the gate-to-source voltage (V_{GS}) cannot be exceeded. This is sometimes protected using a zener diode across the gate to source. Remember that using such devices tends to generate undesirable harmonics when the drive signal is clipped and a low-pass filter or equivalent is required in the output.

While power FET amplifiers can be operated in class A, B, AB, and C, it is of strong interest to consider class D for AM broadcast service. Power FETs can have a wide linear operating range and swinging them hard to an ON condition allows the efficiency to be quite high. Nautical Electronic Laboratories Limited of Nova Scotia has developed a very efficient AM transmitter using power FETs as switches (class D operation). Figure 11.5.4 shows the basic configuration of the final rf amplifier. A low-power rf drive signal at the carrier frequency is applied via T_1 to bias FET pairs Q_1/Q_3 and commutated between input terminals of T_2 as a square wave of reversing polarity at the carrier frequency. The resulting high-power signal at T_2 is filtered by low-pass filter F_1 to remove unwanted harmonics. The final rf amplifier is thus simply a device that converts from dc to rf. Efficiencies of greater than 90 percent are achievable.

The pulse width modulator also uses FETs in a switched mode to vary the negative supply to the rf power amplifier in sympathy with an audio modulating signal to produce high level modulation with a similar high efficiency. Nautical Electronic Laboratories has developed a 50-kW solid-state transmitter of this type with distortion typically less than 1.0 percent.

MOSFET AUDIO AMPLIFIERS AND SWITCHING APPLICATIONS

The power MOSFET offers a very linear transfer characteristic. This can be used effectively with the design of audio power amplifiers with proper gate biasing.

The gain characteristic is identified with the transconductance of the MOSFET. The voltage gain is as follows:

$$A_v = g_{fs} R_L$$

where g_{fs} is the transconductance and R_L is the equivalent load. The transconductance is defined as the ratio of the change in drain current relating to a change in gate voltage. This rating on a device is typically taken at half

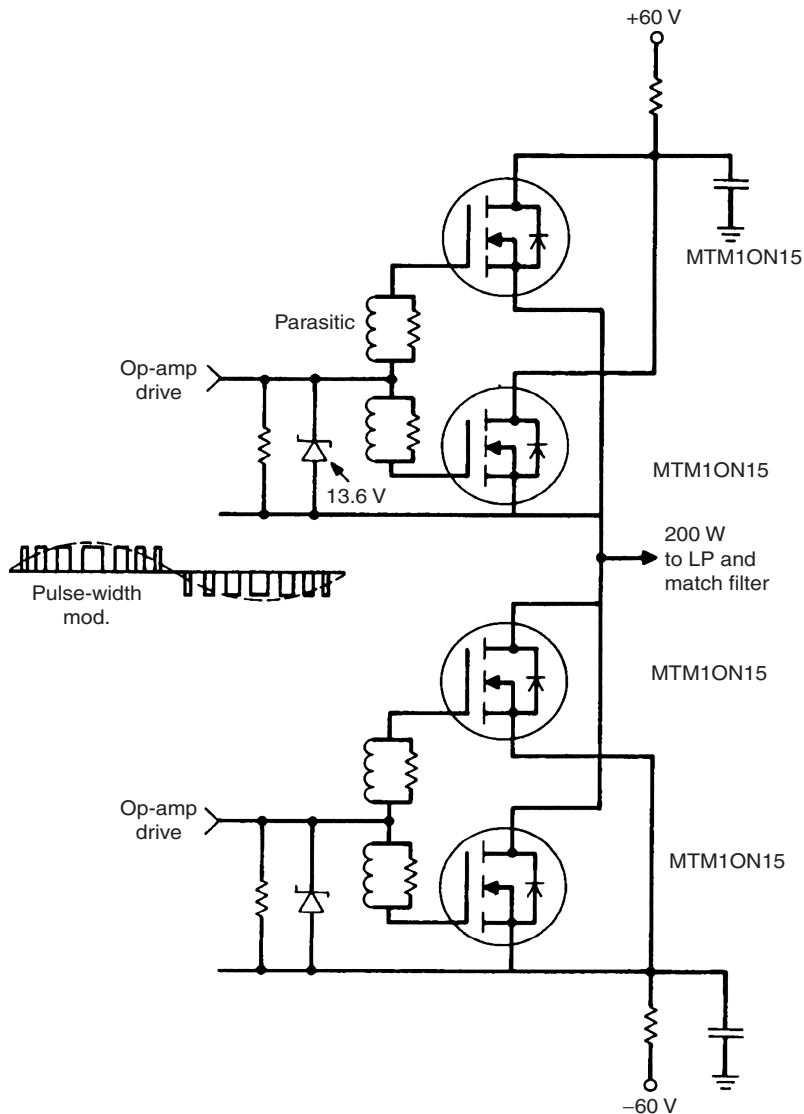

FIGURE 11.5.5 Class D audio amplifier using power MOSFET.

the rated continuous drain current at a V_{gs} of 15 V. The linear increase in g_{fs} with V_{gs} occurs in the square law region but levels off to a constant in the velocity-saturated region.

Considering the very high switching efficiency the power MOSFET has, it can be effectively used as a “class D” audio amplifier or one that is pulse-width modulated at the audio rate. A high-frequency carrier is used which is on the order of 6 to 10 times the highest audio-modulated frequency. The waveform is demodulated at the output for driving large speaker systems. Very high audio power amplifiers can be designed with high fidelity, small size, and high efficiency. Power FETs can be placed in parallel with few problems of current sharing. Figure 11.5.5 shows a simple version of this approach. With the high carrier frequency, coupling capacitors and supply decoupling become much less severe.

CHAPTER 11.6

MICROWAVE AMPLIFIERS AND OSCILLATORS

John W. Lunden, Jennifer E. Doyle

MICROWAVE SOLID-STATE DEVICES

Since the 1950s, solid-state devices have replaced tubes in most amplifier and oscillator applications. Solid-state devices are preferred because of better long-term reliability, lower cost, and improved noise characteristics. In the 1960s and 1970s, avalanche and Gunn diodes were used extensively in the generation of microwave power.

More recently, junction and field-effect transistors have been increasingly used in microwave amplifiers and oscillators. Gallium arsenide (GaAs) FETs have replaced other solid-state devices in many microwave applications; however, impact ionization avalanche transit-time (IMPATT) and Gunn diodes are still commonly used at frequencies above 20 GHz.

IMPATT DIODE CIRCUITS

The generation of microwave power in a reverse-biased pn junction was originally suggested by Read (1958). He proposed that the finite delay between applied rf voltage and the current generated by avalanche breakdown, with the subsequent drift of the generated carriers through the depletion layer of the junction, would lead to negative resistance at microwave frequencies. The diode is biased in the avalanche-breakdown region. As the rf voltage rises above the dc breakdown voltage during the positive half cycle, excess charge builds up in the avalanche region, reaching a peak when the rf voltage is zero. Hence this charge waveform lags the rf voltage by 90° . Subsequently, the direction of the field in the diode causes the multiplied carriers to drift across the depletion region. This, in turn, induces a positive current in the external circuit while the diode rf voltage is going through its negative half cycle. This is equivalent to negative resistance, which is maximum when the transit angle is approximately 0.74π .

A simplified equivalent circuit of the IMPATT diode circuit is shown in Fig. 11.6.1. The resistance R_D includes both the parasitic positive resistance because of contacts, bulk material, and so forth, and the dynamic negative resistance. The net magnitude is typically in the range -0.5 to -4.0Ω and varies with current. The capacitance C_D is the voltage-sensitive depletion-layer capacitance and can be approximated sufficiently accurately with the value at breakdown. The diode resistance variation results in a stable operating point for any positive load resistance equal to or less than the diode's peak negative value.

Oscillations will build up and be maintained at the frequency for which the net inductive reactance of the package parasitics and the external load equals the capacitive reactance of C_D . The values for L_p and C_p vary

with package or mounting style. Typical values range from 0.3 to 0.6 nH and 0.2 to 0.4 pF, respectively. It is important to minimize these parasitics since they limit the operating frequency and band-width.

FIGURE 11.6.1 Approximate equivalent circuit of IMPATT oscillator.

IMPATT diodes can be used in several mounting configurations, including coaxial, waveguide, strip-line, or microstrip. It is important to ensure that a good heat flow path is provided (owing to the typically low efficiency) and that low-electrical-resistance contacts be made to both anode and cathode.

In avalanche breakdown, the diode tends to look like a voltage source. Hence a current source is desirable for dc bias. Several circuits are possible. The RC bias circuit (Fig. 11.6.2a) is the simplest but is inefficient, and the transistor current regulator (Fig. 11.6.2b) may be more desirable. In either case, the loading of the diode with shunt capacitance or a resonance path to ground (at some frequency) must be avoided to prevent instabilities (noise and/or spurious frequencies).

Two broadly tunable diode loading circuits are the multiple-slug cavity and the variable-package-inductance types. Coaxial implementations of these two techniques are shown in the cross sections of Fig. 11.6.3. In Fig. 11.6.3a slugs $\lambda/8$ and/or $\lambda/4$

long at the desired center frequency of operation with characteristic impedance of between 10 and 20 Ω are adjusted in position along the centerlines to provide a load reactance equal to the negative of the diode reactance and a load resistance equal to or less than the magnitude of the diode net negative resistance. Circuit b tunes the diode by recessing it into the holder, effectively decreasing the net series inductance, which is resonant with the diode capacitance. Single- or multisection transformers can also be included for resistive matching to the load R_L . Similar waveguide-circuit implementations can be used with typically narrower bandwidths, better frequency stability, and lower FM noise.

The IMPATT diode can function as an amplifier if the load resistance presented to it is larger in magnitude than the negative resistance of the diode. Typically, a circulator is used in conjunction with the tuned diode circuit to separate input and output signals. At the center frequency, the power gain of the amplifier is given by

$$G_0 = \left(\frac{R_D - R_L}{R_D + R_L} \right)^2$$

where R_D and R_L are as shown in Fig. 11.6.1.

In general, amplifier operation for a given diode requires a smaller shunt tuning capacitor or a large transformer characteristic impedance. An estimate of the diode rf current and voltage can be obtained from

$$V_D \approx \frac{\sqrt{2P_o R_L}}{\omega C_j(V_b)} \left(1 + \frac{1}{\sqrt{G_0}} \right) \quad I_D \approx \omega C_j(V_b) V_D$$

FIGURE 11.6.2 Bias circuits for IMPATT diodes: (a) RC type; (b) transistor-regulated type.

FIGURE 11.6.3 Mechanical tuning of IMPATT circuit: (a) multiple-slug type; (b) variable-inductance (diode-recess) type. (Hewlett-Packard Company.)

where V_b = diode breakdown voltage
 C_j = junction capacitance
 P_o = power output
 G_o = gain

Higher output powers have been achieved by multiple-diode series-parallel configurations and/or hybrid combining techniques.

In general, properly designed IMPATT oscillator circuits can have noise performance comparable with reflex klystron or Gunn oscillators. The noise performance of both Si and GaAs IMPATT diode amplifiers and oscillators has been extensively treated in the literature.

IMPATT diodes are usable at higher frequencies than any other solid-state device currently available. Silicon IMPATT diodes can be used at frequencies as high as 300 GHz. Some of the disadvantages of IMPATTs are a low gain-bandwidth product, difficult adjustments necessary for long-term performance reliability, bias circuit instabilities, and inherent nonlinearity. The cw power output achievable with a single

FIGURE 11.6.4 Typical TRAPATT diode circuit configuration.

IMPATT diode is 3 W at 11 GHz, 2 W at 15 GHz, or 1 W at 20 GHz. Diodes can be paralleled to obtain higher power, for example, 10 W at 41 GHz, with 30 dB gain and 250 MHz bandwidth, by combining 12 diodes in one cavity.

TRAPATT DIODE CIRCUITS

The trapped plasma avalanche triggered transit (TRAPATT) mode of operation is characterized by high efficiency, operation at frequencies well below the transit-time frequency, and a significant change in the dc operating point when the diode switches into the mode. The basic understanding of this high-efficiency mode of operation has proceeded from consideration of IMPATT diode behavior with large signals. Two saturation mechanisms in the IMPATT diode, space-charge suppression of the avalanche and carrier trapping, reduce the power generated at the transit-time frequency, but play an important role in establishing the “trapped-plasma” states for high-efficiency operation.

To manifest the high efficiency of the TRAPATT mode, four important circuit conditions must be met: large IMPATT-generated voltage swings must be obtained by trapping the IMPATT oscillation in a high-*Q*-cavity circuit; selective reflection and/or rejection of all subharmonics of the IMPATT frequency except the desired subharmonics must be realized (typically with a low-pass filter); sufficient capacitance must be provided near the diode to sustain the high-current state; and tuning or matching to the load must be provided at the TRAPATT frequency. Figure 11.6.4 illustrates a widely used circuit that achieves the foregoing conditions.

The TRAPATT diode is typically represented by a current pulse generator and the diode’s depletion-layer capacitance, as shown in the simplified schematic of Fig. 11.6.5. This permits a simple interpretation of operation. Initially, a large voltage pulse reaches the diode, triggering the traveling avalanche zone in the diode. This initiates a high-current low-voltage state. The drop in voltage propagates down the line *l*, is inverted (owing to the -1 reflection coefficient of the low-pass filter), and travels back toward the diode. The process then repeats. Consequently, the frequency of operation is inversely proportional to the length of line *l*. The period of oscillation is slightly modified by the finite time required for the diode voltage to drop to zero. The inductance *L* is a result of the bond lead and is helpful in driving the diode voltage high enough to initiate the TRAPATT plasma state. The capacitance *C* is provided to supply the current required by the diode to the extent that the transmission line is insufficient. The total capacitance which can be discharged during the short interval of high conduction current in the diode is

$$C_T = C + \tau_p/Z_0$$

FIGURE 11.6.5 Simplified schematic diagram of TRAPATT circuit.

FIGURE 11.6.6 TRAPATT diode circuit arrangements: (a) tuned coaxial cavity; (b) lumped circuit; (c) coaxial circuit.

where τ_p is the time high-current or trapped plasma state exists. τ_p must be at least as large as the transit time of carriers through the diode, thus putting an upper limit on C . This is contrary to the high-current requirements to initially drive the avalanche zone through the diode (10 to 20 kA/cm²) in large-area devices.

Since the TRAPATT frequency is generally an integral submultiple of the diode transit-time frequency, the line length l ($l = \lambda/2$ at f_{TRAPATT}) presents the low-pass-filter short circuit to the diode as a series resonance at the IMPATT frequency. This net series resonance, however, includes the diode series-reactive elements. Further, this circuit should have a high Q at the transit-time frequency to reduce the buildup time to TRAPATT initiation.

Several TRAPATT circuit configurations are shown in Fig. 11.6.6. The coaxial cavity circuit in Fig. 11.6.6a places the diode in the reentrant gap of the half-wave cavity resonator. The output coupling loop passes only the fundamental to a triple stub tuner to match to the load. Proper dc biasing and bypassing are included. This circuit is good into the lower L band. The lumped circuit (Fig. 11.6.6b) is compact and very useful for VHF and UHF. The series capacitor is resonated with the inductance of a copper bar and the self-inductance of the diode. The trimmer controls the resonance of the third and fifth harmonics. The circuit of Fig. 11.6.6c is a variation on the circuit of Fig. 11.6.4. The use of additional filter sections and/or lumped elements provides better harmonic filtering and results in higher efficiencies. Circuits analogous to those of Fig. 11.6.4, can be implemented in waveguide for the higher frequencies. In all these circuits, the presence of the third and fifth harmonics has been found essential for stable and high-efficiency performance. Higher power levels can be achieved by operating multiple diodes in series and/or parallel configurations.

Another useful technique for extending both power and frequency is the antiparallel diode configuration. The circuit consists of two diodes, placed with opposite polarity approximately one-half fundamental wavelength apart in a transmission line. Operation is similar to a free-running multivibrator. Output may be extracted with a transmission line connected to the midpoint of the diodes, followed by the usual low-pass filter. The position of this filter should be adjusted so that the roundtrip delays from midpoint to diodes and the filter are equal. A microstrip circuit realization for antiparallel operation is given in Fig. 11.6.7.

FIGURE 11.6.7 Microstrip version of antiparallel TRAPATT circuit.

Operation of the anomalous avalanche diode for microwave amplification has also been established. A 10-dB dynamic range is typical, with a low-level threshold gain decreasing with increasing power level to a saturated condition. The pulsed bias can be replaced by a simple dc source and storage capacitor. Unlike the *locked-oscillator* mode of operation, only a small residual output is present without the input signal. The locked oscillator will typically display only a 3:1 power change between locked and unlocked cases.

TRAPATT operation has yielded output power levels of 10 to 500 W with efficiencies of 20 to 75 percent in the frequency range from 0.5 to 10 GHz.

BARITT AND DOVETT DIODES

The barrier-injected transit-time (BARITT) diode is the newest active microwave diode. It is similar to the IMPATT diode; however, carriers are injected into the drift zone by a forward-biased junction rather than being extracted from an avalanche region. Holes emitted by the *pn* junction cross the intrinsic region at their saturation velocity and are collected at the *p* contact. The diode behaves as a negative resistance with a phase shift of π rad. BARITT diodes operate at a lower bias voltage and are much lower in noise figure than an IMPATT; however, BARITT diode operating bandwidths are narrow, and output power capability is very low. For C band operation the following results have been attained: 15 dB noise figure and 50 mW output power at 1.8 percent efficiency.

The double velocity transit-time (DOVETT) diode is a new type of BARITT diode. The carrier velocity within a DOVETT diode increases between the injection point and the collection contact. The DOVETT diode has a large negative resistance than the BARITT diode and therefore operates at higher current density.

TRANSFERRED ELECTRON EFFECT DEVICE (TED) CIRCUITS

This class of circuit, using both the Gunn and limited-space-charge accumulation (LSA) devices depends on the internal negative resistance owing to carrier motion in the semiconductor at high electric fields. When the material is biased above the critical threshold field, a negative dielectric relaxation time is exhibited, which results in amplification of any carrier concentration fluctuations, causing a deviation from space-charge neutrality. The resultant *domain* drifts toward the anode and is extinguished, and a new domain is formed at the cathode. The current through the device consists of a series of narrow spikes with a period equal to the transit time of the domain.

- C_D = Domain capacitance
- $-R_D$ = Negative differential resistance
- R_D, C_D = Due to bulk material
- C_P, L_P = Packaging parasitics

FIGURE 11.6.8 Approximate equivalent circuit of a TED device and its package.

When an rf voltage is superimposed on the bias, in a given period of time, the terminal voltage can be below both the threshold voltage V_{th} and the domain-sustaining voltage V_s . The domain is quenched at any place in the device when the latter occurs, and the nucleation of a new domain is delayed until the voltage again exceeds V_{th} . Therefore the frequency of oscillation is determined by the resonant circuit, including the impedance of the device. Experimental results and computer modeling have shown that the device can be tuned over greater than an octave bandwidth by the external circuit cavity. Although other modes of operation are possible, depending on the characteristics of the external circuit, the LSA mode appears to be the most important.

An approximate equivalent circuit is given in Fig. 11.6.8 with values dependent on frequency, bias, and power level. The capacitance includes the diode static capacitance, in addition to that because of traveling high-field domains.

One of the simplest tuned circuits is the coaxial-line cavity, as shown in Fig. 11.6.9a. The diode is mounted concentric with the line, at one end to facilitate heat sinking. The frequency of oscillation is determined

FIGURE 11.6.9 Gunn diode cavity circuits: (a) coaxial form; (b) waveguide-cavity form.

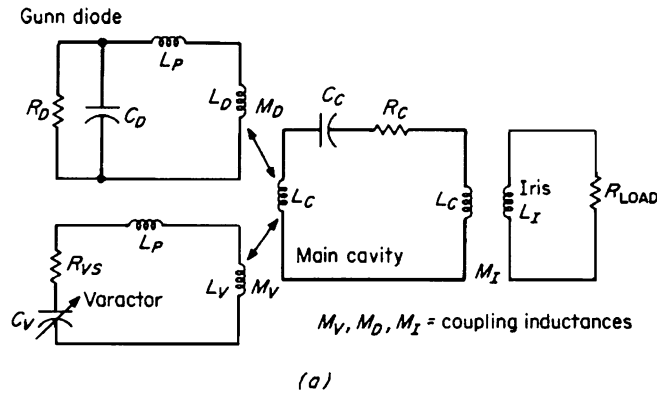

FIGURE 11.6.10 Varactor tuning of Gunn oscillator: (a) simplified equivalent circuit; (b) tuning characteristic.

primarily by the length of the cavity. The position of the output coupling loop (or plate) determines the load impedance.

A rectangular waveguide cavity configuration (Fig. 11.6.9b) is more widely used because of its higher Q and better performance at X band and higher frequencies. The diode post acts as a large inductive susceptance,

FIGURE 11.6.11 Varactor tuning techniques for Gunn diodes: (a) front and side views of double-port waveguide-type; (b) type used at K_u band.

FIGURE 11.6.12 Four-stage ganged TED amplifier chain for 5.7 GHz: (a) block diagram; (b) power-transfer curve.

which, with the inductive iris, produces the resonant frequency for which the length l is $\lambda/2$. The tuning rod lowers the frequency as its insertion length increases.

In addition to mechanical tuning, both YIG and varactor tuning techniques are applicable. YIG tuning has the potential for the widest tuning range but is limited in tuning speed, hysteresis, and physical bulk. Figure 11.6.10 illustrates a typical varactor-tuned Gunn oscillator equivalent circuit and characteristics. The varactor diode Q is highest at the maximum reverse voltage and decreases with decreasing voltage because of an increase in R_{vs} . Figure 11.6.11 illustrates two varactor-tuned implementation techniques.

The noise characteristic of a GaAs TED is comparable with that of a klystron and is 10 to 20 dB better than an IMPATT diode. Various noise-source models and measuring equipments are discussed in the literature. Several methods can be employed to reduce the AM and FM noise of a Gunn oscillator, including increasing the loaded Q of the cavity circuit: biasing at or near the frequency and/or power turnover points (i.e., bias at which $df/dv = 0$ and $dP_o/dv = 0$); minimizing power-supply ripple; and diode selection.

The TED can also be operated as an amplifier, typically using circulator or hybrid techniques similar to the IMPATT circuits. Parameters of importance are saturation characteristics, bandwidth, gain and phase tracking, linearity, efficiency, and dynamic range. The block diagram of a four-stage chain is shown in Fig. 11.6.12a, with operating characteristics in Fig. 11.6.12b. Hybrid coupling was found to provide greater linear power output. Gains in excess of 20 dB can be realized. Efficiency and bandwidth are typically less than 10 percent and greater than 35 percent, respectively.

The use of Gunn and LSA diodes extends to frequencies in excess of 90 Hz, with higher peak power capability for the LSA diode than for the IMPATT or for any other Gunn-effect device. TEDs can be operated with a pulsed bias, allowing extremely high power density without damage to the device. Over 1000 W at 10 GHz has been achieved in the LSA mode with short low-duty cycle pulses. Reactive termination and unloading of the circuit at the harmonic frequencies can significantly improve the efficiency. A problem associated with pulsed oscillators is the significant frequency change during each pulse caused by rapid temperature rise. Starting-time jitter can be alleviated by *priming*, i.e., injecting a weak cw signal into the circuit.

TRANSISTOR AMPLIFIER AND OSCILLATOR MICROWAVE CIRCUITS

Silicon bipolar and GaAs FETs are available with cutoff frequencies extending well into X and K_a bands, respectively. Equivalent circuits for these transistor types are given in Fig. 11.6.13. The intrinsic chip element values, with variations considered at low frequencies, are further modified by high-frequency effects.

FIGURE 11.6.13 Equivalent circuits of microwave solid-state devices: (a) bipolar transistor; (b) field-effect transistor (chip only).

A small-signal figure of merit has been defined in terms of the contributing time constants, for a bipolar transistor,

$$K = (\text{power gain})^{1/2} (\text{bandwidth}) = 1/4\pi(r'_b C_c \tau_{ec})^{1/2}$$

where $\tau_{ec} = \tau_e + \tau_b + \tau_l + \tau_c$, τ_e = emitter barrier charging time, τ_b = base transit time, τ_l = collector transit time, and τ_c = collector depletion-layer charging time. The maximum frequency of oscillation is defined as the frequency for which the power gain is unity

$$f_{\max} \approx 1/4\pi(r'_b C_c \tau_{ec})^{1/2}$$

The application of transistors at microwavelengths demands that considerable attention be given to packaging, fixturing, and impedance characterization. Historically, characterization has taken the form of f_T , $f_b C_c$ specification and/or h -y-parameter techniques. A more desirable method for high-frequency characterization is by scattering parameters. Scattering parameters describe the relationship between the incident and reflected power waves in any N -port network. As such, this technique offers substantial advantages, including remote measurement, broadband (no tuning), stability (no short-circuited or open terminations), accuracy, and ease of measurement.

FIGURE 11.6.14 Basic two-port configuration for a microwave transistor.

From Fig. 11.6.14, the scattering equations describing the two-port network can be written.

$$b_1 = S_{11}a_1 + S_{12}a_2 \quad b_2 = S_{21}a_1 + S_{22}a_2$$

Solving for the S parameters yields

$$S_{11} = \left. \frac{b_1}{a_1} \right|_{a_2=0} = \text{input reflection coefficient with } Z_L = Z_0$$

$$S_{12} = \left. \frac{b_1}{a_2} \right|_{a_1=0} = \text{reverse transmission gain with } Z_L = Z_0$$

$$S_{21} = \left. \frac{b_2}{a_1} \right|_{a_2=0} = \text{forward transmission gain with } Z_L = Z_0$$

$$S_{22} = \left. \frac{b_2}{a_2} \right|_{a_1=0} = \text{output reflection coefficient with } Z_L = Z_0$$

Other linear two-port parameters can be calculated from S parameters (for example, y parameters for feedback analysis). Either manual or complex automatic measurement techniques can be used. In either case, the transistor chip package is embedded in a system with a given reference impedance Z_0 and well-defined reference wave planes.

A number of useful relationships can be calculated from the S parameters and used in amplifier-oscillator design.

Reflection coefficient-impedance relationship:

$$S_{11} = \frac{Z - Z_0}{Z + Z_0}$$

where Z_0 is the reference impedance.

Input reflection coefficient with arbitrary Z_L :

$$S'_{11} = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L}$$

Output reflection coefficient with arbitrary Z_S :

$$S'_{22} = S_{22} + \frac{S_{12}S_{21}\Gamma_S}{1 - S_{11}\Gamma_S}$$

Stability factor:

$$K = \frac{1 + |D|^2 - |S_{11}|^2 - |S_{22}|^2}{2(S_{12}S_{21})}$$

Transducer power gain:

$$G_T = \frac{|S_{21}|^2(1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|(1 - S_{11}\Gamma_S)(1 - S_{22}\Gamma_L) - S_{12}S_{21}\Gamma_S\Gamma_L|^2}$$

Maximum available power gain:

$$G_{\max} = \left| \frac{S_{21}}{S_{12}} (k \pm \sqrt{k^2 - 1}) \right| \quad \text{for } k > 1$$

Source and load reflection coefficients for simultaneous match:

$$\Gamma_{ms} = M^* \left[\frac{B_1 \pm \sqrt{B_1^2 - 4|M|^2}}{2|M|^2} \right] \quad \Gamma_{mL} = N^* \left[\frac{B_2 \pm \sqrt{B_2^2 - 4|N|^2}}{2|N|^2} \right]$$

where Γ_S, Γ_L = source and load reflection coefficients

$$\begin{aligned} M &= S_{11} - DS_{22}^* \\ N &= S_{22} - DS_{11}^* \\ D &= S_{11}^*S_{22} - S_{12}S_{21} \\ B_1 &= 1 + |S_{11}|^2 - |S_{22}|^2 - |D|^2 \\ B_2 &= 1 + |S_{22}|^2 - |S_{11}|^2 - |D|^2 \end{aligned}$$

The maximum power gain is obtained only if the transistor is terminated with the Γ_{ms} and Γ_{mL} resultant impedances. A lossless transforming network is placed between the source and load to realize this transformation.

Generally, the embedding circuits used take the form of simple ladder networks: series-shunt combinations of L 's and C 's or their transmission-line equivalents. These elements can be determined by moving on the Smith chart from the value of the terminating impedance to the center of the chart along constant resistance-conductance, reactance-susceptance contours for series-shunt elements, respectively. The circuits are typically implemented in strip-line or lumped form, as shown in Fig. 11.6.15.

Optimum design at more than one frequency requires plotting of gain circles at each frequency, with subsequent terminating impedance iteration to obtain the best compromise across the band. Several computer-aided optimization programs are available to simplify this routine. A plot of gain circles and impedance loci for a typical S-band design is shown in Fig. 11.6.16, which corresponds to the collector circuit of Fig. 11.6.15a.

NOISE PERFORMANCE OF MICROWAVE BIPOLAR TRANSISTOR CIRCUITS

The noise performance of a well-designed amplifier depends almost entirely on the noise figure of the first transistor. The noise factor of a bipolar transistor amplifier is related to its equivalent circuit parameters and external circuit by

$$NF = 1 + \frac{r'_{bb}}{R_g} + \frac{r_e}{2R_g} + \frac{(r'_{bb} + r_e + R_g)^2}{2r_e R_g h_{feo}} \left[1 + \left(\frac{f}{f_\alpha} \right)^2 (1 + h_{feo}) \right]$$

As a result, r'_{bb} should be as low as possible, and the alpha cutoff frequency should be high. The source resistance providing minimum noise figure is

$$R_s|_{F_{min}} = (r'_{bb} + r_e)^2 + \frac{(r'_{bb} + 0.5r_e)(2h_{feo}r_e)}{1 + (f/f_\alpha)^2(1 + h_{feo})}$$

This value is typically close to the value providing maximum power gain for the common-emitter configuration. Care must be taken in the matching-circuit implementation to minimize any losses in the signal path, e.g., by using high- Q elements and isolated bias resistances. Bipolar junction transistors are available with less than 1 dB noise figure for frequencies below 1 GHz. At 4 GHz the best bipolar transistor noise figure is approximately 3 dB.

HIGH-POWER MICROWAVE TRANSISTOR AMPLIFIERS (USING BIPOLAR TRANSISTORS)

The difficulties arising in power-amplifier operation are because of the nonlinear variation of device parameters as a function of time and to bias conditions. Saturation, junction capacitance-voltage dependence, h_{fe} current (and voltage) level dependence, and charge-storage effects are the prime contributors to this situation. Class A operation is normally not used, implying collector-current conduction angles less than 360° , resulting in further complication of the time-averaging effects. With these qualifications, the basic equivalent circuit given in Fig. 11.6.13a applies. Figure 11.6.17a shows a greatly simplified equivalent circuit useful for first-order design. Of particular note is the low input resistance, high output capacitance, and a nonnegligible feedback element causing bandwidth, gain, and stability limitations.

FIGURE 11.6.15 Circuit realizations for microwave transistor circuits: (a) strip-line; (b) lumped design; (c) coaxial design.

Several methods have been used to determine large-signal-device characteristics with varying degree of success. One method involves the measurement of the embedding circuitry at the plane of the transistor terminals, with the transistor removed and the source and load properly terminated. The circuit is tuned for maximum power gain before the transistor is removed to make the measurement. An average or effective device impedance is then the complex conjugate of the measured circuit impedance at that frequency. The maximum power obtainable from a particular transistor is determined by thermal considerations (cw operation), avalanche-breakdown voltages, current-gain falloff at high current levels, and second-breakdown effects.

Bandwidth. The input impedance has been found to be the primary bandwidth-limiting element. R_S varies inversely with the area of the transistor. Hence, for a given package L_S , the Q increases and bandwidth decreases with higher-power transistors

$$Q = \omega_0 L_S / R_S \quad BW|_{3\text{ dB}} \approx f_0 / Q$$

Impedance matching. The problem of matching complex impedances over a wide band of frequencies has been treated by a number of authors. Essentially, high-order networks can be used to achieve nearly rectangular

FIGURE 11.6.16 Use of Smith chart in microwave transistor circuit design.

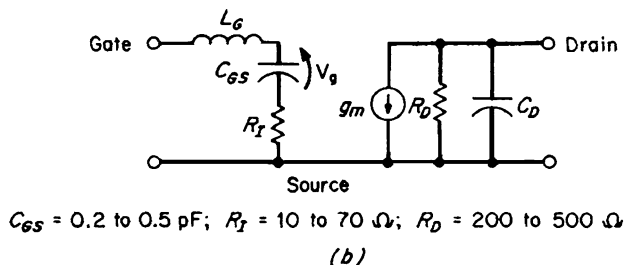

FIGURE 11.6.17 Simplified equivalent circuits of microwave power transistors: (a) bipolar transistor; (b) FET.

bandpass characteristics. However, without mismatching, the 3-dB bandwidth determined above cannot be extended. In fact, the greater the ratio of generator resistance R_g to transistor input resistance R_s the greater will be the reduction of the intrinsic bandwidth, for a given ripple and number of circuit elements. Hence the external circuit design must consider both the transistor-input-circuit Q value and the impedance level relative to the driving source for a given bandwidth.

Either lumped- or transmission-line-element networks of relative simplicity are typically used to achieve the necessary input-output matching. Although the bandpass type yields somewhat better performance, the low-pass configuration is more convenient to realize physically. Quarter-wave line sections are particularly useful for broadband impedance transformations and bias feed-bypassing functions. Eighth-wave transformers are useful to match the small complex impedances directly without tuning-out mechanisms. The input impedance to a $\lambda/8$ section is real if it is terminated in an impedance with magnitude equal to the Z_0 of the line.

Load resistance. The desired load resistance can be determined to first order by

$$R_L \approx (V_{CC} - V_{CE,sat})^2 / 2P_o$$

where P_o is the desired fundamental power output and V_{CC} is the collector supply voltage. This expression is altered by several factors, including circuit Q , harmonic frequencies, leakage, current conduction angle, and so forth. Assuming only the presence of the fundamental frequency, V_{CC} is limited to $1/2BV_{CBO}$ by resonant effects. Recently, it has been shown that BV_{CBO} can be exceeded for short pulses without causing avalanche.

Power gain. The power gain depends on the dynamic f_T or large-signal current gain-bandwidth capability, the dynamic input impedance, and the collector load impedance. A simple expression for power gain is

$$PG = \frac{(f_T/f)^2 R_L}{4R_e(Z_{in})}$$

The current gain at f_T is of particular importance. The effect of parasitic common-terminal inductance is to reduce this gain in the common-emitter and to cause regeneration in the common-base connection. The latter configuration is more commonly used at frequencies near or above the f_T value, whereas the former generally results in a more stable circuit below f_T . This situation is highly dependent on the parasitic-element situation with respect to the specific frequency. Various forms of instabilities, such as hysteresis (jump modes), parametric, low-frequency, and thermal, can occur because of the parameter values changing with time-varying high-signal levels. Usually, most of these difficulties can be eliminated or minimized by careful design of bias circuits (including fewer elements), ground returns, parasitics, and out-of-band terminating impedances.

FIGURE 11.6.18 Typical voltage-current waveforms in power applications: (a) collector voltage; (b) collector current; (c) second-harmonic enhancement.

The *collector efficiency* of a transistor amplifier is the ratio of rf power output to dc power input. High efficiency implies low circuit losses, high ratio of output resistance to load resistance, high f_T , and low collector saturation voltage. In addition, experiments and calculations show that for high efficiency, the impedance presented to the collector by the output network should be inductive for the favored generation of second harmonic. If the phase is correct, the amplitude of the fundamental is raised beyond the limit otherwise set by the difference between the supply voltage and $V_{C,sat}$. Figure 11.6.18 illustrates this effect.

A high value of f_T relative to the operating frequency improves efficiency by causing the operating point to spend less time (per cycle) in the high-dissipation active region between cutoff and saturation. The integrity of the transistor die bond has been found to have a substantial effect on efficiency because of the effects of low intrinsic bulk collector resistance and thermal gradient.

spend less time (per cycle) in the high-dissipation active region between cutoff and saturation. The integrity of the transistor die bond has been found to have a substantial effect on efficiency because of the effects of low intrinsic bulk collector resistance and thermal gradient.

GaAs FIELD-EFFECT TRANSISTOR CIRCUITS

The state of the art of GaAs field-effect transistors for both small-signal and power applications is rapidly improving, thanks to the intrinsically higher carrier mobility in GaAs, coupled with significantly improved fabrication techniques, e.g., in the area of photolithography. Many devices fabricated today use feature sizes as small as $0.25 \mu\text{m}$. GaAs FETs are particularly attractive since the parameter values are less variable as a function of operating conditions and their impedances are generally higher than in comparable bipolar devices. As a result, GaAs FET circuits are easier to design and typically achieve lower noise, wider bandwidth, and higher linearity. The common-source configuration has been found to work well for both amplifiers and oscillators.

NOISE PERFORMANCE OF MICROWAVE FET CIRCUITS

The noise figure of an FET can be represented as a minimum noise figure plus a noise factor which depends on the signal source impedance presented to the FET. For an optimum signal source impedance of $R_{SS} + jX_{SS} = R_{OP} + jX_{OP}$, the noise figure is minimized.

$$\text{NF} = F_{\min} + \frac{K_2 (R_{SS} - R_{OP})^2 + (X_{SS} - X_{OP})^2}{g_m^2 R_{SS} (R_{OP}^2 + X_{OP}^2)}$$

$$F_{\min} = 1 + K_f (f/f_T) \sqrt{g_m (R_G + R_S)} \quad K_2 \approx 0.03 \quad K_f \approx 2.5$$

K_2 and K_f are fitting factors, with K_2 depending on the channel carrier concentrations and dimensions, and K_f depending on the quality of the channel material. The optimum source impedance is

$$R_{SS} = R_{OP} \approx 2.2[1/4g_m + R_G + R_S] \quad X_{SS} = X_{OP} \approx 160/fC_{GS}$$

It is evident that a low-noise figure requires a high cutoff frequency f_T , and the cutoff frequency is inversely proportional to the gate length. Therefore, a short gate length is important to low-noise operation. The noise figure can also be improved by minimizing the parasitic resistances R_G and R_S .

GaAs FETs are commercially available with noise figures less than 0.5 dB at 4 GHz, less than 1 dB at 8 GHz, and less than 2 dB at 16 GHz.

HIGH ELECTRON MOBILITY TRANSISTORS

The performance of low-noise GaAs FETs is approaching a lower limit because of the finest gate geometry currently attainable ($0.25 \mu\text{m}$). The new high electron mobility transistor (HEMT) on GaAs offers superior performance because of its carrier transport mechanism, which resembles transport within undoped GaAs, which has little impurity scattering. The structure of an HEMT is similar to a GaAs MESFET, using a heterojunction between GaAs and AlGaAs. The carrier velocity and mobility are twice that of carriers in a MESFET, which results in a higher cutoff frequency and lower noise figure for the same gate geometry. The following results have been achieved with HEMTs: 2 dB noise figure up to 20 GHz without cooling, and 5 dB gain with 7.8 dB noise figure at 71 GHz.

HIGH-POWER MICROWAVE FET AMPLIFIERS

High-power field-effect transistors, like bipolar transistors, exhibit nonlinear device parameter variation with bias conditions. Figure 11.6.17*b* shows a greatly simplified equivalent circuit of a power FET. The parameters C_{GS} , R_P , g_m , R_D , and C_D are bias voltage dependent. The dominant nonlinear effects on power FET operation

are the variation of the channel capacitance C_{GS} with gate and drain bias voltages, the variation of the transconductance g_m with gate voltage, and the variation in drain resistance R_D with drain voltage.

The high-power performance of an FET depends mainly on the gate width, the common lead inductance and other parasitics, the transistor thermal impedance, and the maximum drain voltage capability of the device. The total gate width can be increased by combining a number of individual cells in parallel on one chip. Cells are connected by wire bonding, “flip-chip” mounting techniques, or via-hole connections. A single FET cell may consist of many gate fingers connected in parallel by crossover structures, or wrap-around-plating. Using these techniques total gate widths of 30 mm or more have been attained.

The bias point of the FET has an important effect on the output power capability of the amplifier circuit. The optimum load resistance is determined from the device I - V characteristic. V_{GD} is the gate-drain avalanche breakdown voltage when the FET gate is biased at pinch-off (V_P). The limiting drain-source voltage is $V_T = V_{GD} - V_P$. Beyond this voltage, excess current will flow which is unaffected by the input signal at the gate. Therefore, V_L is the level of V_{DS} which corresponds to the maximum rf output power. If V_K is the “knee” drain voltage above which the drain current is approximately flat (independent of drain voltage), then the maximum drain voltage swing can be expressed as $V_L - V_K$ or $V_{GD} - V_P - V_K$. If I_F is the maximum drain current available with a forward-biased gate, then the optimum load resistance for maximum output power is $(V_{GD} - V_P - V_K)/I_F$ and the maximum rf power available to the load is $I_F(V_{GD} - V_P - V_K)/8$.

With a single high-power FET the following cw output power levels can be achieved at 1 dB gain compression: 12 W at 2 GHz, 8 W at 12 GHz, and 1 W at 24 GHz. Efficiencies are typically 25 to 35 percent for class A cw operation. GaAs FETs are commonly used in moderate power applications at microwave frequencies up to 26 GHz. Devices are frequently combined in balanced amplifier circuits to achieve higher output powers. Internally matched chip carrier structures are often used to reduce the effects of package parasitics, and to provide low-loss matching close to the chip. One type of input circuit for an internally matched FET comprises a small SiO_2 chip capacitor connected to the FET gate with a bond wire, forming a π -matching section with the FET input capacitance. Input and output circuits and typically LC ladder networks implemented in both discrete and semidistributed circuit forms.

MONOLITHIC MICROWAVE INTEGRATED CIRCUITS

Monolithic circuits, or MMICs, consist of active devices and associated circuitry fabricated together on the same substrate. GaAs MMICs are used to achieve very broad bandwidths and high-frequency operation. Because of the high area of GaAs required and low production yields, MMICs are very expensive. They are best suited to low- and medium-power applications above 20 GHz, where high production volume is expected. The advantages of monolithic circuitry are multioctave bandwidths, millimeter-frequency operation, small size and weight. With MMICs on GaAs the following results have been attained: 4 dB gain, 9 dB noise figure, and +12 dBm output power from 2 to 40 GHz with a distributed amplifier.

TRANSISTOR OSCILLATORS

Transistor oscillators can be designed by choosing the source (or load) terminating impedances such that $S'_{11} \Gamma_S \geq 1$ ($S'_{22} \Gamma_L \geq 1$). The design is facilitated by plotting stability circles on the Smith chart.

A number of circuit configurations are appropriate, including the standard Colpitts, Hartley, Clapp, coupled-hybrid, and so forth. The major difference, however, is the proper inclusion of device parasitic reactances into the intended configuration. The frequency-determining element(s) may be in the input, output, or feedback circuit but should have a high Q for good frequency stability. Care must be taken to decouple or resistively load the circuit at frequencies outside the band where oscillatory conditions are satisfied. This is particularly true for lower frequencies where the current gain is much better.

For bipolar transistors, the common-base and common-collector connections are generally more unstable than common-emitter and most commonly used, depending on the power requirements and frequency of oscillation.

For a GaAs FET oscillator, the device may be in common-source, gate, or drain configuration. The common grounded source arrangement provides the lowest thermal resistance which makes this configuration the

FIGURE 11.6.19 Varactor-tuned microstrip oscillator-buffer circuit.

most likely choice for a power FET oscillator. In the grounded source case a parallel feedback element is used to couple the gate and drain terminals and must be small enough to minimize parasitics.

Transistor oscillators have the advantage of the third terminal which may be used for compensation, modulation, or stabilization. A high- Q cavity resonator is often used in the feedback path for stabilization. The resonator may also be placed between the transistor and the load where it acts as a bandpass filter, or the resonator may be used as a band-reject filter coupled to one oscillator port with the load coupled to the other oscillator port. A high dielectric constant ceramic is usually used for the cavity material to result in a resonator of very small physical size. Barium nanotitanate, which provides a relative dielectric constant of 39, and a Q of up to 8000, is often used as a resonator. Oscillators that use this type of stabilization are called dielectric resonator oscillators, or DROs.

The frequency of an oscillator which is stabilized by a dielectric resonator can be mechanically tuned by varying the gap between the resonator and a metal tuning plate.

Several methods are available to vary the frequency of an oscillator dynamically. Bias variation is effective only over a narrow band and results in substantial power variation. The YIG sphere provides very high Q but is somewhat bulky and of limited tuning speed. The varactor diode provides very low power, octave-tuning bandwidth, and fast tuning in a form compatible with hybrid integration. Figure 11.6.19 shows the schematic of an S-band varactor-tuned wide-band oscillator implemented in hybrid thin-film form. The frequency-determining elements are connected in the high- Q common-base input circuit. This also allows maximum isolation from load mismatch effects (pushing) and permits the balance of the circuitry to be low- Q (broadband).

Both high- and low-power oscillators are large-signal; i.e., the output power is limited primarily by beta falloff, with increasing current at a given frequency and collector voltage.

Bipolar transistors are generally used for oscillators up to X band. Output powers of +16 dBm at 8 GHz and +7 dBm at 13 GHz have been achieved with bipolar transistor oscillators by using a finline mount. The near carrier noise for the silicon bipolar transistor was 10 to 20 dB better than the noise characteristic of an FET oscillator operating at the same frequency.

The maximum frequency of oscillation of a GaAs FET is about 80 GHz for a 0.25 μm gate length. The following results have been attained at 35 GHz: +1 dBm output power and noise-to-carrier ratios of -78 dBc/Hz at 10 kHz and -87 dBc/Hz at 25 kHz.

TRAVELING-WAVE-TUBE CIRCUITS

The traveling-wave tube is a unique structure capable of providing high amplification of rf signals varying in frequency over several octaves without the need for any tuning or voltage adjustment (Sec. 7). Figure 11.6.20

FIGURE 11.6.20 Traveling-wave amplifier circuit.

shows the principal components of an amplifier using this tube. Electrons emitted by the electron-gun assembly are sharply focused, drawn through the length of the slow-wave rf structure, and eventually dissipated in the collector. Synchronism between the rf electromagnetic wave and the beam electrons results in a cumulative interaction which transfers energy from the dc beam to the rf wave. For details on this type of amplifier see Sec. 7.

Figure 11.6.21 shows the gain characteristics of a typical broadband TWT amplifier. As more energy is extracted from the electron beam, it slows down. This loss of synchronism results in lower gains at higher power levels. One advantage of this overdrive characteristic is the protection of following stages against strong signals.

Traveling-wave tube amplifiers provide high gain for signals up to about 30 GHz. Power TWT technology is still advancing. TWTs are available with as high as 30 W cw output power at 12 GHz and 42 percent efficiency. Long-term reliability and noise figure remain poor in comparison to most solid-state devices.

The *backward-wave oscillator* is essentially a TWT device making use of the interaction of the electron stream with an electromagnetic wave whose phase and group velocities are 180° apart. At a sufficient beam current, oscillations are produced as discussed above, without a reverse-wave attenuator. These devices are

FIGURE 11.6.21 Typical gain characteristic of a broadband TWT amplifier.

voltage-tunable. Frequency is proportional to the half power of the cathode-helix voltage and the dimensions of the structure. Multioctave tuning is possible, depending on output-power-variation requirements. These oscillators have low pulling figures and, typically, high pushing figures. Frequency stability is excellent, usually dependent on power-supply variations. These devices are typically low power (<1 W).

KLYSTRON OSCILLATORS AND AMPLIFIERS

The chief advantages of the klystron amplifier oscillator are that it is capable of large stable output power (10 MW) with good efficiency (40 percent) and high gain (70 dB). Basically, the mechanism involves modulation of the velocity of electrons in a beam by an input rf signal. This is converted into a density-modulated (bunching) beam from which a resonant cavity extracts the rf energy and transforms it to a useful load.

Klystron amplifiers can be conveniently divided into three categories: (1) two-resonator single-stage high- and low-noise voltage amplifiers, (2) two-resonator single stage (*optimum bunching*) power amplifiers, and (3) multiresonator cascade-stage voltage and power amplifiers. The power gain of a two-cavity voltage amplifier can be given by

$$G = \frac{M_1^2 N_2^2 \left(\frac{\pi a}{\lambda} \right)^2 G_0}{240 \beta (G_{BR})^2}$$

where M_1, M_2 = beam coupling factors

a = beam radius

G_0 = beam conductance

G_{BR} = cavity shunt conductance contributions because of beam loading and ohmic losses

β = (electron velocity)/(velocity of light)

A simplified schematic representation of a klystron amplifier is shown in Fig. 11.6.22. Multicavity tubes are typically used for high pulse power and cw applications. The intermediate cavities serve to remodulate the beam, causing additional bunching and higher gain-power output. Optimum power output is obtained with the second cavity slightly detuned. Further, loading of this cavity serves to increase the bandwidth (at the expense of gain). These tubes typically use magnetically focused high-perveance beams.

The broadbanding of a multicavity klystron is accomplished in a manner analogous to that of multistage i.f. amplifiers. A common technique is stagger tuning, which is modified somewhat, because of nonadjacent cavity interactions.

FIGURE 11.6.22 Klystron amplifier structure.

The two-cavity amplifier can be made to oscillate by providing a feedback loop from output to input with proper phase relationship. Klystrons can also be used for frequency multiplication, using the high harmonic content of the bunched-beam current waveforms.

Reflex Klystron

A simple klystron oscillator results if the electron-beam direction is reversed by a negative electrode, termed the *reflector*. A schematic diagram of such a structure is given in Fig. 11.6.23. Performance data for a reflex klystron are usually given in the form of a reflector-characteristic chart. This chart displays power output and frequency deviation as a function of reflector voltage. Two distinct classes of reflex klystrons are low-power tubes for oscillator, pump, and test applications and higher-power tubes (10 W) for frequency-modulator applications. Operating voltage varies from 300 to 2000 V with bandwidths up to ~200 MHz.

FIGURE 11.6.23 Reflex klystron with coaxial-line loop output.

CROSSED-FIELD-TUBE CIRCUITS

Practically all crossed-field tubes have integrally attached distributed constant circuits. Operation within a critical range of beam current is necessary to maintain the proper bandpass characteristics.

Magnetron

The original microwave tube was a magnetron diode switch with oscillations owing to the cyclotron resonance frequency. Several oscillator circuits were used until the standard cavity-resonator magnetron was introduced in 1940.

The relations between power, frequency, and voltage versus the load admittance are shown in the Rieke diagram (Fig. 11.6.24). Such charts illustrate the compromises necessary to obtain desired operating conditions. In general, good efficiency results from increasing anode current and magnetic field strength.

Various load effects can be considered with the Rieke diagram. The pulling figure [measure of frequency change for a defined load mismatch – (SWR) = 1.5 at all phase angles] and long-line effect are examples.

The area of highest power on the Rieke diagram is called the *sink* and represents the tightest load coupling to the tube. The highest efficiency results in this region; however, a poor spectrum or instability typically results. The buildup of oscillations in the antisink region is closer to ideal; however, this lightly loaded condition may also result in instability. Stability is a measure of the percentage of missing pulses, usually defined at 30 percent energy loss.

Tuning

Methods used to tune a magnetron are classified as mechanical, electronic, and voltage tuning. In the mechanical methods, the frequency of oscillation is changed by the motion of an element in the resonant circuit. Two types are shown in Fig. 11.6.25. An electron beam injected into the cavities will change the effective dielectric constant and hence the frequency. By using the frequency pushing effect it has been possible to tune the magnetron over a frequency range of 4 to 1 (typically, 0.1 to 2 MHz/V) using voltage tuning. The frequency change is usually linear, but the power output is not constant over the tuning range. Magnetrons with power output greater than 5 MW and efficiencies 50 percent or more are available.

FIGURE 11.6.24 Rieke diagram for an L-band magnetron at 1250 MHz. Solid curves are contours of constant power; dashed curves of constant frequency. (Raytheon Company.)

Amplitron

The Amplitron is essentially a magnetron with two external couplings, enabling amplifier operation. It is characterized by high power, broad bandwidth, very high efficiency, and low gain. The output is independent of rf input but dependent on dc input. It acts as a low-loss passive transmission line in the absence of high voltage. A typical plot of power for an Amplitron is shown in Fig. 11.6.26. Conversion efficiency of an Amplitron can be as high as 85 percent. The gain can be increased by inserting mismatches into the input and output transmission lines.

GYROTRON CIRCUITS

Beyond 30 GHz, the power available from classical microwave tubes declines sharply. The gyrotron offers the possibility of high power at millimeter wave frequencies.

The gyrotron is a cyclotron resonance maser. The structure of the gyrotron includes a cathode, a collector, and a circular waveguide of a gradually varying diameter. Electrons are emitted at the cathode with small variations in speed. The electron current density is very high. The electrons are accelerated by an electric field and guided by a static magnetic field. The nonuniform induction field causes the rotational

FIGURE 11.6.25 Mechanical magnetron tuning mechanisms: (a) capacitance type; (b) inductance type.

FIGURE 11.6.26 Gain characteristic of model QK520 L-band amplifier.

speed of the electrons to increase, which in turn causes the linear velocity of the electrons to decrease, while they follow a helical trajectory. The microwave field exists within the circular waveguide, where the cutoff of the mode is only slightly above the microwave signal frequency. The electrons give up energy because of interaction with the field of the rotating mode. This causes bunching of the electrons, similar to the bunching within a klystron. Finally there is a decompression zone where the induction decreases and the electrons are collected.

The smooth shape of the gyrotron circular waveguide produces less loss than other microwave tubes. The power available with a gyrotron is 100 or more times greater than that available from classical microwave tubes at the same frequency. The output power levels which can be attained

with a gyrotron in cw operation are as follows: 12 kW at 107 GHz and 31 percent efficiency, or 1.5 kW at 330 GHz and 6 percent efficiency.

SECTION 12

MODULATORS, DEMODULATORS, AND CONVERTERS

Understanding modulation is important to understanding AM and FM broadcasting and receiving. The advantages of both are presented and methods of improving both are discussed. The key features of modulation and demodulation are discussed in this section.

Pulse modulation and demodulation is widely used in communications and control. Various techniques are discussed and compared.

Although optical radiation is just another form of electromagnetic radiation, the transmitters and receivers are considerably different from those used at radio frequencies. The use of these devices has increased rapidly necessitating a better understanding of the devices themselves.

We conclude the section with a discussion of frequency converters and detectors. Characteristics that lead to effective design are presented and discussed. C.A.

CHAPTER 12.1

AMPLITUDE MODULATION/ DEMODULATION

Joseph P. Hesler

INTRODUCTION

Frequency translation is fundamental to radio communications in that it produces signal energy, in proportion to variations of an information source, at frequencies that have desirable transmission characteristics, such as antenna size, freedom of interference from similar information sources, line-of-sight to long-range propagation, and freedom of interference from particular noise sources. Frequency translation permits the efficient utilization of open and closed propagation media by many simultaneous users and/or signals.

One of the most used forms of frequency translation is linear modulation, the most common of which is amplitude modulation. In general, amplitude modulation consists in varying the magnitude of a carrier signal in direct correspondence to the instantaneous fluctuations of a modulating signal source, as illustrated in Fig. 12.1.1.

Variations of the basic amplitude-modulation process have been developed to achieve more efficient spectrum utilization and to reduce transmitter power requirements. These include suppressed-carrier systems such as vestigial-sideband, single-sideband, and double-sideband modulation systems. The companion form of frequency translation used in amplitude-modulation systems is *detection*. This is the process whereby the originally translated information is recovered as a baseband signal. Linear amplitude modulation has been the most widely used form of frequency translation in general communications for three reasons: relative ease of implementation, efficient utilization of bandwidth, and availability of devices to implement a simple detection procedure.

It can be argued that amplitude modulation includes such modulation methods as pulse-code keying, pulse-amplitude modulation, frequency-shift keying (the sequential keying of multiple carrier signals), and variations of them, such as pulse-position modulation and pulse-width modulation. This subsection, however, is restricted to the amplitude modulation by signal sources whose outputs are continuous time functions. The special types of modulation mentioned above are discussed in Chap. 12.3.

The general expression for the output of a linear amplitude modulator with a sinusoidal modulation input is

$$E = E_0(1 + m \sin \omega_m t) \sin (\omega_c t - \phi) \quad (1)$$

where E_0 = peak amplitude of carrier signal
 ω_m = modulating signal frequency (rad/s)
 ω_c = carrier frequency (rad/s)
 m = modulation index
 ϕ = arbitrary carrier phase angle (rad)
 t = time (s)

FIGURE 12.1.1 Amplitude modulation: (a) modulating signal; (b) double-sideband amplitude-modulated signal; (c) double-sideband suppressed-carrier amplitude-modulated signal; (d) single-sideband suppressed-carrier amplitude-modulated signal.

Expansion of Eq. (1) provides

$$E = E_0 \sin (\omega_c t + \phi) + \frac{mE_0}{2} \cos [(\omega_c - \omega_m)t + \phi] - \frac{mE_0}{2} \cos [(\omega_c + \omega_m)t + \phi] \quad (2)$$

Note that the carrier signal is reproduced exactly as if it carried no modulation. The carrier in itself does not carry any information. The second and third terms in Eq. (2) represented sideband signals produced in the modulation process. These signals are displaced from the carrier signal in the frequency spectrum, on each side of the carrier, by a frequency difference equal to the modulating-signal frequency. The magnitudes of the sideband signals are equal and are proportional to the modulation index m .

Both positive and negative amplitude modulation can be produced in an unsymmetrical manner. For each case the amplitude-modulation index m is defined as

$$m = \begin{cases} \frac{E_{\max} - E_0}{E_0} & \text{positive modulation} \\ \frac{E_0 - E_{\min}}{E_0} & \text{negative modulation} \end{cases} \quad (3)$$

where E_{\max} is the peak amplitude of modulated carrier and E_0 is the peak amplitude of unmodulated carrier.

The maximum negative-modulation index of unity results from the reduction of the instantaneous amplitude modulation that can be produced corresponds to a modulation index of unity.

For a complex modulating signal $G(t)$ the modulated carrier spectrum is

$$\begin{aligned} F(\omega) &= \mathfrak{F}\{E_0[1+mG(t)] \sin(\omega_c t + \phi)\} \\ &= \frac{E_0}{2\pi} \int_{-\infty}^{\infty} [1+mG(t)] \sin(\omega_c t + \phi) e^{-j\omega t} dt \end{aligned} \quad (4)$$

where $F(\omega)$ is the Fourier transform of the time function $\mathcal{E}[f(t)]$.

TYPES OF AMPLITUDE MODULATION

Generation of an amplitude-modulated waveform requires the multiplication of signals, $f_1(t)f_2(t)$. Both signals need not be time-variant, e.g., a carbon microphone modulates a dc potential with voice signals. The main applications, however, concern the modulation of *carrier* signals to exploit desirable transmission characteristics, that is, $f_1(t)[A \sin(\omega_c t + \phi)]$. Two classes of circuits are used as modulators, *square-law* devices and *linear* modulators.

Square-Law Modulation

Any device having a nonlinear transfer function can be expressed in a power series form, e.g., the current in a diode, $i(e) = a_0 + a_1 e + a_2 e^2 + a_3 e^3 + \dots$.

When the diode characteristics and bias conditions are chosen so as to enhance the coefficient a_2 with respect to the other coefficients, the device is considered to be a square-law nonlinear element.

Under these conditions, when two signal inputs $f_1(t)$ and $f_2(t)$ are summed and used as the driving function e , a significant portion of the output will exist as $a_2 e^2$.

$$e = f_1(t) + f_2(t) \quad (5)$$

$$e^2 = 2f_1(t)f_2(t) + [f_1(t)]^2 + [f_2(t)]^2 \quad (6)$$

Suitable nonlinear characteristics are exhibited by various types of rectifiers, triodes, and transistors.

Linear Modulation

Linear modulators are devices with transfer functions that are linearly related to a control parameter. Examples include the outputs of class C rf amplifiers as a function of the B-plus supply voltage, the transconductance gain of transistor differential amplifiers versus emitter current-source magnitude, and Hall effect devices whose transconductance is proportional to the applied magnetic field.

METHODS OF AMPLITUDE MODULATION

Square-Law Amplitude Modulators

A square-law modulator requires three features: a method of summing the two input signals $f_1(t)$ and $f_2(t)$, a device with a nonlinear transfer function, and a tuned circuit and coupling network for extracting the desired modulation products. Voltage summing or current summing are used depending on the transfer characteristic of interest. The nonlinear device is biased in a region that enhances the second-order coefficient of the power series that represents the nonlinear transfer function. The most common devices used for this type of modulation are semiconductor diodes and vacuum-tube triodes. An example of a typical circuit is shown in Fig. 12.1.2.

The efficiency of this type of amplitude modulation is generally low, and all the output energy is supplied by the driving functions.

FIGURE 12.1.2 Square-law modulator.

Consider two input signals:

$$e_m = E_m \cos \omega_m t \quad \text{modulating signal} \quad (7)$$

$$e_c = E_c \cos \omega_c t \quad \text{carrier signal} \quad (8)$$

The input applied to the nonlinear device is

$$e_s = E_m \cos \omega_m t + E_c \cos \omega_c t \quad (9)$$

If the transfer function is represented by the two terms of interest from a Taylor series,

$$e_o = a_1 e_s + a_2 e_s^2 \quad (10)$$

The output components resulting are

$$\begin{aligned} e_o &= (a_2/2)(E_m^2 - e_c^2) && \text{dc rectified component} \\ &-a_1 E_m \cos \omega_m t && \text{modulating signal} \\ &-a_1 E_c \cos \omega_c t && \text{carrier} \\ &-(a_2/2)E_m^2 \cos^2 2\omega_m t && \text{second harmonic of modulation} \\ &-(a_2/2)E_c^2 \cos^2 2\omega_c t && \text{second harmonic of carrier} \\ &-a_2 E_c E_m \cos (\omega_c - \omega_m)t && \text{lower sideband} \\ &-a_2 E_c E_m \cos (\omega_c + \omega_m)t && \text{upper sideband} \end{aligned} \quad (11)$$

There would be other terms, also, from the higher-order coefficients of the Taylor series. The degree of modulation is expressed as

$$\text{Modulation index} = 2(a_2/a_1)E_m \quad (12)$$

The desired outputs for double-sideband amplitude modulation are

$$e'_o = a_1 E_c \cos \omega_c t + a_2 E_c E_m \cos (\omega_c \pm \omega_m)t \quad (13)$$

The square-law devices are reciprocal in that the modulating frequency will appear as an output if a modulated signal is applied as the input. Thus the square-law device can also be used as a demodulator or detector.

LOW- AND MEDIUM-POWER LINEAR MODULATORS

Many applications exist in mobile equipment for amplitude modulators with output powers from milliwatts to tens of watts. Transistor circuits are used almost exclusively for these circuits. Carrier frequencies above 1 GHz can be used in the lower-power transistor circuits. The most common methods of amplitude modulation used are class C collector-modulated stages with the rf applied in the common-emitter or common-base configuration, as shown in Fig. 12.1.3. The common-emitter configuration provides the maximum power gain and excellent efficiency. Common-base stages are used to increase the upward modulation capabilities, where the maximum modulation indices are important. Increased linearity can be achieved at the expense of efficiency by biasing the amplifier class B so that a nominal collector current flows under no-modulation conditions.

For class C operation the transistor transfer characteristics of the modulated amplifier are determined from the large-signal input and output parallel equivalent-impedance data. These are determined experimentally or provided on device specification sheets. The transistors are operated in a very nonlinear manner as class C amplifiers; therefore the experimental data should be representative of the expected operating point, because the small-signal transistor parameters are not adequate.

POWER RELATIONSHIPS

The instantaneous rms output voltage E varies about the unmodulated carrier rms level E_0 . The maximum rms output is $E_0(1 + m)$, where m is the modulation index that can vary from zero to unity for symmetrical modulation. The minimum rms output is $E_0(1 - m)$. The unmodulated power into the load R is

- A** = input impedance matching network
- B** = modulator circuit for producing V_{CC} which follows the modulating signal, e_m , and provides a low source impedance at f_c
- C** = Frequency selective network, $f_c \pm f_m$, and output impedance matching network

FIGURE 12.1.3 Collector-modulated transistor (class C) rf amplifier.

dc collector bias and the input rf drive, and the output rf power. The input rf drive for an amplifier with power gain A is

$$P_{drive} = E_0^2/RA \tag{18}$$

The input dc bias, unmodulated, is slightly greater than

$$P_{dc} = \sqrt{2}E_0\bar{I}_c \tag{19}$$

where \bar{I}_c is the average dc collector current.

The output transistor dissipation unmodulated is

$$P_{TR_o} \approx \sqrt{2}E_0\bar{I}_c + P_{drive} - E_0^2/R \tag{20}$$

$$P_{TR_o} \approx \sqrt{2}E_0\bar{I}_c - \frac{E_0^2}{R} \frac{A-1}{A} \tag{21}$$

$$P_o = E_0^2/R \tag{14}$$

The peak power into the load is

$$P_{max} = [E_0(1 + m)]^2/R \tag{15}$$

The minimum is

$$P_{min} = [E_0(1 - m)]^2/R \tag{16}$$

The average power into the load for sinusoidal modulation is

$$P_{av} = P_o(1 + m^2/2) = (E_0^2/R)(1 + m^2/2) \tag{17}$$

The unmodulated output power E_0^2/R is supplied by the class C amplifier, and the sideband energy $(E_0^2/R)(m^2/2)$ is supplied by the modulator. The class C amplifier can be biased very close to the peak modulated-output envelope swing, $V_{CC} \approx \sqrt{2}mE_0$. For 100 percent modulation, $V_{CC} \approx \sqrt{2}E_0$. The dissipation in the output voltage stage is the difference between the total input power, consisting of the

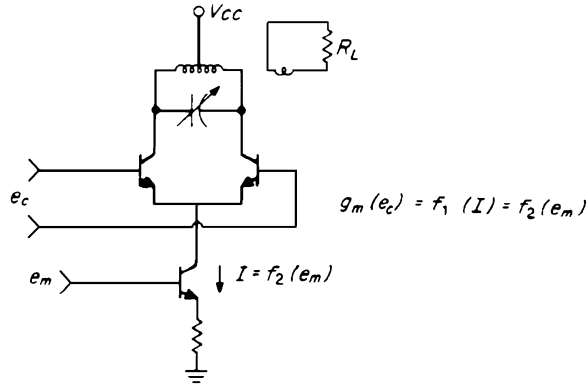

FIGURE 12.1.4 Differential amplifier amplitude modulator (without dc bias details).

In higher-power systems the output transistors can be paralleled. At higher frequencies the gain of the output transistors may be such that the output power is limited by the dissipation in the driver. In these instances the driver may also be collector-modulated to achieve adequate upward modulation and to reduce the power dissipation in the driver.

The input and output impedances of the transistor class C amplifiers are characteristically low. Typical parallel equivalent input impedances are

$$2 < R_{in} < 50 \Omega \quad 30 < C_{in} < 5000 \text{ pF}$$

The collector load impedance-resistance component is determined from the bias voltage and output power

$$R'_L = (V_{CC})^2 / 2P_o \tag{22}$$

where V_{CC} is the dc collector bias voltage and the output voltage swing $2V_{CC}$ peak to peak and P_o is the unmodulated output power.

The collector parallel output capacitance depends on the device geometry and may range from a few picofarads for very-high-frequency lower-power devices to a few hundred picofarads for large-geometry high-power devices.

Interstage and output networks are used to obtain conjugate matches for maximum power gain.

Other types of linear transistor modulators can be used where efficiency is less critical or where very-wide-band operation precludes effective output filtering for the elimination of harmonics. A differential amplifier circuit, as shown in Fig. 12.1.4, will have a transconductance gain that is very nearly proportional to the emitter current-source magnitude. Modulation of the current source will produce a nearly ideal multiplication of the rf input signal and the modulation signal for a wide range of low current levels. The differential amplifier must be biased class A with minimum dc offset at the base inputs. A single transistor multiplier can also be used, as shown in Fig. 12.1.5 for very-low-level outputs. An emitter bypass capacitor for the rf signal is used in place of the additional transistor for the rf return.

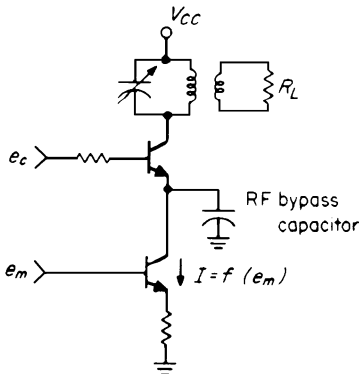

FIGURE 12.1.5 Two-transistor transconductance modulator.

HIGH-POWER LINEAR MODULATORS

High-power linear modulators, 50 W and up, are generally constructed using class C plate-modulation vacuum-circuits. Some of the intermediate power and frequency applications use paralleled transistor configurations with class C collector modulation.

Triodes, tetrodes, and pentodes are used in the vacuum-tube circuits. Multigrid tubes require screen-grid modulation in conjunction with the control-grid modulation to achieve space-charge modulation and to minimize screen current and screen dissipation. The two methods of screen modulation commonly used are: (1) self-bias of the screen grid with a bypassed dropping resistor or inductor from the screen to the plate supply or the screen-grid supply and (2) screen modulation via a separate winding on the modulation transformer.

GRID MODULATION

The amplitude of a class C rf amplifier output can also be modulated by changing the grid bias with the modulating signal. The modulating signal is added to the rf input signal. The effect is to change the magnitude of the plate-current pulses, and hence the fundamental component of the plate current.

The disadvantage associated with grid modulation is that the fixed-plate supply voltage must be twice the peak rf voltage without modulation. This causes high plate dissipation and lowers the plate efficiency to the range of 35 to 45 percent when unmodulated.

The carrier power obtained from a plate-modulated class C amplifier is about three times that available from a grid-modulated circuit using the same tube.

CATHODE MODULATION OF CLASS C RF AMPLIFIERS

Cathode modulation can be used with a class C rf amplifier. The modulation transformer output varies the grid-cathode as well as the plate-cathode voltages. The ratio of grid and plate modulation can be selected by varying the tap; thus the circuit provides a means of producing varying combinations of grid and plate modulation. Some grid-leak bias is normally used to improve linearity.

MODIFIED AM METHODS

The information transmitted by an amplitude-modulated carrier is contained wholly in the modulation sidebands. The transmission of the carrier energy simplifies the receiver-detector implementation but adds no information. In addition, each sideband contains the same information, and only one is required to transmit the intelligence. Elimination of the carrier and/or one sideband can affect a substantial transmitter power saving. For 100 percent amplitude modulation the carrier power is two-thirds of the transmitter power and each sideband one-sixth. Elimination of the carrier will result in *double-sideband suppressed-carrier modulation*. Elimination of one sideband while retaining the carrier or a substantial portion of the carrier results in *vestigial-sideband transmission*. Elimination of the carrier and one sideband is called *single-sideband suppressed-carrier modulation*.

The easiest of these modulation schemes to implement is the vestigial-sideband transmission, both from a transmitter and a receiver viewpoint. The unwanted sideband is generally filtered out at low levels in the transmitter chain and is known as *transmitter attenuation (TA)*. One sideband can also be eliminated in the receiver by selective filtering and is called *receiver attenuation (RA)*. The latter scheme is not practical from a spectrum-utilization sense; hence it is normally used only as in television broadcast to complete unwanted sideband rejection performed primarily at the transmitter.

A vector notation can be used to illustrate the phenomena of various types of amplitude modulation. The vector is a complex function. The sinusoidal function of time that is of interest is the real part or the vector projection on the real axis of the complex plane. Thus the real part of $Ae^{j\omega t}$ is $A \cos \omega t$, as shown in Fig. 12.1.6a.

FIGURE 12.1.6 Vector representation of amplitude modulation, (a) Rotating carrier vector and its real projection. (b) Vector representation with sideband vectors resulting from 100 percent amplitude modulation. Envelope function is locus of projection on the real axis with a nonrotating carrier vector. (c) Double-sideband suppressed-carrier vector representation. Envelope function is locus of projection on the real axis with coordinate rotation as in (b). (d) Vector representation of a single-sideband amplitude-modulated waveform showing peak-to-peak carrier phase modulation ϕ resulting from the absence of the other sideband signal.

The projection on the real axis of the vector $Ae^{j\omega t}$ can be considered as the carrier signal in subsequent amplitude-modulation (AM) discussions. Since the unmodulated carrier signal in amplitude-modulation processes is a fixed peak amplitude and fixed frequency function of time, a modified vector representation can be used to describe the envelope of the modulated waveform. The modified vector diagram maintains the carrier vector as a fixed, nonrotating vector. By this means subsequent illustrations are referenced to a complex plane rotating at the carrier angular rate, and the projection on the real axis corresponds to the *modulation envelope variations with time*.

For an amplitude-modulation system using a sinusoidal modulating function at 100 percent modulation, $m = 1$, the addition of two vectors to the basic vector diagram is required. The two additional vectors represent the sideband signals produced in the modulation process. The two sideband signals are displaced on either side of the carrier signal in the modulated signal spectrum by a frequency equal to the modulating frequency. Therefore, with respect to the modified reference system, the lower sideband vector will rotate clockwise at the modulation-signal angular rate, and the upper sideband will rotate counterclockwise at the same rate.

The relative phases of the two sideband vectors are such that no change in carrier phase angle is introduced when they are both present, i.e., the imaginary parts of the sideband contributions cancel. The initial angles are set by the phase of the modulating function. As the sideband vectors rotate in the modified complex plane, the vector sum of the carrier plus sidebands describes sinusoidal projection on the real axis at the modulating frequency rate.

Note that the unmodulated carrier projection is constant and equal to the peak carrier magnitude. The 100 percent modulated carrier projection is nonnegative. If the original complex plane were used, the entire vector system would rotate at the carrier angular rate, and the projection on the real axis would be the actual time function produced by the modulator. This function would have negative portions and would fill the envelope function and its image with amplitude-modified sinusoids at the carrier frequency, as shown in Fig. 12.1.6*b* with the dashed lines within the envelope.

VESTIGIAL-SIDEBAND SYSTEMS

Vestigial-sideband transmission introduces angle modulation on the carrier because the symmetry of the contrarotating sideband vectors is lost, as illustrated in Fig. 12.1.6*d*. A standard envelope detector can still be used to recover the modulating signal, however. The primary objective in the application of vestigial-sideband transmission is to conserve spectrum in the transmission medium.

SUPPRESSED-CARRIER SYSTEMS

Suppressed-carrier systems for AM transmission and reception require modifications to the receiver. The double-sideband suppressed-carrier signal cannot be envelope-detected without the reinsertion of a carrier signal. The frequency and the phase of the reinserted carrier are critical. This type of transmission is used with special phase-locked receivers or with the transmission of low-level carrier to permit the reconstitution of the carrier frequency and phase at the receiver. A double-sideband suppressed-carrier signal can be generated with a balanced modulator, as shown in Fig. 12.1.7*a*.

The nonlinear devices can be diodes or modulated class C rf amplifiers. The balanced modulator simplifies the tuned-output-circuit design because all even harmonics of the modulating process tend to be canceled along with the carrier.

Single-sideband suppressed-carrier modulation simplifies the receiver design in some applications. The phase of the reinserted carrier at the receiver is not critical as in double-sideband suppressed-carrier systems. Also, a frequency error in the reconstituted carrier will result only in a corresponding shift in the demodulated signal frequencies, which may be tolerable. If accurate modulation-frequency preservation is required, a low-level carrier can be transmitted to aid in the reconstruction of the carrier signal at the receiver. The reinserted carrier amplitude with respect to the received sideband signal is generally made large to minimize angle modulation of the carrier at the detector.

Two methods are usually employed to generate suppressed-carrier single-sideband transmissions. The most direct method is to filter out the undesired sideband and carrier at low levels in the transmitter chain.

FIGURE 12.17 Double-sideband suppressed-carrier modulators: (a) general form of a balanced modulator for suppressed-carrier output using nonlinear elements A and bias voltage E_b , (b) four-quadrant multiplier.

This filtering problem is difficult when the modulation sidebands of interest are close to the carrier and the carrier frequency is high.

An alternative method of suppressed-carrier single-sideband modulation is by unwanted sideband cancellation. Two balanced modulators are used, with their outputs combined in push-pull.

MODULATED OSCILLATORS

A direct modulated class C oscillator can be used as an AM transmitter. The linearity of such circuits is generally as good as or better than the plate-modulated class C amplifiers. The main disadvantage is the tendency for carrier-frequency pulling that results from the changes in the oscillator operating point as the modulation signal varies.

A very useful circuit for the generation of low-level double-sideband suppressed-carrier signals is the four-quadrant multiplier. The same circuit will also operate as a double-sideband modulator with carrier and as low-level demodulator in phase-locked receiver systems. Multipliers are available in integrated-circuit form, and they can be used at frequencies from dc to beyond 100 MHz (Fig. 12.1.7b).

DETECTORS

The most common AM detector or demodulator is a diode rectifier. The ideal diode detector passes current in only one direction and will essentially follow the envelope of an amplitude-modulated waveform when used in a circuit as shown in Fig. 12.1.8.

FIGURE 12.1.8 Diode envelope detector.

FIGURE 12.1.9 Four-quadrant multiplier used as a product detector. The local-oscillator input e_{LO} must be phase-coherent with the carrier of the modulated input signal e_C . Complementary outputs are obtained at A and B .

The charging time constant $R_s C$ must be short, so that the capacitor voltage follows the input signal E_r when the diode is forward-biased or conducting. Conversely, the discharge time constant $R_L C$ must be long enough to retain most of the rectified voltage between cycles of the carrier signal but not so large that the capacitor voltage will not discharge at the maximum rate of change of the input signal envelope. The envelope detector is essentially insensitive to residual angle modulation of the carrier, and it is therefore usable in single-sideband receivers.

Practical diode rectifiers have nonlinear resistance characteristics in the conduction bias region and are therefore operated at fairly high input signal levels, on the order of 2 to 10 V peak for semiconductor diodes.

PRODUCT DETECTORS

Another type of amplitude demodulator is the product detector, or multiplier circuit (Fig. 12.1.9). This circuit has distinct advantages and disadvantages. The advantages include the ability to detect lower-level signals with a linear response; the ability to differentiate phase reversals in the modulated waveform, resulting from balanced amplitude modulation with suppressed carrier; and the ability to produce, in some designs, error signals for automatic-frequency-control systems in receivers.

The analytical expression for the output of a product detector is

$$e(t) = E \underbrace{[1 + m \sin(\omega_m t + \phi_m)]}_{\text{amplitude-modulated signal}} \underbrace{\cos(\omega_c t + \phi_c)}_{\text{local-oscillator signal}} \cos(\omega_c t + \phi_d) \quad (23)$$

Expansion of Eq. (23) shows that the product of the incoming carrier signal, $\cos(\omega_c t + \phi_c)$, and the local-oscillator signal, $\cos(\omega_c t + \phi_d)$, produces a dc term except when these two inputs are in quadrature phase. The output dc term is proportional to the cosine of the relative phase angle of the carrier and local-oscillator signals. A four-quadrant multiplier circuit capable of performing this type of detection is shown in Fig. 12.1.9.

The details of the dc bias network are not included in the elementary schematic of the multiplier circuit. The input signals, rf and local-oscillator, are applied to either input port. Balanced-differential or single-ended inputs can be used, although the balanced inputs give the added performance of increased linearity and common-mode signal rejection. Two outputs of opposite polarity are available at the collectors of the upper-rank transistors. Design options are available to increase the efficiency and linearity of the circuit. Normally, an overdrive is applied to the local-oscillator port to make that section of the multiplier operate in a switching mode. The effect is to multiply the rf signal with a square wave at the carrier frequency instead of a sine wave. This type of operation also produces additional outputs at the higher harmonics of the carrier frequency.

12.16 MODULATORS, DEMODULATORS, AND CONVERTERS

For balanced linear in-phase inputs at both ports, the outputs consist of

$$\begin{aligned} e_0 &= 1/2(A_{LO} + A_{LO} \cos 2\omega_c t)E[1 + m \sin(\omega_m t + \phi_m)] \\ &= 1/2A_{LO}E[1 + m \sin(\omega_m t + \phi_m)] + 1/2A_{LO}E \cos 2\omega_c t \end{aligned} \quad (24)$$

The disadvantages of the product detector are relative circuit complexity and the need for a phase-coherent local-oscillator signal. The circuit complexity can be circumvented for input signal frequencies up to 100 MHz by using integrated-circuit multipliers. This approach also minimizes the possibility of serious dc offset problems because of device mismatch. The generation of the coherent local-oscillator signal can be achieved in two ways. For simple double-sideband (DSB) amplitude-modulated signals, the carrier can be stripped from the input rf signal, with a parallel limiting amplifier with narrow bandwidth. This approach cannot be used in suppressed-carrier AM systems, where the carrier phase reversals are introduced in the modulation process.

The more general approach is to use an additional multiplier circuit as a phase detector. When the rf and local-oscillator signals are equal in frequency and in phase quadrature, the multiplier output has no dc component. Any relative phase shift from quadrature will produce an odd-function-error signal at dc. This signal can be used with a voltage-controlled oscillator to correct the phase of the local oscillator or input rf signal. The system described is a phase-locked loop. The bandwidth of this loop can be controlled independently from the rf bandwidth for optimum acquisition and noise-suppression characteristics. This type of system is capable of producing a stable and noise-free local-oscillator signal that tracks any variations in the frequency and phase of the input rf signal.

With additional modifications the phase-locked receiver system is capable of reinserting the desired carrier in suppressed-carrier double- and vestigial-sideband systems.

CHAPTER 12.2

FREQUENCY AND PHASE MODULATION

Nobel R. Powell

ANGLE MODULATION

The representation of angle modulation is conveniently made in terms of the notion of the analytic function. For real continuous functions of time $x(t)$, consider

$$m(t) = x(t) + jHx(t)$$

where $x(t)$ = real continuous function

$$j = (-1)^{1/2}$$

Hx = Hilbert transformation of x

$$Hx(t) = \pi^{-1} \int_{-\infty}^{\infty} x(\tau)(t - \tau)^{-1} d\tau$$

The angle of $m(t)$ is said to be the angle θ , defined by

$$\theta = \tan^{-1} (Hx/x)$$

Angle modulation may be considered as the change in θ with time or as that portion of the total change in θ which can be associated with the phenomenon of interest. If the relationship between the changes in θ and the effect of interest is direct, the modulation is called *phase modulation* (PM) and the devices producing this relationship *phase modulators*. If the relationship between the changes in the derivative $d\theta/dt$ and the effect of interest is direct, the modulation is called *frequency modulation* (FM), and the devices producing this relationship are called *frequency modulators*.

The derivative $d\theta/dt = \dot{\theta}$ is related to the components of the analytical function $m(t)$ by

$$\dot{\theta} = \frac{\begin{vmatrix} x & Hx \\ \dot{x} & H\dot{x} \end{vmatrix}}{x^2 + (Hx)^2} \quad (1)$$

for functions $x(t)$ for which the differential and Hilbert operators commute.

Thus in angle modulators, whether implemented functionally in the general form (as with a general-purpose computer) suggested by the representation of θ and $\dot{\theta}$, or as some special combination of electronic networks,

12.18 MODULATORS, DEMODULATORS, AND CONVERTERS

FIGURE 12.2.1 Linear angle modulator.

a direct or proportional relationship is established within the device between either of these two functions and an effect, call it the input $v(t)$, of interest. Diagrammatically, a linear angle modulator can be considered to be a device that transforms $v(t)$, as shown in Fig. 12.2.1.

Demodulators simply perform the inverse of this operation, providing an output function proportional to $\theta(t)$ from a function proportional to the angle of $m(t)$ as an input.

ANGLE-MODULATION SPECTRA

The spectral distribution of power for angle-modulated waveforms varies widely with the nature of the input function $v(t)$.

Random Modulation

For a random process having sample functions

$$x(t) = b \sin (2\pi ft + \phi) \quad b\text{-const}$$

where f and ϕ are independent random variables, ϕ being uniformly distributed over $-\pi \leq \phi \leq \pi$ and f having a symmetric probability density $p(f)$, this stationary random process has a spectral density function

$$S_{xx}(f) = (b^2/2)p(f) \tag{2}$$

Note that if $p(f)$ is not a discrete distribution, the process is not in general periodic and $S_{xx}(f)$ must be considered continuous.

Periodic Modulation

For a random process having sample functions

$$x(t) = b \cos [\omega_c t - \phi(t) + \theta] \quad b, \omega_c\text{-const}$$

θ uniformly distributed over $-\pi \leq \theta \leq \pi$. $\phi(t)$ is a stationary process independent of θ ; that is,

$$\phi(t) = d \cos (\omega_m t + \theta') \quad d, \omega_m\text{-const}$$

For θ' uniformly distributed over $-\pi \leq \theta' \leq \pi$, the spectral density function is

$$S_{xx}(f) = (b^2/4) \left(J_0^2(d) [\delta(f - f_c) + \delta(f + f_c)] + n \sum_{n=1}^{\infty} J_n^2(d) \{ \delta[f - (f_c \pm nf_m)] + \delta[f + (f_c \pm nf_m)] \} \right) \tag{3}$$

where $J_n(d) = n$ th-order Bessel function of first kind evaluated at d

$\delta =$ Kronecker delta function

$S_{xx}(f) =$ Fourier transformation of autocorrelation function of x

Deterministic Modulation

For a function of a completely specified type, e.g.,

$$x(t) = b \sin(\omega_c t + d \sin \omega_m t) \tag{4}$$

frequently it is possible to reexpress $x(t)$ in terms of $J_n(d)$ as

$$x(t) = \sum_{n=-\infty}^{\infty} J_n^2(d) \sin(\omega_c t + n\omega_m t) \tag{5}$$

Examination of Eqs. (1) and (3) and tables of Bessel functions permits the construction of Fig. 12.2.2 showing the implied increase in bandwidth versus modulation index for FM. Modulation index for sinusoidal modulation can be defined as

$$d = |\Delta f|/f_m$$

where $(\Delta f) = df_m$ = amount of instantaneous frequency change $\dot{\theta}$ to be associated with the input $v(t)$.

Such a set of curves can be readily constructed for most deterministic modulation waveforms, since $J_n(d)$ decreases monotonically and rapidly with n for $n > d > 1$. Using the criteria for n indicated for curves A, B, and C, the frequency range (or bandwidth) centered about ω_c , which contains all such spectral components, is indicated. These are the components that are found to be below the value of nf_m for which $J_n(d)$ is monotonically decreasing and equal to the value for each case. Thus the bandwidth (BW) required at the frequency ω_c is

$$BW = 2df_m(1 + I) \tag{6}$$

Such criteria should be used with care, since the relationship which these measures bear to distortion of the input $v(t)$ when carried at frequency ω_c through linear-tuned circuits as angle modulation is rather indirect.

FIGURE 12.2.2 Bandwidth increase vs. modulation index.

ANGLE-MODULATION SIGNAL-TO-NOISE IMPROVEMENT

One of the principal reasons for using frequency modulation in communications and telemetry systems is that it provides a convenient and power-efficient method of trading power for bandwidth while providing high-quality transmission of the input. This is expressed in phase modulation by the relationship

$$\left. \frac{S}{N} \right|_{f_m} = ad^2 \left. \frac{C}{N} \right|_{f_m} \tag{7}$$

where $(S/N)_{f_m}$ = demodulated output signal-to-noise ratio measured in a bandwidth f_m
 $(C/N)_{f_m}$ = demodulator input signal-to-noise ratio measured in a bandwidth f_m
 d = modulation index
 a = a constant of proportionality

The constant of proportionality a is unity for sinusoidal phase modulation of constant-amplitude sinusoidal carrier. The constant varies between 0.5 and 3.0 with class of modulation waveforms, type of network compensation, and noise spectrum; however, Eq. (7) can be conservatively applied to FM single-channel voice systems for $a = 3/2$ and preemphasis and deemphasis networks that preshape the spectrum of the modulation to match the sloped noise spectrum and to restore the original spectrum after demodulation.

The trade-off between the signal-to-noise improvement and the required bandwidth corresponding to curve A in Fig. 12.2.2 is shown for FM in Fig. 12.2.3. These curves have been prepared for a conventional demodulator operating at an input carrier-to-noise ratio 1 dB above the threshold (13 dB) measured in the input noise bandwidth to the demodulator, with a constant of proportionality a equal to 0.5. Output signal-to-noise ratio referred to the output information bandwidth $(S/N)_{f_m}$ is

$$(S/N)_{f_m} = 10 + G \text{ (dB)} \tag{8}$$

where G is obtained from the figure along with r , the ratio of premodulator bandwidth to output information bandwidth. The carrier-to-noise ratio in a noise bandwidth equal to the output information bandwidth is

$$(C/N)_{f_m} = 13 + 10 \log r \text{ (dB)} \tag{9}$$

NOISE-THRESHOLD PROPERTIES OF ANGLE MODULATION

The signal-to-noise improvement represented by Eq. (7) is achievable only when the input carrier-to-noise ratio is above certain minimum levels. These levels depend on the type of modulating waveforms, the type of noise interference prevalent, and the type of demodulator. As the foregoing discussion indicates, whenever a demodulator without phase or frequency feedback is used, an input carrier-to-noise ratio (measured in the premodulator bandwidth) of roughly 12 dB is required. Unless this condition is met, a small decrease in carrier-to-noise ratio will result in a sharp decrease in output signal-to-noise ratio, accompanied by undesirable noise effects, such as load clicking sounds in the case of voice modulation.

ANGLE MODULATORS

Angle modulators for communications and telemetry purposes generally fall into the category of what may be termed “hard” oscillators having relatively high- Q frequency-determining networks; or they fall into the category of “soft” oscillators having supply and bias sources as the frequency-determining networks. Examples of each are shown in Fig. 12.2.4.

FIGURE 12.2.3 Process gain and rf bandwidth vs. deviation ratio.

Control of the hard oscillator is executed by symmetrical incremental variation of the reactive components. For the case of a Hartley oscillator, Z_1 and Z_2 are inductors and Z_3 is a capacitor, allowing the use of varicaps paralleling, Z_3 as the voltage-controllable reactance. In such a case

$$f_o = (2\pi)^{-1} [C_3(L_1 + L_2)]^{-1/2}$$

FIGURE 12.2.4 Voltage-controlled oscillators: (a) soft oscillator; (b) hard oscillator.

FIGURE 12.2.5 Frequency-modulator configuration.

where C_3 = total capacitance of varicaps and fixed capacitor of Z_3 . Note that the bandwidth of this modulator is determined by the frequency-determining impedances of the network, i.e., the overall Q and center frequency. In view of the need for certain minimum bandwidth requirements from Fig. 12.2.2 and the need for good oscillator stability, the total frequency deviation required is sometimes obtained by following the oscillator with a series of frequency multipliers and frequency translators, as shown in Fig. 12.2.5. This configuration permits the attainment of good oscillator stability, constant proportionality between output frequency change and input voltage change, and the necessary modulator bandwidth to achieve wide-band FM.

Control for the soft oscillator is introduced as a change in the switching level of the active-device switches. The frequency of a transistor version of the oscillator is, roughly,

$$f = [2R_1 C \ln(1 + V/V_i)]^{-1} \quad (10)$$

Since this type of oscillator is a relaxation oscillator, the rate at which the frequency of oscillation can be changed is limited only by the rate at which the switching points can be altered by voltage control. Modulators of this kind can be designed with bandwidths greater than the frequency of oscillation. The disadvantage of such networks is the relatively poor frequency stability compared with the high- Q hard oscillators.

DISCRIMINATORS

Basic angle demodulators can be designed using balanced tuned networks with suitably connected nonlinearities (such as diode switches); or angle demodulators can be designed using voltage-controlled oscillators (VCO), multipliers, and appropriate feedback networks.

The former are simpler to implement than the latter but require much higher input signal-to-noise ratios for operation above the noise threshold at which the angle modulation produces signal process gain. Two popular versions of the discriminator type of frequency demodulator are shown in Fig. 12.2.6. The diode discriminator is designed so that one diode conducts more with increases, the other with decreases, in frequency. For greatest linearity, the mutual coupling between the tuned circuits is generally greater than unity. The other basic type of conventional demodulator simply implements a version of the definition [Eq. (1)] of FM for the case of a constant-amplitude sinusoidal waveform. The mixing operation can be replaced by a simple phase shifter that provides a 90° phase relationship between x and Hx . Frequently, the reference oscillator will be phase-locked to the average value of the $J_0(d)$ component indicated by Eqs. (3) and (5).

FM FEEDBACK (FMFB) DEMODULATORS

These angle demodulators have the advantage of lower distortion, lower noise threshold, and little or no drift in center frequency of operation and can be designed to be less sensitive to interference. No limiter is required for good performance, and there is no requirement to maintain a minimum predemodulator input carrier-to-noise ratio to avoid noise threshold.

A block diagram of a basic synchronous-filtering demodulator is shown in Fig. 12.2.7. The synchronous filter is indicated by the dashed lines that enclose a phase-locked loop designed to follow the instantaneous

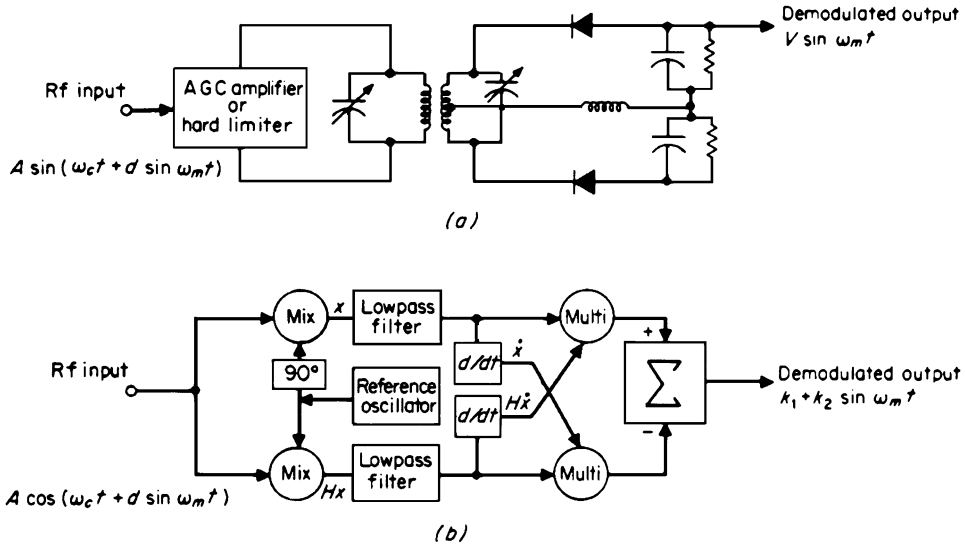

FIGURE 12.2.6 Conventional demodulators: (a) diode discriminator; (b) phase-shift discriminator.

excursions in the phase of the angle-modulated signal ϕ_2 . The mixer, i.f. amplifier, discriminator, filter 2, and the VCO-2 form a frequency feedback loop for the demodulator.

Aside from the synchronous method, the basic configuration can be considered that of a conventional FMFB demodulator which compresses the wide-band FM input signal so that it can be passed through a relatively narrow bandwidth fixed-tuned filter and to a discriminator for detection. It should be noted that the configuration shown here can also be considered simply as a phase-locked loop (PLL) with frequency feedback around it.

The significant advantages of each of these techniques (FMFB and PLL) can be combined. It is important to consider the design from both the synchronous and frequency-feedback viewpoints. Note in this regard Figs. 12.2.8 and 12.2.9 in which $F_1(S)$ and $F_2(S)$ have been assigned. Observe that Fig. 12.2.10 is an

FIGURE 12.2.7 Block diagram of basic feedback demodulator.

FIGURE 12.2.8 Equivalent network of basic demodulator shown in Fig. 12.2.7.

FIGURE 12.2.9 Direct linear equivalent form of basic demodulator.

FIGURE 12.2.10 FMFB demodulator.

FMFB equivalent linear form obtained by substituting the closed-loop transfer function for the synchronous filter; however, by retaining the inner loop and combining phase comparators, we obtain the synchronous phase-locked-loop form, as shown in Fig. 12.2.11. To the extent that linear analysis and quasi-linear substitutions can be made in these block diagrams, the remarks that follow are thus relevant to both PLL and FMFB forms implemented with synchronous filters or with broadband amplifiers in cascade with single-tuned filters.

PHASE-LOCKED-LOOP DEMODULATORS

The introduction of the phase-locked loop between the i.f. amplifier and discriminator may be viewed simply as a means by which the i.f. signal can be tracked, limited, and filtered regardless of Doppler shift or oscillator drift. The synchronous filter is employed in conjunction with the relatively wide-bandwidth i.f. amplifier shown on the block diagram to perform this critical filtering function, as well as to take advantage of the phase coherence between the FM signal sidebands.

The operation of the demodulator can be understood from an examination of the equivalent network shown in Fig. 12.2.8, in which the transfer functions relate to phase as the input and output variables. If the bandwidth of the i.f. amplifier is broad by comparison with both the synchronous-filter bandwidth and significant modulation sidebands, it can be ignored in the equivalent linear representation of the demodulator. Since the synchronous-filter function is

$$\frac{\phi_3(s)}{\phi_2(s)} = \frac{(K_1/s)F_1(s)}{1 + (K_1/s)F_1(s)} \tag{11}$$

FIGURE 12.2.11 PLL demodulator.

the signal ϕ_2 is related to the input by

$$\frac{\phi_2(s)}{\phi_1(s)} = \frac{1}{1 + K_1 K_2 K_d F_1(s) F_2(s) / [s(1 + (K_1/s) F_1(s))]} \quad (12)$$

For frequency components of $\phi_1(s)$ lying well within the bandwidths of $F_2(s)$ and the synchronous filter, this transfer function reduces to the familiar form of a type-zero feedback network: i.e.,

$$\frac{\phi_2(s)}{\phi_1(s)} = \frac{1}{1 + K_2 K_d} = \frac{s\phi_2(s)}{s\phi_1(s)} \quad (13)$$

Since this is also the transfer function with respect to frequency variations, the compression of frequency excursions is evident. If

$$\phi_1(t) = (\Delta\omega/\omega_m)\sin \omega_m t = D \sin \omega_m t \quad (14)$$

where $\phi(t)$ represents the instantaneous variation of the phase of the input signal relative to some reference carrier phase, and if the synchronous filter follows this instantaneous variation, the effective phase excursion to the discriminator is reduced to

$$\phi_3(t) = \frac{D}{1 + K_f} \sin \omega_m t \quad K_i = K_2 K_d \quad (15)$$

if ω_m is well within the passband of $F_2(s)$ and the phase-locked loop. This reduction in deviation ratio by the use of frequency feedback gain K_f suggests that an optimum gain and synchronous-filter bandwidth combination should be sought for given modulation and noise characteristics, just as the proper i.f. amplifier and K_f must be chosen in a conventional FMFB demodulator.

Figure 12.2.10 shows the closed-loop transfer function of the synchronous filter along with the frequency-feedback loop. It has been assumed that the i.f. amplifier bandwidth is very broad compared with the bandwidth occupied by the significant portions of the signal spectrum as it appears at i.f. frequencies. This amounts to assuming that the dispersive effect produced by the i.f. amplifier is negligible. If the phase-locked-loop gain can be considered large compared with the filter zero ($K_1 \gg \omega_1$ is usually satisfied in practice), the following relationships between the synchronous-filter and the complete feedback-demodulator parameters can be written

$$\zeta_f^2 = (K_f + 1)\zeta_\phi^2 \quad \omega_{nf}^2 = (K_f + 1)\omega_{n\phi}^2 \quad B_{nf} = B_{n\phi} \left(1 + K_f \frac{1}{1 + 1/4\zeta_\phi^2} \right) \quad (16)$$

where ζ_f = damping of demodulator

ω_{nf} = natural frequency of demodulator

ζ_ϕ = damping of synchronous filter

$\omega_{n\phi}$ = natural frequency of synchronous filter

B_{nf} = noise bandwidth of demodulator

$B_{n\phi}$ = noise bandwidth of synchronous filter

and in terms of the actual network parameters

$$\zeta_\phi^2 = \frac{K_1 \omega_2}{4\omega_1^2} \quad \omega_{n\phi}^2 = K_1 \omega_2 \quad B_{n\phi} = \frac{1}{2} \left(\frac{K_1 \omega_2}{\omega_1} + \omega_1 \right) \quad (\text{Hz}) \quad (17)$$

Note that all the demodulator response variables can be controlled by simple RC adjustments.

FM FEEDBACK-DEMODULATOR DESIGN FORMULAS

Acquisition. The rate at which the VCO in a phase-locked demodulator can be swept through the frequency and phase at which pull-in and phase lock will occur is indicated by the representative curves of Fig. 12.2.12.

Pull-In

The frequency difference $\Delta\omega$ (between an unmodulated carrier and the VCO) within which a phase-locked loop will pull into phase synchronism is, roughly,

$$|\Delta\omega|_p = (2\rho K\omega_n)^{1/2} \quad \text{for } K/\omega_n \gg 1$$

where K = total open-loop gain (rad/s)
 ω_n = loop natural frequency (rad/s)
 ρ = dimensionless constant ≈ 1

The time required for pull-in is given by

$$T = 4(\Delta f)^2/B_n^3 \quad (\text{seconds})$$

for loop damping of 0.5 and $|\Delta f| < 0.8|\Delta f|_p$, where Δf = difference frequency (Hz) and B_n = closed-loop noise bandwidth (Hz).

Stability

The condition of sustained beat-note stability without the loop capacity to be swept into lock, which is exhibited by high-gain narrow-bandwidth phase-locked demodulators, is a condition of loop oscillation arising from the presence of the phase detector nonlinearity and extraneous memory, such as that in the tuned circuits in

FIGURE 12.2.12 Probability of acquisition vs. sweep-rate per unit bandwidth.

phase detectors and in voltage-controlled oscillators. This condition can be predicted from the approximate condition

$$\frac{K^2 G |\omega_0|}{2|\omega_0|^2} [\cos \phi(\omega_0)] + 1 = 0 \tag{18}$$

where K = total open-loop gain

G = complete transfer function between phase detector and VCO

ϕ = angle of G

This condition can be used to predict to nonlinear network oscillations preventing lockup.

Parameter Variations

The rate at which second-order demodulators damped for minimum-noise bandwidth can have the loop natural frequency changed at constant damping is given by

$$\frac{d\omega_n/dt}{\omega_n^2} \leq 0.1 \tag{19}$$

for peak phase errors less than 5°, where ω_n is the natural frequency of the loop.

Minimum-Threshold Parameters

The parametric relationships for minimum-noise threshold for the demodulator in Fig. 12.2.9 are shown in Fig. 12.2.13.

FIGURE 12.2.13 Parametric relationships for minimum threshold (voice).

CHAPTER 12.3

PULSE MODULATION/ DEMODULATION

George F. Pfeifer

PULSE MODULATION

Pulse modulation is, in general, the encoding of information by means of varying one or more pulse parameters. It finds application in both the communication and the control fields. The control applications are usually confined to the use of pulse-time modulation (PTM) and pulse-frequency modulation (PFM), where on-off control power can be used to minimize device dissipation. All pulse modulation schemes require sampling analog signals, and some, such as pulse-code modulation (PCM) and delta modulation, require the additional quantization of the analog signals.

In communications, the chief application of pulse modulation is found where it is desired to time-multiplex by interleaving a number of single-channel, low-duty-cycle pulse trains. The pulse trains may, in turn, be used for compound modulation by amplitude or angle modulation of a continuous carrier. In usual applications, sub-carriers are pulsed, time-division-multiplexed, and then used to frequency-modulate a carrier.

Since noise is present in all systems, a prime consideration in modulation selection is the choice of a waveform based on its signal-to-noise efficiency. For instance, PTM is more efficient than pulse amplitude modulation (PAM), which offers no improvement over continuous AM; however, PTM is less efficient than PCM or delta modulation. A chief advantage of pulsed systems such as PTM, PCM, and delta is improved signal-to-noise ratio in exchange for increased bandwidth, in the same manner as continuous FM improves over AM.

SAMPLING AND SMOOTHING

An ideal impulse sampler can be considered as the multiplication of an impulse train, period T seconds, with the continuous signal $f(t)$. This is shown in Fig. 12.3.1a for the impulse train defined as $p_T(t) = \text{rep}_T[\delta(t)]$, where $\delta(t)$ is an impulse at $t = 0$ and

$$\text{rep}_T[u(t)] = \sum_{n=-\infty}^{\infty} u(t - nT) \quad (1)$$

The output spectrum function is the convolution of $F(f)$, the Fourier transform of the input signal, and the transform of $p_T(t)$, which is $(1/T) \text{comb}_{1/T}(1)$, defined as

$$\text{comb}_{1/T}[U(f)] = \sum_{n=-\infty}^{\infty} U\left(\frac{n}{T}\right) \delta\left(f - \frac{n}{T}\right) \quad (2)$$

FIGURE 12.3.1 Pulse modulation: (a) output spectrum; (b) sampling configuration.

Thus the transform $R(f) = F(f) * (1/T) \text{comb}_{1/T}(1)$ with spectrum is as shown in Fig. 12.3.1b. The result of ideal impulse sampling has been to repeat the original signal spectrum, assumed to be band-limited, each $1/T$ Hz and multiply each by a $1/T$ scale factor. Since all the signal information is present in each lobe of Fig. 12.3.1b, it is only necessary to recover a single lobe through filtering in order to recover the signal function reduced by a scale factor.

Consider an ideal low-pass rectangular filter of bandwidth of f_f Hz defined as $T(jf) = A(f) \exp[-j\theta(jf)]$, where

$$A(f) = \begin{cases} 1 & |f| < f_f \\ 0 & |f| > f_f \end{cases} \text{ and } \theta(jf) = 2\pi\alpha f \text{ for all } f$$

The cutoff frequency f_f is adjusted to select the output spectral lobe about zero $f_c < f_f < 1/T - f_c$ and will fall in the guard band between lobes. That portion of filter output $R(f)$ selected is

$$R_0(f) = (1/T)F(f) \exp(-j2\pi\alpha f) \tag{3}$$

that will inverse transform as

$$r_0(t) = (1/T)f(t - \alpha) \tag{4}$$

which is identical with the signal function, with the amplitude reduced by a scale factor and function shifted by α seconds. If $\alpha = 0$, signifying no delay, the filter is termed a “cardinal data hold”; otherwise, it is an “ideal low-pass filter.” Unfortunately, these filters cannot be realized in practice, since they are required to respond before they are excited.

Examination of Fig. 12.3.1b gives rise to the sampling theorem accredited to Shannon and/or Nyquist, which states that when a continuous time function with band-limited spectrum $-f_c < f < f_c$ is sampled at twice the highest frequency, $f_s = 2f_c$, the original time function can be recovered. This corresponds to the point where the sampling frequency $f_s = 1/T$ is decreased so that the spectral lobes of Fig. 12.3.1b are just touching. To decrease f_s beyond the value of $2f_c$ would cause spectral overlap and make recovery with an ideal filter impossible. A more general form of the sampling theorem states that any $2f$ independent samples per second will

completely describe a band-limited signal, thus removing the restriction of uniform sampling, as long as independent samples are used. In general, for a time-limited signal of T seconds, band-limited to f_c Hz, only $2f_c T$ samples are needed to specify the signal completely.

In practice, the signal is not completely band-limited, so that it is common to allow for a greater separation of spectral lobes, called the *guard band*. This guard band is generated simply by sampling at greater than $2f_c$, as in the case for Fig. 12.3.1b. Although the actual tolerable overlap depends on the signal spectral slope, setting the sampling rate at about $3f_c = f_s$ is usually adequate to recover the signal.

In practice, narrow but finite-width pulse trains are used in place of the idealized impulse sampling train.

PULSE-AMPLITUDE MODULATION

Pulse-amplitude modulation is essentially a sampled-data type of encoding where the information is encoded into the amplitude of a train of finite-width pulses. The pulse train can be looked upon as the carrier in much the same way as the sine wave is for continuous-amplitude modulation. There is no improvement in signal-to-noise when using PAM, and furthermore, PAM is not considered wideband in the sense of FM or PTM. Thus PAM would correspond to continuous AM, while PTM corresponds to FM. Generally, PAM is used chiefly for time-multiplex systems employing a number of channels sampled, consistent with the sampling theorem.

There are a number of ways of encoding information as the amplitude of a pulse train. They include both bipolar and unipolar pulse trains for both instantaneous or square-topped sampling and for exact or top sampling. In top sampling, the magnitude of the individual pulses follows the modulating signal during the pulse duration, while for square-topped sampling, the individual pulses assume a constant value, depending on the particular exact sampling point that occurs somewhere during the pulse time. These various waveforms are shown in Fig. 12.3.2.

The top-modulation bipolar sampling case is shown in Fig. 12.3.2c; it is simply sampling with a finite-pulse-width train. Carrying out the convolution yields

$$R_{\text{STB}}(f) = \frac{\tau}{T} \sum_{n=-\infty}^{\infty} \left(\text{sinc} \frac{\tau n}{T} \right) F \left(f - \frac{n}{T} \right) \quad (5)$$

The spectrum for top-modulation bipolar sampling, using a square-topped rectangular spectrum for the original signal spectrum, is shown in Fig. 12.3.3a. The signal spectrum repeats with a $(\sin x)/x$ scale factor determined by the sampling pulse width, with each repetition a replica of $F(f)$.

Unipolar sampling can be implemented by adding a constant bias A to $f(t)$, the signal, to produce $f(t) + A$, where A is large enough to keep the sum positive; that is, $A > |f(t)|$. Sampling the new sum signal by multiplication with the pulse train results in the unipolar top-modulated waveform of Fig. 12.3.2e. The spectrum is

$$R_{\text{STU}}(f) = \frac{\tau}{T} \sum_{n=-\infty}^{\infty} \left(\text{sinc} \frac{\tau n}{T} \right) \left[F \left(f - \frac{n}{T} \right) + A \delta \left(f - \frac{n}{T} \right) \right] \quad (6)$$

The delta-function part of the summation reduces to the spectrum function of the pulse train $S(f)$

$$R_{\text{STU}}(f) = AS(f) + \frac{\tau}{T} \sum_{n=-\infty}^{\infty} \left(\text{sinc} \frac{\tau n}{T} \right) F \left(f - \frac{n}{T} \right) \quad (7)$$

The resulting spectrum of top-modulation unipolar sampling is the same as with bipolar sampling plus the impulse spectrum of the sampling pulse train, as shown in Fig. 12.3.3b. For square-topped-modulation bipolar sampling, the time-domain result is

$$r_{\text{SSB}}(t) = \text{rect}(t/\tau) * \text{comb}_T f(t) \quad (8)$$

FIGURE 12.3.2 PAM waveforms: (a) modulation; (b) square-top sampling, bipolar pulse train; (c) top sampling, bipolar pulse train; (d) square-top sampling, unipolar pulse train; (e) top sampling, unipolar pulse train.

with spectrum function

$$R_{SSB}(f) = \frac{\tau}{T} (\text{sinc } f\tau) \sum_{n=-\infty}^{\infty} F\left(f - \frac{n}{T}\right) \quad (9)$$

In this case, the signal spectrum is distorted by the $\text{sinc } f\tau$ envelope, as shown in Fig. 12.3.2c. This frequency distortion is referred to as *aperture effect* and may be corrected by use of an equalizer $\text{sinc } f\tau$ form, following the low-pass reconstruction filter.

As in the previous case of unipolar sampling, the resulting spectrum for square-topped modulation will contain the pulse-train spectrum, as shown in Fig. 12.3.2d. The expression is

$$R_{SSU}(f) = AS(f) + \frac{\tau}{T} (\text{sinc } f\tau) \sum_{n=-\infty}^{\infty} F\left(f - \frac{n}{T}\right) \quad (10)$$

FIGURE 12.3.3 PAM spectra: (a) top modulation, bipolar sampling; (b) top modulation, unipolar sampling; (c) square-top modulation, bipolar sampling; (d) square-top modulation, unipolar sampling.

The signal information is generally recovered, in PAM systems, by use of a low-pass filter that acts on the reduced signal energy around zero frequency, as shown in Fig. 12.3.3.

PULSE-TIME, PULSE-POSITION, AND PULSE-WIDTH MODULATION

In PTM the information is encoded into the time parameter instead of, for instance, the amplitude, as in PAM. There are two basic types of PTM: pulse-position modulation (PPM) and pulse-width modulation (PWM), also known as pulse-duration (PDM) or pulse-length (PLM) modulation. The PTM allows the power-driver circuitry to operate at saturation level, thus conserving power loss. Operating driver circuitry full on, full off, is especially important for heavy-duty high-load control applications, as well as for communication applications.

In PPM the information is encoded into the time position of a narrow pulse, generally with respect to a reference pulse. The basic pulse width and amplitude are kept constant, while only the pulse position is changed, as shown in Fig. 12.3.4. There are three cases of PWM which are the modulation of the leading edge, trailing edge, or both edges, as displayed in Fig. 12.3.5. In this case the information is encoded into the width of the pulse, with the pulse amplitude and period held constant. The derivative relationship existing between PPM and PWM can be illustrated by consideration of trailing-edge PWM modulation. The pulses of PPM can be derived from the edges of trailing-edge PWM (Fig. 12.3.5*b*) by differentiation of the PWM signal and a sign change of the trailing-edge pulse. Pulse-position modulation is essentially the same as PWM, with the information-carrying variable edge replaced by a pulse. Thus, when that part of the signal power of PWM that carries no information is deleted, the result is PPM.

Generally, in PTM systems a guard interval is necessary because of the pulse rise times and system responses. Thus 100 percent of the interpulse period cannot be used without considerable channel cross-talk because of pulse overlap. It is necessary to trade off crosstalk versus channel utilization at the system design level.

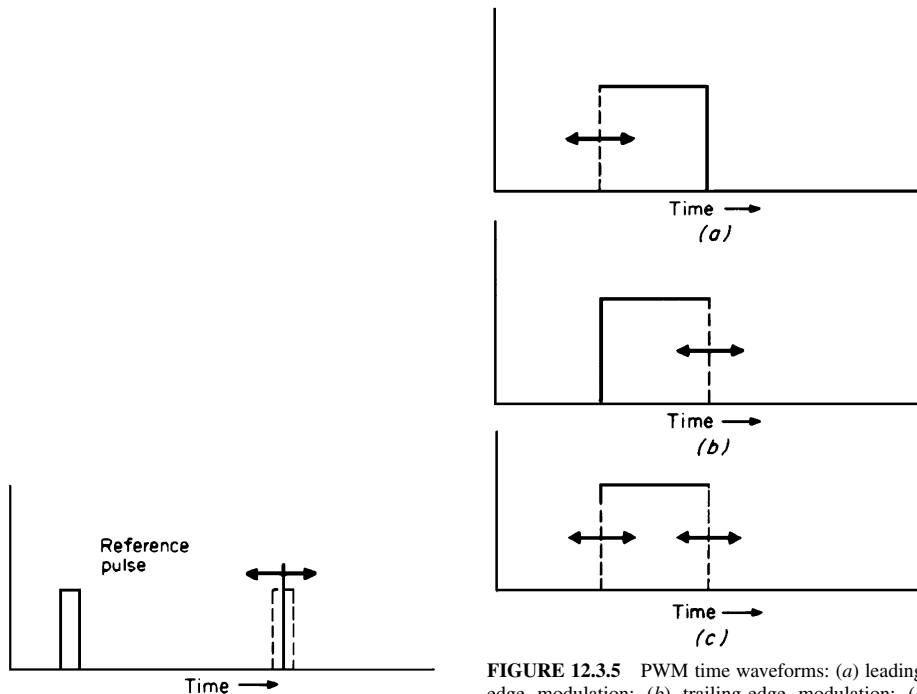

FIGURE 12.3.4 PPM time waveform.

FIGURE 12.3.5 PWM time waveforms: (a) leading-edge modulation; (b) trailing-edge modulation; (c) both-edge modulation.

Another consideration is that the information sampling rate cannot exceed the pulse repetition frequency and would be less for a single channel of a multiplexed system where channels are interwoven in time.

Generation of PTM

There are two basic methods of pulse-time modulation: (1) based on uniform sampling in which the pulse-time parameter is directly proportional to the modulating signal at uniformly sampled points and (2) in which there is some distortion of the pulse-time parameter because of the modulation process. Both methods of modulation are illustrated in Fig. 12.3.6 for PWM. Basically, PPM can be derived from trailing-edge PWM, as shown in Fig. 12.3.6c by use of an edge detector or differentiator and a standard narrow-pulse generator.

In the uniform sampling case for PWM of Fig. 12.3.6a, the modulating signal is sampled uniformly in time and the special PAM derived by a sample-and-hold circuit as shown in Fig. 12.3.7a. This PAM signal provides a pedestal for each of the three types of sawtooth waveforms producing leading, trailing, or double-edge PWM, as shown in Fig. 12.3.7c, e, and g, respectively. The uniform sampled PPM is shown in Fig. 12.3.7h, as derived from the trailing-edge modulation of g.

Nonuniformly sampled modulation, termed *natural sampling* by some authors, is shown in Fig. 12.3.8, and results from the method of Fig. 12.3.8b, where the sawtooth is added directly to the modulating signal. In this case the modulating waveform influences the time when the samples are actually taken. This distortion is small when the modulating-amplitude change is small during the interpulse period T . The distortion is caused by the modulating signal distorting the sawtooth wave-form when they are added, as indicated in Fig. 12.3.6b. The information in the PPM waveform is similarly distorted because it is derived from the PWM waveform, as shown in Fig. 12.3.7h.

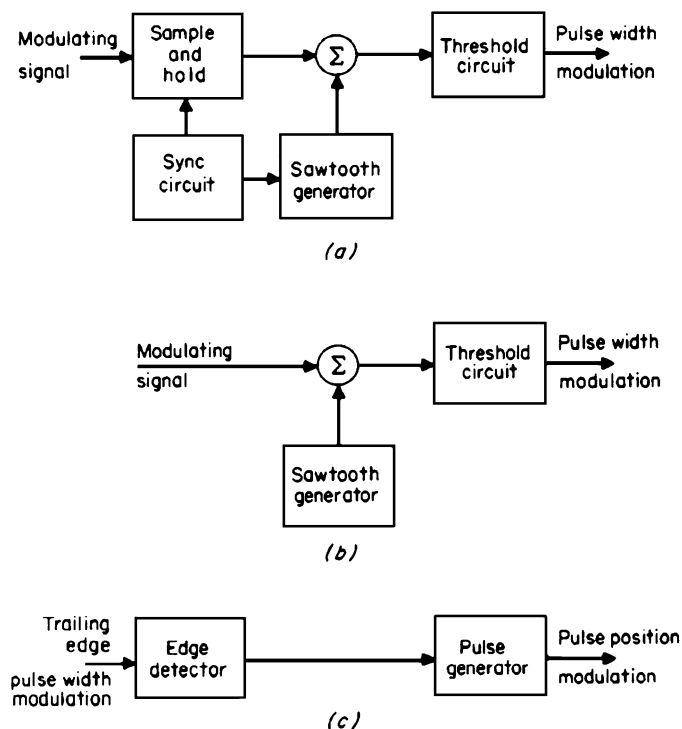

FIGURE 12.3.6 PTM generation: (a) pulse-width-modulation generation, uniform sampling; (b) pulse-width-modulation generation, nonuniform sampling; (c) pulse-position-modulation generation.

FIGURE 12.3.7 Pulse-time modulation, uniform sampling: (a) modulating signal and sample-and-hold waveform; (b) sawtooth added to sample-and-hold waveform; (c) leading-edge modulation; (d) sawtooth added to sample-and-hold waveform; (e) double-edge modulation; (f) sawtooth added to sample-and-hold waveform; (g) trailing-edge modulation; (h) pulse-position modulation (reference pulse dotted).

PULSE-TIME MODULATION SPECTRA

The spectra are smeared in general, for most modulating signals, and are difficult to derive; however, it is possible to get some idea of what happens to the spectra with modulation by considering a sinusoidal modulation of form

$$A \cos 2\pi f_s t \quad (11)$$

The amplitude $A < T/2$, where T is the interpulse period, assuming no guard band.

For PPM with uniform sampling and unity pulse amplitude, the spectrum is given by

$$\begin{aligned}
 x(t) = & \frac{\tau}{T} + \frac{2\tau}{T} \sum_{m=1}^{\infty} (\text{sinc } mf_0) J_0(2\pi A m f_0) \cos 2\pi m f_0 t \\
 & + \frac{2\tau}{T} \sum_{n=1}^{\infty} \text{sinc}(n f_s) J_n(2\pi A n f_s) \cos \left(2\pi n f_s t - \frac{n\pi}{2} \right) \\
 & + \frac{2\tau}{T} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \left\{ \text{sinc}(m f_0 + n f_s) J_n[2\pi A(m f_0 + n f_s)] \cos \left[2\pi(m f_0 + n f_s)t - \frac{n\pi}{2} \right] \right. \\
 & \left. + \text{sinc}(n f_s - m f_0) J_n[2\pi A(n f_s - m f_0)] \cos \left[2\pi(n f_s - m f_0)t - \frac{n\pi}{2} \right] \right\} \quad (12)
 \end{aligned}$$

where τ = pulse width

T = pulse period

f_s = modulation frequency

J_n = Bessel function of first kind, n th order

$f_0 = 1/T$

As is apparent, all the harmonics of the pulse-repetition frequency and the modulation frequency are present, as well as all possible sums and differences. The dc level is τ/T , with the harmonics carrying the modulation. The pulse shape effects the line amplitudes as a sinc function, reducing the spectra for higher frequencies.

The spectrum for PWM is similar to that of PPM, and for uniformly sampled trailing-edge sinusoidal modulation is given by

$$\begin{aligned}
 x(t) = & \frac{1}{2} + \frac{1}{\pi T} \sum_{m=1}^{\infty} \frac{1}{m f_0} \cos \left[2\pi m f_0 t + \frac{\pi}{2}(2m-1) \right] \\
 & + \frac{1}{\pi T} \sum_{m=1}^{\infty} \frac{1}{m f_0} J_0(2\pi A m f_0) \cos \left(2\pi m f_0 t - \frac{\pi}{2} \right) \\
 & + \frac{1}{\pi T} \sum_{n=1}^{\infty} \frac{1}{n f_s} J_n(2\pi A n f_s) \cos \left[2\pi n f_s t - (n+1) \frac{\pi}{2} \right] \\
 & + \frac{1}{\pi T} \sum_{m=1}^{\infty} \left\{ \frac{1}{m f_0 + n f_s} J_n[2\pi A(m f_0 + n f_s)] \cos \left[2\pi(m f_0 + n f_s)t - (n+1) \frac{\pi}{2} \right] \right. \\
 & \left. + \frac{1}{n f_s - m f_0} J_n[2\pi A(n f_s - m f_0)] \cos \left[2\pi(n f_s - m f_0)t - (n+1) \frac{\pi}{2} \right] \right\} \quad (13)
 \end{aligned}$$

The same comments apply for PWM as for PPM.

A more compact form is given for PPM and PWM, respectively, as

$$x(t) = \frac{1}{T} \sum_{n=-\infty}^{\infty} (-j)^n J_n[2\pi A(m f_0 + n f_s)] P(m f_0 + n f_s) \exp [j2\pi(m f_0 + n f_s)t] \quad (14)$$

FIGURE 12.3.8 Pulse-time modulation, nonuniform sampling; (a) modulating signal; (b) sawtooth added to modulation; (c) leading-edge modulation; (d) sawtooth added to modulation; (e) double-edge modulation; (f) sawtooth added to modulation; (g) trailing-edge modulation; (h) pulse-position modulation.

where $P(f)$ is the Fourier transform of the pulse shape $p(t)$, and

$$x(t) = \frac{1}{2} + \frac{1}{T} \sum_{\substack{m=-\infty \\ m \neq 0}}^{\infty} j^{2m-1} \frac{e^{j2\pi m f_0 t}}{2\pi m f_0} - \frac{1}{T} \sum_{\substack{m=-\infty \\ n=-\infty \\ |m| + |n| \neq 0}}^{\infty} (-j)^{n+1} \frac{J_n[2\pi A(mf_0 + nf_s)]}{2\pi(mf_0 + nf_s)} \exp [j2\pi(mf_0 + nf_s)t] \quad (15)$$

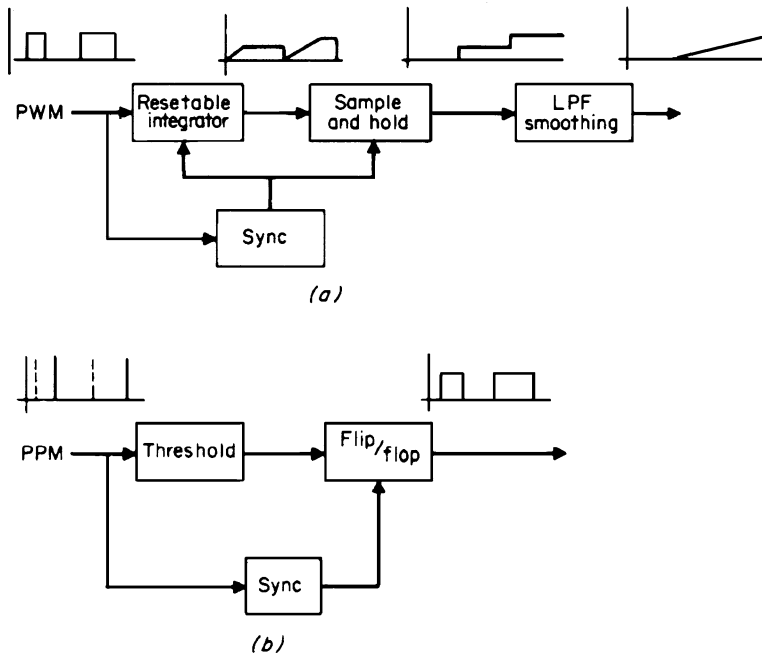

FIGURE 12.3.9 Pulse-time demodulation: (a) PWM demodulation; (b) PPM to PWM for demodulation.

DEMODULATION OF PTM

Demodulation of PWM or PPM can be accomplished by low-pass filtering if the modulation is small compared with the impulse period. However, in general, it is best to demodulate on a pulse-to-pulse basis that usually requires some form of synchronization with the pulses. The distortion introduced by nonuniform sampling cannot be eliminated and will be present in the demodulated waveform. However, if the modulation is small compared with the interpulse period T , the distortion will be minimized.

To demodulate PWM each pulse can be integrated and the maximum value sampled and held and low-pass-filtered, as shown in Fig. 12.3.9a. To sample and reset the integrator, it is necessary to derive sync from the PWM waveform, in this case trailing-edge-modulated.

Generally, PPM is demodulated by conversion to PWM and then demodulated as PWM. Although in some demodulation schemes the actual PWM waveform may not exist as such, the general demodulation scheme is the same. PPM can be converted to PWM by the configuration of Fig. 12.3.9b. The PPM signal is applied to an amplitude threshold, usually termed a *slicer*, that rejects noise except near the pulses. The pulses are applied to a flip-flop synchronized to one particular state by the reference pulse, and it generates the PWM as its output.

PULSE FREQUENCY MODULATION

In PFM the information is contained in the frequency of the pulse train, which is composed of narrow pulses. The highest frequency possible ideally occurs when there is no more interpulse spacing left for finite-width pulses. This frequency, given by $1/\tau$, where τ is the pulse width, will not be achieved in practice, owing to the pulse rise time. The lowest frequency is determined by the modulator, usually a voltage-controlled oscillator

FIGURE 12.3.10 PFM modulation.

(VCO), in which in practice a 100:1 ratio of high to low frequency is easily achievable. Examination of Fig. 12.3.10 indicates why PFM is used mostly for control purposes rather than communications. The wide variation and uncertainty of pulse position do not lend themselves to time multiplexing, which requires the interweaving of channels in time. Since one of the chief motivations for pulse modulation in communication systems is to be able to time-multiplex a number of channels, PFM is not used. On the other hand, PFM is a good choice for on-off control applications, especially where fine control is required. A classic example of PFM control is for the attitude control of near-earth satellites that have on-off gas thrusters where a very close approximation to a linear system response is achievable.

Generation of PFM

Basically, PFM is generated by modulation of a VCO as shown in Fig. 12.3.11a. A constant reference voltage is added to the modulation so that the frequency can swing above and below the reference-determined value. For control applications it is usually required that the frequency follow the magnitude of the modulation, its sign determining which actuators are to be turned on, as shown in Fig. 12.3.11b.

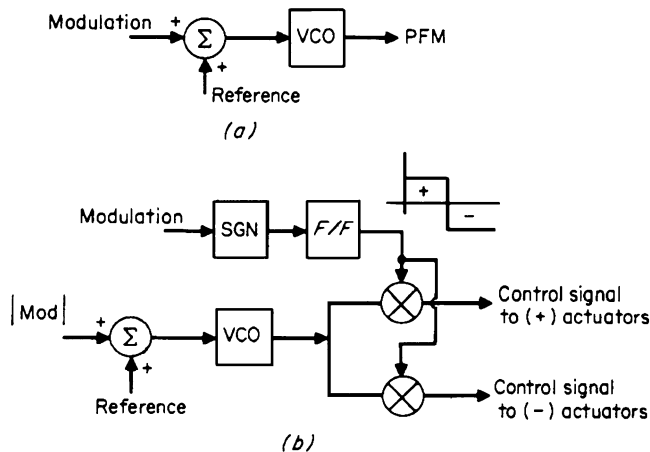

FIGURE 12.3.11 Generation of PFM: (a) PFM modulation; (b) PFM for control.

PULSE-CODE MODULATION

In PCM the signal is encoded into a stream of digits. This differs from the other forms of pulse modulation by requiring that the sample values of the signal be quantized into a number of levels and subsequently coded as a series of pulses for transmission. By selecting enough levels, the quantized signal can be made to approximate closely the original continuous signal at the expense of transmitting more bits per sample. The PCM scheme lends itself readily to time multiplexing of channels and will allow widely different types of signals; however, synchronization is strictly required. This synchronization of the system can be on a single-sample or code-group basis. The synchronizing signal is most likely inserted with a group of samples from different channels, on a frame or subframe basis to conserve space.

The motivation behind modern PCM is that improved implementation techniques of solid-state circuitry allow extremely fast quantization of samples and translation to complex codes with reasonable equipment constraints. PCM is an attractive way to trade bandwidth for signal-to-noise and has the additional advantage of transmission through regenerative repeaters with a signal-to-noise ratio that is substantially independent of the number of repeaters. The only requirement is that the noise, interference, and other disturbances be less than one-half a quantum step at each repeater. Also, systems can be designed that have error-detecting and error-correcting features.

PCM CODING AND DECODING

Coding is the generation of a PCM waveform from an input signal, and decoding is the reverse process. There are many ways to code and many code groups to use: hence standardization is necessary when more than one user is considered. Each sample value of the signal waveform is quantized and represented to sufficient accuracy by an appropriate code character. Each code character is composed of a specified number of code elements. The code elements can be chosen as two-level, or binary; three-level, or ternary; or n -ary. However, general practice is to use binary, since it is not affected as much by interference introduced by the required increased bandwidth. An example of binary coding is shown in Fig. 12.3.12 for 3-bit or eight levels of quantization. Each code group is composed of three pulses, with the pulse trains shown for on-off pulses in Fig. 12.3.12*b* and bipolar pulses in Fig. 12.3.12*c*.

A generic diagram of a complete system is shown in Fig. 12.3.13. The recovered signal is a delayed copy of the input signal degraded by noise because of sources such as sampling, quantization, and interference. For this type of system to be efficient, both sending and receiving terminals must be synchronized. The synchronism is

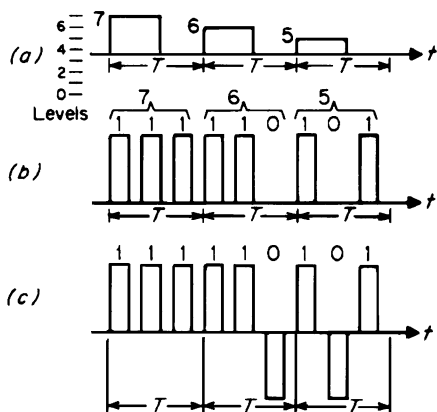

FIGURE 12.3.12 Binary pulse coding: (a) quantized samples; (b) on-off coded pulses; (c) bipolar coded pulses.

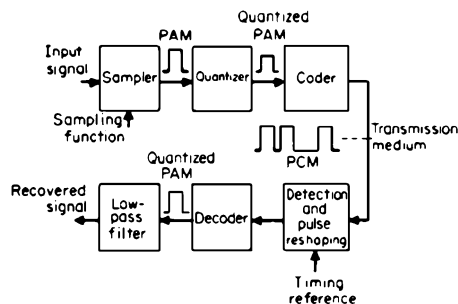

FIGURE 12.3.13 Basic operations of a PCM system.

required to be monitored continuously and be capable of establishing initial synchronism when the system is out of frame. The synchronization is usually accomplished by use of special sync pulses that establish frame, subframe, or word sync.

There are three basic ways to code, namely, feedback and subtraction, pulse counting, and parallel comparison. In *feedback subtraction* the sample value is compared with the most significant code-element value and that value subtracted from the sample value if the element value is less. This process of comparison and subtraction is repeated for each code-element value down to the least significant bit. At each subtraction the appropriate code element or bit is selected to complete the coding. In *pulse counting* a gate is established by using the PWM pulse corresponding to a sample value. Clock pulses are gated using the PWM gate and are connected in a counter. The output of a decoding network attached to the counter is read out as the PCM. *Parallel comparison* is the fastest method since the sampled value is applied to a number of different threshold values. The thresholds are read out as the PCM.

SYSTEM CONSIDERATIONS FOR PCM

Quantization introduces an irremovable error into the system, referred to as *quantization noise*. This kind of noise is characterized by the fact that its magnitude is always less than one-half a quantum step, and it can be treated as uniformly distributed additive noise with zero mean value and rms value equal to $1/\sqrt{12}$ times the total height of a quantum step. When the ratio of signal power to quantization noise power at the quantizer output is used as a measure of fidelity the improvement with quantizer levels is as shown in Fig. 12.3.14 for different kinds of signals.

FIGURE 12.3.14 PCM signal-to-noise improvement with number of quantization levels.

In general, using an n -ary code with m pulses allows transmission of n^m values. For the binary code this reduces the 2^m values which approximate the signal to 1 part in $2^m - 1$ levels. Encoding into pulse and minus pulses, assuming either pulse is equally likely, results in an average power of $A^2/4$, which is half the on-off power of $A^2/2$, where the total pulse amplitude, peak to peak, is A . The channel capacity for a system sampled at the Nyquist rate of $2f_m$ and quantized into s levels is

$$C = 2f_m \log_2 s \quad (\text{bits/s}) \quad (16)$$

or for m pulses of n values each

$$C = mf_m \log_2 n^2 \quad (\text{bits/s}) \quad (17)$$

Since the encoding process squeezes one sample into m pulses, the pulse widths are effectively reduced by $1/m$; thus the transmission bandwidth is increased by a factor of m , or $B = mf_m$.

The maximum possible ideal rate of transmission of binary bits is

$$C = B \log_2 (1 + S/N) \quad (\text{bits/s}) \quad (18)$$

according to Shannon. For a system sampled at the Nyquist rate, quantized to $K\sigma$ per level and using the plus and minus pulses, the channel capacity is

$$C = B \log_2 (1 + 12S/K^2N) \quad (\text{bits/s}) \quad N = \sigma^2 \quad (19)$$

where S is the average power over large time interval and σ is the rms noise voltage at decoder input.

DELTA MODULATION

Delta modulation (DM) is basically a one-digit PCM system where the analog waveform has been encoded in a differential form. In contrast to the use of n digits in PCM, simple DM uses only one digit to indicate the changes in the sample values. This is equivalent to sending an approximation to the signal derivative. At the receiver the pulses are integrated to obtain the original signal. Although DM can be simply implemented in circuitry, it requires a sampling rate much higher than the Nyquist rate of $2f_m$ and a wider bandwidth than a comparable PCM system. Most of the other characteristics of PCM apply to DM.

Delta modulation differs from differential PCM in which the difference in successive signal samples is transmitted. In DM only 1 bit is used to express and transmit the difference. Thus DM transmits the sign of successive slopes.

Coding and Decoding DM

There are a number of coding and decoding variations in DM, such as single-integration, double-integration, mixed-integration, delta-sigma, and high-information DM (HIDM). In addition, companding the signal which is compressing the signal at transmission and expanding it at reception is also used to extend the limited dynamic range. The simple single-integration DM of the coding-decoding scheme is shown in Fig. 12.3.15. In the encoder the modulator produces positive pulses when the sign of the difference signal $\epsilon(t)$ is positive and negative pulses otherwise; and the output pulse train is integrated and compared with the input signal to provide an error signal $\epsilon(t)$, thus closing the encode feedback loop. At the receiver the pulse train is integrated and filtered to produce a delayed approximation to the signal, as shown in Fig. 12.3.16. The actual circuit implementation with operational amplifiers and logic circuits is very simple.

By changing to a double-integration network in the decoder, a smoother replica of the signal is provided. This decoder has the disadvantage, however, of not recognizing changes in the slope of the signal. This gave rise to a scheme to encode differences in slope instead of amplitude, leading to coders with double integration; however, systems of this type are marginally stable and can oscillate under certain conditions. Waveforms of a double-integrating delta coder are shown in Fig. 12.3.17. Single and double integration can be combined to give improved performance while avoiding the stability problem. These mixed systems are often referred to in the literature as *delta modulators* with double integration. A comparison of waveforms is shown in Fig. 12.3.18.

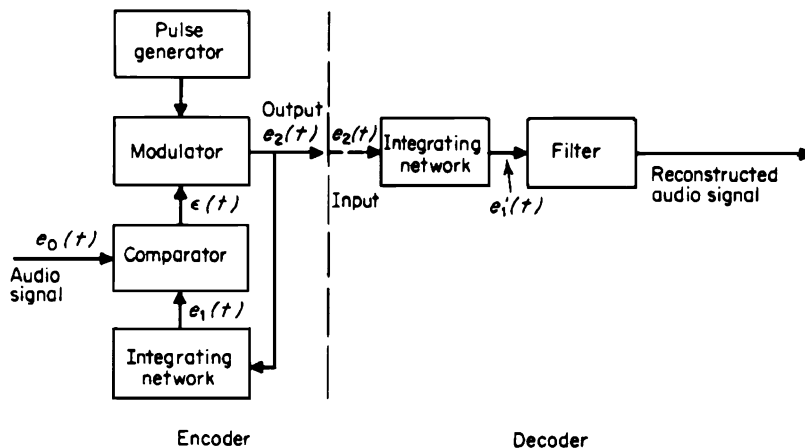

FIGURE 12.3.15 Basic coding-decoding diagram for DM.

FIGURE 12.3.16 Delta-modulation waveforms using single integration.

System Considerations for DM

The synthesized waveform can change only one level each clock pulse; thus DM overloads when the slope of the signal is large. The maximum signal power will depend on the type of signal, since the greatest slope that can be reproduced is the integration of one level in one pulse period. For a sine wave of frequency f , the maximum-amplitude signal is

$$A_{\max} = f_s \sigma / 2\pi \tag{20}$$

where f_s is the sampling frequency and σ is one quantum step.

It has been observed that a DM system will transmit a speech signal without overloading if the amplitude of the signal does not exceed the maximum permissible amplitude of an 800-Hz sine wave. The DM

FIGURE 12.3.17 Waveforms for delta coder with double integration.

FIGURE 12.3.18 Waveforms for various integrating systems.

coder overload characteristic is shown in Fig. 12.3.19 along with the spectrum of a human voice. Notice that they decrease in frequency together, indicating that DM can be used effectively with speech transmission. Generally speaking, transmission of speech is the chief application of DM, although various modifications and improvements are being studied to extend DM to higher frequencies and transmission of the lost dc component.

Among these techniques is delta-sigma modulation, where the signal is integrated and compared with an integrated approximation to form the error signal similar to $\epsilon(t)$ of Fig. 12.3.15. The decoding is accomplished with a low-pass filter and requires no integration.

The signal-to-quantization noise ratio for single-integration DM is given by

$$S/N = 0.2 f_s^{3/2} / f f_0^{1/2} \quad (21)$$

FIGURE 12.3.19 Spectrum of the human voice compared with delta-coder overload level.

FIGURE 12.3.20 Signal-to-noise ratio for DM and PCM.

where f_s = sampling frequency
 f = signal frequency
 f_0 = signal bandwidth

For double or mixed DM

$$S/N = 0.026 f_s^{5/2} / f f_0^{3/2} \tag{22}$$

A comparison of signal-to-noise ratio (SNR) for DM and PCM is shown in Fig. 12.3.20, along with an experimental DM system for voice application. Note that DM at 40 kbits/s sampling rate is equal in performance with a 5-bit PCM system.

Extended-Range DM

A system termed *high-information DM* (HIDM, developed by M. R. Winkler in 1963) falls in the category of companded systems and encodes more information in the binary sequence than normal DM. Basically, the method doubles the size of the quantization step when two identical, consecutive binary values appear and takes one-half of the step after each transition of the binary train. The HIDM system is capable of reproducing the signal with smaller quantization and overload errors. This technique also increases the dynamic range. The response of HIDM compared with that of DM is shown in Fig. 12.3.21.

FIGURE 12.3.21 Step response for a high-information delta modulation.

Implementation of HIDM is similar to that of DM, as shown in Figs. 12.3.22 and 12.3.23, with the difference only in the demodulator. The flip-flop of Fig. 12.3.23 changes state on the polarity of the input pulses. While the impulse generator initializes the experimental generators each pulse time, the flip-flop selects either the positive or negative one. The integrator adds and smooths the exponential waveforms to form the output signal. The scheme has a dynamic range with slope limiting of 11.1 levels per pulse period, which is

much greater than DM and is equivalent to a 7-bit linear-quantized PDM system.

FIGURE 12.3.22 Block diagram of HIDM system.

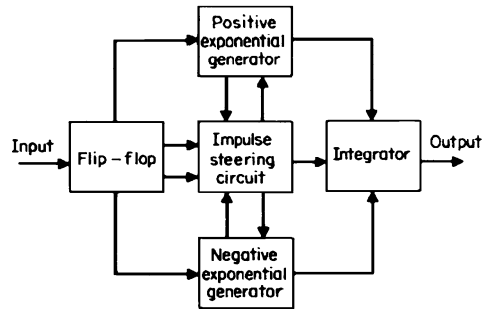

FIGURE 12.3.23 Block diagram of HIDM demodulator.

DIGITAL MODULATION

Digital modulation is concerned with the transmission of a binary pulse train over some medium. The output of, say, a PCM coder would be used to modulate a carrier for transmission. In PCM systems, for instance, the high-quality reproduction of the analog signal is a function only of the probability of correct reception of the pulse sequences. Thus the measure of digital modulation is the probability of error resulting from the digital modulation. The three basic types of digital modulation, amplitude-shift keying (ASK), frequency-shift keying (FSK), and phase-shift (PSK), are treated below.

AMPLITUDE-SHIFT KEYING

In ASK the carrier amplitude is turned on or off, generating the waveform of Fig. 12.3.24 for rectangular pulses. Pulse shaping, such as raised cosine, is sometimes used to conserve bandwidth. The elements of a binary ASK receiver are shown in Fig. 12.3.25. The detection can be either coherent or noncoherent; however, if the added complexity of coherent methods is to be applied, a higher performance can be achieved by using one of the other methods of digital modulation.

FIGURE 12.3.24 ASK modulation.

The error rate of ASK with noncoherent detection is given in Fig. 12.3.26. Note that the curves approach constant values of error for high signal-to-noise ratios.

The probability of error for the coherent detection scheme of Fig. 12.3.25c is shown in Fig. 12.3.27. The coherent-detection operation is equivalent to bandpass filtering of the received signal plus noise, followed by synchronous detection, as shown. At the optimum threshold shown in Fig. 12.3.27, the probability of error of marks and spaces is the same. The curves also tend toward a constant false-alarm rate, as in the noncoherent case.

FREQUENCY-SHIFT KEYING

In FSK the frequency is shifted rapidly between one of two frequencies. Generally, two filters are used in favor of a conventional FM detector to discriminate between the marks and spaces, as illustrated in Fig. 12.3.28. As with ASK, either noncoherent or coherent detection can be used, although in practice coherent detection is not often used. This is because it is just as easy to use PSK with coherent detection and achieve superior performance.

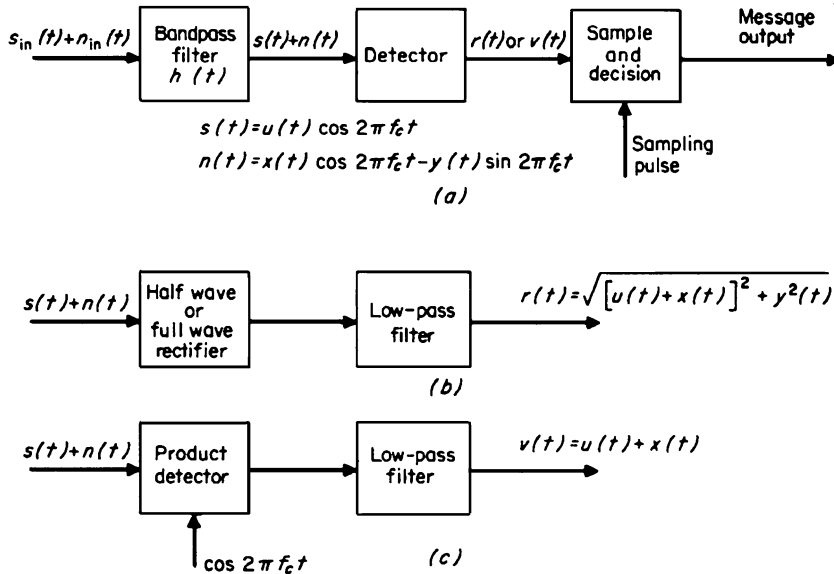

FIGURE 12.3.25 Elements of a binary digital receiver: (a) elements of a simple receiver; (b) noncoherent (envelope) detector; (c) coherent (synchronous) detector.

FIGURE 12.3.26 Error rate for on-off keying, noncoherent detection.

FIGURE 12.3.27 Error-rate for on-off keying, coherent detection.

FIGURE 12.3.28 FSK waveform, rectangular pulses.

In the noncoherent FSK system shown in Fig. 12.3.29a, the largest of the output of the two envelope detectors determines the mark-space decision. Using this system results in the curve for noncoherent FSK in Fig. 12.3.30. Comparison of the noncoherent FSK error with that of the noncoherent ASK results in the conclusion that both achieve an equivalent error rate at the same average SNR at low error rates. FSK requires twice the bandwidth of ASK because of the use of two tones.

In ASK, in order to achieve this performance, it is required to optimize the detection threshold at each SNR. The FSK system threshold is independent of SNR, and thus is preferred in practical systems where fading is encountered.

By synchronous detection of FSK (Fig. 12.3.29b) is meant the availability of an exact replica of each possible transmission at the receiver. The coherent-detection process has the effect of rejecting a portion of the bandpass noise. Coherent FSK involves the same difficulties as phase-shift keying but achieves poorer performance. Also, coherent FSK is significantly advantageous over noncoherent FSK only at high error rates. The probability of error is shown in Fig. 12.3.30.

PHASE-SHIFT KEYING

Phase-shift keying is optimum in the minimum-error-rate sense from a decision-theory point of view. The PSK of a constant-amplitude carrier is shown in Fig. 12.3.31, where the two states are represented by a phase difference of π rad. Thus PSK has the form of a sequence of plus and minus rectangular pulses of a continuous sinusoidal carrier. It can be generated by double-sideband suppressed-carrier modulation by a bipolar rectangular waveform or by direct phase modulation. It is also possible to phase-modulate more complex signals than a sinusoid.

There is no performance difference in binary PSK between the coherent detector and the normal phase detector, both of which are shown in Fig. 12.3.32. Reference to Fig. 12.3.32 shows that there is a 3-dB design advantage for ideal coherent PSK over ideal coherent FSK, with about the same equipment requirements. Practically, PSK can suffer if very much phase error $\Delta\phi$ is present in the system, since the signal is reduced by $\cos \Delta\phi$. This phase error can be introduced by relative drifts in the master oscillators at transmitter or receiver

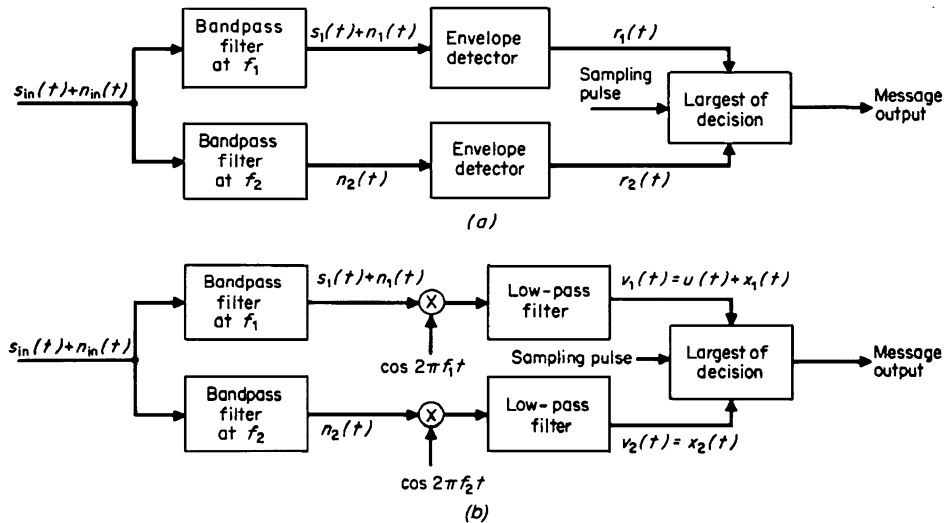

FIGURE 12.3.29 Dual-filter detection of binary FSK signals: (a) noncoherent detection tone f_1 signaled; (b) coherent detection tone f_1 signaled.

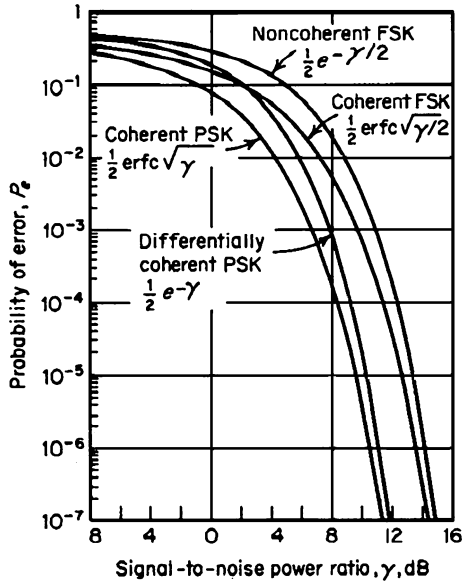

FIGURE 12.3.30 Error rates for several binary systems.

FIGURE 12.3.31 PSK signal, rectangular pulses.

or be a result of phase drift or fluctuation in the propagation path. In most cases this phase error can be compensated at the expense of requiring long-term smoothing.

An alternative to PSK is differential phase-shift keying (DPSK), where it is required that there be enough stability in the oscillators and transmission path to allow negligible phase change from one information pulse to the next. Information is encoded differentially in terms of phase change between two successive pulses. For instance, if the phase remains the same from one pulse to the next (0° phase shift), a mark would be indicated; however, a phase shift of π from the previous pulse to the next would indicate a space. A coherent detector is still required where one input is the current pulse with the other input the previous pulse.

The probability of error is shown in Fig. 12.3.30. At all error rates DPSK requires 3 dB less SNR than noncoherent FSK for the same error rate. Also, at high SNR, DPSK performs almost as well as ideal coherent PSK at the same keying rate and power level.

CHAPTER 12.4

SPREAD-SPECTRUM MODULATION

Myron D. Egtvedt

SPREAD-SIGNAL MODULATION

In a receiver designed exactly for a specified set of possible transmitted waveforms (in the presence of white noise and in the absence of such propagation defects as multipath and dispersion), the performance of a matched filter or cross-correlation detector depends only on the ratio of signal energy to noise power density E/n_o , where E is the received energy in one information symbol and $n_o/2$ is the rf noise density at the receiver input. Since signal bandwidth has no effect on performance in white noise, it is interesting to examine the effect of spreading the signal bandwidth in situations involving jamming, message and traffic-density security, and transmission security. Other applications include random-multiple-access communication channels, multipath propagation analysis, and ranging.

The information-symbol waveform can be characterized by its time-bandwidth (TW) product. Consider a binary system with the information symbol defined as a *bit* (of time duration T), while the fundamental component of the binary waveform is called a *chip*. For this *direct-sequence* system, the ratio (chips per bit) is equal to the TW product. An additional requirement on the symbol waveforms is that their cross-correlation with each other and the noise or extraneous signals be minimal.

Spread-spectrum systems occupy a signal bandwidth much larger (>10) than the information bandwidth, while the conventional systems have a TW of well under 10. FM with a high modulation index might slightly exceed 10 but is not optimally detectable and has a processing gain only above a predetection signal-to-noise threshold.

NOMENCLATURE OF SECURE SYSTEMS

While terminology is not subject to rigorous definition, the following terms apply to the following material:

Security and privacy. Relate to the protection of the signal from an unauthorized receiver. They are differentiated by the sophistication required. Privacy protects against a casual listener with little or no analytical equipment, while security implies an interceptor familiar with the principles and using an analytical approach to learn the *key*. Protection requirements must be defined in terms of the interceptor's applied capability *and* the time value of the message. Various forms of *protection* include:

Crypto security. Protects the information content, generally without increasing the TW product.

Antijamming (AJ) security. Spreads the signal spectrum to provide discrimination against energy-limited interference by using cross-correlation or matched-filter detectors. The interference may be natural (impulse noise), inadvertent (as in amateur radio or aircraft channels), or deliberate (where the jammer may transmit continuous or burst cw, swept cw, narrow-band noise, wide-band noise, or replica or deception waveforms).

Traffic-density security. Involves capability to switch data rates without altering the apparent characteristics of the spread-spectrum waveform. The TW product (processing gain) is varied inversely with the data rates.

Transmission security. Involves spreading the bandwidth so that, beyond some range from the transmitter, the transmitted signal is buried in the natural background noise. The process gain (TW) controls the reduction in detectable range vis-à-vis a “clear” signal.

Use in Radar

It is usual to view radar applications as a variation on communication; that is, the return waveforms are known except with respect to noise, Doppler shift, and delay. Spectrum spreading is applicable to both cw and pulse radars. The major differentiation is in the choice of cross-correlation or matched-filter detector. The TW product is the key performance parameter, but the covariance function properties must frequently be determined to resolve Doppler shifts as well as range delays.

CLASSIFICATION OF SPREAD-SPECTRUM SIGNALS

Spread-spectrum signals can be classified on the basis of their spectral occupancy versus time characteristics, as sketched in Fig. 12.4.1. Direct-sequence (DS) and pseudo-noise (PN) waveforms provide continuous full

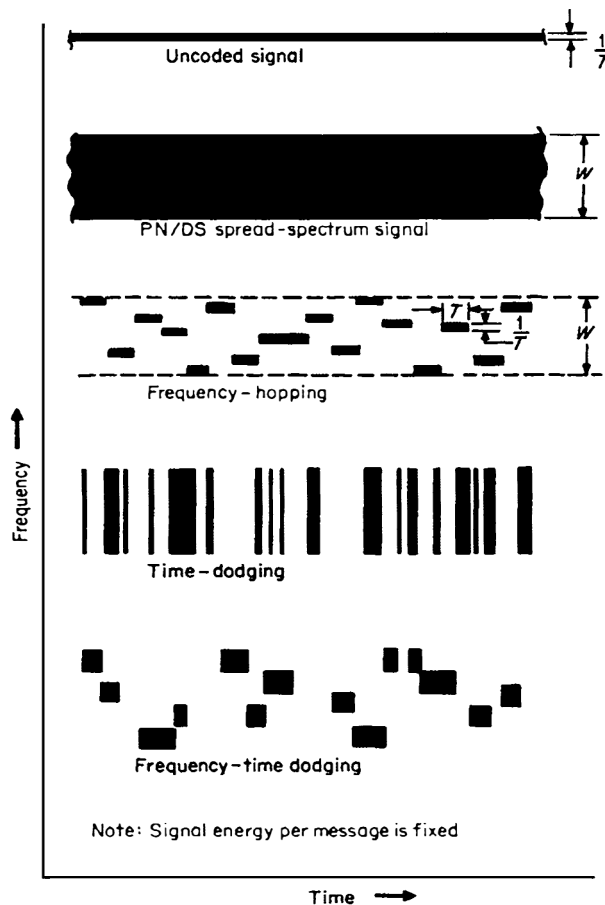

FIGURE 12.4.1 Spectral occupancy vs. time characteristics of spread-spectrum signals.

coverage, while frequency-hopping (FH), time-dodging, and frequency-time dodging (F-TD), fill the frequency-time plane only in a long-term averaging sense.

DS waveforms are pseudo-random digital streams generated by digital techniques and transmitted without significant spectral filtering. If heavy filtering is used, the signal amplitude statistics become quite noiselike, and this is called a *PN waveform*. In either case correlation detection is generally used because the waveform is dimensionally too large to implement a practical matched filter, and the sequence generator is relatively simple and capable of changing codes.

In FH schemes the spectrum is divided into subchannels spaced orthogonally at $1/T$ separations. One or more (e.g., two for FSK) are selected by pseudo-random techniques for each data bit. In time-dodging schemes the signal burst time is controlled by pulse repetition methods, while F-TD combines both selections. In each case a jammer must either jam the total spectrum continuously or accept a much lower effectiveness (approaching $1/TW$). Frequency-hopped signals can be generated using SAW chirp devices.

CORRELATION-DETECTION SYSTEMS

The basic components of a typical DS type of link are shown in Fig. 12.4.2. The data are used to select the appropriate waveform, which is shifted to the desired rf spectrum by suppressed-carrier frequency-conversion

FIGURE 12.4.2 Direct-sequence link for spread-spectrum system.

techniques, and transmitted. At the receiver identical locally generated waveforms multiply with the incoming signal. The stored reference signals are often modulated onto a local oscillator, and the incoming rf may be converted to an intermediate frequency, usually with rf or i.f. limiters.

The mixing detectors are followed by linear integrate-and-dump filters, with a “greatest of” decision at the end of each period. The integrator is either a low-pass or bandpass quenchable narrowband filter. Digital techniques are increasingly being used.

Synchronization is a major design and operational problem. Given a priori knowledge of the transmitted sequences, the receiver must bring its stored reference timing to within $\pm 1/(2W)$ of the width of the received signal and hold it at that value. In a system having a 19-stage *pn* generator, a 1-MHz *pn* clock, and a 1-kHz data rate, the width of the correlation function is $\pm 1/2 \mu\text{s}$, repeating $1/2$ s separations, corresponding to 524.287 clock periods. In the worst case, it would be necessary to inspect each sequence position for 1 ms; that is, 524 s would be required to acquire sync. If oscillator tolerances and/or Doppler lead to frequency uncertainties equal to or greater than the 1-kHz data rate, then parallel receivers or multiple searches are required.

Ways to reduce the sync acquisition time include using jointly available timing references to start the *pn* generators, using shorter sequences for acquisition only; “clear” sync triggers; and paralleling detectors. Titsworth (see bibliography) discusses composite sequences which allow acquiring each component sequentially, searching $N_1 + N_2 + N_3$ delays, while the composite sequence has length $N_1 N_2 N_3$. These methods have advantages for space-vehicle ranging applications but have reduced security to jamming.

Sync tracking is usually performed by measuring the correlation at early and late times, $\pm\tau$, where $\tau \leq 1/W$, as shown in Fig. 12.4.3. Subtracting the two provides

FIGURE 12.4.3 Sync tracking by early-late correlators.

provides a useful time discrimination function, which controls the *pn* clock. The displaced values can be obtained by two tracking-loop correlators or by time-sharing a single unit. “Dithering” the reference signal to the signal correlator can also be used, but with performance compromises.

The tracking function can also be obtained by using the time derivative of one of the inputs

$$\frac{d}{d\tau} \varphi_{xy}(\tau) = \frac{dX(t)}{dt} \cdot Y(t + \tau) \quad (1)$$

A third approach has been to add by mod 2 methods the clock to the transmitted *pn* waveform. The spectral envelope is altered, but very accurate peak tracking can be accomplished by phase locking to the recovered clock.

LIMITERS IN SPREAD-SPECTRUM RECEIVERS

Limiters are frequently used in spread-spectrum receivers to avoid overload saturation effects, such as circuit recovery time, and the incidental phase modulation. In the usual low-input signal-noise range, the limiter tends to normalize the output noise level, which simplifies the decision circuit design. In repeater applications (e.g., satellite), a limiter is desirable to allow the transmitter to be fully modulated regardless of the input-signal

strength. When automatic gain control (AGC) is used, the receiver is highly vulnerable to pulse jamming, while the limiter causes a slight reduction of the instantaneous signal-to-jamming ratio and a proportional reduction of transmitter power allocated to the desired signal.

DELTIC-AIDED SEARCH

The sync search can be accelerated by use of deltic-aided (delay-line time compression) circuits if logic speeds permit. The basic deltic consists of a recirculating shift register (or a delay line) which stores M samples, as

FIGURE 12.4.4 Delay-line time compression (deltic) configuration.

shown in Fig. 12.4.4. The incoming spread-spectrum signal must be sampled at a rate above W ($W = \text{bandwidth}$). During each intersample period the shift register is clocked through $M + 1$ shifts before accepting the next sample. If $M \geq 2W$, a signal period at least equal to the data integration period is stored and is read out at M different delays during each period T , permitting many high-speed correlations against a similarly accelerated (but not time-advancing) reference.

For a serial-deltic and shift-register delay line the clock rate is at least $4TW^2$. Using a deltic with K parallel interleaved delay lines, the internal delay lines are clocked at $4TW^2/K^2$ and the demultiplexed output has a bit rate of $4TW^2/K$, providing only M/K discrete delays. This technique is device-limited to moderate signal bandwidths, primarily in the acoustic range up to about 10 kHz.

WAVEFORMS

The desired properties of a spread-spectrum signal include:

- An autocorrelation function, which is unity at $\tau = 0$ and zero elsewhere
- A zero cross-correlation coefficient with noise and other signals
- A large library of orthogonal waveforms

Maximal-Length Linear Sequences

A widely used class of waveforms is the maximal-length sequence (MLS) generated by a tapped refeed shift register, as shown in Fig. 12.4.5a and as one-tap unit in Fig. 12.4.5b. The mod 2 half adder (\oplus) and EXCLUSIVE-OR logic gate are identical for 1-bit binary signals.

If analog levels $+1$ and -1 are substituted, respectively, for 0 and 1 logic levels, the circuit is observed to function as a 1-bit multiplier.

FIGURE 12.4.5 Maximal-length-sequence (MLS) system.

FIGURE 12.4.6 Spectrum of MLS system.

Pertinent properties of the MLS are as follows. Its length, for an n -stage shift register, is $2^n - 1$ bits. During $2^n - 1$ successive clock pulses, all n -bit binary numbers (except all zeros) will have been present. The autocorrelation function is unity at $\tau = 0$, and at each $2^n - 1$ clock pulses displacement, and $1/(2^n - 1)$ at all other displacements. This assumes that the sequences repeat cyclically, i.e., the last bit is closed onto the first. The autocorrelation function of a single (noncyclic) MLS shows significant time side lobes. Titsworth (see bibliography) has analyzed the self-noise of incomplete integration over p chips, obtaining for MLSs,

$$\sigma^2(t) = (p - t)(p^2 - 1)/p^3t \quad (2)$$

which approaches $1/t$ for the usual case of $p \gg t$. Since $t \approx TW$, the self-noise component is usually negligible.

Another self-noise component is frequently present owing to amplitude and dispersion differences, caused by filtering, propagation effects, and circuit nonlinearities. In addition to intentional clipping, the correlation multiplier is frequently a balanced modulator, which is linear only to the smaller signal, unless deliberately operated in a bilinear range. The power spectrum is shown in Fig. 12.4.6. The envelope has a $(\sin^2 X)/X^2$ shape ($X = \pi\omega/\omega_{\text{clock}}$), while the individual lines are separated by $\omega_{\text{clock}}/(2^n - 1)$.

An upper bound on the number of MLS for an n -stage shift register is given in terms of the Euler ϕ function:

$$N_u = \phi(2^n - 1)/n \leq 2^{(n - \log 2n)} \quad (3)$$

where $\phi(k)$ is the number of positive integers less than k , including 1, which are relatively prime to k .

CHAPTER 12.5

OPTICAL MODULATION AND DEMODULATION

Joseph L. Chovan

MODULATION OF BEAMS OF RADIATION

This discussion of optical modulators is restricted to devices that operate on a directed beam of optical energy to control its intensity, phase, or frequency, according to some time-varying modulating signal. Devices that deflect a light beam or spatially modulate a light beam, such as light-valve projectors, are treated in Chap. 21.

Phase or frequency modulation requires a coherent light source, such as a laser. Optical heterodyning is then used to shift the received signal to lower frequencies, where conventional FM demodulation techniques can be applied.

Intensity modulation can be used on incoherent as well as coherent light sources. However, the properties of some types of intensity modulators are wavelength-dependent. Such modulators are restricted to monochromatic operation but not limited to the extremely narrow laser line widths required for frequency modulation.

Optical modulation depends on either perturbing the optical properties of some material with a modulating signal or mechanical motion to interact with the light beam. Modulation bandwidths of mechanical modulators are limited by the inertia of the moving masses. Optical-index modulators generally have a greater modulation bandwidth but typically require critical and expensive optical materials.

Optical-index modulation can be achieved with electric or magnetic fields or by mechanical stress. Typical modulator configurations are presented below, as in heterodyning, which is often useful in demodulation. Optical modulation can also be achieved using semiconductor junctions.

OPTICAL-INDEX MODULATION: ELECTRIC FIELD MODULATION

Pockels and Kerr Effects

In some materials, an electric field vector \mathbf{E} can produce a displacement vector \mathbf{D} whose direction and magnitude depend on the orientation of the material. Such a material can be completely characterized in terms of three independent dielectric constants associated with three mutually perpendicular natural directions of the material. If all three dielectric constants are equal, the material is *isotropic*. If two are equal and one is not, the material is *uniaxial*. If all three are unequal, the material is *biaxial*.

The optical properties of such a material can be described in terms of the *ellipsoid of wave normals* (Fig. 12.5.1). This is an ellipsoid whose semi-axes are the square roots of the associated dielectric constants. The behavior of any plane monochromatic wave through the medium can be determined from the ellipse formed by the intersection of the ellipsoid with a plane through the center of the ellipsoid and perpendicular to the direction of wave travel. The instantaneous electric field vector \mathbf{E} associated with the optical wave has components

along the two axes of this ellipse. Each of these components travels with a phase velocity that is inversely proportional to the length of the associated ellipse axis.

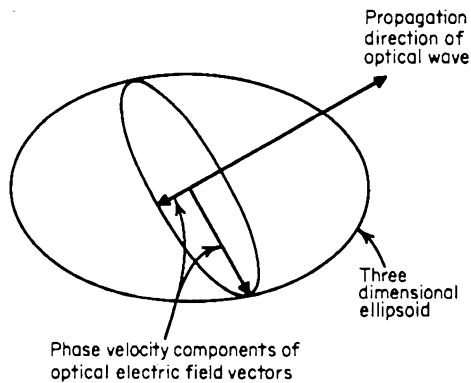

FIGURE 12.5.1 Ellipsoid of wave normals.

Thus there is a differential phase shift between the two orthogonal components of the electric field vector after it has traveled some distance through such a birefringent medium. The two orthogonal components of the vector vary sinusoidally with time but have a phase difference between them, which results in a vector whose magnitude and direction vary to trace out an ellipse once during each optical cycle. Thus linear polarization is converted into elliptical polarization in a birefringent medium.

In some materials it is possible to induce a perturbation in one or more of the ellipsoid axes by applying an external electric field. This is the electrooptical effect. The electrooptical effect is most commonly used in optical modulators presently available. More detailed configurations using these effects are discussed later. Kaminow and Turner (1966), present design considerations for various configurations and tabulates material properties.

Stark Effect

Materials absorb and emit optical energy at frequencies which depend on molecular or atomic resonances characteristic of the material. In some materials an externally applied electric field can perturb these natural resonances. This is known as the Stark effect.

Kaminow and Turner (1966) discusses a modulator for the CO₂ laser on the 3- to 22- μm region. The laser output is passed through an absorption cell whose natural absorption frequency is varied by the modulating signal, using the Stark effect. Since the laser frequency remains fixed, the amount of absorption depends on how closely the absorption cell is tuned to the laser frequency—intensity modulation results.

MAGNETIC FIELD MODULATION

Faraday Effect

Two equal-length vectors circularly rotating at equal rates in opposite directions in space combine to give a nonrotating resultant whose direction in space depends on the relative phase between the counterrotating components. Thus any linearly polarized light wave can be considered to consist of equal right and left circularly polarized waves.

In a material which exhibits the Faraday effect, an externally applied magnetic field causes a difference in the phase velocities of right and left circularly polarized waves traveling along the direction of the applied magnetic field. This results in a rotation of the electric field vector of the optical wave as it travels through the material. The amount of the rotation is controlled by the strength of a modulating current producing the magnetic field.

Zeeman Effect

In some materials the natural resonance frequencies at which the material emits or absorbs optical energy can be perturbed by an externally applied magnetic field. This is known as the Zeeman effect.

Intensity modulation can be achieved using an absorption cell modulated by a magnetizing current in much the same manner as the Stark effect absorption cell is used. The Zeeman effect has also been used to tune the frequency at which the active material in a laser emits.

MECHANICAL-STRESS MODULATION

In some materials the ellipsoid of optical-wave normals can be perturbed by mechanical stress. An acoustic wave traveling through such a medium is a propagating stress wave that produces a propagating wave of perturbation in the optical index.

When a sinusoidal acoustic wave produces a sinusoidal variation in the optical index of a thin isotropic medium, the medium can be considered, at any instant of time, as a simple phase grating. Such a grating diffracts a collimated beam of coherent light into discrete angles whose separation is inversely proportional to the spatial period of the grating.

This situation is analogous to an rf carrier phase-modulated by a sine wave. A series of sidebands results which correspond to the various orders of diffracted light. The amplitude of the m th order is given by an m th-order Bessel function whose argument depends on the peak phase deviation produced by the modulating signal. The phases of the sidebands are the appropriate integral multiples of the phase of the modulating signal.

The m th order of diffracted light has its optical frequency shifted by m times the acoustic frequency. The frequency is increased for positive orders and decreased for negative orders.

Similarly, a thick acoustic grating refracts light mainly at discrete input angles. This condition is known as *Bragg reflection* and is the basis for the *Bragg modulator* (Fig. 12.5.2). In the Bragg modulator, essentially all the incident light can be refracted into the desired order, and the optical frequency is shifted by the appropriate integral multiple of the acoustic frequency.

Figure 12.5.2 shows the geometry of a typical Bragg modulator. The input angles for which Bragg modulation occurs are given by

$$\sin \theta = m\lambda/2\Lambda$$

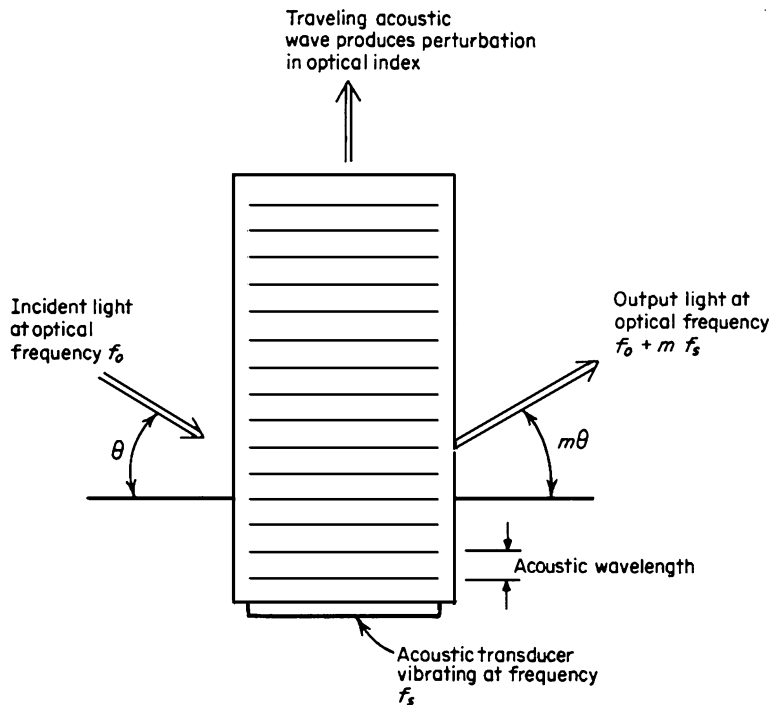

FIGURE 12.5.2 The Bragg modulator.

where θ = angle between propagation of input optical beam and planar acoustic wavefronts
 λ = optical wavelength in medium
 Λ = acoustic wavelength in medium
 $m = \pm 1, \pm 2, \pm 3, \dots$
 $m\theta$ = angle between propagation direction of output optical beam and planar acoustic wavefronts

The ratio of optical to acoustic wavelength is typically quite small, and m is a low integer, so that the angle θ is very small. Critical alignment is thus required between the acoustic wavefronts and the input light beam.

If the modulation bandwidth of the acoustic signal is broad, the acoustic wavelength varies, so that there is a corresponding variation in the angle θ for which Bragg reflection occurs. To overcome this problem, a phased array of acoustic transducers is often used to steer the angle of the acoustic wave as a function of frequency in the desired manner.

A limitation on bandwidth is the acoustic transit time across the optical beam. Since the phase grating in the optical beam at any instant of time must be essentially constant frequency if all the light is to be diffracted at the same angle, the bandwidth is limited so that only small changes can occur in this time interval.

MODULATOR CONFIGURATIONS: INTENSITY MODULATION

Polarization Changes

Linearly polarized light can be passed through a medium exhibiting an electrooptical effect and the output beam passed through another polarizer. The modulating electric field controls the eccentricity and orientation of the elliptical polarization and hence the magnitude of the component in the direction of the output polarizer. Typically, the input linear polarization is oriented to have equal components along the fast and slow axes of the birefringent medium, and the output polarizer is orthogonal to the input polarizer. The modulating field causes a phase differential varying from 0 to π rad. This causes the polarization to change from linear (at 0) to circular (at $\pi/2$) to linear normal to the input polarization (at π). Thus the intensity passing through the output polarizer varies from 0 to 100 percent as the phase differential varies from 0 to π rad.

Figure 12.5.3 shows this typical configuration. The following equations relate the optical intensity transmission of this configuration to the modulation.

$$I_o/I_i = 1/2(1 - \cos \phi)$$

where I_o = output optical intensity
 I_i = input optical intensity
 ϕ = differential phase shift between fast and slow axes.

In the Pockels effect the differential phase shift is linearly related to applied voltage; in the Kerr effect it is related to the voltage squared.

$$\phi = \begin{cases} \pi v/V & \text{Pockels effect} \\ \pi(v/V)^2 & \text{Kerr effect} \end{cases}$$

where v is the modulation voltage and V is the voltage to produce π rad differential phase shift.

Figure 12.5.4 shows the intensity transmission given by the above expression. The most linear part of the modulation curve is at $\phi = \pi/2$. Often a quarter-wave plate is added in series with the electrooptical material to provide this fixed bias at $\pi/2$. A fixed-bias voltage on the electrooptical material can also be used.

This arrangement is probably the most commonly used broadband intensity modulator. Early modulators of this type used a uniaxial Pockels cell with the electric field in the direction of optical propagation. In this arrangement, the induced phase differential is directly proportional to the optical path length, but the electric field is inversely proportional to this path length (at fixed voltage). Thus the phase differential is independent of the path length and depends only on applied voltage. Typical materials require several kilovolts for a differential phase shift of π in the visible-light region.

FIGURE 12.5.3 Electrooptical intensity modulator.

Since the Pockels cell is essentially a capacitor, the energy stored in it is $\frac{1}{2} CV^2$ where C is the capacitance and V is the voltage. This capacitor must be discharged and charged during each modulation cycle. Discharge is typically done through a load resistor, where this energy is dissipated. The high voltages involved mean that the dissipated power at high modulation rates is appreciable.

The high-voltage problem can be overcome by passing light through the medium in a direction normal to the applied electric field. This permits a short distance between the electrodes (so that a high- E field is obtained from a low voltage) and a long optical path in the orthogonal direction (so that the cumulative phase differential is experienced).

Unfortunately, materials available are typically uniaxial, having a high eccentricity in the absence of electric fields. When oriented in a direction that permits the modulating electric field to be orthogonal to the propagation direction, the material has an inherent phase differential which is orders of magnitude greater than that induced by the modulating field. Furthermore, minor temperature variations cause perturbations in this phase differential which are large compared with those caused by modulation.

This difficulty is overcome by cascading two crystals which are carefully oriented so that temperature effects in one are compensated for by temperature effects in the other. The modulation electrodes are then connected so that their effects add. Commercially available electrooptical modulators are of this type.

The Kerr effect is often used in a similar arrangement. Kerr cells containing nitrobenzene are commonly used as high-speed optical shutters.

Polarization rotation produced by the Faraday effect is also used in intensity modulation by passing through an output polarizer in a manner similar to that discussed above. The Faraday effect is more commonly used at wavelengths where materials exhibiting the electrooptical effect are not readily available.

Controlled Absorption

As noted above, the frequency at which a material absorbs energy because of molecular or atomic resonances can be tuned over some small range in materials exhibiting the Stark or Zeeman effect. Laser spectral widths are typically narrow compared with such an absorption line width. Thus the absorption of the narrow laser line can be modulated by tuning the absorption frequency over a range near the laser frequency. Although such modulators have been used, they are not as common as the electrooptical modulators discussed above.

FIGURE 12.5.4 Transmission of electrooptical intensity modulator.

PHASE AND FREQUENCY MODULATION OF BEAMS

Laser-Cavity Modulation

The distance between mirrors in a laser cavity must be an integral number of wavelengths. If this distance is changed by a slight amount, the laser frequency changes to maintain an integral number. The following equation relates the change in cavity length to the change in frequency:

$$\Delta f = \frac{C}{L} \frac{\Delta L}{\lambda}$$

where Δf = change in optical frequency
 ΔL = change in laser-cavity length
 L = laser-cavity length
 λ = optical wavelength of laser output
 C = velocity of light in laser cavity.

In a cavity 1 m long, a change in mirror position of one optical wavelength produces about 300 MHz frequency shift. Thus a laser can be frequency-modulated by moving one of its mirrors with an acoustic transducer, but the mass of the transducer and mirror limit the modulation bandwidths that can be achieved.

An electrooptical cell can be used in a laser optical cavity to provide changes in the optical-path length. The polarization is oriented so that it lies entirely along the axis of the modulated electrooptical material. This produces the same effect as moving the mirror but without the inertial restrictions of the mirror's mass.

Under such conditions, the ultimate modulation bandwidth is limited by the Q of the laser cavity. A light beam undergoes several reflections across the cavity, depending on the Q , before an appreciable portion of it is coupled out. The laser frequency must remain essentially constant during the transit time required for these multiple reflections. This limits the upper modulation frequency.

Modulation of the laser-cavity length produces a conventional FM signal with modulating signal directly proportional to change in laser-cavity length. Demodulation is conveniently accomplished by optical heterodyning to lower rf frequencies where conventional FM demodulation techniques can be used.

EXTERNAL MODULATION

The Bragg modulator (Fig. 12.5.2) is commonly used to modulate the optical frequency. As such it produces a single-sideband suppressed-carrier type of modulation.

Demodulation can be achieved by optical heterodyning to lower rf frequencies, where conventional techniques can be employed for this type of modulation. It is also possible to reinsert the carrier at the transmitter for a frequency reference. This is done by using optical-beam splitters to combine a portion of the unmodulated laser beam with the Bragg modulator output.

Conventional double-sideband amplitude modulation has also been achieved by simultaneously modulating two laser beams (derived from the same source) with a common Bragg modulator to obtain signals shifted up and down. Optical-beam splitters are used to combine both signals with an unmodulated carrier. Conventional power detection demodulates such a signal.

Optical phase modulation is commonly accomplished by passing the laser output beam through an electrooptical material, with the polarization vector oriented along the modulated ellipsoid axis of the material. Demodulation is conveniently achieved by optical heterodyning to rf frequencies, FM demodulation, and integrating to recover the phase modulation in the usual manner.

For low modulation bandwidths, the electrooptical material can be replaced by a mechanically driven mirror. The light reflected from the mirror is phase modulated by the changes in the mirror position. This effect is often described in terms of the Doppler frequency shift, which is directly proportional to the mirror velocity and inversely proportional to the optical wavelength.

TRAVELING-WAVE MODULATION

In the electrooptical and magnetooptical modulators described thus far, it is assumed that the modulating signal is essentially constant during the optical transit time through the material. This sets a basic limit on the highest modulating frequency that can be used in a lumped modulator.

This problem is overcome in a traveling-wave modulator. The optical wave and the modulation signal propagate with equal phase velocities through the modulating medium, allowing the modulating fields to act on the optical wave over a long path, regardless of how rapidly the modulating fields are changing. The degree to which the two phase velocities can be matched determines the maximum interaction length possible.

OPTICAL HETERODYNING

Two collimated optical beams, derived from the same laser source and illuminating a common surface, produce straight-line interference fringes. The distance between fringes is inversely proportional to the angle between the beams. Shifting the phase of one of the beams results in a translation of the interference pattern, such that a 2π -rad phase shift translates the pattern by a complete cycle. An optical detector having a sensing area small compared with the fringe spacing has a sinusoidal output as the sinusoidal intensity of the interference pattern translates across the detector.

A frequency difference between the two optical beams produces a phase difference between the beams that changes at a constant rate with time. This causes the fringe pattern to translate across the detector at a constant rate, producing an output at the difference frequency. This technique is known as *optical heterodyning* in which one of the beams is the signal beam, the other the local oscillator.

The effect of the optical alignment between the beams is evident. As the angle between the two collimated beams is reduced, the spacing between the interference fringes increases, until the spacing becomes large compared with the overall beam size. This permits a large detector which uses all the light in the beam. If converging or diverging beams are used instead of collimated beams, the situation is similar, except that the interference fringes are curved instead of straight. Making the image of the local-oscillator point coincide with the image of the signal-beam point causes the desired infinite fringe spacing.

Optical heterodyning provides a convenient solution to several possible problems in optical demodulation. In systems where a technique other than simple amplitude modulation has been used (e.g., single-sideband, frequency, or phase modulation), optical heterodyning permits shifting to frequencies where established demodulation techniques are readily available.

In systems where background radiation, such as from the sun, is a problem, heterodyning permits shifting to lower frequencies, so that filtering to the modulation bandwidth removes most of the broadband background radiation. The required phase front alignment also eliminates background radiation from spatial positions other than that of the signal source.

Many systems are limited by thermal noise in the detector and/or front-end amplifier. Cooled detectors and elaborate amplifiers are often used to reduce this noise to the point that photon noise in the signal itself dominates. This limit also can be achieved in an optical heterodyne system with noncooled detector and normal amplifiers by increasing the local-oscillator power to the point where photon noise in the local oscillator is the dominant noise source. Under these conditions, the signal-to-noise power ratio is given by the following equation:

$$S/N = \eta\lambda P/2hBC$$

where S/N = signal-power-noise-power ratio

η = quantum efficiency of photo detector

λ = optical wavelength

h = Planck's constant

C = velocity of light

B = bandwidth over which S/N is evaluated

P = optical signal power received by detector

CHAPTER 12.6

FREQUENCY CONVERTERS AND DETECTORS

Glenn B. Gawler

GENERAL CONSIDERATIONS OF FREQUENCY CONVERTERS

A frequency converter usually consists of an oscillator (called a *local oscillator* or LO) and a device used as a mixer. The mixing device is either nonlinear or its transfer parameter can be made to vary in synchronism with the local oscillator. A signal voltage with information in a frequency band centered at frequency f_s enters the frequency converter, and the information is reproduced in the intermediate-frequency (i.f.) voltage leaving the converter. If the local-oscillator frequency is designated f_{LO} , the i.f. voltage information is centered about a frequency $f_{if} = f_{LO} \pm f_s$. The situation is shown pictorially in Fig. 12.6.1. Characteristics of interest for design in systems using frequency converters are gain, noise figure, image rejection, spurious responses, intermodulation and cross-modulation capability, desensitization, area local-oscillator to rf, and to i.f. isolation. These characteristics will be discussed at length in the descriptions of different types of frequency-converter mixers and their uses in various systems. First, explanations are in order for the above terms.

Frequency-Converter Gain. The available power gain of a frequency converter is the ratio of power available from the i.f. port to the power available at the signal port. Similar definitions apply for transducer gain and power gain.

Noise Figure of Frequency Converter. The noise factor is the ratio of noise power available at the i.f. port to the noise power available at the i.f. port because of the source alone at the signal port.

Image Rejection. For difference mixing $f_{if} = f_{LO} - f_s$ and the image is $2f_{LO} - f_s$. For sum mixing $f_{if} = f_{LO} + f_s$, and the image is $2f_{LO} + f_s$. An undesired signal at the difference mixing frequency $2f_{LO} - f_s$ results in energy at the i.f. port. This condition is called *image response* and attenuation of the image response is image rejection, measured in decibels.

Spurious Responses. Spurious external signals reach the mixer and result in generation of undesired frequencies that may fall into the intermediate-frequency band. The condition for an interference in the i.f. band is

$$mf'_s \pm nf_1 = \pm f_{if}$$

where m and n are integers and f'_s represents spurious frequencies at the signal port of the mixer.

Example. There is a strong local station in the broadcast band at 810 kHz and a weak distant station at 580 kHz. A receiver is tuned to the distant station, and a whistle, or beat, at 5 kHz is heard on the receiver (refer to Fig. 12.6.2).

FIGURE 12.6.1 Frequency-converter terminals and spectrum.

An analysis shows that the second harmonic of the local oscillator interacts with the second harmonic of the 810-kHz signal to produce a mixer output at 450 kHz in the i.f. band of the receiver:

$$580 + 455 = 1035 \text{ kHz} = \text{LO frequency}$$

$$2 \times 1035 - 2 \times 810 = 450 \text{ kHz} = \text{i.f. interference frequency}$$

The interference at 450 kHz then mixes with the 455-kHz desired signal in the second detector to produce the 5-kHz whistle. Notice that if the receiver is slightly detuned upward by 5 kHz, the whistle will zero-beat. Further upward detuning will create a whistle of increasing frequency.

INTERMODULATION

Intermodulation is particularly troublesome because a pair of strong signals that pass through a receiver preselector can cause interference in the i.f. passband, even though the strong signals themselves do not enter the passband.

Consider two undesired signals at 97 MHz passing through a superheterodyne receiver tuned to 100 MHz. Suppose, further, that the i.f. is so selective that a perfect mixer allows no response to the signals (see Fig. 12.6.3). Third-order intermodulation in a physically realizable mixer will result in interfering signals at the i.f. frequency and 9 MHz away (corresponding to 100 and 91 MHz rf frequencies, respectively). Fifth-order intermodulation will produce interferences 3 and 12 MHz from the intermediate frequency (103 and 88 MHz rf frequencies).

There is a formula for variation of intermodulation products that is quite useful. Figure 12.6.4 shows typical variations of desired output and intermodulation with input power level. Desired output increases 1 dB for each 1-dB increase of input level, whereas third-order intermodulation increases 3 dB for each 1-dB increase of input level. At some point the mixer saturates and the above behavior no longer obtains. Since the interference of the intermodulation product is primarily of interest near the system sensitivity limit (usually somewhere below -20 dBm), the 1 dB per 1 dB and 3 dB per 1 dB patterns hold. The formula can be written

$$P_{21} = 2P_N + P_F - 2P_{/21}$$

where P_{21} = level of intermodulation product (dBm)
 P_N = power level of interfering signal nearest P_{21}
 P_F = power interfering signal farthest from P_{21}

FIGURE 12.6.2 Spurious response in AM receiver.

FIGURE 12.6.3 Spurious-response analysis.

P_{i21} is the third-order intercept power. For proper orientation, $f_N = 97$ MHz, $f_F = 94$ MHz, $f_{21} = 100$ MHz in Fig. 12.6.5. The intercept power is a function of frequency. It can be used for comparisons between mixer designs and for determining allowable preselector gain in a receiving system.

FREQUENCY-CONVERTER ISOLATION

There are two paths in a mixer where isolation is important. The so-called *balanced mixers* give some isolation of the local-oscillator energy at the rf port. This keeps the superheterodyne receiver from radiating excessively. The doubly balanced mixers also give rf-to-i.f. isolation. This keeps interference in the receiver rf environment from penetrating the mixer directly at the i.f. frequency. Less important, but still significant, is the LO-to-i.f. isolation. This keeps LO energy from overloading the i.f. amplifier. Also, in multiple-conversion receivers low LO-to-i.f. leakage minimizes spurious responses in subsequent frequency converters.

Desensitization

A strong signal in the rf bandwidth, not directly converted to i.f., drives the operating point of the mixer into a nonlinear region. The mixer gain is then either decreased or increased. In radar, the characteristic of concern is pulse desensitization. In television receivers the characteristic is called cross-modulation. Here the strong

FIGURE 12.6.4 Third-order intermodulation intercept power.

FIGURE 12.6.5 Intermodulation in a superheterodyne receiver.

undesired adjacent TV station modulates the mixer gain, especially during synchronization intervals, where the signal is strongest. The result appears in the desired signal as a contrast modulation of picture with the pattern of the undesired sync periods, corresponding to mixer gain *pumping* by the strong adjacent channel.

SCHOTTKY DIODE MIXERS

The Schottky barrier diode is an improvement over the point-contact diode. The Schottky diode has two features that make it very valuable in high-frequency mixers: (1) it has low series resistance and virtually no charge storage, which results in low conversion loss; (2) it has noise-temperature ratio very close to unity. The noise factor of a mixed-i.f. amplifier cascade is

$$F = L_M(t_D + F_{if} - 1)$$

where L_M = mixer loss
 t_D = diode noise-temperature ratio
 F_{if} = i.f. noise factor

Since t_D is near unity and L_M is in the range of 2.4 to 6 dB, overall noise factor is quite good, with F_{if} near 1.5 dB in well-designed systems.

The complete conversion matrix involves LO harmonic sums and differences, as well as signal, i.f., and image frequencies. They restrict their treatment of crystal rectifiers to the third-order matrix

$$\begin{bmatrix} I_1 \\ I_2 \\ I_3^* \end{bmatrix} = [Y] \begin{bmatrix} V_1 \\ V_2 \\ V_3^* \end{bmatrix} \quad Y = \begin{bmatrix} y_{11} & y_{12} & y_{13} \\ y_{21} & y_{22} & y_{23} \\ y_{31} & y_{32} & y_{33} \end{bmatrix}$$

where 1 denotes signal port; 2, i.f. port; and 3, image port.

With point-contact diodes, the series resistance is so large that not much improvement is realized by terminating the image frequency, and terminating the other frequencies involved is less significant.

With the advent of Schottky barrier diodes, which have much smaller series resistances, proper termination of pertinent frequencies, other than signal and i.f. frequencies, results in a minimizing of conversion loss. This, in turn, leads to a minimizing of noise figure.

Several different configurations are used with Schottky mixers. Figure 12.6.6 shows an image-rejection mixer, which is used for low i.f. frequency systems where rf filtering of the image is impractical.

There is a general rule of thumb for obtaining good intermodulation, cross-modulation, and desensitizable performance in mixers. It has been found experimentally that pumping a mixer harder extends its range of

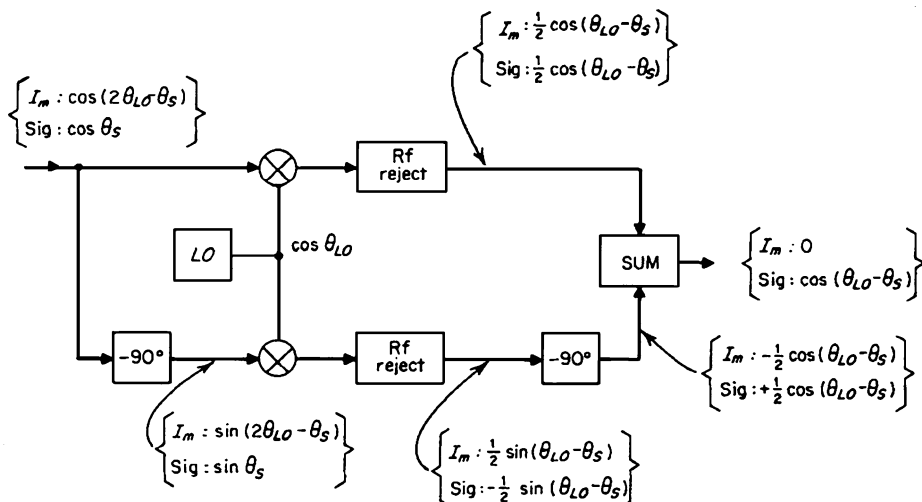

FIGURE 12.6.6 Mixer designed for image rejection.

linear operation. The point-contact diode had a rapidly increasing noise figure with high LO power level and could easily burn out with too much power. The Schottky diode, however, degrades in noise figure relatively slowly with increasing LO power, and it can tolerate quite large amounts of power without burnout. There is a limit to this process of increasing LO power: the Schottky diode series resistance begins to appear nonlinear. This leads to another rule of thumb: pump the diode between two linear regions, and spend as little time as possible in the transition region. Application of these two rules leads to the doubly balanced Schottky mixer. The reason for this is that one pair of diodes conducts hard and holds the other pair off. Hence large LO power is required, and one diode pair is conducting well into its linear region while the other diode pair is held in its linear nonconducting region.

DOUBLY BALANCED MIXERS

The diode doubly balanced mixer, or ring modulator, is shown in Fig. 12.6.7. The doubly balanced mixer is used up to and beyond 1 GHz in this configuration. The noise-figure optimization process previously discussed applies to this type of mixer. It exhibits good LO-to-rf and LO-to-i.f. isolation, as shown in Fig. 12.6.8. Typical published data on mixers quote 30 dB rf-to-i.f. isolation below 50 MHz and 20 dB isolation from 50 to 500 MHz.

Another feature of balanced mixers is their LO noise-suppression capability. Modern mixers using Schottky diodes in a ring modulator provide somewhat better LO noise suppression. The ring modulator provides suppression only to AM LO noise, not FM noise.

FIGURE 12.6.7 Doubly balanced mixer.

PARAMETRIC CONVERTERS

Parametric converters make use of time-varying energy-storage elements. Their operation is in many ways similar to that of parametric amplifiers (see Section 11). The difference is that output and input frequencies are the same in parametric amplifiers, while the frequencies differ in parametric converters. The device most widely

FIGURE 12.6.8 Generation of 920-kHz beat in TV tuners.

used for microwave parametric converters today is the varactor diode, which has a voltage-dependent junction capacitance. The time variation of varactor capacitance is provided by a local oscillator, usually called the *pump*.

Attainable gain of a parametric converter is limited by the ratio of output to input frequencies. Therefore up conversion is generally used to achieve some gain. Because lower-sideband up conversion results in negative resistance, the upper sideband is generally used. This results in simpler circuit elements to achieve stability.

There is a distinct advantage to up conversion; image rejection is easily achievable by a simple low-pass filter.

TRANSISTOR MIXERS

One of the original concerns in transistor mixers was their noise performance. The base spreading resistance r_b is very important in noise performance. The reason is that mixing occurs across the base-emitter junction; then the i.f. signal is amplified by transistor action; however, r_b is a lossy part of the termination at the i.f. signal, image, and all other frequencies present in the mixing process. Hence r_b dissipates some energy at each of the frequencies present, and all these contributions add to appear as a loss in the signal-to-i.f. conversion. This loss, in turn, degrades noise figure.

Manufacturers do not promote transistors used as mixers, probably because of their intermodulation and spurious-response performance. Estimates of intermodulation intercept power go as high as +12 dBm, while one measurement gave +5 dBm at 200 MHz; however, a cascade transistor mixer is used in a commercial VHF television tuner.

MEASUREMENT OF SPURIOUS RESPONSES

Figure 12.6.9 shows an arrangement for measuring mixer spurious responses. The filter following the signal generator implies that generator harmonics are down, say 40 dB. This ensures that frequency-multiplying action is owing only to the mixer under test. The attenuator following the mixer can be used to be sure that a spurious response of the receiver is not being measured. That is, a 6-dB change in attenuator setting should be accompanied by a 6-dB change on the indicator.

Generally the most convenient way of performing the spurious-response test is first to obtain an indication of the indicator. Then tune the signal generator to the desired frequency and record the level required to obtain the original response. This should be repeated at one or two more levels of the undesired signal to ensure that the spur follows the appropriate laws. For example, if the response is fourth-order (four times the signal frequency $\pm n$

FIGURE 12.6.9 Test equipment for measuring mixer spurious responses.

times the LO frequency), the measured value should change 4 dB for a 1-dB change in undesired frequency level. The order of the spurious response can be determined by either of two methods. The first method is simply by knowing with some accuracy the undesired signal frequency and the LO frequency and then determining the harmonic numbers required to obtain the i.f. frequency. The other technique entails observing the incremental changes of the i.f. frequency with known changes in the undesired signal frequency and the LO signal frequency.

This completes the measurement for one spurious response. The procedure should be repeated for each of the spurious responses to be measured.

The intermodulation test setup is shown in Fig. 12.6.10. In general, a diplexer is preferable to a directional coupler for keeping generator 1 signal out of generator 2. This is necessary so that the measurement is not limited by the test setup. A good idea would be to establish that no third-order intermodulation occurs because of the setup alone. To do this, initially remove the mixer-LO circuit. Then tune generator 1 off from center frequency to about 10 or 20 dB down on the skirt of the receiver preselector. Tune generator 2 twice this amount from the receiver center frequency. Set generator levels equal and at some initial value, say -30 dBm. Then vary one generator frequency slightly and look for a response peak on the indicator. If none is noticed, increase the generator level to -20 dBm and repeat the procedure. Usually, except for very good receivers, the third-order intermodulation response is found. Vary the attenuator by 6 dB, and look for a 6-dB variation in the indicator reading. If the latter is not 6 dB but 18 dB, intermodulation is occurring in the receiver. If the indicator variation is between 6 and 18 dB, intermodulation is occurring in the circuitry preceding the attenuator and in the receiver. To obtain trustworthy measurements with a mixer in the test position, the indicator should read at least 20 dB greater than without the mixer, while the generator levels should be lower by mixer gain +10 dB than they were without the mixer. This ensures that the test setup is contributing an insignificant amount to the intermodulation measurement.

With the mixer in test position and the above conditions satisfied, obtain a reading on the indicator and let the power referred to the mixer input be denoted by P (dBm). Turn down both generator levels, and retune generator 1 to center frequency. Adjust generator 1 level to obtain the previous indicator reading. This essentially calibrates the measurement setup. Denote generator 1 level referred to the mixer input by P_{21} dBm. Then the intermodulation intercept power is given by

$$P_{/21} \text{ dBm} = (3P - P_{21})/2$$

The subscripts on intercept power $P_{/21}$ refer to second order for the near frequency and first order for the far frequency (see Fig. 12.6.4).

FIGURE 12.6.10 Test equivalent for measurement of mixer intermodulation.

The procedure should be repeated for one or two lower values of P . The corresponding values of $P_{/21}$ should asymptotically approach a constant value. The constant value of $P_{/21}$ so obtained is then a valid number for predicting behavior of the mixer near its sensitivity limit.

DETECTORS (FREQUENCY DECONVERTERS)

Detectors have become more complex and versatile since the advent of integrated circuits. Up to the mid-1950s most radio receivers used the standard single-diode envelope detector for AM and a Foster-Seeley discriminator or ratio detector for FM. Today, integrated circuits are available with i.f. amplifier, detector, and audio-amplifier functions in a single package.

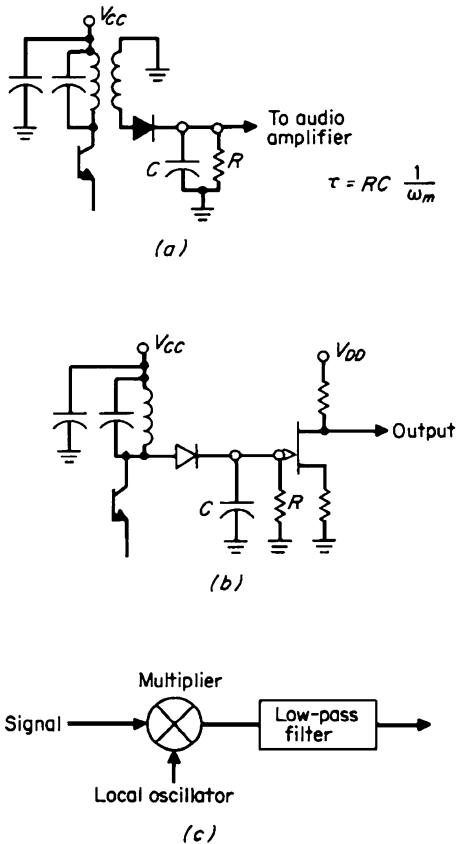

FIGURE 12.6.11 AM detectors: (a) AM envelope detector; (b) peak detector; (c) product detector.

Figure 12.6.11 shows three conventional AM detectors. In Fig. 12.6.11a an envelope detector is shown. In order for the detected output to follow the modulation envelope faithfully, the RC time constant must be chosen so that $RC < 1/\omega_m$, where ω_m is the maximum angular modulation frequency in the envelope. Figure 12.6.11b shows a peak detector. Here the RC time constant is chosen large, so that C stays charged to the peak voltage. Usually, the time constant depends on the application. In a television field-strength meter, the charge on C should not decay significantly between horizontal sync pulses separated by $62.5 \mu s$. Hence a time constant of 1 to 6 ms should suffice. On the other hand, an AGC detector for single-sideband use should have a time constant of 1 s or longer.

Figure 12.6.11c shows a product (synchronous) detector. This type of detector has been used since the advent of single-sideband transmission. The product detector multiplies the signal with the LO, or beat frequency oscillator (BFO), to produce outputs at sum and difference frequencies. Then the low-pass filter passes only the difference frequency. The result is a clean demodulation with a minimum of distortion for single-sideband signals.

The two classical FM detectors widely used up to the present are the Foster-Seeley discriminator and the ratio detector. Figure 12.6.12 shows the Foster-Seeley discriminator and its phasor diagrams. The circuit consists of a double-tuned transformer, with primary and secondary voltages series-connected. The diode connected to point A detects the peak value of $V_1 + V_2/2$, and the diode at B detects the peak value of $V_1 - V_2/2$. The audio output is then the difference between the detected voltages. When the incoming frequency is in the center of the passband, V_2 is in quadrature with V_1 , the detected voltages are equal, and audio output is zero. Below the center frequency the detected voltage from B decreases, while that from A increases, and the audio output is positive. By similar reasoning, an incoming frequency above band center produces a negative audio output. Optimum linearity requires that $KQ = 2$, where K is the transformer coupling and Q is the primary and secondary quality factor.

Figure 12.6.12c shows a ratio detector, which has an advantage over the Foster-Seeley discriminator in being relatively insensitive to AM. The ratio detector uses a tertiary winding (winding 3) instead of the primary voltage, and one diode is reversed; however, the phasor diagrams also apply to the ratio detector. The AM

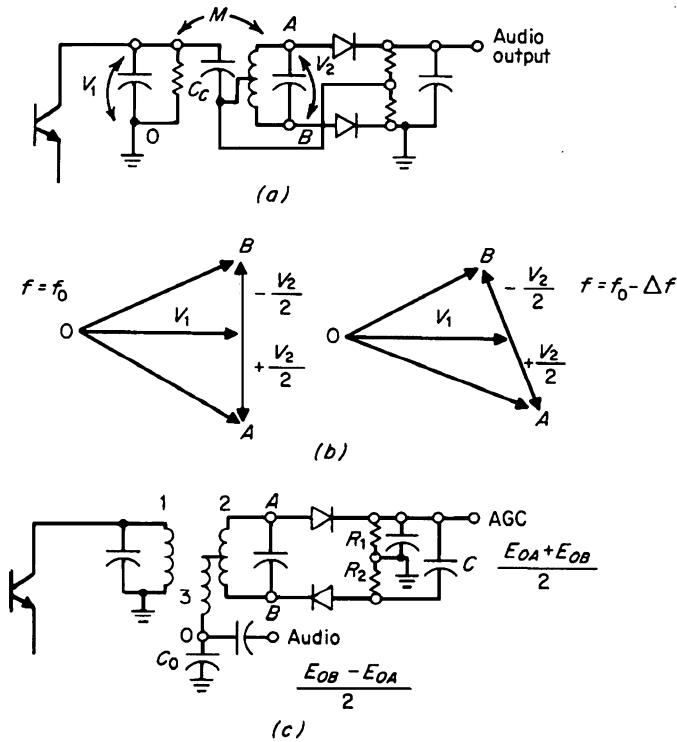

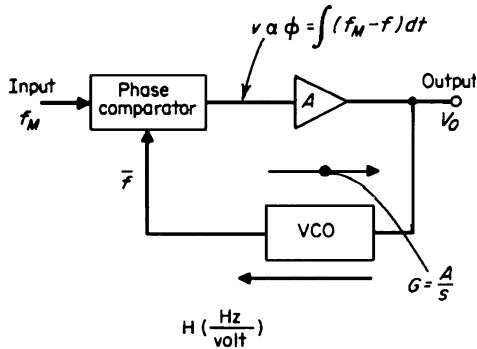

FIGURE 12.6.12 FM detectors: (a) Foster-Seeley FM discriminator; (b) phasor diagrams; (c) ratio detector.

rejection feature results from choosing the $(R_1 + R_2)C$ time constant large compared with the lowest frequency to be faithfully reproduced. The voltages E_{OA} and E_{OB} represent the detected values of rf voltages across OA and OB , respectively. With the large time constant above, voltage on C changes slowly with AM and the conduction angles of the diodes vary, loading the tuned circuit so as to keep the rf amplitudes relatively constant.

$$\frac{V_0}{f_M} = \frac{G}{1+GH} = \frac{1}{H} \frac{1}{1 + \frac{1}{GH}}$$

FIGURE 12.6.13 FM detector using phase-locked loop.

Capacitor C_0 is chosen to be an rf short circuit but small enough to follow the required audio variations. In the AM rejection process, AF voltage on C_0 does not follow the AM because the charge put on by one diode is removed by the other diode. With FM variations on the rf, voltage on C_0 changes to reach the condition, again, that charge put on C_0 by one diode is removed by the other diode. The ratio detector is generally used with little or no previous limiting of the rf, while the Foster-Seeley discriminator must be preceded by limiters to provide AM rejection.

With the recent trend toward integrated circuits, there has been increased interest in using phase-locked loops and product detectors. These techniques have been selected because they do not require inductors, which are not readily available in integrated form. Figure 12.6.13 shows a phase-locked loop (PLL) as an

FM detector. The phase comparator merely provides a dc voltage proportional to the difference in phase between signals represented by f_M and f . Initially, f and f_M are unequal, but because of high loop gain, $GH \gg 1$, f and f_M quickly become locked and stay locked. Then as f_M varies, f follows exactly. But because of the high loop gain, response is essentially $1/H$, which is the voltage-controlled oscillator (VCO) characteristic. Hence the PLL serves as an FM detector.

AM product detectors also make use of the PLL to provide a carrier locked to the incoming signal carrier. The output of the VCO is used to drive the product detector. Probably one of the most stringent uses of the product detector is in an FM stereo decoder. The *left minus right* (L – R) subcarrier is located at 38 kHz with sidebands from 23 to 53 kHz. There may also be an SCA signal centered about 67 kHz which is used to provide a music service for restaurants and commercial offices. The L – R product detector is driven by a 38-kHz VCO, the output of which also goes to a 2-to-1 counter. The counter output is compared with the 19-kHz pilot signal in a phase comparator, and the phase-comparator output then controls the VCO. Because of the relatively small pilot signal and the presence of L + R, L – R, and SCA information, the requirement for phase locking is stringent.

SECTION 13

POWER ELECTRONICS

Power electronics deals with the application of electronic devices and associated components to the conversion, control, and conditioning of electric power. The primary characteristics of electric power, which are subject to control, include its basic form (ac or dc), its effective voltage or current (including the limiting cases of initiation and interruption of conduction), and its frequency and power factor (if ac). The control of electric power is a means for achieving control or regulation of one or more nonelectrical parameters, e.g., the speed of a motor, the temperature of an oven, the rate of an electrochemical process, or the intensity of lighting.

Aside from the obvious difference in function, power-electronics technology differs markedly from the technology of low-level electronics for information processing in that much greater emphasis is required on achieving high-power efficiency. Few low-level circuits exceed a power efficiency of 15 percent, but few power circuits can tolerate a power efficiency less than 85 percent. High efficiency is vital, first, because of the economic and environmental value of wasted power and, second, because of the cost of dissipating the heat it generates. This high efficiency cannot be achieved by simply scaling up low-level circuits; a different approach must be adopted.

This different approach is attained by using electronic devices as switches, e.g., approximating ideal closed (no voltage drop) or open (no current flow) switches. This differs from low-level digital switching circuits in that digital systems are primarily designed to deliver two distinct small voltage levels while conducting small currents (ideally zero). Power electronic circuits, though, must have the capability of delivering large currents and be able to withstand large voltages. Power can be controlled and modified by controlling the timing of repetitive switch action. Because of wear and limited switching speed, mechanical switches are ordinarily not suitable, but electronic switches have made this approach feasible into the multigigawatt power region while maintaining high-power efficiencies over wide ranges of control. However, the inherent nonlinearity of the switching action leads to the generation of transients and spurious frequencies that must be considered in the design process.

Reliability of the power electronics circuits is just as important as efficiency. Modern power converter and control circuits must be extremely robust, with MTBF (mean time between failure) for typical systems in the order of 1,000,000 h of operation.

Power electronic circuits are often divided into categories depending on their intended function. Converter circuits that change ac into dc are called rectifiers, circuits that change the dc operating voltage or current are called dc-to-dc converters, circuits that convert dc into ac power are called inverters, and those that change the amplitude and frequency of the ac voltage and/or current without using an intermediate dc stage are ac-to-ac converters (also called cycloconverters).

Rectifiers are used in many power electronics applications because of the widespread availability of ac power sources, and rectification is often a first step in the power conditioning scheme. Rectifiers are used in very low voltage systems (e.g., 3 V logic circuits) as well as very high voltage applications of commercial utilities. The control and circuit topology can vary according to the application requirements.

Dc-dc converters have many implementations that depend on the intended application, and can make use of different types of input power sources. Often, ac power is rectified and filtered to supply the requisite input dc levels. An inverter section is then used to transform the dc power to high frequency ac voltage or current, which a transformer then steps up or down. The new ac from the transformer secondary is then rectified and filtered to provide the desired output dc level. Other dc-dc converters step voltage up or down without the intervening transformer.

Inverters convert dc into ac power. Many applications require the production of three-phase power waveforms for speed control of large motors used in industry. The reconstruction of single-frequency, near-sinusoidal

voltage, or current waveforms requires precisely controlled switching circuits. The exact mode and timing of the switching action in the associated power electronic devices can be complex, especially when regenerative schemes are employed to recover energy from the mechanical system and convert it back to electrical energy for more efficient operation. Inverter circuit design and control has been the subject of much research and development over the past several decades.

Ac–ac power control, without changing frequency, is accomplished by simple converters that allow conduction to begin at a time past the zero-crossing of the voltage or current waveform (referred to as phase control), or more complex converters that create completely new amplitudes and frequencies for the output ac power.

Note: Original contributions to this section were made by W. Newell. Portions of the material on diodes were contributed by P. F. Pittman, J. C. Engel, and J. W. Motto. D.C.

CHAPTER 13.1

POWER ELECTRONIC DEVICES

Jerry L. Hudgins

POWER ELECTRONIC DEVICE FAMILIES

Power electronic devices have historically been separated into three broad categories: diodes, transistors, and thyristors. Modern devices can still be classified in this way, though there is increasing overlap in device design and function. Also, new materials as well as novel designs have increased the suitability and broadened the applications of semiconductor switches in energy conversion circuits and systems. Diodes are two-terminal devices that perform functions such as rectification and protection of other components. Diodes are not controllable in the sense that they will conduct current when a positive forward voltage is applied between the anode and cathode. Transistors are three-terminal devices that include the traditional power bipolar (two types of charge carriers), power MOSFETs (metal-oxide-semiconductor field-effect transistor), and hybrid devices that have some aspect of a control-FET element integrated with a bipolar structure, such as an IGBT (insulated-gate bipolar transistor). Thyristors are also three-terminal devices that have a four-layer structure (several $p-n$ junctions) for the main power handling section of the device. All transistors and thyristor types are controllable in switching from a forward blocking state (very little current flows) into a forward conduction state (large forward current flows). All transistors and most thyristors (except SCRs) are also controllable in switching from forward conduction back to a forward blocking state.

Typically, thyristors are used at the highest energy levels in power conditioning circuits because they are designed to handle the largest currents and voltages of any device technology (systems approximately with voltages above 3 kV or currents above 100 A). Many medium-power circuits (systems operating at less than 3 kV or 100 A) and particularly low-power circuits (systems operating below 100 V or several amperes) generally make use of transistors as the main switching elements because of the relative ease in controlling them. IGBTs are also replacing thyristors (e.g., GTEs) in industrial motor drives and traction applications as the IGBT voltage blocking capability improves. Diodes are used throughout all levels of power conditioning circuits and systems.

COMMON DEVICE CHARACTERISTICS

A high-resistivity region of silicon is present in all power semiconductor devices. It is this region that must support the large applied forward voltages that occur when the switch is in its off state (nonconducting). The higher the forward blocking voltage rating of the device, the thicker this region must be. Increasing the thickness of this high-resistivity region results in slower turn-on and turn-off (i.e., longer switching times and/or lower frequency of operation). For example, a device rated for a forward blocking voltage of 5 kV will by its physical construction switch much more slowly than one rated for 100 V. In addition, the thicker high-resistivity region

of the 5 kV device will cause a larger forward voltage drop during conduction than the 100 V device carrying the same current. There are other effects associated with the relative thickness and layout of the various regions that make up modern power devices, but the major trade-off between forward blocking voltage rating and switching times and between forward blocking voltage and forward voltage drop during conduction should be kept in mind. Another physical aspect of the semiconductor material is that the maximum breakdown voltage achievable using a semiconductor is proportional to the energy difference between the conduction and valence bands (bandgap). Hence, a material with a larger bandgap energy than that in silicon (Si) can in principle achieve the same blocking voltage rating with a thinner high-resistivity region. This is one of the reasons that new semiconductor devices are being designed and are recently becoming available in materials such as silicon carbide (SiC).

The time rate of rise of device current (di/dt) during turn-on and the time rate of rise of device voltage (dv/dt) during turn-off are important parameters to control for ensuring proper and reliable operation. Many power electronic devices have maximum limits for di/dt and dv/dt that must not be exceeded. Devices capable of conducting large currents in the on-state are necessarily made with large surface areas through which the current flows. During turn-on, localized regions of a device begin to conduct current. If the local current density becomes too large, then heating will damage the device. Sufficient time must be allowed for the entire area to begin conducting before the localized currents become too high and the device's di/dt rating is exceeded. The circuit designer sometimes adds series inductance to limit di/dt below the recommended maximum value.

During turn-off, current is decreasing while voltage across the device is increasing. If the forward voltage becomes too high while sufficient current is still flowing, then the device will drop back into its conduction mode instead of completing its turn-off cycle. Also, during turn-off, the power dissipation can become excessive if the

current and voltage are simultaneously too large. Both of these turn-off problems can damage the device as well as other portions of the circuit. Another problem that occurs is associated primarily with thyristors. Thyristors can self-trigger into a forward conduction mode from a forward blocking mode if their dv/dt rating is exceeded (because of excessive displacement current through parasitic capacitances). Protection circuits, known as snubbers, are used with power semiconductor devices to control dv/dt .

The snubber circuit specifically protects devices from a large di/dt during turn-on and a large dv/dt during turn off. A general snubber topology is shown in Fig. 13.1.1. The turn-on snubber is made by inductance L_1 (often L_1 is stray inductance only). This protects the device from a large di/dt during the turn-on process. The auxiliary circuit made by R_1 and D_1 allows the discharging of L_1 when the device is turned off. The turn-off snubber is made by resistor R_2 and capacitance C_2 . This circuit protects the power electronic device from large dv/dt during the turn-off process. The auxiliary circuit made by D_2 and R_2 allows the discharging of C_2 when the device is turned on. The circuit of capacitance C_2 and inductance L_1 also limits the value of dv/dt across the device during forward blocking. In addition, L_1 protects the device from reverse overcurrents.

All power electronic devices must be derated (e.g., power dissipation levels, current conduction, voltage blocking, and switching frequency must be reduced), when operating above room temperature

FIGURE 13.1.1 Turn-on (top elements) and turn-off (bottom elements) snubber circuits for typical power electronic devices.

(defined as about 25°C). Bipolar-type devices have thermal runaway problems, in that if allowed to conduct unlimited current, these devices will heat up internally causing more current to flow, thus generating more heat, and so forth until destruction. Devices that exhibit this behavior are *pin* diodes, bipolar transistors, and thyristors. MOSFETs must also be derated for current conduction and power dissipation when heated, but they do not suffer from thermal runaway as other device types do. IGBTs fall in between the behavior of MOSFETs and bipolar transistors. At low current levels they behave similar to bipolar transistors, whereas operating at high currents causes them to behave more like MOSFETs.

There are many subtleties of power device fabrication and design that are made to improve the switching times, forward voltage drop during conduction, dv/dt , dI/dt , and other ratings. Many of these improvements cause the loss of the ability of the device to hold-off large applied reverse voltages. In other devices the inherent structure itself precludes reverse blocking capability. In general, only some versions of two types of thyristors have equal (symmetric) forward and reverse voltage hold-off capabilities: GTOs (gate turn-off thyristor) and SCRs (silicon controlled rectifier).

A simple diagram of the internal structure of the major power semiconductor devices, the corresponding circuit symbols, some simple equivalent circuits, and a summary of the principal characteristics of each device are shown in Fig. 13.1.2. A comparison between types of devices illustrating the useable switching frequency range and switched power capability is shown in Fig. 13.1.3. Switched power capability is defined here as the maximum forward hold-off voltage obtainable multiplied by the maximum continuous conduction current. Further information on power electronic devices can be obtained from manufacturer's databooks and applications notes, textbooks (Baliga, 1987, 1996; Ghandi, 1977; Sze, 1981), and in many technical journal publications (including Azuma and Kurata, 1988; Hower, 1988; Hudgins, 1993).

DIODES

Diode Types

Schottky and *pin* diodes are used extensively in power electronic circuits. Schottky diodes are formed by placing a metal layer directly on a lightly doped (usually *n*-type) semiconductor. The naturally occurring potential barrier at the metal-semiconductor interface gives rise to the rectifying properties of the device. A *pin* diode is a *pn*-junction device with a lightly doped (near intrinsic) region placed between the typical diode *p*- and *n*-type regions. The lightly doped region is necessary to support large applied reverse voltages. The diode characteristic is such that current easily flows in one direction while it is blocked in the other. Power Schottky diodes are limited to about 200 V reverse blocking capability because the forward voltage drop becomes excessive in the high-resistivity region of the semiconductor and the lowering of the interface potential barrier (and associated increase in reverse leakage current) owing to the applied reverse voltage also increases (Sze, 1981). However, new Schottky structures made from SiC material are commercially available that have much higher voltage blocking capability. It is likely that these SiC diodes will be available with multi-kV ratings soon.

Reverse blocking of up to 10 kV is obtainable with a *pin* structure in Si. These types of diodes can easily handle surge currents of tens of thousands of amperes and rms currents of several thousand amperes. The *pin* diode has the advantages of much higher voltage and current capabilities than the Schottky diode, though the new SiC Schottky diodes are moving into higher power ratings all the time. Also, *pin* diodes are inherently slower in switching speed than Schottky devices, and for low reverse-blocking values, they have a larger forward voltage drop than Schottky diodes. For devices rated for 50 V reverse blocking, a Schottky diode has a forward drop of about 0.6 V as compared to a *pin* diode's forward drop of about 0.9 V at the same current density. The fast switching of the Schottky structure can be used to advantage in high-frequency power converter circuits. The Schottky's low forward drop can be used to advantage on the output rectifiers of low-voltage converter circuits, also. There have been several structures proposed that merge the features of the *pin* (for high reverse-blocking capability) and Schottky (for fast switching and low forward drop) diodes (Hower, 1988; Baliga, 1987). This concept is beginning to be implemented into the newer SiC diodes.

The switched power refers to the maximum forward blocking voltage multiplied by the maximum forward conduction current that each device is capable of handling.

Diode Ratings*

Silicon diode ratings include voltage, current, and junction temperature. A list of some of the more important parameters is shown in Table 13.1.1. The device current rating I_F is primarily determined by the area of the silicon die, power dissipation, and the method of heat sinking, while the spread of voltage ratings V_{RRM} is determined by silicon resistivity and die thickness.

Reverse voltage ratings are designated as repetitive V_{RRM} and nonrepetitive V_{RSM} . The repetitive value pertains to steady-state operating conditions, while the nonrepetitive peak value applies to occasional transient or fault conditions. Care must be exercised when applying a device to ensure that the voltage rating is never exceeded, even momentarily. When the blocking capability of a conventional diode is exceeded, leakage currents flow through the localized areas at the edge of the crystal. The resulting localized heating can cause rapid device failure.

Although even low-energy reverse overvoltage transients are likely to be destructive, the silicon diode is remarkably rugged with respect to forward current transients. This property is demonstrated by the I_{FSM} rating that permits one-half-cycle peak surge current of over ten times the I_F rating. For shorter current pulses, less than 4 ms, the surge current is specified by an I^2t rating similar to that of a fuse.

Proper circuit design must ensure that the maximum average junction temperature will never exceed its design limit of typically 150°C. Good design practice for high reliability, however, limits the maximum junction temperature to a lower value. The average junction-temperature rise above ambient is calculated by multiplying the average power dissipation, given approximately by the product of V_F and I_F , by the thermal resistance $R_{\theta JC}$. Transient junction temperatures can be computed from the transient thermal-impedance curve.

Device ratings are normally specified at a given case temperature and operating frequency. The proper use of a device at other operating conditions requires an appreciation of certain basic device characteristics.

*Major portions of this subsection were originally contributed by P. F. Pittman, J. C. Engel, and J. W. Motto.

TABLE 13.1.1 Symbols for Some Diode Ratings and Characteristics

Maximum Ratings	
V_{RRM}	Peak repetitive reverse voltage
V_{RSM}	Peak nonrepetitive reverse voltage
$I_{F(RMS)}$	RMS forward current
$I_{F(AV)}$	Average forward current
I_{FSM}	Surge forward current
I^2t	Nonrepetitive pulse overcurrent capability
T_j	Junction temperature
Characteristics	
V_F	Forward voltage drop (at specified temperature and forward current)
I_R	Maximum reverse current (at specified temperature and reverse voltage)
t_{RR}	Reverse recovery time (under specified switching of forward and reverse currents)
$R_{\theta jC}$	Junction-to-case thermal resistance

This is especially true in applications where the operating conditions of a number of devices are interdependent, as in series and parallel operation. For example, the forward voltage drop of a silicon diode has a negative temperature coefficient of 2 mV/°C for currents below the rated value. This variation in forward drop must be considered when devices are to be operated in parallel.

The reverse blocking voltage of a diode, at a specified reverse current, effectively decreases with an increase in temperature. The tendency to decrease comes from the fact that the reverse leakage current of a junction increases with temperature, thereby decreasing the voltage attained at a given measuring-current level. If the leakage current is very low, the maximum reverse voltage will be determined by avalanche breakdown (which has a coefficient of approximately 0.1 percent per °C in silicon). Thus, the voltage required to cause avalanche actually increases as the temperature rises. It should be noted that the reverse blocking voltage of a conventional diode is usually determined by imperfections at the edge of the die, and thus an ideal avalanche breakdown is usually not observed.

The reverse recovery time of a diode causes its performance to degrade with increasing frequency. Because of this effect, the rectification efficiency of a conventional diode used in a power circuit at high frequency is poor. In order to serve this application, a family of fast-recovery diodes has been developed. The stored charge of these devices is low, with the result that the amplitude and duration of the sweep-out current are greatly reduced compared with those of a conventional diode. However, improved turnoff characteristics of the fast-recovery diodes are obtained at some sacrifice in blocking voltage and forward drop compared with a conventional diode.

TRANSISTORS

Power MOSFETs

MOSFETs and IGBTs have an insulating oxide layer separating the gate contact and the silicon substrate. This insulating layer provides a large effective input resistance so that the control power necessary to switch these devices is considerably lower than that for a comparable bipolar transistor. The oxide layer also makes MOSFETs and IGBTs subject to damage from electrostatic charge build-up at the gate so that care must be exercised in their handling. Because of the internal structure of the power MOSFET, a *pn* junction (referred to as the “body diode”) is present that conducts when a reverse voltage is applied across the drain and source. Power MOSFETs do not suffer from second breakdown as bipolar transistors do and generally switch much faster, particularly during turn-off. Power MOSFETs have a large, voltage-dependent, effective input capacitance (combination of the gate-to-source and gate-to-drain capacitances) that can interact with stray circuit inductance in the gate-drive circuit to create oscillations. An external, small-valued resistor is usually placed

in series with the gate lead to damp the oscillatory behavior. Even with a fairly large input capacitance, power MOSFETs can be made to turn on and off faster than any other type of power electronic device.

Power MOSFETs are enhancement-type devices; a nonzero gate-to-source voltage must be applied to form a conducting channel between the drain and source to allow external current to flow. n -channel MOSFETs require a positive applied voltage at the gate with respect to the source for turn-on, while p -channel MOSFETs require a negative gate-source voltage. The gate electrode must be externally shorted to the source electrode for the device to support the maximum drain-source voltage V_{DS} , and keep the device in its forward-blocking mode. Drain current will flow if the gate-source voltage V_{GS} is above some minimum value (threshold voltage $V_{GS(TH)}$) necessary to form the conducting channel between the drain and source. In the saturated-mode of operation (i.e., drain current I_D , primarily dependent only on the gate-source voltage V_{GS}) the most important device characteristic is the forward transconductance g_{fs} , usually specified by the manufacturer with a graph showing the value as a function of I_D .

The linear-mode of operation is preferred for switching applications. Here, V_{GS} is typically in the range of 10 to 20 V. In this mode, I_D is approximately proportional to the applied V_{DS} for a given value of V_{GS} . The proportionality constant defines the on-resistance $r_{DS(ON)}$. The on-resistance is the total resistance between the source and drain electrodes in the on-state and it determines the maximum I_D rating (based on power dissipation restrictions). As temperature increases, the ability of charge to move through the conduction channel from source to drain decreases. The effect appears as an increase in $r_{DS(ON)}$. The increase in $r_{DS(ON)}$ as a function of temperature goes approximately as $T^{2.3}$. Because of the positive temperature exponent, power MOSFETs can be operated in parallel, for increased current capacity, with relative ease. In addition, the safe operating area (SOA) of MOSFETs is relatively large and the devices can be operated reliably near the SOA limits.

Power MOSFETs can be obtained with a forward voltage hold-off capability BV_{DSS} of around 1.2 kV (n -channel) and current handling capacity of up to 100 A at lower BV_{DSS} values. P -channel devices typically have less spread in ratings and are generally not available in extremes of current handling or hold-off voltage values like n -channel devices. MOSFETs can be obtained as discretely packaged parts or with several die configured together to form various half-bridge or full H-bridge topologies in a module. Advanced MOSFETs have integrated features that provide capabilities such as current limiting, voltage clamping, and current sensing for more intelligent system design. Trench- or buried-gate technology has contributed to the reduction of the $R_{on} \times$ Area product in power MOSFETs (and IGBTs) by a factor of 3 or more compared to surface gate devices (see Fig. 13.1.2). The trench-gate technology has been further adapted into the newest structure called the Superjunction MOSFET (see Fig. 13.1.2). The horizontal distribution of alternating p - and n -regions modifies the electric field distribution in the forward blocking mode such that the n -regions can be designed with a smaller vertical dimension, for the same blocking capability, as the trench-gate structure. Hence, the shorter current path causes the forward drop to be greatly reduced during conduction. At 100 A/cm² the SJ-MOSFET has been shown to have a forward drop of 0.6 V as compared to 0.9 V for the traditional MOSFET (Fujihira, 1998). Table 13.1.2 lists some of the more important power MOSFET ratings and characteristics.

IGBTs. Insulated-gate bipolar transistors are designated as n -type or p -type. The n -type of device dominates the marketplace because of its ease of use (it is controlled by a positive gate-emitter voltage). The n -type device can be thought of as an n -channel enhancement-mode MOSFET controlling the base current of a pnp bipolar transistor, as shown in Fig. 13.1.2. The naming convention is somewhat confusing because the external leads are labeled with the idea of an IGBT being a direct replacement for an nnp transistor with a gate lead replacing the base lead (i.e., the emitter of the equivalent pnp , in Fig. 13.1.2, is the collector of the IGBT, and so forth).

Applying a positive gate voltage above the threshold value, $V_{GE(TH)}$, turns the IGBT on. For switching applications, V_{GE} is typically in the range of 10 to 20 V. The IGBT has a saturated mode of operation (similar to a MOSFET), where the collector current is relatively independent of collector-to-emitter voltage V_{CE} . The base-collector junction, of the equivalent pnp , can never become forward biased because of drain current flow through the equivalent MOSFET. Therefore, the IGBT always has a forward drop, during conduction, of at least one pn junction (typically around 1 V). This is why the forward voltage drop $V_{CE(ON)}$ of the IGBT is greater than a comparable bipolar transistor, but less than a pure MOSFET structure at rated current flow. The switching times of the IGBT are shorter than comparable bipolar transistors (resulting in higher frequency of operation) and are not as susceptible to failure modes as are bipolars. The turn-off of an IGBT is characterized by two distinct portions of its current waveform. The first portion is characterized by a steep drop associated with the interruption of base-current to the equivalent pnp transistor (i.e., the internal MOSFET turns off). The second

TABLE 13.1.2 Symbols for Some MOSFET Ratings and Characteristics

Maximum Ratings	
V_{DS}	Drain-source voltage
I_D	Continuous drain current
I_{DM}	Pulsed drain current
T_j	Junction temperature
P_D	Maximum power dissipation
Characteristics	
BV_{DSS}	Drain-source breakdown voltage
$V_{GS(TH)}$	Gate threshold voltage
I_{DSS}	Zero gate-voltage drain current
$I_{D(on)}$	On-state drain current
$r_{DS(ON)}$	Static drain-source on-state resistance
g_{fs}	Common-source forward transconductance
C_{ISS}	Input capacitance
C_{OSS}	Output capacitance
C_{RSS}	Reverse transfer capacitance
$t_{d(on)}$	Turn-on delay time
t_r	Rise time
$t_{d(off)}$	Turn-off delay time
t_f	Fall time
Q_g	Total gate charge (gate-source + gate-drain)
Q_{gs}	Gate-source charge
Q_{gd}	Gate-drain ("Miller") charge
L_D	Internal drain inductance
L_S	Internal source inductance

I_S	Continuous source current
I_{SM}	Pulse source current
V_{SD}	Diode forward voltage drop
t_{rr}	Reverse recovery time
Q_{RR}	Reverse recovered charge
t_{ON}	Forward turn-on time

portion is known as the current-tail and can be very long in time. This is associated with final turn-off of the bipolar transistor structure. Much of the IGBT design efforts are aimed at modifying this current-tail to control switching time and/or power dissipation during turn-off.

If a large collector current is allowed to flow, the self-heating can cause the internal parasitic thyristor structure to latch into conductance (the gate thus loses the ability to turn the device off). This behavior is known as the short-circuit, shoot-through, or latch-up current limit. The maximum current that can flow (limited only by the device impedance), before latch-up occurs, must usually be limited to less than $10 \mu\text{s}$ duration. The behavior as a function of temperature is complicated for IGBTs. At low collector current values, the forward drop dependency as a function of temperature is similar to bipolar transistors. At high collector current values, the forward drop dependency on temperature is closer to that of a MOSFET. The exact design and fabrication steps used in the production of the device plays a strong role in the exact behavior because of temperature changes. Further details are available from Baliga (1987) and Hefner (1992).

IGBTs can now be obtained with hold-off voltage ratings of up to 6.3 kV and pulsed forward current capability of over 200 A. These devices can be obtained as discrete components or with several parallel die (to form one switch) and then several sets of switches configured into bridge or half-bridge topologies in modules. They are also

available with an integrated current sensing feature for active monitoring of device performance. There are two types of IGBT designs—punch through (PT) and non-punch through (NPT). NPT structures have no n^+ buffer layer next to the p^+ emitter (see Fig. 13.1.2). This means that the applied forward blocking voltage can extend the associated depletion region all the way across the n^- base causing breakdown at the p -emitter/ n -base junction if the applied voltage is high enough. In a PT structure (shown in Fig. 13.1.2) the depletion region is pinned to the n^+ buffer layer, thus allowing a thinner n^- base (high-resistivity region) to be used in the device design.

Previous generation IGBTs have a punch-through structure designed around a p^+ Si substrate with two epitaxial regions (n^- base region and n^+ buffer layer). Carrier lifetime reduction techniques are often used in the drift region to modify the turn-off characteristics. Recently, trench-gate devices have been designed with local lifetime control in the buffer layer (Motto, 1998). High-voltage devices (>1.2 kV) have been created using a non-punch-through structure beginning with the n^- base region as the substrate upon which a shallow (transparent) p^+ emitter is formed (Cotorogea, 2000). Cross-sections of typical unit cells for planar-gate IGBTs are shown in Fig. 13.1.2.

Third-generation IGBTs make use of improved cell density and shallow diffusion technologies that create fast switching devices with lower forward drops than have been achieved with previous devices. These lateral channel structures have nearly reached their limit for improvements. New trench-gate technologies offer the promise of greatly improved operation (Santi, 2001). Trench technologies can create an almost ideal IGBT structure because it connects in series the MOSFET and a p - n diode. There is no parasitic JFET as is created by the diffused p -wells in a lateral channel device (see Fig. 13.1.2). A simplified cross-section of the trench-gate IGBT is shown in Fig. 13.1.2. The forward drop in a trench-gate device is reduced significantly from the value in a third-generation lateral-gate IGBT. For example, in devices rated for 100 A and 1200 V, the forward drop, V_{CE} , is 1.8 V in a trench-gate IGBT as compared to 2.7 V in a lateral-gate (third generation) IGBT at the same current density, gate voltage, and temperature (Motto, 1998.) Local lifetime control is obtained in the n^+ base layer by using proton irradiation. This helps decrease the effective resistance in the n^- base by increasing the on-state carrier concentration. The surface structure of the gate is such that the MOS-channel width is increased (causing a decrease in channel resistance). The trend is for devices to be of the PT type as processing technology is improved. Table 13.1.3 lists some of the more important IGBT ratings and characteristics.

Bipolar Transistors. Power bipolar transistors and bipolar Darlington are seldom used in modern converter systems because of the amount of power required by the control signal and the limited SOA of the traditional

TABLE 13.1.3 Symbols for Some IGBT Ratings and Characteristics

Maximum Ratings	
V_{CES}	Collector-emitter voltage
V_{CGR}	Collector-gate voltage
V_{GE}	Gate-emitter voltage
I_C	Continuous collector current
T_j	Junction temperature
P_D	Maximum power dissipation
Characteristic	
BV_{CES}	Collector-emitter breakdown voltage
$V_{GE(TH)}$	Gate threshold voltage
I_{CES}	Zero gate-voltage collector current (at specified T_j and V_{CE} value)
$V_{CE(ON)}$	Collector-emitter on-voltage (at specified T_j , I_C , and V_{GE} values)
$Q_{G(ON)}$	On-state gate charge (at specified I_C and V_{CE} values)
$t_{D(ON)}$	Turn-on delay time (for specified test)
t_{RI}	Rise time (for specified test)
$t_{D(OFF)}$	Turn-off delay time (for specified test)
t_{FI}	Fall time (or specified test)
W_{OFF}	Turn-off energy loss per cycle
$R_{\theta JC}$	Junction-to-case thermal resistance

power bipolar transistor. Because of their declining use, no further discussion will be given. Further details should be obtained from manufacturers' databooks.

THYRISTORS

There are four major types of thyristors: (i) silicon-controlled rectifier (SCR), (ii) gate turn-off (GTO) thyristor, (iii) MOS-controlled thyristor (MCT) and related forms, and (iv) static induction thyristor (SITh). MCTs are so-named because many parallel enhancement-mode, MOSFET structures of one charge type are integrated into the thyristor for turn-on and many more MOSFETs of the other charge type are integrated into the thyristor for turn-off. A static induction thyristor (SITh), or field-controlled thyristor (FCTh), has essentially the same construction as a power diode with a gate structure that can pinch-off anode current flow. The advantage of using MCTs, derivative forms of the MCT, or SIThs is that they are essentially voltage-controlled devices, (e.g., little control current is required for turn-on or turn-off) and therefore require simplified control circuits attached to the gate electrode (Hudgins, 1993). Less important types of thyristors include the Triac (a pair of low-power, anti-parallel SCRs integrated together to form a bi-directional current switch) and the programmable unijunction transistor (PUT).

A thyristor used in some ac power circuits (50 or 60 Hz in commercial utilities or 400 Hz in aircraft) to control ac power flow can be made to optimize internal power loss at the expense of switching speed. These thyristors are called phase-control devices, because they are generally turned from a forward-blocking into a forward-conducting state at some specified phase angle of the applied sinusoidal anode-cathode voltage waveform. A second class of thyristors is used in association with dc sources or in converting ac power at one amplitude and frequency into ac power at another amplitude and frequency, and must generally switch on and off relatively quickly. The associated thyristors used are often referred to as inverter thyristors.

SCRs and GTOs. The voltage hold-off ratings for SCRs and GTOs is above 6 kV and continuing development will push this higher. The pulsed current rating for these devices is easily tens of kiloamperes. A gate signal of 0.1 to 100 A peak is typical for triggering an SCR or GTO from forward blocking into forward conduction. These thyristors are being produced in silicon with diameters greater than 100 mm.

The large wafer area places a limit on the rate of rise of anode current, and hence a di/dt limit (rating) is specified. The depletion capacitances around the pn junctions, in particular the center junction, limit the rate of rise in forward voltage that can be applied even after all the stored charge, introduced during conduction, is removed. The associated displacement current under application of forward voltage during the thyristor blocking state sets a dv/dt limit. Some effort in improving the voltage hold-off capability and over-voltage protection of conventional SCRs is underway by incorporating a lateral high-resistivity region to help dissipate the energy during breakover. Most effort, though, is being placed in the further development of high-performance GTO thyristors because of their controllability and to a lesser extent in optically triggered structures that feature gate circuit isolation.

Optically gated thyristors have traditionally been used in power utility applications where series stacks of devices are necessary to achieve the high voltages required. Isolation between gate-drive circuits for circuits such as static VAR compensators and high voltage dc to ac inverters have driven the development of this class of devices. One of the most recent devices can block 6 kV forward and reverse, conduct 2.5 kA average current, and maintain a di/dt capability of 300 A/ μ s and a dv/dt capability of 3000 V/ μ s, with a required trigger power of 10 mW.

High-voltage GTO thyristors with symmetric blocking capability require thick n -base regions to support the high electric field. The addition of an n^+ buffer-layer next to the p^+ -anode allows high voltage blocking capability and yet produces a low forward voltage drop during conduction because of the thinner n^- -base required. Many other design modifications have been introduced by manufacturers so that GTOs with a forward blocking capability of around 8 kV and anode conduction of 1 kA have been produced. Also, a reverse conducting GTO has been fabricated that can block 6 kV in the forward direction, interrupt a peak current of 3 kA, and has a turn-off gain of about 5.

A modified GTO structure, called a gate-commutated thyristor (GCT), has been designed and manufactured that commutates all of the cathode current away from the cathode region and diverts it out the gate contact. The GCT is similar to a GTO in structure except that it has a low-loss n -buffer region between the n -base and

p-emitter. The GCT device package is designed to result in very low parasitic inductance and is integrated with a specially designed gate-drive circuit (IGCT). The specially designed gate drive and ring-gate package circuit allows the GCT to be operated without a snubber circuit and switch with higher anode di/dt , than a similar GTO. At blocking voltages of 4.5 kV and higher, the IGCT seems to provide better performance than a conventional GTO. The speed at which the cathode current is diverted to the gate (di_{GO}/dt) is directly related to the peak snubberless turn-off capability of the GCT. The gate-drive circuit can sink current for turn-off at di_{GO}/dt values in excess of 7000 A/ μ s. This hard gate drive results in a low-charge storage time of about 1 μ s. The low storage time and the fail-short mode makes the IGCT attractive for high-voltage series applications.

The bi-directional control thyristor (BCT) is an integrated assembly of two anti-parallel thyristors on one Si wafer. The intended application for this switch is VAR compensators, static switches, soft starters, and motor drives. These devices are rated up to 6.5 kV blocking. Cross-talk between the two halves has been minimized. The small gate-cathode periphery necessarily restricts the BCT to low-frequency applications because of its di/dt limit.

The continuing improvement in GTO performance has caused a decline in the use of SCRs, except at the very highest power levels. In addition, the improvement in IGBT design further reduces the attractiveness of SCRs. These developments make the future use of SCRs seemingly diminish.

MCTs. There is a *p*-channel and an *n*-channel MOSFET integrated into the MCT, one FET-structure for turn-on and one for turn-off. The MCT itself comes in two varieties: *p*-type (gate voltage applied with respect to the anode) and an *n*-type (gate voltage applied with respect to the cathode). Just as in a GTO, the MCT has a maximum controllable cathode current value. The inherent optimization for good switching and forward conduction characteristics make the MCT unable to block reverse applied voltages.

MCTs are presently limited to operation at medium power levels. The seeming variability in fabrication of the turn-off FET structure continues to limit the performance of MCTs, particularly current interruption capability, though these devices can handle two to five times the conduction current density of IGBTs. All MCT device designs center on the problem of current interruption capability. Turn-on is relatively simple, by comparison, with it and conduction properties approaching the one-dimensional thyristor limit. Other types of integrated MOS-thyristor structures can be operated at high power levels, but these devices are not commonly available or are produced for specific applications. Typical MCT ratings are for 1 kV forward blocking and a peak controllable current of 75 A. A recent version of the traditional MCT design is a diffusion-doped (instead of the usual epitaxial growth) device. They are rated for 3 kV forward blocking, have a forward drop of 2.5 V at 100 A, and are capable of interrupting around 300 A with a recovery time of 5 μ s.

An MCT that uses trench-gate technology, called a depletion-mode thyristor (DMT), has been designed. A similar device is the base resistance controlled thyristor (BRT). Here, a *p*-channel MOSFET is integrated into the *n*-drift region of the MCT. These devices operate in an "IGBT" mode until the current is large enough to cause the thyristor structure to latch.

Another new MCT-type structure is called an emitter switched thyristor (EST), and uses an integrated lateral MOSFET to connect a floating thyristor *n*-emitter region to an n^+ thyristor cathode region. All thyristor current flows through the lateral MOSFET so it can control the thyristor current. Integrating an IGBT into a thyristor structure has been proposed. One device, called an IGBT triggered thyristor (ITT), is similar in structure and operation to the EST. The best designed EST, however, is the dual gate emitter switched thyristor (DG-EST). The device has two gate electrodes. One gate controls an integrated IGBT section, while the other gate controls a thyristor section. The DG-EST is intended to be switched in IGBT mode, to exploit the controllability and snubberless capabilities of an IGBT. During forward conduction, the thyristor section takes over and thus the DG-EST takes advantage of a low forward drop and the latching nature of a thyristor.

Static Induction Thyristors. A static induction thyristor (SITh) or field controlled thyristor (FCTh) is essentially a *pin* diode with a gate structure that can pinch-off anode current flow. High-power SIThs have a subsurface gate (buried-gate) structure to allow larger cathode areas to be used, and hence larger current densities can be conducted. Other SITh configurations have surface gate structures.

Planar gate devices have been fabricated with blocking capabilities of up to 1.2 kV and conduction currents of 200 A, while step-gate (trench-gate) structures have been produced that are able to block up to 4 kV and conduct 400 A. Similar devices with a "Verigrad" structure have been demonstrated that can block 2 kV and conduct 200 A, with claims of up to 3.5 kV blocking and 200 A conduction. Buried gate devices that block 2.5 kV and conduct 300 A have also been fabricated.

An integrated light-triggered and light-quenched SITH has been produced that can block 1.2 kV and conduct up to 20 A (at a forward drop of 2.5 V). This device is an integration of a normally off buried-gate static induction photothyristor and a normally off p -channel Darlington surface-gate static induction phototransistor. The optical trigger and quenching power required is less than 5 and 0.2 mW, respectively.

Thyristor Behavior. The thyristor is a three-terminal semiconductor device comprising four layers of silicon so as to form three separate pn junctions. In contrast to the linear relation that exists between load and control currents in a transistor, the thyristor is bistable. The four-layer structure of the thyristor is shown in Fig. 13.1.2. The anode and cathode terminals are connected in series with the load to which power is to be controlled. The thyristor is turned on by application of a low-power control signal between the third terminal, or gate, and the cathode (between gate and anode for p -type MCT).

The reverse characteristic is determined by the outer two junctions, which are reverse-biased in this operating mode. With zero gate current, the forward characteristic in the off- or blocking-state is determined by the center junction, which is reverse biased. However, if the applied voltage exceeds the forward blocking voltage, the thyristor switches to its on- or conducting state. The effect of gate current is to lower the blocking voltage at which switching takes place.

This behavior can be explained in terms of the two-transistor analog shown in Fig. 13.1.2. The two transistors are regeneratively coupled so that if the sum of their current gains (α 's) exceeds unity, each drives the other into saturation. In the forward blocking-state, the leakage current is small, both α 's are small, and their sum is less than unity. Gate current increases the current in both transistors, increasing their α 's. When the sum of the two α 's equals 1, the thyristor switches to its on-state (latches).

The form of the gate-to-cathode VI characteristic of SCRs and GTOs is similar to that of a diode. With positive gate bias, the gate-cathode junction is forward-biased and permits the flow of a large current in the presence of a low voltage drop. When negative gate voltage is applied to an SCR, the gate-cathode junction is reverse-biased and prevents the flow of current until the avalanche breakdown voltage is reached. In a GTO, a negative gate voltage is applied to provide a low impedance for anode current to flow out of the device instead of out of the cathode. In this way the cathode region turns off, thus pulling the equivalent npn transistor out of conduction. This causes the entire thyristor to return to its blocking state. The problem with the GTO is that the gate-drive circuitry is typically required to sink from 5 to 10 percent of the anode current to achieve turn-off. The MCT achieves turn-off by internally diverting current through an integrated MOSFET. Switching the equivalent MOSFET only requires a voltage signal to be applied at the gate electrode.

A summary is provided in Table 13.1.4 of some of the ratings which must be considered when choosing a thyristor for a given application. Both forward and reverse repetitive and nonrepetitive voltage ratings must be considered, and a properly rated device must be chosen so that the maximum voltage ratings are never exceeded. In most cases, either forward or reverse voltage transients in excess of the nonrepetitive maximum ratings result in destruction of the device.

The maximum rms or average current ratings given are usually those which cause the junction to reach its maximum rated temperature. Because the maximum current will depend on the current waveform and on thermal conditions external to the device, the rating is usually shown as a function of case temperature and conduction angle. The peak single half-cycle surge-current rating must be considered, and in applications where the thyristor must be protected from damage by overloads, a fuse with an I^2t rating smaller than the maximum rated value for the device must be used. Maximum ratings for both forward and reverse gate voltage, current, and power also must not be exceeded.

The maximum rated operating junction temperature T_j must not be exceeded, since device performance, in particular voltage-blocking capability, will be degraded. Junction temperature cannot be measured directly but must be calculated from a knowledge of steady-state thermal resistance $R_{\theta JC}$ and the average power dissipation. For transients or surges, the transient thermal impedance ($Z_{\theta JC}$) curve must be used. The maximum average power dissipation P_T is related to the maximum rated operating junction temperature and the case temperature by the steady-state thermal resistance. In general, both the maximum dissipation and its derating with increasing case temperature are provided.

The number of thyristor characteristics specified varies widely from one manufacturer to another. Some characteristics are given only as typical values of minima or maxima, while many characteristics are displayed graphically. Table 13.1.4 summarizes some of the characteristics provided. Thyristor types shown in parentheses

TABLE 13.1.4 Symbols for Some Thyristor Ratings and Characteristics

Maximum Ratings	
V_{RRM}	Peak repetitive reverse voltage
V_{RSM} (SCR & GTO)	Peak nonrepetitive reverse voltage
V_{DRM}	Peak repetitive forward off-state voltage
V_{DSM} (SCR & GTO)	Peak nonrepetitive forward off-state voltage
$I_{T(RMS)}$	RMS forward current
$I_{T(AV)}$ (I_K for MCT)	Average forward current
I_{TSM} (I_{KSM} for MCT)	Surge forward current
I_{TGO} (I_{KC} for MCT)	Peak controllable current
I^t (SCR & GTO)	Nonrepetitive pulse overcurrent capability
P_T (MCT)	Maximum power dissipation
di/dt	Critical rate of rise of on-state current
dvl/dt	Critical rate of rise of off-state voltage
P_{GM} (P_{FGM} for GTO)	Peak gate forward power dissipation
P_{RGM} (GTO)	Peak gate reverse power dissipation
V_{FGM}	Peak forward gate voltage
V_{RGM}	Peak reverse gate voltage
I_{FGM} (SCR & GTO)	Peak forward gate current
I_{RGM} (GTO)	Peak reverse gate current
T_j	Junction temperature
Characteristics	
V_{TM}	On-state voltage drop (at specified temperature and forward current)
I_{DRM}	Maximum forward off-state current (at specified temperature and forward voltage)
I_{RRM}	Maximum reverse blocking current (at specified temperature and reverse voltage)
C_{ISS} (MCT)	Input capacitance (at specified temperature and gate and anode voltages)
V_{GT} (SCR & GTO)	Gate trigger voltage (at specified temperature and forward applied voltage)
V_{GD} (SCR & GTO)	Gate nontrigger voltage (at specified temperature and forward applied voltage)
I_{GT} (SCR & GTO)	Gate trigger current (at specified temperature and forward applied voltage)
t_{gt} (GTO)	Turn-on time (under specified switching conditions)
t_d (SCR & GTO)	Turn-off time (under specified switching conditions)
$t_{D(ON)}$ (MCT)	Turn-on delay time (for specified test)
t_{RI} (MCT)	Rise time (for specified test)
$t_{D(OFF)}$ (MCT)	Turn-off delay time (for specified test)
t_{FI} (MCT)	Fall time (for specified test)
W_{OFF} (MCT)	Turn-off energy loss per cycle
$R_{\theta JC}$	Junction-to-case thermal resistance

indicate a characteristic unique to that device or devices. Gate conditions of both voltage and current to ensure either nontriggered or triggered device operation are included.

The turn-on and turn-off transients of the thyristor are characterized by switching times like the turn-off time listed in Table 13.1.4. The turn-on transient can be divided into three intervals—gate-delay interval, turn-on of initial area, and spreading interval. The gate-delay interval is simply the time between application of a turn-on pulse at the gate and the time the initial area turns on. This delay decreases with increasing gate drive current and is of the order of a few microseconds. The second interval, the time required for turn-on of the initial area, is quite short, typically less than $1 \mu\text{s}$. In general, the initial area turned on is a small percentage of the total useful device area. After the initial area turns on, conduction spreads (spreading interval) throughout the device in tens of microseconds.

It is during this spreading interval that the di/dt limit must not be exceeded. Typical di/dt values range from 100 to 1000 A/ μs . Special inverter-type SCRs and GTOs are made that have increased switching speed (at the expense of higher forward voltage drop during conduction) with di/dt values in the range of 2000 A/ μs . The rate

of application of forward voltage is also restricted by the dv/dt characteristic. Typical values range from 100 to 1000 V/ μ s.

Thyristors are available in a wide variety of packages, from small plastic ones for low-power (i.e., TO-247), to stud-mount packages for medium-power, to press-pack (also called flat-pack) for the highest power devices. The press-packs must be mounted under pressure to obtain proper electrical and thermal contact between the device and the external metal electrodes. Special force-calibrated clamps are made for this purpose.

OTHER POWER SEMICONDUCTOR DEVICES

Semiconductor materials such as silicon carbide (SiC), gallium arsenide (GaAs), and gallium nitride (GaN) are being used to develop pn -junction and Schottky diodes, power MOSFET structures, some thyristors, and other switches. SiC diodes are commercially available now. No other commercial power devices made from these materials yet exist, but will likely be available in the future. Further information about advanced power semiconductor materials and device structures can be found in (Baliga, 1996) and (Hudgins, 1993, 1995, 2003).

CHAPTER 13.2

NATURALLY COMMUTATED CONVERTERS

Arthur W. Kelley

INTRODUCTION

The applications for this family of naturally commutated converters embrace a very wide range, including dc power supplies for electronic equipment, battery chargers, dc power supplies delivering many thousands of amperes for electrochemical and other industrial processes, high-performance reversing drives for dc machines rated at thousands of horsepower, and high-voltage dc transmission at the gigawatt power level.

The basic feature common to this class of converters is that one set of terminals is connected to an ac voltage source. The ac source causes natural commutation of the converter power electronic devices. In these converters, a second set of terminals operates with dc voltage and current. This class of converters is divided in function depending on the direction of power flow. In *ac-to-dc rectification*, the ac source, typically the utility line voltage, supplies power to the converter, which in turn supplies power to a dc load. In *dc-to-ac inversion*, a dc source, typically a battery or dc generator, provides power to the converter, which in turn transfers the power to the ac source, again, usually the utility line voltage. Because natural commutation synchronizes the power semiconductor device turn on and turn off to the ac source, this converter is also known as a *synchronous inverter* or a *line-commutated inverter*. This process is different from supplying power to an ac load, which usually requires forced commutation.

The power electronic devices in these converters are typically either *silicon controlled rectifiers* (SCRs) *diodes*. To simplify the discussion that follows, the SCRs and diodes are assumed to (1) conduct forward current with zero forward voltage drop, (2) block reverse voltage with zero leakage current, and (3) switch instantaneously between conduction and blocking. Furthermore, stray resistive loss is ignored and balanced three-phase ac sources are assumed.

Converter Topologies

Basic Topologies. The number of different converter topologies is very large (Schaeffer, 1965; Pelly, 1971; Dewan, 1975; Rashid, 1993). Using SCRs as the power electronic devices, Table 13.2.1 illustrates four basic topologies from which many others are derived. These ac-to-dc converters are rectifiers that provide a dc voltage V_O to a load. The rectifier often uses an output filter inductor L_O and capacitor C_O , but one or the other or both are often omitted. Rectifiers are usually connected to the ac source through a transformer. Note that the transformer is often utility equipment, located separately from the rectifier. The transformer adds a series leakage inductance L_S , which is often detrimental to rectifier operation.

Rectifier topologies are classified by whether the rectifier operates from a single- or three-phase source and whether the rectifier uses a bridge connection or transformer midpoint connection. The *single-phase bridge rectifier* shown in Table 13.2.1a requires four SCRs and a two-winding transformer. The *single-phase midpoint*

TABLE 13.2.1 Basic Converter Topologies

rectifier shown in Table 13.2.1b requires only two SCRs but requires a transformer with a center-tapped secondary to provide the midpoint connection. The three-phase bridge rectifier shown in Table 13.2.1c requires six SCRs and three two-winding transformers. The three-phase midpoint rectifier shown in Table 13.2.1d requires three SCRs and three transformers using a Y-connected “zig-zag” secondary. The Y-connected secondary provides the necessary midpoint connection and the zig-zag winding prevents unidirectional secondary winding currents from causing magnetic saturation of the transformers.

The bridge rectifier is better suited to using the simple connection provided by the typical utility transformer. For the same power delivered to the load, the bridge rectifier often requires a smaller transformer. Therefore, in the absence of other constraints, the bridge rectifier is often preferred over the midpoint rectifier.

Pulse Number. Converters are also classified by their pulse number q , an integer that is the number of current pulses appearing in the rectifier output current waveform i_x per cycle of the ac source voltage. Higher pulse number rectifiers generally have higher performance but usually with a penalty of increased complexity. Of the rectifiers shown in Table 13.2.1, both single-phase rectifiers are two-pulse converters ($q = 2$) with one current pulse in i_x for each half-cycle of the ac source voltage. The three-phase midpoint rectifier is a three-pulse converter ($q = 3$) with one current pulse in i_x for each cycle of each phase of the three-phase ac source voltage. The three-phase bridge rectifier is a six-pulse converter ($q = 6$) with one current pulse in i_x for each half cycle of each phase of the three-phase ac source voltage.

BASIC CONVERTER OPERATION

Given a certain operating point, rectifier operation and performance are dramatically influenced by the values of source inductance L_S , output filter inductance L_O , and output filter capacitance C_O .

Operation with Negligible Ac Source Inductance. Figures 13.2.1 and 13.2.2 show example time waveforms for the single- and three-phase bridge rectifiers of Table 13.2.1a and 13.2.1c, respectively. In these

FIGURE 13.2.1 Time waveforms for single-phase bridge rectifier with $\alpha = 40^\circ$: (a) CCM and (b) DCM.

FIGURE 13.2.2 Time waveforms for three-phase bridge rectifier with $\alpha = 20^\circ$: (a) CCM and (b) DCM.

examples L_S is comparatively small and its influence is neglected. The value of C_O is relatively large so that the ripple in the output voltage V_O is relatively small. Operation of single- and three-phase phase-controlled rectifiers is described in detail in (Kelley, 1990).

Figure 13.2.1a shows time waveforms for the single-phase bridge rectifier when the current i_X in L_O flows continuously without ever falling to zero. The rectifier is said to be operating in the *continuous conduction mode* (CCM). The CCM occurs for relatively large L_O , heavy loads, and small α . Figure 13.2.1b shows time waveforms for the single-phase bridge rectifier when i_X drops to zero twice each cycle and the rectifier is said to be operating in the *discontinuous conduction mode* (DCM). The DCM occurs for relatively small L_O , light loads, and large α .

Figure 13.2.1 also shows the conduction intervals for SCRs Q_1 to Q_4 and the rectifier voltage, v_X . A controller, not shown in Fig. 13.2.1, generates gating pulses for the SCRs. The controller gates each SCR at a *firing angle* α (alpha) with respect to a *reference* that is the point in time at which the SCR is first forward biased. The SCR ceases conduction at the *extinction angle* β (beta). The reference, α , and β for Q_1 are illustrated in Fig. 13.2.1. The SCR *conduction angle* γ (gamma) is the difference between β and α . In DCM the SCR ceases conduction because i_X falls naturally to zero, while in the CCM the SCR ceases conduction even though i_X is not zero because the opposing SCR is gated and begins conducting i_X . Therefore in CCM, γ is limited to a maximum of one-half of an ac source voltage cycle, while in DCM γ depends on L_O , load, and α .

Note that v_X equals v_S when Q_1 and Q_4 are conducting and that v_X equals $-v_S$ when Q_2 and Q_3 are conducting. The output filter L_O and C_O reduces the ripple in v_X and delivers a relatively ripple-free voltage V_O to the load. The firing angle α determines the composition of v_X and ultimately the value of V_O . Increasing α reduces V_O and is the mechanism by which the controller regulates V_O against changes in ac source voltage and load.

This method of output voltage regulation is referred to as *phase control*, and a rectifier using it is said to be a *phase-controlled rectifier*.

Since in CCM the conduction angle is always one half of a source voltage cycle, the dc output voltage is easily found from v_X as

$$V_O = \frac{2}{\pi} \sqrt{2} V_S \cos \alpha \tag{1}$$

where V_S is the rms value of the transformer secondary voltage v_S . Unfortunately, the conduction angle in DCM depends on L_O , the load, and α , and V_O cannot be calculated except by numerical methods.

For the three-phase bridge rectifier, Figures 13.2.2a and 13.2.2b show time waveforms for CCM and DCM, respectively. Operation is similar to the single-phase rectifier except that v_X equals each of the six line-to-line voltages— v_{AB} , v_{AC} , v_{BC} , v_{BA} , v_{CA} , and v_{CB} —in succession. In CCM, the SCR conduction angle γ is one-third of an ac source voltage cycle, and in DCM γ depends on L_O , load, and α . In CCM the dc output voltage V_O is found from v_X as

$$V_O = \frac{3}{\pi} \sqrt{3} \sqrt{2} V_S \cos \alpha \tag{2}$$

where V_S is the rms value of the transformer secondary line-to-neutral voltage. In DCM, the value of V_O must be calculated by numerical means. To produce a ripple-free output voltage V_O , the time waveform of v_X for the three-phase rectifier naturally requires less filtering than the time waveform of v_X for the single-phase rectifier.

FIGURE 13.2.3 Time waveforms for three-phase bridge rectifier with appreciable L_S .

Therefore, if a three-phase ac source is available, a three-phase rectifier is always preferred over a single-phase rectifier.

Operation with Appreciable Ac Source Inductance. The preceding discussion assumes that the value of L_S is small and does not influence circuit operation. In practice the effect of L_S must often be considered. The three-phase rectifier CCM time waveforms of Fig. 13.2.2 are repeated in Fig. 13.2.3 but for an appreciable L_S . Since i_X is always nonzero in CCM, the principal effect of L_S is to prevent instantaneous transfer of i_X from one transformer secondary winding to the next transformer secondary winding as the SCRs are gated in succession. This process is called *commutation* and the interval during which it occurs is called *commutation overlap*.

For example, at some point in time Q_1 is conducting i_{SA} equal to i_X and Q_3 is gated by the controller. Current i_{SA} through Q_1 falls while i_{SB} through Q_3 rises. During this interval both Q_1 and Q_3 conduct simultaneously and the sum of i_{SA} and i_{SB} is equal to i_X . As a result transformer secondary v_{SA} is directly connected to transformer secondary v_{SB} effectively creating a line-to-line short circuit. This connection persists until i_{SA} falls to zero and Q_1 ceases conduction. The duration of the connection is the *commutation angle* μ (mu). During this interval v_{SA} experiences a positive-going voltage “notch” while v_{SB} experiences a negative-going voltage notch. The enclosed area of the positive-going notch equals the enclosed area of the negative-going notch and represents the flux linkage or “volt seconds” necessary to produce a change in current through L_S equal to i_X . If L_O is sufficiently large so that i_X is relatively constant with value I_X during the time that both SCRs conduct, then the notch area is used to find

$$\cos\alpha - \cos(\mu + \alpha) = \sqrt{\frac{2}{3}} (2\pi f L_S I_X / V_S) \tag{3}$$

which can be solved numerically for μ . Note that the commutation angle is always zero in DCM since i_X is zero when each SCR is gated to begin conduction.

CONVERTER POWER FACTOR

Source Current Harmonic Composition. The time waveforms of the prior section show that the rectifier is a nonlinear load that draws a highly distorted nonsinusoidal waveform i_S . Fourier series is used to decompose i_S into a fundamental-frequency component with rms value $I_{S(1)}$ and phase angle $\phi_{S(1)}$ with respect to v_S , and into harmonic-frequency components with rms value $I_{S(h)}$ where h is an integer representing the harmonic number. In general, the $I_{S(h)}$ are zero for even h . Furthermore, depending on converter pulse number q , certain $I_{S(h)}$ are also zero for some odd h . Apart from $h = 1$ for which $I_{S(1)}$ is always nonzero, the $I_{S(h)}$ are nonzero for

$$h = kq \pm 1 \quad (k \text{ integer} \geq 1) \tag{4}$$

Therefore harmonic currents for certain harmonic numbers are eliminated for higher pulse numbers. For example, the single-phase bridge rectifier with $q = 2$ produces nonzero $I_{S(h)}$ for $h = 1, 3, 5, 7, 9, \dots$, while the three-phase bridge rectifier with $q = 6$ produces nonzero $I_{S(h)}$ for $h = 1, 5, 7, 11, 13, \dots$. If rectifier operation is unbalanced, then harmonics are produced for all h . An unbalanced condition can result from asymmetrical gating of the SCRs or from voltage or impedance unbalance of the ac source. The effect is particularly pronounced for three-phase rectifiers with a comparatively small L_O and a comparatively large C_O since these rectifiers act like “peak detectors” and C_O charges to the point where V_O approaches the peak value of the line-to-line voltage. One phase needs to be only several percent below the other two phases for it to conduct a greatly reduced current and shift most of the current to the other two phases. An unbalanced condition is always evident from the waveform of i_X because the heights of the pulses are not all the same.

Power Factor. The rms value I_S of i_S is found from

$$I_S = \sqrt{I_{S(1)}^2 + \sum_{h>1} I_{S(h)}^2} \tag{5}$$

The ac source is rated for apparent power S , which is the product of V_S and I_S (in volt-amperes, VA). However, the source delivers real input power P_I (in watts, W), which the rectifier converts to dc and supplies to the load. The *total power factor* PF is the ratio of the real input power and the apparent power supplied by the ac source

$$PF = \frac{P_I}{S} = \frac{P_I}{V_S I_S} \quad (6)$$

and measures the fraction of the available apparent power actually delivered to the rectifier. The source voltage v_S is an undistorted sine wave only if L_S is negligible. In this case power is delivered only at the fundamental frequency so that

$$P_I = V_S I_{S(1)} \cos \phi_{S(1)} \quad (7)$$

Note that the harmonics $I_{S(h)}$ draw apparent power from the source by increasing I_S but do not deliver real power to the rectifier. Using this assumption, the expression for power factor reduces to

$$PF = \cos \phi_{S(1)} \frac{I_{S(1)}}{I_S} \quad (8)$$

The *displacement power factor* $\cos \phi_{S(1)}$ is the traditional power factor used in electric power systems for sinusoidal operation and is unity when the fundamental of i_S is in phase with v_S . The *purity factor* $I_{S(1)}/I_S$ is unity when i_S is a pure sine wave and the rms values of $I_{S(h)}$ are zero so that I_S equals $I_{S(1)}$. The distortion of i_S is often and equivalently represented by the *total harmonic distortion for current* THD_i

$$THD_i = 100 \frac{\sqrt{\sum_{h>1} I_{S(h)}^2}}{I_{S(1)}} = 100 \sqrt{\frac{1}{(I_{S(1)}/I_S)^2} - 1} \quad (\text{expressed in percent}) \quad (9)$$

The purity factor $I_{S(1)}/I_S$ is also called the distortion power factor, which is easily confused with the total harmonic distortion THD_i .

The theoretical maximum power factor for the single-phase bridge rectifier is 0.90, which occurs for $\alpha = 0^\circ$ and usually requires an uneconomically large value of L_O . The actual power factor often ranges from 0.5 to 0.75. The theoretical maximum power factor for the three-phase bridge rectifier is 0.96 which also occurs for $\alpha = 0^\circ$. Because the three-phase bridge rectifier requires less filtering, it is often possible to approach this theoretical maximum power factor with an economical value of L_O . However, for cost reasons, L_O is often omitted in both the single- and three-phase rectifiers which dramatically reduces the power factor and leaves it to depend on the value of L_S .

Source Voltage Distortion and Power Quality. The time waveforms of Fig. 13.2.3 show that with appreciable L_S the rectifier distorts the voltage source v_S supplying the rectifier. Fourier series is also used to represent v_S as a fundamental voltage of rms value $V_{S(1)}$ and harmonic voltages of rms value $V_{S(h)}$. The distortion of v_S is often represented by the total harmonic distortion for voltage THD_v

$$THD_v = 100 \frac{\sqrt{\sum_{h>1} V_{S(h)}^2}}{V_{S(1)}} \quad (\text{expressed in percent}) \quad (10)$$

Note that the definition of power factor (Eq. (7)) is valid for appreciable L_S and distorted v_S but (Eq. (8)) is strictly valid only when L_S is negligible and v_S is undistorted.

Voltage distortion can cause problems for other loads sharing the rectifier ac voltage source. Computer-based loads, which have become very common, appear to be particularly sensitive. Issues of this kind have been receiving increased attention and fall under the general heading of *power quality*. Increasingly strict

power factor and harmonic current limits are being placed on ac-to-dc converters (IEEE-519, 1992; IEC-1000, 1995). In particular, limits on the total harmonic distortion of the current THD_i , the rms values $I_{S(h)}$ of the harmonics, and the rms values of the harmonics relative to the fundamental $I_{S(h)}/I_{S(1)}$ are often specified. These limits present new challenges to the designers of ac-to-dc converters.

ADDITIONAL CONVERTER TOPOLOGIES

This section summarizes the large number of converters that are based on the rectifiers of Table 13.2.1. These converters are shown in Table 13.2.2.

Uncontrolled Diode Rectifier. Replacing SCRs with diodes produces an uncontrolled rectifier as shown in Table 13.2.2a. In contrast to the SCRs, which are gated by a controller, the diodes begin conduction when initially forward biased by the circuit so that an uncontrolled diode rectifier behaves like a phase-controlled rectifier operated with $\alpha = 0^\circ$. Details of uncontrolled diode rectifier operation are described in Kelley (1992).

Half-Controlled Bridge Rectifier. In the half-controlled bridge rectifier the even-numbered SCRs (Q_2 and Q_4 for the single-phase rectifier, and Q_2 , Q_4 , and Q_6 for the three-phase rectifier) are replaced with diodes as shown in Table 13.2.2b. The remaining odd-numbered SCRs (Q_1 and Q_3 for the single-phase rectifier, and Q_1 , Q_3 , and Q_5 for the three-phase rectifier) are phase controlled to regulate the dc output voltage V_O . This substitution is advantageous because diodes are cheaper than SCRs and the cathodes of the remaining SCRs are connected to a common point that simplifies SCR gating.

Note that the diodes begin conduction when first forward biased while the SCRs begin conduction only after being gated while under forward bias. As a result, during a certain portion of each cycle, i_x freewheels through the series connection of a diode and SCR, thereby reducing i_s to zero. For example, in the single-phase bridge rectifier i_x freewheels through Q_1 and D_2 for one part of the cycle and through Q_3 and D_4 for another part of the cycle. In the three-phase rectifier i_x freewheels through Q_1 and D_2 , Q_3 and D_4 , and Q_5 and D_6 during different parts of the cycle. This freewheeling action prevents v_x from changing polarity and improves rectifier power factor as α increases and V_O decreases.

Freewheeling Diode. The same effect is achieved if a freewheeling diode D_x is connected across terminals 1 and 2 of the rectifier as shown in Table 13.2.2c. The freewheeling diode is used with both the bridge and mid-point rectifier connections.

Dc Motor Drive. Any of the phase-controlled rectifiers described above can be used as a dc motor drive by connecting the motor armature across terminals 1 and 2 as shown in Table 13.2.2d. Phase control of SCR firing angle α controls motor speed.

Battery Charger. Phase-controlled rectifiers are widely used as battery chargers as shown in Table 13.2.2e. Phase control of SCR firing angle α regulates battery charging current.

Line Commutated Inverter. A line-commutated inverter transfers power from the dc terminals 1 and 2 of the converter to the ac source. As shown in Table 13.2.2f, the dc terminals are connected to a dc source of power such as a dc generator or a battery. The polarity of each SCR is reversed and the rectifier is operated with $\alpha > 90^\circ$. This circuit is called a line-commutated inverter or a synchronous inverter. Note that the half-controlled bridge and the freewheeling diode cannot be used with a line-commutated inverter because they prevent a change in the polarity of v_x .

Operation with $\alpha > 90^\circ$ causes the majority of the positive half cycle of i_s to coincide with the negative half cycle of v_s . Similarly, the negative half cycle of i_s coincides with the positive half cycle of v_s . It is this mechanism that, on average, causes power flow from the dc source into the ac source. In principle α could approach 180° , but in practice α must be limited to 160° or less to permit sufficient time for the SCRs to stop conducting and regain forward voltage blocking capability before forward voltage is reapplied to them. This requirement is particularly important when L_s is appreciable.

TABLE 13.2.2 Additional Converter Topologies

	Single-Phase Source	Three-Phase Source
(a) Uncontrolled diode rectifier	Replace all SCRs  with diodes 	
(b) Half-controlled bridge rectifier	Replace SCRs Q_2, Q_4  with diodes D_2, D_4 	Replace SCRs Q_2, Q_4, Q_6  with diodes D_2, D_4, D_6 
(c) Freewheeling diode	Retain L_O, C_O , and load, adding diode D_X	
(d) Dc motor drive	Replace L_O, C_O , and load with dc motor 	
(e) Battery charger	Replace L_O, C_O , and load with L_O and battery 	
(f) Line commutated inverter	Reverse polarity of all SCRs  changing to  Replace L_O, C_O , and load with dc generator  or battery and L_O 	

TABLE 13.2.2 Additional Converter Topologies (Continued)

	Single-Phase Source	Three-Phase Source
(g) Alternate three-phase transformer connections	Not applicable	Replace Y primary and/or secondary with Δ primary and/or secondary
(h) Bidirectional converter	Replace all SCRs with two SCRs in antiparallel Replace L_O , C_O , and load with dc generator or battery and L_O 	
(i) Active power factor correction	Replace all SCRs with diodes Replace L_O , C_O , and load with high-frequency filter, dc-to-dc converter, C_O and load

TABLE 13.2.2 Additional Converter Topologies (Continued)

	Single-Phase Source	Three-Phase Source
(j) Series-connected 12-pulse rectifier	Not-applicable	
(k) Parallel-connected 12-pulse rectifier	Not-applicable	

Alternate Three-Phase Transformer Connections. Both primary and secondary transformer windings may be either Y-connected or Δ-connected, as shown in Table 13.2.2g except for the midpoint connection, which requires a Y-connected secondary winding. If the connection is Y-Y or Δ-Δ the waveform of secondary current i_s is scaled by the transformer turn ratio to become the waveform of primary current i_p . Therefore, the secondary current fundamental $I_{S(1)}$ and harmonics $I_{S(h)}$, when scaled by the turn ratio, become the primary fundamental $I_{P(1)}$ and harmonics $I_{P(h)}$.

Similarly, if the transformer connection is Y-Δ or Δ-Y, the secondary current fundamental $I_{S(1)}$ and harmonics $I_{S(h)}$, when scaled by the turn ratio, become the primary fundamental $I_{P(1)}$ and harmonics $I_{P(h)}$. However, the Y-Δ and Δ-Y transformer connections introduce different phase shifts for each harmonic so that the primary current waveform i_p differs in shape from the secondary current wave-form i_s . Rectifier power factor remains unchanged; however, this phase shift is used to produce harmonic cancellation in rectifiers with high pulse numbers as described subsequently.

Bidirectional Converter. Many applications require bidirectional power flow from a single converter. Table 13.2.2h illustrates one example in which a phase-controlled rectifier is, effectively speaking, connected in parallel with a line commutated inverter by replacing each SCR with a pair of SCRs connected in antiparallel. The load is replaced either by a battery or by a dc motor. In the bidirectional converter, one polarity of SCRs is used to transfer energy from the ac source to the battery or motor while the opposite polarity of SCRs is used to reverse the power flow and transfer energy from the battery or motor to the ac source.

For example, using the battery, the converter operates as a battery charger to store energy when demand on the utility is low and at a subsequent time the converter operates as a line commutated inverter to supply energy

when demand on the utility is high. Using a dc motor, the converter operates as a dc motor drive to supply power to a rotating load. Depending on the direction of motor rotation and on which polarity of SCRs is used, the bidirectional converter can both brake the motor efficiently by returning the energy stored in the rotating momentum back to the ac source and subsequently reverse the motors direction of rotation.

Active Power Factor Corrector. In many instances the basic converter topologies of Table 13.2.1 and the additional converter topologies of Table 13.2.2a to 13.2.2g cannot meet increasingly strict power factor and harmonic current limits without the addition of expensive passive filters operating at line frequency. The active power factor corrector, illustrated in Table 13.2.2i, is one solution to this problem (Rippel, 1979; Kocher, 1982; Latos, 1982). The output filter inductor L_o is replaced by a high-frequency filter and a dc-to-dc converter. The dc-to-dc converter uses high-frequency switching and a fast control loop to actively control the waveshape of i_x , and therefore control the waveshape of i_s , for near unity displacement power factor and near unity purity factor resulting in near unity power factor ac-to-dc conversion (Huliehel, 1992). A high-frequency filter is required to prevent dc-to-dc converter switching noise from reaching the ac source.

A slower control loop regulates V_o against changes in source voltage and load. Because the dc-to-dc converter regulates V_o over a wide range of source voltage, the active power factor corrector can be designed for a *universal input* that allows the corrector to operate from nearly any ac voltage source. The active power factor corrector is used most commonly for lower powers.

Higher Pulse Numbers. When strict power factor and harmonic limits are imposed at higher power levels, and the active factor corrector cannot be used, the performance of the basic rectifier is improved by increasing the pulse number q and elimination of current harmonics $I_{S(h)}$ for certain harmonic numbers as shown by Eq. (4). Table 13.2.2j and 13.2.2k illustrate two examples based on the three-phase six-pulse bridge rectifier ($q = 6$) of Table 13.2.1c. The six-pulse rectifiers are shown connected in series in Table 13.2.2j and in parallel in Table 13.2.2k. The parallel connection in Table 13.2.2k requires an *interphase reactor* to prevent commutation of the SCRs in one rectifier from interfering with commutation of the SCRs in the other rectifier. The interphase reactor also helps the two rectifiers share the load equally.

Both approaches use a Y-Y transformer connection to supply one six-pulse rectifier and a Δ -Y transformer connection to supply the second six-pulse rectifier. The primary-to-secondary voltage phase shift of the Δ -Y transformer means the two rectifiers operate out of phase with each other producing 12-pulse operation ($q = 12$). As described previously, the Δ -Y transformer also produces a secondary-to-primary phase shift of the current harmonics. As a result, at the point of connection to the ac source, harmonics from the Δ -Y connected six-pulse rectifier cancel the harmonics from the Y-Y connected six-pulse rectifier for certain harmonic numbers. For example, the harmonics cancel for $h = 5$ and 7, but not for $h = 11$ and 13. Thus the total harmonic distortion for current THD_i and the total power factor for the 12-pulse converter is greatly improved in comparison to either six-pulse converter alone. The 12-pulse output voltage ripple filtering requirement is also greatly reduced compared to a single six-pulse rectifier. This principle can be extended to even higher pulse numbers by using additional six-pulse rectifiers and transformer phase-shift connections.

High Voltage Dc Transmission. High Voltage dc (HVDC) Transmission is a method for transmitting power over long distances while avoiding certain problems associated with long distance ac transmission. This requirement often arises when a large hydroelectric power generator is located a great distance from a large load such as a major city. The hydroelectric generator's relatively low ac voltage is stepped up by a transformer, and a phase-controlled rectifier converts it to a dc voltage of a megavolt or more. After transmission over a long distance, a line commutated inverter and transformer convert the dc back to ac and supply the power to the load. Alternately, the rectifier and inverter are co-located and used as a tie between adjacent utilities. The arrangement can be used to actively control power flow between utilities and to change frequency between adjacent utilities operating at 50 and 60 Hz.

With power in the gigawatt range, this is perhaps the highest power application of a power electronic converter. To ensure a stable system, the control algorithms of the rectifier and inverter must be carefully coordinated. Note that since the highest voltage rating of an individual SCR is less than 10 kV, many SCRs are connected in series to form a *valve* capable of blocking the large dc voltage. Both the rectifier and inverter use a high pulse number to minimize filtering at the point of connection to the ac source.

CHAPTER 13.3

DC-DC CONVERTERS

Philip T. Krein

INTRODUCTION

Power conversion among different dc voltage and current levels is important in applications ranging from spacecraft and automobiles to personal computers and consumer products. Power electronics technology can be used to create a *dc transformer* function for power processing. Today, most dc power supplies rectify the incoming ac line, then use a dc-dc converter to provide a transformer function and produce the desired output voltages. Dc-dc designs often use input voltages near 170 V (the peak value of rectified 120-V ac) or 300–400 V (the peak values of 230, 240 V ac, and many three-phase sources). For direct dc inputs, 48-V sources and 28-V sources reflect practice in the telecommunications and aerospace industries. *Universal input power* supplies commonly handle rectified power from sources ranging between 85 and 270 V ac.

There are a number of detailed treatments of dc-dc converters in the literature. The book by Severns and Bloom (1985) explores a wide range of topologies. Mitchell (1988) offers detailed analysis and extensive treatment of control issues. Chryssis (1989) compares topologies from a practical standpoint, and addresses many aspects associated with actual implementation. Middlebrook has published several exhaustive treatments of various topologies; one example (Middlebrook, 1989) addresses some key attributes of analysis and control. The discussion here follows the treatment in Krein (1998). More recently, Erickson and Maksimovich (2001) have detailed many operation and control aspects of modern dc-dc converters.

DIRECT DC-DC CONVERTERS

The most general dc-dc conversion process is based on a switch matrix that interconnects two dc ports. The two dc ports need to have complementary characteristics, since Kirchhoff's laws prohibit direct interconnection of unlike voltages or currents. A generic example, called a *direct converter*, is shown in Fig. 13.3.1a. A more complete version is shown in Fig. 13.3.1b, in which an inductor provides the characteristics of a current source. In the figure, only four switch combinations can be used without shorting the voltage source or opening the current source:

Combination	Result
Close 1,1 and 2,2	$V_d = V_{IN}$
Close 2,1 and 2,2	$V_d = 0$
Close 1,1 and 1,2	$V_d = 0$
Close 1,2 and 2,1	$V_d = -V_{IN}$

FIGURE 13.3.1 Dc voltage to dc current direct converter: (a) general arrangement; (b) circuit realization.

Switch action selects among $-V_{in}$, 0, and $+V_{in}$ to provide a desired average output. The energy flow is controlled by operating the switches periodically, then adjusting the *duty ratio* to manipulate the average behavior. Duty-ratio control, or *pulse width modulation*, is the primary control method for most dc-dc power electronics. The switching frequency can be chosen somewhat arbitrarily with this method. Typical rates range from 50 kHz to 500 kHz for converters operating up to 200 W, and from 20 kHz to 100 kHz for converters operating up to 2 kW. In dc-dc circuits that use soft switching or *resonant switching* techniques, the switching frequency is usually adjusted to match internal circuit resonances.

Switching functions $q(t)$ can be defined for each switch in the converter. A switching function has the value 1 when the associated switch is on, and 0 when it is off. The converter voltage v_d in Figure 13.3.1b can be written in terms of the switching functions in the compact form

$$v_d(t) = q_{1,1}q_{2,2}V_{in} - q_{1,2}q_{2,1}V_{in} \quad (1)$$

For power flow in one direction, two switches suffice. The usual practice is to establish a common ground between the input and output, equivalent to permanently turning on switch 2,2 and turning off switch 1,2 in Fig. 13.3.1. This simplified circuit is shown in Fig. 13.3.2. The transistor is generic: a BJT, MOSFET, IGBT, or other fully controlled device can be used. The voltage $v_d(t)$ in this circuit becomes $v_d(t) = q_1(t)V_{in}$. Of interest is the dc or average value of the output, indicated by the angle brackets as $\langle v_{out}(t) \rangle$. The inductor cannot sustain an average voltage in the periodic steady state, so the resistor voltage average value $\langle v_{out}(t) \rangle = \langle v_d(t) \rangle$. The voltage $v_d(t)$ is a pulse train with period T , amplitude V_{in} , and an average value related to the duty ratio of the switching function. Therefore,

$$\langle v_d(t) \rangle = \langle v_{out}(t) \rangle = \frac{1}{T} \int_0^T q_1(t)V_{in} dt = D_1 V_{in} \quad (2)$$

where T is the switching period and D_1 is the duty ratio of the transistor. (Typically, an average value in a dc-dc converter is equivalent to substituting a switch duty ratio D for a switching function q .) If the L-R pair serves

FIGURE 13.3.2 Common-ground direct converter (*buck converter*).

TABLE 13.3.1 Buck Converter Characteristics

Characteristic	Value
Input–output relationships	$V_{\text{out}} = D_1 V_{\text{in}}, I_{\text{in}} = D_1 I_{\text{out}}$
Device ratings	Must handle V_{in} when off, and I_{out} when on.
Open-loop load regulation	Load has no direct effect on output.
Open-loop line regulation	No line regulation: line changes are reflected directly at the output. Feedback control is required.
Ripple	Governed by choice of inductor. Typically 50 mV _{peak-to-peak} or 1 percent (whichever is higher) can be achieved.

as an effective low-pass filter, the output voltage will be a dc value $V_{\text{out}} = \langle v_d(t) \rangle$. The circuit has the basic characteristics of a transformer, with the restriction that $V_{\text{out}} \leq V_{\text{in}}$. The name *buck converter* is used to reflect this behavior.

The buck converter, sometimes called a *buck regulator*, or a *step-down converter*, is the basis for many more sophisticated dc-dc converters. Some of its characteristics are summarized in Table 13.3.1. Load regulation is perfect in principle if the inductor maintains current flow. Line regulation requires closed-loop control. Although these relationships are based on ideal, lossless switches, the analysis process applies to more detailed circuits. The following example illustrates the approach.

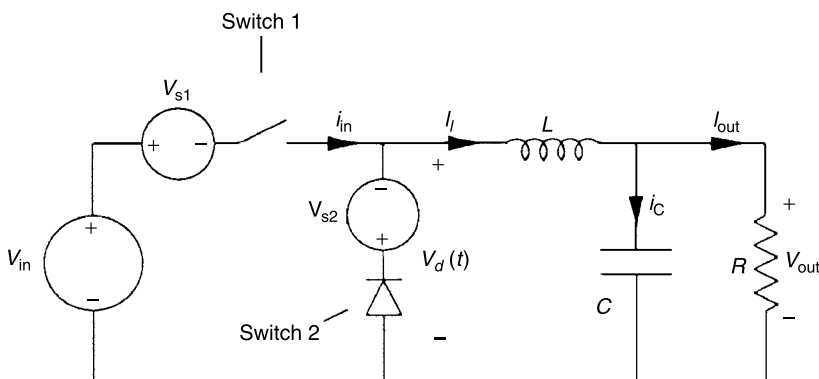

Example: Relationships in a dc-dc converter.

The circuit of Fig. 13.3.3 shows a dc-dc buck converter with switch on-state voltage drops taken into account. What is the input–output voltage relationship? How much power is lost in the converter?

To analyze the effect of switch voltages, KVL and KCL relations can be written in terms of switching functions. When averages are computed, variables such as inductor voltages and capacitor currents are eliminated since these elements cannot sustain dc voltage and current, respectively. Circuit laws require

$$\begin{aligned} v_d(t) &= q_1(t)(V_{\text{in}} - V_{s1}) - q_2(t)V_{s2}, & V_{\text{out}} &= v_d(t) - v_L \\ i_{\text{in}}(t) &= q_1(t)I_L, & I_{\text{out}}(t) &= I_L - i_C(t) \end{aligned} \quad (3)$$

In this circuit, the inductor will force the diode to turn on whenever the transistor is off. This can be represented with the expression $q_1(t) + q_2(t) = 1$. When the average behavior is computed, the duty ratios must follow the relationship $D_1 + D_2 = 1$. The average value of $v_d(t)$ must match V_{out} , and the average input will be the duty ratio of switch 1 multiplied by the inductor current. These relationships reduce to

**FIGURE 13.3.3** Buck converter with switch forward drop models.

FIGURE 13.3.4 Buck converter waveforms.

$$\begin{aligned}
 V_{\text{out}} &= D_1(V_{\text{in}} - V_{s1} + V_{s2}) - V_{s2} \\
 \langle i_{\text{in}}(t) \rangle &= D_1 I_{\text{out}} \\
 P_{\text{in}} &= \langle i_{\text{in}}(t) V_{\text{in}} \rangle = D_1 V_{\text{in}} I_{\text{out}} \\
 P_{\text{out}} &= V_{\text{out}} I_{\text{out}} = D_1(V_{\text{in}} - V_{s1} + V_{s2}) I_{\text{out}} - V_{s2} I_{\text{out}}
 \end{aligned} \tag{4}$$

When the switch voltage drops V_{s1} and V_{s2} have similar values, the loss fraction is approximately the ratio of the diode drop to the output voltage.

The primary design considerations are to choose an inductor and capacitor to meet requirements on output voltage ripple. The design process is simple if a *small ripple assumption* is used: since V_{out} is nearly constant, the voltage across the inductor will be a pulsed waveform at the switching frequency. The current $i_L(t)$ will exhibit triangular ripple. Some waveform samples appear in Fig. 13.3.4. The current swings over its full peak-to-peak ripple during either the transistor on time or the diode on time. The example below takes advantage of the triangular variation to compute the expected ripple.

Example: Buck converter analysis.

A buck converter circuit with an R-L load and a switching frequency of 200 kHz is shown in Fig. 13.3.5. The transistor exhibits on-state drop of 0.5 V, while the diode has a 1 V forward drop. Determine the output ripple for 15 V input and 5 V output. From Eq. (5), the duty ratio of switch 1 should be $6/15.5 = 0.387$. Switch 1 should be on for $1.94 \mu\text{s}$, then off for $3.06 \mu\text{s}$. At 5 V output, the inductor voltage is 9.5 V with switch 1 on and -6 V with switch 1 off. The inductor current has $di/dt = (9.5 \text{ V})/(200 \mu\text{H}) = 47.5 \text{ kA/s}$ when #1 is on and $di/dt = -30 \text{ kA/s}$ when #2 is on. During the on time of switch 1, the current increases $(47500 \text{ A/s}) \cdot (1.93 \mu\text{s}) = 0.092 \text{ A}$. Here, the time constant $L/R = 200 \mu\text{s}$, which is 65 times the switch 2 on time. It would be expected that the current change is small and linear. The current change of 0.092 A produces an output voltage change of 0.092 V for this 1Ω load. Figure 13.3.6 shows some of the important waveforms in idealized form. The output voltage is nearly constant, with $V_{\text{out}} = 5 \pm 0.046 \text{ V}$, consistent with the assumptions in the analysis. The output power is 25 W. The input average current is $D_1 I_{\text{out}} = 0.387(5 \text{ A}) = 1.94 \text{ A}$. The input power therefore is 29.0 W, and the efficiency is 86 percent. This neglects any energy consumed in the commutation process.

FIGURE 13.3.5 Buck converter example.

More generally, the buck converter imposes $V_{in} - V_{out}$ on the inductor while the transistor is on. The current derivative di/dt over a given time interval is the linear change $\Delta i_L/\Delta t$. For the on-time interval $\Delta t = D_1 T$, the peak-to-peak ripple Δi_L is

$$\Delta i_L = \frac{(V_{in} - V_{out})D_1 T}{L} = \frac{V_{in}(1 - D_1)D_1 T}{L} \quad (5)$$

If only inductive filtering is used, the output voltage ripple is the load resistance times the current ripple.

If an output capacitor is added across the load resistor, its effect can be found by treating the inductor as an equivalent triangular current source, then solving for the output voltage. Assuming that the capacitor handles the full ripple current, it is straightforward to integrate the triangular current to compute the ripple voltage. The process is illustrated in Fig. 13.3.7. Voltage $v_c(t)$ will increase whenever $i_c(t) > 0$. The voltage increase is given by

$$\Delta v_c = \frac{1}{C} \int_0^{T/2} i_c(t) dt \quad (6)$$

The integral is the triangular area $1/2(T/2)(\Delta i_L/2)$, so

$$\Delta v_c = \frac{T \Delta i_L}{8C} \quad (7)$$

FIGURE 13.3.6 Buck converter inductor voltage and output current.

FIGURE 13.3.7 Output ripple effect given the addition of capacitive filter.

This expression is accurate if the capacitor is large enough to provide significant voltage ripple reduction.

An alternative direct dc-dc converter has a current source input and voltage source output. The relationships for this *boost converter* are dual to those of the buck circuit. The input current and output voltage act as fixed source values, while the input voltage and output current are determined by switch matrix action. For the common-ground version in Fig. 13.3.8b, the transistor and diode must operate in complement, so that $q_1 + q_2 = 1$ and $D_1 + D_2 = 1$. For ideal switches,

$$\begin{aligned}
 q_1 + q_2 &= 1 \\
 v_i(t) &= q_2 V_{out} = (1 - q_1) V_{out} \\
 i_{out} &= q_2 I_{in} = (1 - q_1) I_{in} \\
 \langle v_i \rangle &= D_2 V_{out} = (1 - D_1) V_{out} \\
 \langle i_{out} \rangle &= (1 - D_1) I_{in}
 \end{aligned}
 \tag{8}$$

With these energy storage devices, notice that $V_{in} = \langle v_i \rangle$ and $I_{out} = \langle i_{out} \rangle$. The relationships can be written

$$V_{out} = \frac{1}{1 - D_1} V_{in} \quad \text{and} \quad I_{in} = \frac{1}{1 - D_1} I_{out}
 \tag{9}$$

The output voltage will be higher than the input. The boost converter uses an inductor at the input to create current-source behavior and a capacitor at the output to provide voltage source characteristics. The capacitor

FIGURE 13.3.8 Boost dc-dc converter: (a) general arrangement; (b) common-ground version.

TABLE 13.3.2 Relationships for the Boost Converter

Characteristic	Value
Input–output relationships	$V_{\text{out}} = V_{\text{in}}/(1 - D_1)$, $I_{\text{out}} = I_{\text{in}}(1 - D_1)$
Open-loop load regulation	Load does not alter output
Open-loop line regulation	Unregulated without control
Device ratings	Must handle V_{out} when off or I_{in} when on
Input–output relationships with switch drops	$V_{\text{out}} = (V_{\text{in}} - V_{s2} - D_1 V_{s1} + D_1 V_{s2})/(1 - D_1)$, $I_{\text{out}} = I_{\text{in}}(1 - D_1)$
Inductor ripple relationship	$\Delta i_L = V_{\text{in}} D_1 T / L$ (if Δi_L is small compared to the input current)
Capacitor ripple relationship	$\Delta v_C = I_{\text{out}} D_1 T / C$

is exposed to a square-wave current signal, and produces a triangular ripple voltage in response. Table 13.3.2 provides a summary of relationships, based on ideal switches.

INDIRECT DC-DC CONVERTERS

Cascade arrangements of buck and boost converters are used to avoid limitations on the magnitude of V_{out} . A buck-boost cascade is developed in Fig. 13.3.9. This is an example of an *indirect converter* because at no point in time does power flow directly from the input to the output. Some of the switches in the cascade are redundant, and can be removed. In fact, only two switches are needed in the final result, shown in Fig. 13.3.10. The current source, called a *transfer current source*, has been replaced by an inductor.

The voltage across the inductor, v_t , is V_{in} when switch 1 is on, and $-V_{\text{out}}$ when switch 2 is on. The transfer current source value is I_s . The inductor cannot sustain dc voltage drop, so $\langle v_t \rangle = 0$. The voltage relationships are

$$\begin{aligned}
 q_1 + q_2 &= 1 \\
 v_t &= q_1 V_{\text{in}} - q_2 V_{\text{out}} \\
 \langle v_t \rangle &= 0 = D_1 V_{\text{in}} - D_2 V_{\text{out}}
 \end{aligned} \tag{10}$$

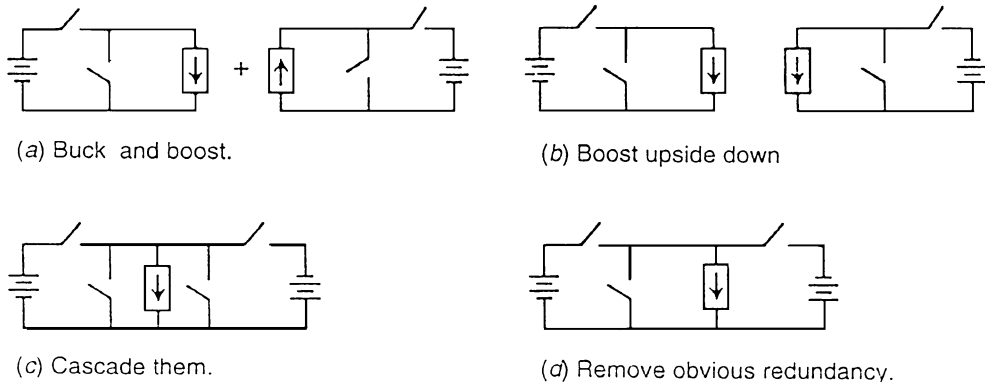

FIGURE 13.3.9 Cascaded buck and boost converters. (From Krein (1998), copyright © 1998 Oxford University Press, Inc., U.S.; used by permission.)

FIGURE 13.3.10 Buck-boost converter.

The last part of Eq. (10) requires $D_1 V_{in} = D_2 V_{out}$ in steady state. The switches must act in complement, so $D_1 + D_2 = 1$, and

$$V_{out} = \frac{D_1}{1 - D_1} V_{in} \tag{11}$$

A summary of results is given in Table 13.3.3. The cascade process produces a negative voltage with respect to the input. This polarity reversal property is fundamental to the buck-boost converter.

A boost-buck cascade also allows full output range with a polarity reversal. As in the buck-boost case, many of the switches are redundant in the basic cascade, and only two switches are required. The final circuit, with energy storage elements in place, as shown in Fig. 13.3.11. The center capacitor serves as a *transfer voltage source*. The transfer source must exhibit $\langle i_c \rangle = 0$, since a capacitor cannot sustain dc current. Some of the major relationships are summarized in Table 13.3.4. In the literature, this arrangement is called a *Cuk converter*, after the developer who patented it in the mid-1970s (Middlebrook and Cuk, 1977). The transfer capacitor must be able to sustain a current equal to the sum of the input and output currents. The RMS capacitor current causes losses in the capacitor's internal equivalent series resistance (ESR), so low ESR components are usually required.

Figure 13.3.12 shows the *single-ended primary inductor converter* or SEPIC circuit (Massey and Snyder, 1977). This is a boost-buck-boost cascade. As in the preceding cases, the cascade arrangement can be simplified to require only two switches. The transfer sources C_1 and L_1 carry zero average power to be consistent with a capacitor and an inductor as the actual devices. The relationships are

$$\begin{aligned} v_{in} &= q_2(V_{out} + V_{r1}), & \langle v_{in} \rangle &= D_2(V_{out} + V_{r1}) \\ i_{out} &= q_2(I_{in} + I_{r2}), & \langle i_{out} \rangle &= D_2(I_{in} + I_{r2}) \\ i_{r1} &= -q_1 I_{r2} + q_2 I_{in}, & \langle i_{r1} \rangle &= 0 = -D_1 I_{r2} + D_2 I_{in} \end{aligned} \tag{12}$$

TABLE 13.3.3 Buck-Boost Converter Relationships

Characteristic	Value
Input-output voltage relationship	$ V_{out} = V_{in} D_1 / (1 - D_1)$, $I_{in} = I_{out} D_1 / (1 - D_1)$, output is negative with respect to input
Device ratings	Must handle $ V_{in} + V_{out} $ when off, $ I_{in} + I_{out} $ when on
Inductor current	$I_L = I_{in} - I_{out} $
Regulation	Perfect load regulation. No open-loop line regulation
Inductor ripple current	$\Delta i_L = V_{in} D_1 T / L$
Capacitor ripple voltage	$\Delta v_C = I_{out} D_1 T / C$
Output range	Ideally, any negative voltage can be produced

FIGURE 13.3.11 Boost-buck converter.

$$v_{t2} = -q_1 V_{t1} + q_2 V_{out}, \quad \langle v_{t2} \rangle = 0 = -D_1 V_{t1} + D_2 V_{out}$$

$$q_1 + q_2 = 1, \quad D_1 + D_2 = 1$$

Some algebra will bring out the transfer source values and input-output ratios:

$$I_{t2} = \frac{D_2}{D_1} I_{in} = \frac{1-D_1}{D_1} I_{in}$$

$$V_{t1} = \frac{D_2}{D_1} V_{out} = \frac{1-D_1}{D_1} V_{out} \quad (13)$$

$$\langle v_{in} \rangle = D_2 \left(V_{out} + \frac{1-D_1}{D_1} V_{out} \right) = \frac{1-D_1}{D_1} V_{out}$$

This is the same input-output ratio as the buck-boost converter, except that there is no polarity reversal.

These and related indirect converters provide opportunities for the use of more sophisticated magnetics such as *coupled inductors*. In the Cuk converter, for example, the input and output filter inductors are often coupled on a single core to cancel out part of the ripple current (Middlebrook and Čuk, 1981). In a buck-boost converter, the transfer source inductor can be split by providing a second winding. One winding can be used to inject energy into the inductor, while the other can be used to remove it. The two windings provide isolation. This arrangement is known as a *flyback converter* because diode turn-on occurs when the inductor output coil voltage “flies back” as the input switch turns off. An example is shown in Fig. 13.3.13.

The flyback converter is one of the most common low-power dc-dc converters. It is functionally equivalent to the buck-boost converter. This is easy to see if the turns ratio between the windings is unity. The possibility of a nonunity turns ratio is a helpful extra feature of the flyback converter. Extreme step-downs, such as the 170-V to 5-V converter, often used in a dc power supply, can be supported with reasonable duty ratios by selecting an appropriate turns ratio. In general, flyback converters are designed to keep the nominal duty ratio close to 50 percent. This tends to minimize the energy storage requirements, and keeps the sensitivity to variation as

TABLE 13.3.4 Relationships for Boost-Buck Converter

Characteristic	Value
Input-output relationships	$ V_{out} = D_1 V_{in} / (1 - D_1)$, $I_{in} = D_1 I_{out} (1 - D_1)$
Device ratings	Must handle $ V_{in} + V_{out} $ when off. Must handle $ I_{in} + I_{out} $ when on
Regulation	Perfect load regulation, no line regulation

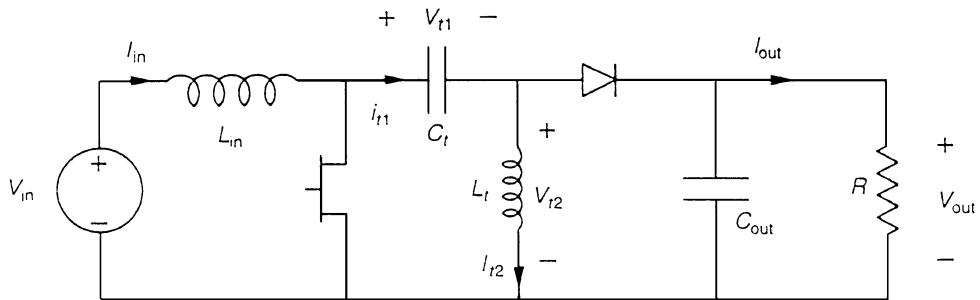

FIGURE 13.3.12 The SEPIC converter. Two transfer sources permit any input-to-output ratio without polarity reversal.

FIGURE 13.3.13 Flyback converter.

low as possible. An additional advantage appears when several different dc supplies are needed: if it is possible to use two separate coils on the magnetic core of the inductor, it should be just as reasonable to use three, four, or even more coils. Each can have its own turns ratio with mutual isolation. This is the basic for many types of multi-output dc power supplies.

One challenge with a flyback converter, as shown in Fig. 13.3.14, is the primary leakage inductance. During transistor turn-off, the leakage inductance energy must be removed. A capacitor or other snubber circuit is used to avoid damage to the active switch during turn-off.

FIGURE 13.3.14 Leakage inductance issue in flyback converter.

FORWARD CONVERTERS

Coupled inductors in indirect converters, unlike transformers, must store energy and carry a net dc current. Basic buck and boost circuits lack a transfer source, so a coupled inductor will not give them isolation properties. Instead, a buck or boost converter can be augmented with a transformer, inserted at a location with only ac waveforms. Circuits based on this technique are called *forward converters*. A transformer can be added either by providing a *catch winding* tertiary or other circuitry for flux resetting, or by using an *ac link* arrangement. With either alternative, the objective is to avoid saturation because of dc current.

Figure 13.3.15 shows the catch-winding alternative in a buck converter. The tertiary allows the core flux to be reset while the transistor is off. Operation is as follows: the transistor carries the primary current i_1 and also the magnetizing current i_m when it is on. Voltage V_{in} is imposed on the primary, and the flux increases. When the transistor turns off, the magnetizing inductance will maintain the current flow in coil 1, such that $i_1 = -i_m$. The diode D_3 permits current $i_3 = i_m(N_1/N_3)$ to flow. The tertiary voltage v_3 flies back to $-V_{in}$, resetting the flux. If $N_1 = N_3$, the duty ratio of switch 1 must not exceed 50 percent so that there will be enough time to bring the flux down sufficiently. If it is desired to reach a higher duty ratio, the ratio N_1/N_3 must be at least $D_1/(1 - D_1)$.

With a catch winding, the primary carries a voltage $v_1 = -N_1/N_3$ after the transistor turns off. The transistor must be able to block $V_{in}(1 + N_1/N_3)$ to support this voltage. For power supplies, this can lead to extreme ratings. For example, an off-line supply designed for 350 V_{dc} input with $N_1/N_3 = 1.5$ to support duty ratios up to 60 percent requires a transistor rating of about 1000 V. This extreme voltage rating is an important drawback of the catch-winding approach.

The secondary voltage v_2 in this converter is positive whenever the transistor is on. The diode D_1 will exhibit the same switching function as the transistor, and the voltage across D_2 will be just like the diode voltage of a buck converter except for the turns ratio. The output and its average value will be

$$v_{out} = q_1 V_{in} \frac{N_2}{N_1}, \quad \langle v_{out} \rangle = D_1 V_{in} \frac{N_2}{N_1} \quad (14)$$

so this forward converter is termed a *buck-derived* circuit.

The ac link configuration comprises an inverter-rectifier cascade, such as the buck-derived half-bridge converter in Fig. 13.3.16. With adjustment of duty ratio, a waveform such as that shown in Fig. 13.3.17a is typically used as the inverter output. The signal has no dc component, and therefore a transformer can be used. Once full-wave rectification is performed, the result will be the square wave of Fig. 13.3.17b. The average output is

$$\langle v_{out} \rangle = 2aDV_{in} \quad (15)$$

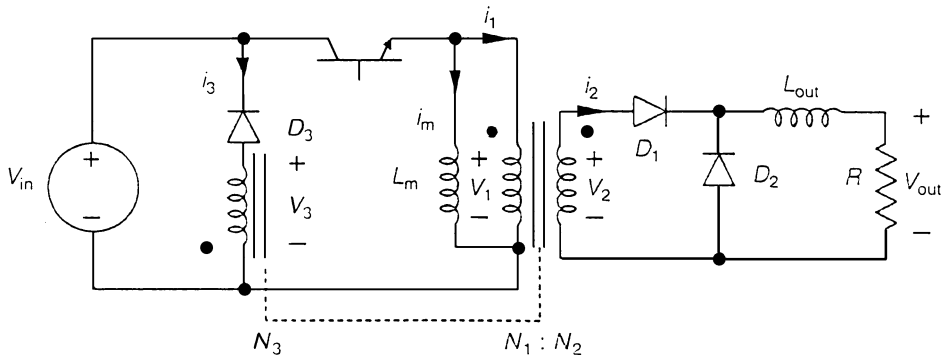

FIGURE 13.3.15 Catch-winding forward converter. (From Krein (1998), copyright © 1998 Oxford University Press, Inc., U.S.; used by permission.)

FIGURE 13.3.16 Half-bridge forward converter.

reflecting the fact that there are two output pulses during each switching period. No switch on the inverter side will be on more than 50 percent of each cycle, and the transistors block only V_{in} when off.

Four other forward converter topologies are shown in Fig. 13.3.18. The full bridge circuit in particular has been used successfully for power levels up to a few kilowatts. The others avoid the complexity of four active switches, although possibly with a penalty. For example, the *push-pull* converter in the figure has the important advantage that both switch gate drives share a common reference node with V_{in} . Its drawback is that the transistor must block $2V_{in}$ when off, because of an autotransformer effect of the center-tapped primary. The topologies are compared in Table 13.3.5.

The full-bridge converter perhaps offers the most straightforward operation. The switches always provide a path for magnetizing and leakage inductance currents, and circuit behavior is affected little by these extra inductances. In other circuits, these inductances are a significant complicating factor. For example, magnetizing inductance can turn on the primary-side diodes in a half-bridge converter, altering the operation of duty

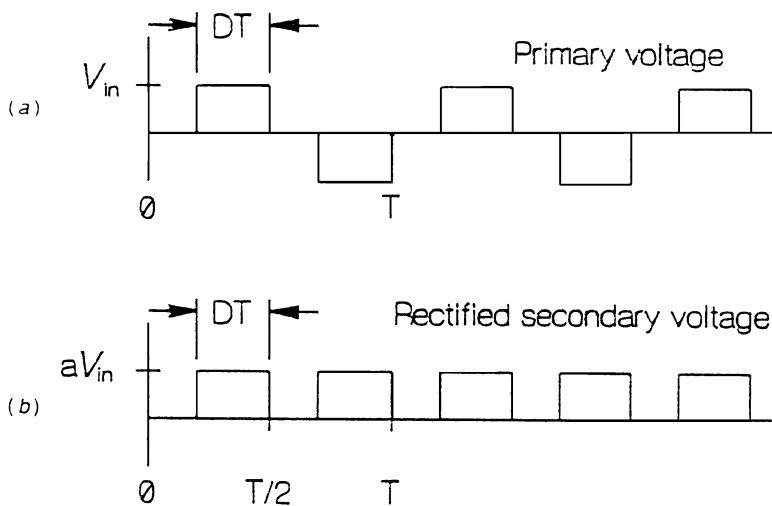

FIGURE 13.3.17 Typical waveforms in inverter-rectifier cascade. (From Krein (1998), copyright © 1998 Oxford University Press, Inc., New York, U.S.; used by permission.)

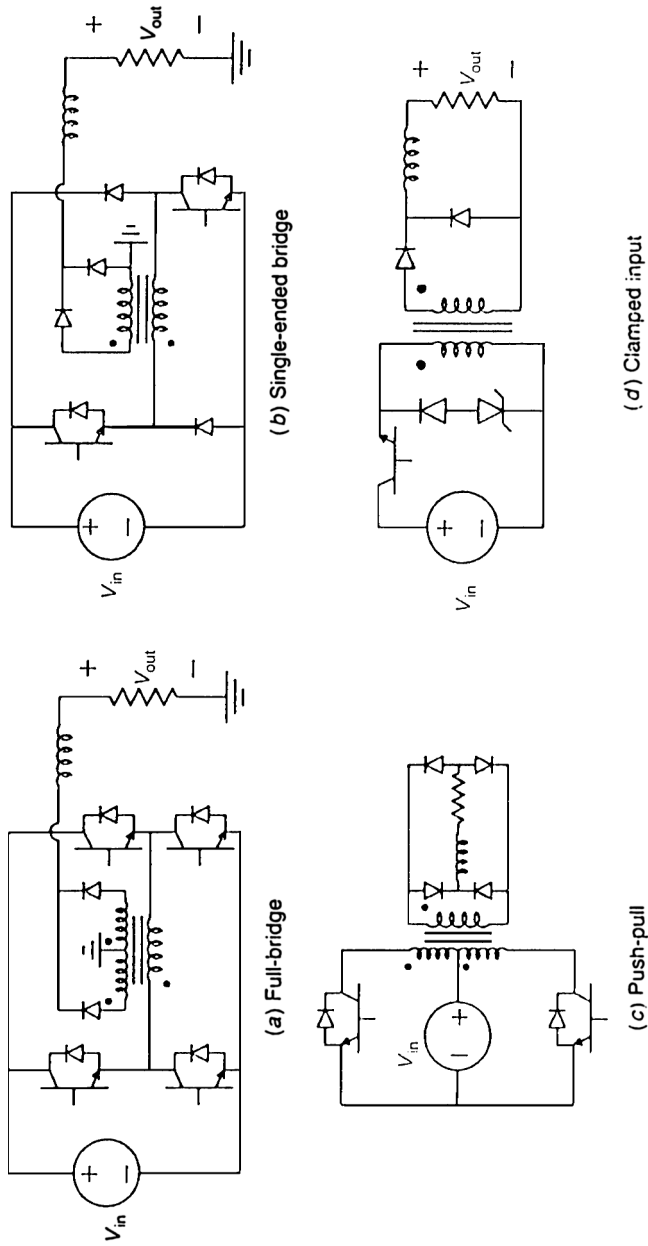

FIGURE 13.3.18 Four alternative forward converter topologies.

TABLE 13.3.5 Characteristics of Common Buck-Derived Forward Converters

Forward Converter Topology	Transistor Off-State Voltage	Flux Behavior	Comments
Full-bridge	V_{in}	Full variation from $-\phi_{max}$ to $+\phi_{max}$	Preferred for high power levels by many designers
Half-bridge	V_{in}	Full variation	Capacitive divider avoids any dc offset in flux. Preferred at moderate power levels by many designers
Single-ended	V_{in}	Variation only between 0 and $+\phi_{max}$	Less effective use of core, but only two transistors
Push-pull	$2V_{in}$	Full variation	Common-ground gate drives. Timing errors can bias the flux and drive the core into saturation
Clamp	$V_{in} + V_z$	Variation only between 0 and $+\phi_{max}$	Similar to catch winding circuit, except that energy in magnetizing inductance is lost

ratio control. Leakage inductance is a problem in the push-pull circuit, particularly since both transistors must be off to establish the portion of time when no energy is transferred from input to output. Snubbers are necessary parts of this converter. These issues are discussed at length in at least one text (Kassakian, Schlecht, and Verghese, 1991).

The boost converter also supports forward converter designs. A boost-derived push-pull forward converter is shown in Fig. 13.3.19. Like the boost converter, this circuit has an output higher than the input but now with a turns ratio. The operation differs from a buck-derived converter in an important way: both transistors must turn on to establish the time interval when no energy flows from input to output. In effect, each transistor has a *minimum* duty ratio of 50 percent, and control is provided by allowing the switching functions to overlap. The output duty ratio associated with each diode becomes $1 - D$, where D is the duty ratio of one of the transistors over a full switching period. The output voltage is

$$V_{out} = \frac{N_2}{N_1} \frac{V_{in}}{2(1-D)} \quad (16)$$

The other forward converter arrangements also have boost-derived counterparts.

**FIGURE 13.3.19** Boost-derived push-pull converter.

In each of the converters discussed so far, it has been assumed that energy storage components have been sufficiently large to be treated as approximate current or voltage sources. This is not always the case. If values of inductance or capacitance are chosen below a certain value, the current or voltage, respectively, will reach zero when energy is extracted. This creates *discontinuous mode* behavior in a dc-dc converter. The values of L and C sufficient to ensure that this does not occur are termed *critical inductance* and *critical capacitance*, respectively. The usual effect of subcritical inductance is that all switches on the converter turn off together for a time. Subcritical capacitance in a boost-buck converter creates times when all switches are on together.

In discontinuous mode, converter load regulation degrades, and closed-loop output control becomes essential. However, discontinuous mode can be helpful in certain situations. It implies fast response times since there is no extra time required for energy buildup. It provides an additional degree of freedom—the extra configuration when all switches are off or on—for control purposes.

Discontinuous mode behavior can be analyzed through the techniques of this subsection, with the additional constraint that all energy in the storage element is removed during each switching period. The literature (Mitchell, 1988; Mohan, Undeland, and Robbins, 1995) provides a detailed analysis, including computation of critical inductance and capacitance.

RESONANT DC-DC CONVERSION TECHNIQUES

The dc-dc converters examined thus far operate their switches in a *square-wave* or *hard-switched* mode. Switch action is strictly a function of time. Since switch action requires finite time, hard-switched operation produces significant switching loss. Resonant techniques for *soft switching* attempt to maintain voltages or currents at low values during switch commutation, thereby reducing losses. *Zero-current switching* (ZCS) or *zero-voltage switching* (ZVS) can be performed in dc converters by establishing resonant combinations. Resonant approaches for soft switching are discussed extensively in Kazimierzczuk and Czarkowski (1995).

The SCR supports natural zero-current switching, since turn-off corresponds to a current zero crossing. A basic arrangement, given in Fig. 13.3.20, is often used as the basis for soft switching in transistor-based dc-dc converters as well as for inverters. Starting from rest, the top SCR is triggered. This applies a step dc voltage to the RLC set. If the quality factor of the RLC set is more than $\frac{1}{2}$, the current is underdamped, and will oscillate. When the current swings back to zero, the SCR will turn off with low loss. After that point, the lower SCR can be triggered for the negative half-cycle.

The SCR inverter represents a *series resonant switch* configuration and provides ZCS action. However, SCRs are not appropriate for high-frequency dc-dc conversion because of their long switching times and control limitations. The circuit of Fig. 13.3.21 shows an interesting arrangement for dc-dc conversion, similar to the SCR circuit, but based on a fast MOSFET. In this case, an inductor and a capacitor have been added to a standard buck converter to alter the transistor action. Circuit behavior will depend on the relative values.

FIGURE 13.3.20 SCR soft-switching inverter. (From Krein (1998), copyright © 1998 Oxford University Press, Inc., U.S.; used by permission.)

FIGURE 13.3.21 A soft-switching arrangement for a buck converter.

If the capacitor C_t is large, its behavior during the transistor's off interval will introduce opportunities for resonant switching. In this case, the basic circuit action is as follows:

- When the transistor turns off, the input voltage excites the pair L_{in} and C_r . The input inductor current begins to oscillate with the capacitor voltage. The capacitor can be used to keep the transistor voltage low as it turns off.
- The capacitor voltage swings well above V_{in} , and the main output diode turns on.

FIGURE 13.3.22 Input current and diode voltage in a resonant buck converter. (From Krein (1998), copyright © 1998 Oxford University Press, Inc., U.S.; used by permission.)

- The capacitor voltage swings back down. There might be an opportunity for zero-voltage turn-on of the transistor when the capacitor voltage swings back to zero.

This represents ZVS action.

When the transistor is on and the main diode is off, the input inductor forms a resonant pair with C_d . This pair provides an opportunity for zero-current switching at transistor turn-off, very much like the zero-current switch action in the SCR inverter. The action is as follows in this case:

- When the transistor is turned on, L_{in} limits the rate of rise of current. The diode remains on initially, and the current builds up linearly because V_{in} appears across the inductor.
- When the current arises to the level I_{out} , the diode shuts off and the transistor carries the full current. The pair L_{in} and C_d form a resonant LC pair, and the current oscillates.
- The current rises above I_{out} because of resonant action, but then swings back down toward the origin.
- When the current swings negative, the transistor's reverse body diode begins to conduct, and the gate signal can be shut off. When the current tries to swing positive again, the switch will turn off.
- The transistor on-time is determined by the resonant frequency and the average output current.

Figure 13.3.22 shows the input current and main diode voltage for a choice of parameters that gives ZCS action in the circuit of Fig. 13.3.21.

Resonant action changes the basic control characteristics substantially. The gate control in both ZVS and ZCS circuits must be properly synchronized to match the desired resonance characteristics. This means that pulse-width modulation is not a useful control option. Instead, resonant dc converters are adjusted by changing the switching frequency—in effect setting the portion of time during which resonant action is permitted. In a ZCS circuit, for example, the average output voltage can be reduced by dropping the gate pulse frequency.

In general, ZCS or ZVS action is very beneficial for loss reduction. Lower switching losses permit higher switching frequencies, which in turn allow smaller energy storage elements to be used for converter design. Without resonant action, it is difficult to operate a dc-dc converter above perhaps 1 MHz. Resonant designs have been tested to frequencies as high as 10 MHz (Tabisz, Gradzki, and Lee, 1989). Designs even up to 100 MHz have been considered for aerospace applications. In principle, resonance provides size reduction of more than an order of magnitude compared to the best nonresonant designs. However, there is one important drawback: The oscillatory behavior substantially increases the on-state currents and off-state voltages that a switch must handle. Under some circumstances, the switching loss improvements of resonance are offset by the extra on-state losses caused by current overshoot. There are magnetic techniques to help mitigate this issue (Erickson, Hernandez, and Witulski, 1989), but they add complexity to the overall conversion system. The switching loss trade-offs tend to favor resonant designs at relatively low voltage and current levels. More sophisticated resonant design approaches, based on Class E methods (Kasimierzczuk and Czarkowski, 1995), can further reduce losses.

Example: Input-output relationships in a ZCS dc-dc converter.

Let us explore ZCS switching in a dc-dc converter and analyze the results. The approach in this example follows an analysis in Kassakian, Schlecht, and Verghese (1991). The circuit in Fig. 13.3.21 is the focus, with C_f selected to be small and L_{out} selected to be large. Parameters are $V_{in} = 24$ V, $C_f = 200$ pF, $L_{in} = 2$ μ H, $C_d = 0.5$ μ F, $L_{out} = 50$ μ H, and a $10\text{-}\Omega$ load in parallel with an 8 μ F filter capacitor. The FET is supplied with a 5- μ s pulse with a period of 12 μ s.

In periodic steady-state operation, the inductor L_{out} will carry a substantial current. The output time constant is long enough to ensure that the current will not change very much. As a result, the output inductor can be modelled as a current source, with value I_{out} . The diode provides a current path while the transistor is off. Consider the moment at which the transistor turns on. Since the current in L_{in} cannot change instantly, the diode remains on for a time while the input current rises. We have

$$i_{in}(t) = \frac{V_{in}}{L_{in}} t \quad (17)$$

until the current i_{in} reaches the value I_{out} . At the moment $t_{on} = I_{out}L_{in}/V_{in}$, the diode current reaches zero and the diode turns off. The input circuit becomes an undamped resonant tank determined by L_{in} and C_d . For C_d circuit laws require

$$V_{in} - v_{Cd}(t) - L_{in}C_d\ddot{v}_{Cd}(t) = 0, \quad v_{Cd}(t_{on}) = 0, \quad \dot{v}_{Cd}(t_{on}) = 0 \quad (18)$$

This has the solution

$$v_{Cd}(t) = V_{in} \{1 - \cos[\omega_r(t - t_{on})]\}, \quad \text{where } \omega_r = \frac{1}{\sqrt{L_{in}C_d}} \quad (19)$$

For the input current, the corresponding solution is

$$i_{in}(t) = I_{out} + \frac{V_{in} \sin[\omega_r(t - t_{on})]}{Z_c}, \quad \text{where } Z_c = \sqrt{\frac{L_{in}}{C_d}} \quad (20)$$

With the selected parameters, $Z_c = 2 \Omega$ and $\omega_r = 10^6$ rad/s, corresponding to about 160 kHz. The inductor current will cross zero again a bit more than one half-period after t_{on} . In this example, I_{out} might be on the order of 1 A, so t_{on} corresponds to only about 83 ns. The half-period of the resonant ring signal will be about 3.2 μ s. Therefore, a 5- μ s gate pulse should ensure that the transistor remains on until the zero crossing point.

When the current crosses zero, the FET turns off, but its reverse body diode turns on and maintains negative flow for approximately another half-cycle, at approximately $t = 6.4 \mu$ s. Since the gate signal is removed between the zero crossings, the FET and its diode will both turn off at the second zero crossing. Figure 13.3.22 is a SPICE simulation for these circuit parameters. The ZCS action should be clear: since the gate pulse is removed while the FET's reverse body diode is active, the complete FET will shut off at a rising current zero crossing. The shut-off point t_{off} is determined by

$$0 = I_{out} + \frac{V_{in} \sin[\omega_r(t_{off} - t_{on})]}{Z_c}, \quad \omega_r(t_{off} - t_{on}) = \sin^{-1}\left(\frac{-I_{out}Z_c}{V_{in}}\right) \quad (21)$$

In solving this expression, it is crucial to be careful about the quadrant for $\sin^{-1}(x)$. The rising zero crossing is sought.

Once the FET is off, capacitor C_d carries the full current I_{out} . The voltage $v_{Cd}(t)$ will fall quickly with slope $-I_{out}/C_d$ until the diode becomes forward biased and turns on. The voltage $v_{Cd}(t)$ is of special interest, since the output is $V_{out} = \langle v_{Cd}(t) \rangle$. The average is

$$\langle v_{Cd} \rangle = \frac{1}{T} \left(\int_{t_{on}}^{t_{off}} V_{in} (1 - \cos[\omega_r(t - t_{on})]) dt + \int_{t_{off}}^{t_{(diode\ on)}} v_{Cd}(t_{off}) - \frac{I_{out}}{C_d} t dt \right) \quad (22)$$

The second integral is a triangular area $1/2 v_{Cd}(t_{off})^2 (C_d/I_{out})$. For $I_{out} \approx 1$ A, the time $t_{off} - t_{on}$ can be found from Eq. (21) to be 6.20 μ s. The value $v_{Cd}(t_{off})$ is therefore 83 mV. The average value is $V_{out} = 12.6$ V. This corresponds to $I_{out} = 1.26$ A. In this example, the average value comes out very close to

$$V_{out} = \frac{4.8 \times 10^{-6} \pi}{T} \quad (23)$$

for $T > 6.4 \mu$ s. The solution comes out quite evenly because the current zero-crossing times nearly match those of the resonant sine wave.

In the ZCS circuit, the on time of the transistor is determined by resonant action, provided the gate pulse turns off during a time window when reverse current is flowing through the device's diode. The gate pulses need to have fixed duration to tune the circuit, but the pulse period can be altered to adjust the output voltage.

CHAPTER 13.4

INVERTERS

David A. Torrey

INTRODUCTION

Inverters are used to convert dc into ac. This is accomplished through alternating application of the source to the load, achieved through proper use of controllable switches. This section reviews the basic principles of inverter circuits and their control. Four major applications of inverter circuits are also reviewed.

Both voltage- and current-source inverters are used in practice. The trend, however, is to use voltage-source inverters for the vast majority of applications. Current-source inverters are still used at extremely high power levels, though voltage-source inverters are gradually filling even these applications. Because of the dominance of voltage-source inverters, this section focuses exclusively on this type of inverter.

There are many issues involved in the design of an inverter. The more prominent issues involve the interactions among the power circuit, the source, the load, and the control. Other subtle issues involve the control of parasitics and the protection of controllable switches through the use of snubber and clamp circuits, and the juxtaposition of controller speed with the desire for increased switching frequency, while maintaining high efficiency.

The technical literature contains abundant information on inverters. A set of technical papers is found in Bose (1992). In addition to technical papers, most power electronics textbooks have a section on inverters (Mohan, Undeland, and Robbins, 1995; Kassakian, Schlecht, and Verghese, 1991; Krein, 1998).

AN INVERTER PHASE-LEG

An inverter phase-leg is shown in Fig. 13.4.1. It comprises two fully controllable switches and two diodes in antiparallel to the controllable switches. This phase-leg is placed in parallel with a voltage source. The center of the phase-leg is taken to the load. The basic circuit shown in Fig. 13.4.1 is usually augmented with a snubber circuit or clamp to shape the switching locus of the controllable switches. Insulated gate bipolar transistors (IGBTs) are shown as the controllable switches in Fig. 13.4.1. While the IGBT finds significant application in inverters, any fully controllable device, such as an FET or a GTO, may be used in its place; see Chapter 13.1 for a description of the fully controllable switches that can be used in an inverter.

Basic Principles. In the phase-leg of Fig. 13.4.1, there are two restrictions on the use of the controllable switches. First, at most one controllable switch may be conducting at any time. The dc supply is shorted if both switches are conducting. In practice, one switch is turned off before the other is turned on. This blanking time, also known as dead time, compensates for the tendency of power devices to turn on faster than they turn off. Second, at least one controllable switch (or an associated diode) must be on at all times if the load current is to be nonzero.

If the upper switch is conducting, the load is connected to the positive side of V_{dc} . If the lower switch is conducting, the load is connected to the negative side of V_{dc} . It follows that the voltage applied to the load will, on

FIGURE 13.4.1 An inverter phase-leg.

average, fall somewhere between 0 and V_{dc} . When the phase-leg of Fig. 13.4.1 is used with one or more additional phase legs, the load voltage can be made to alternate. The details of how it alternates is the responsibility of the controller.

The peak voltage seen by each switch is the total dc voltage across the phase-leg. This is determined by recognizing that one of the two switches is always conducting. The peak current that must be supported by each switch is the peak current of the load. Under balanced control of the two switches, each switch must support the same peak current; each diode must support the same peak current as the switches.

In an effort to improve the efficiency and spectral performance of inverters, the use of inverters with a resonant dc link has been reported in the technical literature (Divan, 1989; Murai and Lipo, 1988).

Through periodic resonance of the dc bus voltage to zero, or the dc bus current to zero, the inverter switches can change states in synchronism with these zero crossings in order to reduce the switching losses in the power devices. Figure 13.4.2 shows a schematic for the basic resonant dc link converter (Divan, 1989). The resonance of L_r and C_r forces the bus voltage (the voltage applied to the controllable switches) to swing between zero and $2V_{dc}$. The inverter switches change states when the voltage across C_r is zero. It is often necessary to hold the bus voltage at zero for a brief time to ensure that sufficient energy has been put into L_r to force resonance back to zero voltage across C_r . The bus can be clamped at zero voltage by turning on both switches in an inverter phase-leg. One drawback of the resonant dc link is the increased voltage or current imposed on the power devices. Auxiliary clamp circuits have been implemented to minimize this drawback (Divan and Skibinski, 1989; He and Mohan, 1991; Simonelli and Torrey, 1994). The control of a resonant link inverter is complicated by the simultaneous need to manage energy flow to the load while managing energy in the resonant link.

Snubber Circuits and Clamps. Snubber circuits are used to control the voltage across and the current through a controllable switch as that device is turning on or off. A complete snubber will typically limit the rate of rise in current as the device is turning on and limit the rate of rise in voltage as the device is turning off. Additional circuit components are used to accomplish this shaping of the switching locus. Figure 13.4.3 shows three snubber circuits that are used with inverter legs, one of which has auxiliary switches (McMurray, 1987; McMurray, 1989;

FIGURE 13.4.2 A basic resonant dc link inverter system.

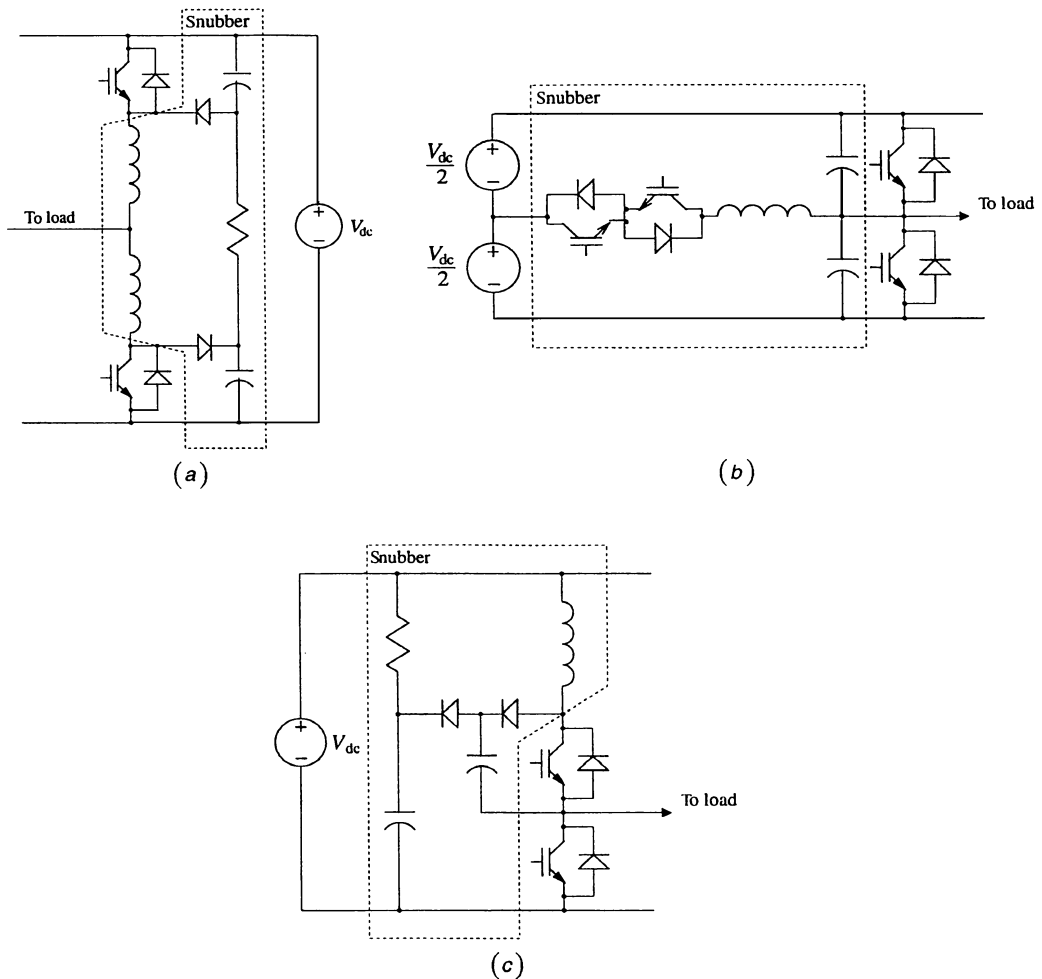

FIGURE 13.4.3 A number of snubber circuits for an inverter phase-leg: (a) a McMurray snubber (McMurray, 1987); (b) a resonant snubber with auxiliary switches (McMurray, 1989); and (c) the Undeland snubber (Undeland, 1976).

Undeland, 1976). Snubber circuits become increasingly important as the power rating of the inverter increases, where the additional cost of small auxiliary devices is justified by improved efficiency and spectral performance.

Clamps differ from snubbers in that a clamp is used only to limit a switch variable, usually the voltage, to some maximum value. The clamp does not dictate how quickly this maximum value is attained. Figure 13.4.4 shows three clamp circuits that are commonly used with inverter legs. The clamp circuits generally become more complex with increasing power level.

Interfacing to Controllable Switches. The interface to the controllable switches within the inverter phase-leg of Fig. 13.4.2 requires careful attention. Power semiconductor devices are generally controlled by manipulating the control terminal, usually relative to one of the power terminals. For example, Figure 13.4.2 shows insulated gate bipolar transistors (IGBTs) as the controllable switches. These devices are turned on and off through the voltage level applied to the gate relative to the emitter. Because the emitter of the upper IGBT moves around, the control of the upper IGBT must accommodate this movement. The emitter voltage of the upper IGBT moves from the positive side of the dc bus when the IGBT is conducting to the negative side of the dc bus when

FIGURE 13.4.4 Clamp circuits for an inverter phase-leg: (a) low power (~ 50 A); (b) medium power (~ 200 A); and (c) high power (~300 A).

the lower IGBT is conducting. The circuit responsible for turning the power semiconductor on and off as commanded by a controller is usually known as a gate-drive circuit. Some gate-drive circuits incorporate protection mechanisms for over current or over temperature.

There are a number of approaches that are used to control the semiconductor devices within the inverter. The choice among these approaches is often dictated by the power levels involved, the switching frequency supported by the switches, and the preference of the designer, among others. It is possible to purchase high-voltage integrated circuits (HVICs) that perform the level shifting necessary to take a logic signal referenced to the negative side of the dc bus and control the upper controllable switch in the phase-leg. This approach is generally limited to applications where the controllable switches do not require a negative bias to hold them in the blocking state. High-frequency applications may use transformer-coupled gate drives that are insensitive to the common-mode voltage between the primary and secondary. This approach runs into problems at lower frequencies because the size of the transformer core begins to get large. High-power applications may use optocouplers to optically couple the control information to the gate drive, where the gate drive is supported by an isolated power supply. Often the power supply is the dominant factor in the overall cost of the gate drive.

Figure 13.4.5a shows how an HVIC is interfaced to a phase-leg. The capacitors are used as local power supplies for the upper and lower gate drives. In this implementation, the upper capacitor is charged through the diode while the lower switch is conducting. Figure 13.4.5b shows a transformer-coupled gate drive for a high-frequency application (International Rectifier). It is important to design a mechanism for resetting the core in

FIGURE 13.4.5 Three common approaches to interfacing to controllable switches: (a) the use of an HVIC; (b) the use of transformer coupling; and (c) the use of an optocoupler.

a transformer-coupled gate drive. In Fig. 13.4.5b, the core is reset by driving the transformer primary with a bipolar voltage that provides sufficient volt-seconds to drive the transformer into saturation. This need for core reset may place unacceptable limitations on the duty ratio of the switches for some applications. Figure 13.4.5c shows the use of an optocoupler to provide isolation of the control signal going to the gate drive. The isolated power supply required to support the use of the optocoupler is not shown.

SINGLE-PHASE INVERTERS

There are two ways to form a single-phase inverter. The first way is shown in Fig. 13.4.6, where the phase leg of Fig. 13.4.1 is used to control the voltage applied to one side of the load. The other side of the load is connected to the common node of two voltage sources. The half-bridge inverter of Fig. 13.4.6 applies positive voltage to the load when the upper switch is conducting and negative voltage to the load when the lower switch is conducting. It is not possible for the half-bridge inverter to apply zero voltage to the load.

FIGURE 13.4.6 A single-phase inverter using one phase-leg and two dc voltage sources.

A single-phase inverter is also formed by placing the load between two inverter phase-legs, as shown in Fig. 13.4.7. This circuit is often referred to as a full- or H-bridge inverter. Through appropriate control of the inverter switches, positive, negative, and zero voltage can be applied to the load. The zero voltage state is achieved by having both upper switches, or both lower switches, conducting at the same time. Note that this state requires one switch and one diode to be supporting the load current.

THREE-PHASE INVERTERS

A three-phase inverter is used to support both Δ - and Y-connected three-phase loads. The three-phase inverter topology can be derived by using three single-phase full-bridge inverters, with each inverter supporting one phase of the load. Upon careful examination of the resulting connection of the 12 controllable switches with the load, it is seen that there are six redundant switches because phase-legs are connected in parallel. Elimination of the six redundant switches yields the topology shown in Fig. 13.4.8.

There are six switches in the three-phase inverter topology of Fig. 13.4.8. Considering all combinations of the switch states, there are seven possible voltages that may be applied to the load; the cases of all three upper switches being closed and all three lower switches being closed are functionally indistinguishable. The controller is responsible for applying the appropriate voltage to the load according to the method used for synthesizing the output voltage.

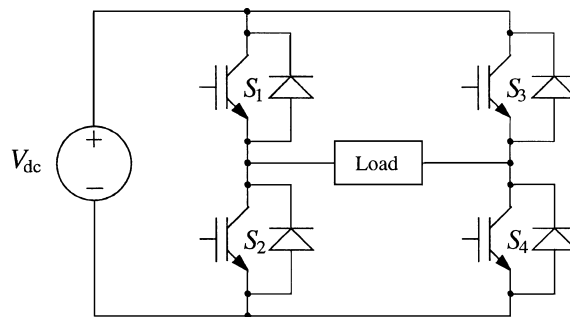

FIGURE 13.4.7 A single-phase inverter using two phase-legs and one dc voltage source.

FIGURE 13.4.8 The three-phase inverter topology.

MULTILEVEL INVERTERS

The three-phase inverter of Fig. 13.4.8 applies one of two voltages to each output load terminal. The output voltage is V_{dc} when the upper switch is conducting, and it is zero when the lower switch is conducting. Accordingly, this inverter could be called a two-level inverter. Multilevel inverters are based on extending this concept and are becoming the inverter of choice for higher-voltage and higher-power applications. The discussion here focuses on a three-level inverter; extensions to five or more levels can be found in the technical literature (Lai and Peng, 1996; Peng, 2001).

Among their advantages, multilevel inverters allow the synthesis of voltage waveforms that have a lower harmonic content than a two-level inverter for the same switching frequency. This is because each output terminal is switched among at least three voltages, not just two. In addition, the input dc bus voltage can be higher because multiple devices are connected in series to support the full bus voltage.

Figure 13.4.9 shows one phase-leg of a three-level inverter. In the three-level inverter the dc bus is partitioned into two equal levels of $V_{dc}/2$. The four controllable switches with antiparallel diodes, S_1 through S_4 , are connected in series to form a phase-leg. In addition, two steering diodes, D_5 and D_6 , are used to support current flow to and from the midpoint of the dc bus. Additional phase-legs would be connected in parallel across the full dc bus.

Operation of four switches is used to connect the load output terminal to either V_{dc} , $V_{dc}/2$, or zero. Switches S_1 and S_2 are used to connect the load to V_{dc} , switches S_2 and S_3 are used to connect the load to $V_{dc}/2$, and switches S_3 and S_4 are used to connect the load to zero.

While switches S_1 and S_2 are conducting, diode D_6 ensures that the voltage across switch S_4 does not exceed $V_{dc}/2$. Similarly, when switches S_3 and S_4 are conducting, diode D_5 ensures that the voltage across switch S_1 does not exceed $V_{dc}/2$. While switches S_2 and S_3 are conducting, the voltage across both S_1 and S_4 is clamped at $V_{dc}/2$; diode D_5 and switch S_2 support positive load current, while diode D_6 and switch S_3 support negative load current.

A three-phase, three-level inverter provides substantially increased flexibility for voltage synthesis over the conventional three-phase inverter of Fig. 13.4.8. The three-phase inverter of Fig. 13.4.8 offers eight switch combinations that support seven different voltage combinations among the three output terminals. A three-phase, three-level inverter offers 27 switch combinations, supporting 19 different voltage combinations among the three output terminals. Further, the increased redundancy of certain voltages provides additional degrees of freedom in designing the voltage synthesis algorithm. These additional degrees of freedom could, for example, be used to minimize the common mode voltage between the three outputs.

Issues within the design and control of the multilevel inverter include the dynamic balancing of the voltages within each level of the dc bus and the switching patterns needed to best synthesize the desired output voltage. One would expect that symmetric operation of the phase-leg should be sufficient for maintaining balanced voltages across each level of the dc bus. The variation in capacitor values, however, will cause the midpoint of the

FIGURE 13.4.9 A phase-leg for a three-level inverter.

dc bus to move to a voltage other than $V_{dc}/2$ for symmetric load currents. This shift in voltage will have repercussions on the synthesis of the output voltage.

VOLTAGE WAVEFORM SYNTHESIS TECHNIQUES

There are three principal ways to synthesize the output voltage waveform in an inverter: harmonic elimination, harmonic cancellation, and pulse-width modulation. The synthesis technique that is applied is generally driven by consideration of the required output quality, the inverter power rating (which is closely tied to the speed of the controllable switches), the computational power of the available controller, and the acceptable cost of the inverter. This subsection reviews some of the common techniques used to synthesize the inverter output voltage.

FIGURE 13.4.10 Elimination of the third harmonic.

Harmonic Elimination. Harmonic elimination implies that the output waveform shape is controlled to be free of specific harmonics through the selection of switch transitions (Patel and Hoft, 1973; Patel and Hoft, 1974). That is, the switches are controlled so that one or more harmonics are never generated. This is often accomplished by notching the output waveform. Examples of harmonic elimination are shown in Figs. 13.4.10 and 13.4.11, which respectively show the elimination of only the third harmonic and simultaneous elimination of the third and fifth harmonics from the output of a single-phase inverter.

As suggested by Figs. 13.4.10 and 13.4.11, additional switch transitions must be inserted in the output waveform for each harmonic that is to be eliminated. As the number of notches gets very large, the output voltage waveform begins to resemble something which could be produced by pulse-width modulation. Harmonic

FIGURE 13.4.11 Simultaneous elimination of the third and fifth harmonics: (a) shows the fifth harmonic superimposed on the waveform of Fig. 13.4.10; (b) shows the switch transitions introduced to eliminate the fifth harmonic without reintroducing the third harmonic.

FIGURE 13.4.12 The superposition of two waveforms to cancel the third harmonic.

elimination is sometimes referred to as programmed PWM because the switching angles of the output voltage are programmed according to the intended harmonic content (Enjeti, Ziogas, and Lindsay, 1985).

Harmonic Cancellation. Harmonic cancellation uses the superposition of two or more waveforms to cancel undesired harmonics (Kassakian, Schlecht, and Verghese, 1991). Figure 13.4.12 shows how two waveforms that contain the third harmonic may be phase-shifted and superimposed in order to create a waveform that is free of the third harmonic. The circuit of Fig. 13.4.13 can be used to synthesize the waveform of Fig. 13.4.12.

By combining harmonic cancellation and harmonic elimination, it is possible to create relatively high-quality voltage waveforms. This quality comes at the expense of a more complicated circuit. This additional complexity may be warranted depending on the power level and the specified quality.

Pulse-Width Modulation. Pulse-width modulation (PWM) is a method of voltage synthesis through which high-frequency voltage pulses are applied to the inverter load (Holtz, 1994). The width of the pulses are made to vary at the desired frequency of the output voltage. Successful application of PWM generally involves a wide frequency separation between the carrier frequency and the modulation frequency. This frequency separation moves the distortion in the output voltage to high frequencies, thereby simplifying the required filtering. This subsection reviews two of the more common techniques used for synthesizing voltage waveforms using modulation.

FIGURE 13.4.13 A circuit capable of synthesizing the waveforms of Fig. 13.4.12.

Sinusoidal PWM. Sinusoidal PWM implies that the pulse widths of the output voltage are distributed sinusoidally. The pulse widths are generally determined by comparing a sinusoidal reference waveform with a triangular waveform. The sinusoidal waveform sets the modulation (output) frequency and the triangular waveform sets the switching frequency. Sinusoidal PWM is routinely applied to single- and three-phase inverters.

In a single-phase inverter, the implementation of sinusoidal PWM depends on whether or not both phase-legs are operated at high frequency. Referring to Fig. 13.4.7, we see that it is not necessary for both phase-legs to operate at high frequency. We could, for example, operate switches S_1 and S_2 at high frequency to control the shape of the voltage, while switches S_3 and S_4 are operated at the frequency of the reference sinusoid to dictate the polarity of the output voltage. One advantage of this approach is that the inverter is more efficient because only two of the switches are operated at high frequency. Figure 13.4.14 shows how the sinusoidal pulse widths are created by a comparator and a unipolar triangular carrier (Kassakian, Schlecht, and Verghese, 1991). An alternative approach is to use switches S_2 and S_4 to control the polarity of the output voltage. While switch S_4 is conducting, switches S_1 and S_2 are used to control the shape of the voltage. Similarly, switches S_3 and S_4 are used to control the shape of the voltage, while switch S_2 is conducting. This approach tends to equalize the stress on the two phase-legs, and can simplify the control logic necessary to implement the PWM.

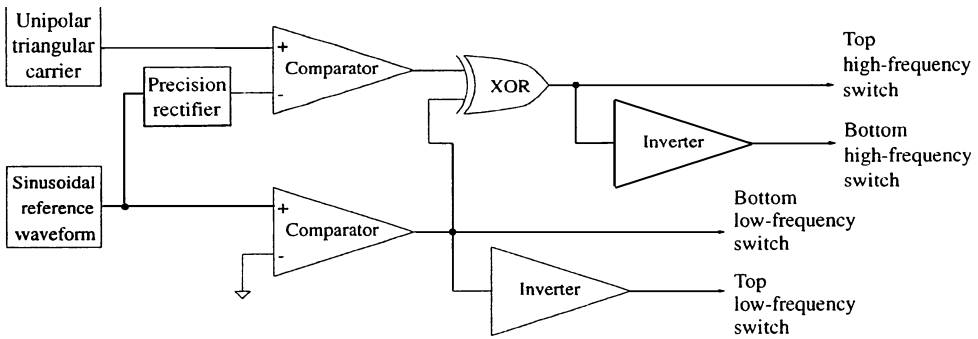

FIGURE 13.4.14 The generation of sinusoidally distributed pulse widths using a unipolar triangular carrier.

A second way of implementing sinusoidal PWM in a single-phase inverter is to operate both phase-legs at high frequency (Vithayathil, 1995). This method of control gives the same output voltage waveform as the high-frequency/low-frequency approach. The basic difference in control structures between the two is that the first method uses a unipolar triangular carrier, while the second way uses a bipolar triangular carrier. Figure 13.4.15 shows how the bipolar triangular carrier is used to create the sinusoidally distributed pulse widths.

Space-Vector PWM. Space-vector modulation is a technique that is becoming the standard method for controlling the output voltage of three-phase inverters. The technique bears great similarity to the field-oriented control techniques which are applied to ac electric machines (Van der Broeck, Skedulny, and Stanke, 1988; Holtz, Lammert, and Lotzkat, 1986; Trzynadlowski and Legowski, 1994).

A balanced set of three-phase quantities can be transformed into direct and quadrature components through the transformation

$$\begin{bmatrix} x_d \\ x_q \end{bmatrix} = \frac{\sqrt{2}}{\sqrt{3}} \cdot \begin{bmatrix} 1 & -1/2 & -1/2 \\ 0 & \sqrt{3}/2 & -\sqrt{3}/2 \end{bmatrix} \begin{bmatrix} x_a \\ x_b \\ x_c \end{bmatrix} \tag{1}$$

FIGURE 13.4.15 The generation of sinusoidally distributed pulse widths using a bipolar triangular carrier.

FIGURE 13.4.16 The eight space vectors that can be produced by the three-phase inverter of Fig. 13.4.8.

where x is a voltage or current. A similar transformation exists for taking direct and quadrature components back to phase quantities, though space-vector modulation does not need to use the inverse transformation.

Applying Eq. (1) to the three-phase inverter of Fig. 13.4.8, we see that each distinct switch state of the inverter corresponds with a different space vector. The zero vector can be produced by the electrically equivalent topologies of all upper switches conducting and all lower switches conducting. It is important to note that the six nonzero space vectors created by the inverter states are of the same magnitude ($\sqrt{2/3}V_{dc}$) and are symmetrically displaced. Figure 13.4.16 shows the connection between the three-phase inverter of Fig. 13.4.8 and the generation of the eight space vectors.

Any desired output voltage, up to the magnitude of $V_{dc}/\sqrt{2}$ may be synthesized by taking the three adjacent space vectors in proper proportion. Figure 13.4.17 shows how the desired voltage V^* is synthesized from the space vectors V_1 , V_2 , and V_0 . Over one sampling interval, the duty ratios of V_1 , V_2 , and V_0 are, respectively,

$$d_1 = \frac{2/\sqrt{3}|V^*| \sin(60^\circ - \gamma)}{\sqrt{2/3}V_{dc}} \tag{2}$$

$$d_2 = \frac{2/\sqrt{3}|V^*| \sin \gamma}{\sqrt{2/3}V_{dc}} \tag{3}$$

$$d_0 = 1 - d_1 - d_2 \tag{4}$$

FIGURE 13.4.17 The synthesis of voltage V^* using space vector modulation.

The order used in implementing the space vectors is driven by the desire to minimize the number of switching operations. Careful examination of Figs. 13.4.16 and 13.4.17 reveals that within any of the six segments delimited by space vectors, the move from one vector to the next requires changing the state of only one switch. In practice, the switching in adjacent sampling intervals would apply the sequence $\dots |V_1|V_2|V_0|V_0|V_2|V_1| \dots$. Different approaches use different criteria for selecting the best implementation of V_0 (Trzynadlowski and Legowski, 1994).

Extension of the space-vector concept is possible with multilevel inverters (Holmes and McGrath, 2001; Tolbert, Peng, and Habetler, 2000). Multilevel inverters, however, offer a substantially greater number of space vectors from which to choose. With three-level inverters, for example, there are now 19 different space vectors. Additional levels would increase the number of space vectors still further. The number of redundant space vectors also increases in multilevel inverters, thereby offering

additional degrees of freedom within the voltage synthesis algorithm. Figure 13.4.18 shows the space vectors that can be created by a three-phase three-level inverter based on the phase-leg of Fig. 13.4.12. The numbers adjacent to each space vector represent the switch configuration of phases a, b, and c, respectively. Space vectors with more than one set of numbers can be achieved with any of the switch combinations indicated. Referring to Fig. 13.4.12, a 0 indicates that switches S_3 and S_4 are connecting the output terminal to the negative side of the dc bus. Similarly, a 1 indicates switches S_2 and S_3 are connecting the output terminal to the midpoint of the dc bus. Finally, a 2 indicates that switches S_1 and S_2 are connecting the load terminal to the positive side of the dc bus.

FIGURE 13.4.19 The principles of hysteretic current control.

CURRENT WAVEFORM SYNTHESIS TECHNIQUES

While voltage-source inverters always output a voltage waveform, there are many applications where the details of the voltage waveform are driven by the creation of a current with a specific shape. In this context, the controller is determining the state of each inverter switch based on how well the inverter output currents are tracking commanded output currents. While the PWM techniques of the previous subsection can often be applied to transform a voltage-source inverter into a controlled current source (Brod and Novotny, 1985; Habetler, 1993), there are some additional techniques that are useful in this type of operation. The control techniques described in this subsection are amenable to synthesizing current waveforms with inverters.

Hysteresis and Sliding-Mode Control. Hysteresis and sliding-mode control are very similar in nature. In both of these control approaches, a reference current waveform is established and the switching of the inverter is tied to the relative location of the actual current and the reference waveform (Brod and Novotny, 1985; Bose, 1990; Slotine and Li, 1991; Torrey and Al-Zamel, 1995). Under hysteretic control, a hysteresis band is introduced around the reference waveform in order to limit the switching frequency. Figure. 13.4.19 illustrates the principles of hysteretic control. Sliding-mode control can be implemented in a manner which is indistinguishable from hysteretic control, or it can be implemented as shown in Fig. 13.4.20 where there is a known upper limit on the switching frequency.

A common problem with hysteretic control is that the switching frequency is not fixed and may vary widely over one cycle of the output. This can complicate the design of filters and may raise reliability concerns relative

FIGURE 13.4.20 One method of implementing sliding-mode control.

to the safe operation of the switches. Fixing the switching frequency is possible (Kazerani, Ziogas, and Joos, 1991), at the expense of a hysteresis band that changes throughout each cycle of the output.

Predictive Current Regulation. Predictive current regulation is similar to hysteresis and sliding-mode control in the establishment of a reference current and acceptable error bounds (Holtz, 1994; Wu, Dewan, and Slemon, 1991). The predictive controller uses a model of the system in conjunction with measurements of the system state in order to predict how long the next switching state is to be maintained so that the actual current remains within the established error bounds. In contrast to hysteresis and sliding-mode control, the predictive controller is always looking ahead one sampling interval into the future.

INVERTER APPLICATIONS

This subsection reviews four important applications of inverters: uninterruptible power supplies, motor drives, active power filters, and utility interfaces for distributed generation. Uninterruptible power supplies have become an extremely large market in support of the expanding use of personal computers and other critical loads. These systems are able to support computer operation in the face of unreliable utility power, thereby preventing the loss of data. Motor drives allow for adjustable speed operation of electric motors, thereby providing a better match between the motor output and the power required by the load. The proper application of adjustable speed drives can result in significant energy savings. The increasing application of active power filters and active power line conditioners is a reflection of increasing harmonic distortion on power systems, and the regulatory responses to this distortion. Distributed generation sources (fuel cells, solar photovoltaics, wind turbines, and microturbines) often function as sources of dc power, thereby requiring an inverter to deliver this power to the ac utility grid.

Uninterruptible Power Supplies. An uninterruptible power supply (UPS) uses a battery to provide energy to a critical load in the event of a power system disturbance. There are two basic topologies used in UPS systems, as shown in the block diagrams of Figs. 13.4.21 and 13.4.22 (Mohan, Undeland, and Robbins, 1995). Both single- and three-phase UPS systems are available.

In Fig. 13.4.21, the critical load is always supplied through an inverter. This inverter is fed from either the utility or the battery bank, depending on the availability of the utility. The battery is continually charged when the utility is present. This type of UPS provides effective protection of the critical load by isolating it from utility under- and over-voltages.

In Fig. 13.4.22, the functions of battery charging and the inverter are combined. While the utility is present, the inverter is run as a controlled rectifier to support battery charging. When the utility fails, the load is supplied from the battery-fed inverter. Because an inverter does not have the ability to deliver a larger voltage than that of the dc source, it may be necessary to include a bidirectional dc/dc converter if a low voltage battery is used in the UPS.

Motor Drives. Motor drives can be found in a very wide range of power levels, from fractional horsepower up to hundreds of horsepower (Bose, 1986; Murphy and Turnbull, 1988). These applications range from very

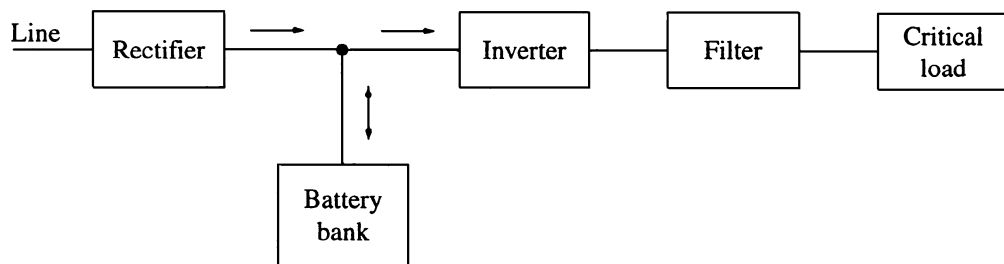

FIGURE 13.4.21 A block diagram for one configuration of a UPS system.

FIGURE 13.4.22 A block diagram for a second UPS system configuration.

precise motion control to adjustable speed operation of pumps and compressors for saving energy. In a motor drive, the inverter is used to provide an adjustable frequency ac voltage to the motor, thereby enabling the motor to operate over a wide range of speeds without derating the torque production of the motor. In order to prevent the motor from being pushed into magnetic saturation, the amplitude of the synthesized voltage is usually tied to the output frequency. In the simplest adjustable speed drives, the ratio of peak output voltage to output frequency is maintained nominally constant, with a small boost at low frequencies to compensate to the resistance of the motor windings. More sophisticated adjustable speed drives implement sensorless flux vector control (Bose, 1997).

Active Power Filters. Active power filters are able to simultaneously provide compensation for the reactive power drawn by other linear loads while compensating for the harmonic currents being drawn by still other nonlinear loads (Gyugyi and Strycula, 1976; Akagi, Kanazawa, and Nabae, 1984; Akagi, Nabae, and Atoh, 1986; Torrey and Al-Zamel, 1995). It is possible to compensate for multiple loads at one point. The basic idea of an active power filter is shown in Fig. 13.4.23. The active power filter is formed by putting an inverter in parallel with the loads for which compensation is needed. The inverter switches are then controlled to force the line current drawn from the utility to be of the desired quality. The inverter is controlled to draw currents that precisely compensate for the undesired components in the currents drawn by the loads. The undesired components may be either reactive or harmonic in nature. In Fig. 13.4.23, $i_{utility}$ is forced to be of the desired quality and phase through the superposition of i_{filter} and $i_{nonlinear loads}$. With control over i_{filter} , the utility current can be forced to track its intended shape and amplitude.

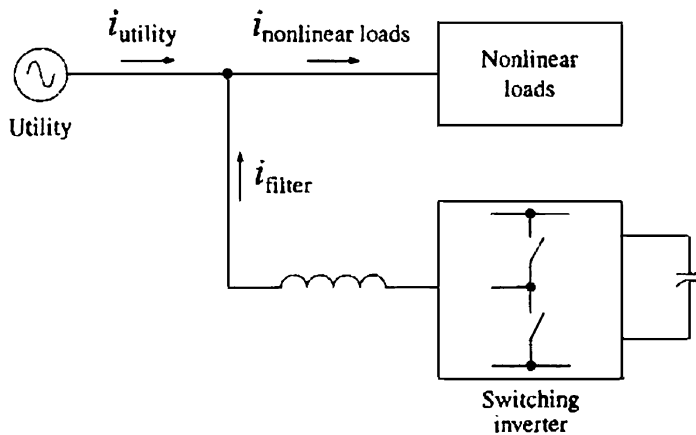

FIGURE 13.4.23 A one-line diagram of an active filter system.

Distributed Generation. There is an ever-increasing interest in the integration of distributed generation sources into the electric utility system. Distributed generation sources include fuel cells, solar photovoltaics, wind energy, hydroelectric, and microturbines, among others. Their application is sometimes driven by the utility in an effort to use a local resource such as hydroelectric energy, to increase generating capacity without having to increase the capacity of their transmission lines, to add generation capacity incrementally without the large capital investment required of a more traditional generating station, or to increase the reliability of the supply for critical customers. Distributed generation sources are sometimes used by electricity customers to reduce their electricity costs or to increase the reliability of their electricity supply.

Some distributed generation sources naturally provide energy through dc, thereby requiring an inverter to deliver the energy to the utility grid. Fuel cells and solar photovoltaics fall into this category. Other distributed generation sources provide energy through ac with variable frequency and amplitude. Wind turbines, microturbines, and some hydroelectric systems fall into this category. This ac energy is usually delivered to the utility by first rectifying the variable ac into dc and then using an inverter to provide fixed frequency ac with a fixed amplitude to the utility grid. In some cases the rectification process is facilitated by an inverter structure where the flow of energy is from the ac side to the dc side. In this way phase currents can be controlled far more precisely than would be possible with an uncontrolled rectifier.

A significant issue with the deployment of distributed generation sources is the prevention of a situation known as islanding. An inverter that is unable to detect the presence or absence of the utility may continue to feed a section of the utility system even after the utility has taken actions to deenergize that section. This creates a serious safety issue for any utility workers who may be working on the utility system. For this reason, any inverter that is designed to interact with the ac utility must include anti-islanding controls that actively and continuously verify the presence of the larger ac utility system. Techniques for accomplishing this are described in Stevens et al. (2000) for photovoltaic systems, but the techniques described are applicable to other energy sources.

Inverters for distributed generation systems are designed to be either utility interactive or utility independent. The difference between them is found in the control. Utility interactive inverters are controlled to behave as a current source, delivering power to the utility with near-unity power factor. Utility independent inverters behave as voltage sources, where the phase difference between the output voltage and the load current is dictated by the load on the inverter.

CHAPTER 13.5

AC REGULATORS

Peter Wood

CIRCUITS FOR CONTROLLING POWER FLOW IN AC LOADS

Switch configurations such as those in Fig. 13.5.1 can be used to control ac waveforms. The control may be merely *transistory*, as in soft starting an induction motor or limiting the inrush current to a transformer, or *perpetual*, as in the control of resistive heating elements, incandescent lamps, and the reactors of a static reactive volt-ampere (VAR) generator.

The basic single-phase ac regulator is depicted in Fig. 13.5.2, using a triac as the ac switch (but any of the ac switch combinations shown in Fig. 13.5.1 is applicable). The various three-phase arrangements possible are shown in Fig. 13.5.3. The first of these, the wye-connected regulator with a neutral connection (Fig. 13.5.3a), exhibits behavior identical to that of the single-phase regulator, since it is merely a threefold replica of the single-phase version.

The delta-connected regulator arrangement of Fig. 13.5.3b is also essentially similar in behavior to the single-phase regulator insofar as load voltages and currents are concerned. Because of the delta connection, however, any symmetrical zero sequence components of the load currents will not flow in the supply lines but will only circulate in the delta-connected loads.

The three-phase three-wire wye-switched regulator of Fig. 13.5.3c behaves differently because two switches must be closed for current to flow in any load. Shown delta-loaded, it may also have the loads wye-connected without a neutral return. In this connection, each ac switch may consist of the antiparallel combination of a thyristor and a diode. The normal wye-delta transformations apply to load voltages and currents.

The “British delta” circuit of Fig. 13.5.3d behaves in the same way as a wye-switched regulator in which thyristors with inverse parallel connected diodes are used as the switches and is unique in that only unidirectional current capability is required of its switches.

When the loads are essentially resistive, two methods of control are currently employed. The technique known as *integral-cycle control* operates the regulator by keeping the switch(es) closed for some number m of complete cycles of the supply and then keeping the switch(es) open for some number n of cycles. The power delivered to the load(s) is then simply $m/(m+n)$ times the power delivered if the switch(es) are kept permanently closed, for the single-phase, wye with neutral, and delta-connected regulators.

For the wye-switched (without neutral) and British delta regulators, the power delivered is slightly greater than $m/(m+n)$ times the power at full switch conduction, and dc and unbalanced ac components develop in the supply unless special control techniques are used. These phenomena arise because of the transient conditions, inevitably attending the first cycle of operation of these circuits.

An undesirable consequence of integral-cycle control is that the load voltages and currents, and hence the supply currents, contain sideband components having frequencies $f_s[1 \pm pm/(m+n)]$, where f_s is the supply frequency and p is any integer, 1 to infinity. Many of these frequencies are obviously lower than the supply frequency and may create problems for the supply system and other connected loads. The existence of this type of unwanted components in the voltage and current spectra makes integral-cycle control unsuitable for inductive loads (including loads fed by transformers). Since none of the sidebands are zero sequence, the line currents of an integral-cycle-controlled delta regulator are identical to the properly transposed load currents.

FIGURE 13.5.1 Single-phase ac switches.

FIGURE 13.5.2 Single-phase ac regulator.

Integral-cycle control results in unity displacement factor (the cosine of the angle between the fundamental component of supply current and the supply voltage). The power factor of the burden they impose on the supply with pure resistive loads is $[m/(m+n)]^{0.5}$. This is true because any regulator that forces the load current to flow in the supply while reducing the rms voltage applied to a resistive load has a power factor equal to the rms load voltage divided by the rms supply voltage.

The other method of control commonly used is termed *phase-delay control*. It is implemented by delaying the closing of the switch(es) by an angle α (called the firing angle) from each zero crossing of the supply voltage(s) and allowing the switch(es) to open again on each succeeding current zero. The load voltages and currents in this case contain only harmonics of the supply frequency as unwanted components, and except for the regulator shown in Fig. 13.5.3c, using thyristor-inverse diode switches, only odd-order harmonics are present. Thus, this control technique can be used with inductive loads.

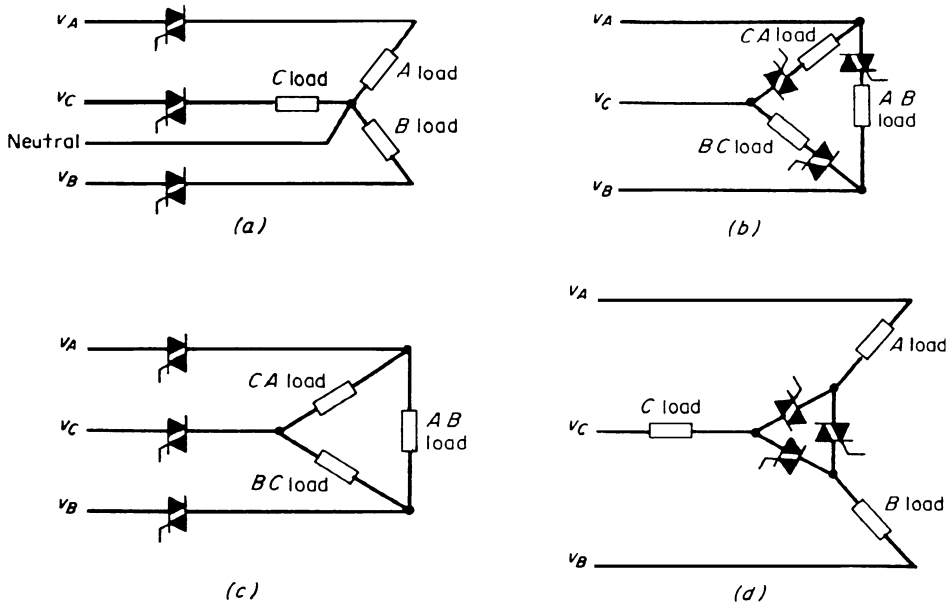

FIGURE 13.5.3 Three-phase ac regulators.

The general expressions for the load voltages and currents produced by the single-phase regulator are very cumbersome but simplify considerably for the two cases of greatest practical importance, pure resistive and pure inductive loads. For a pure resistive load with a supply voltage $V \cos \omega_s t$, the fundamental component of load voltage is given by

$$V_{DIR} = \left(1 - \frac{\alpha}{\pi} + \frac{\sin 2\alpha}{2\pi} \right) V \cos \omega_s t + \frac{\sin^2 \alpha}{\pi} V \sin \omega_s t \quad (1)$$

and the total rms load voltage by

$$V_{RMSR} = \frac{V}{\sqrt{2}} \left(1 - \frac{\alpha}{\pi} + \frac{\sin 2\alpha}{2\pi} \right)^{1/2} \quad (2)$$

where α is the firing angle measured from the supply-voltage zero crossings. For pure inductive load it is convenient to define the firing angle $\alpha' = \alpha - \pi/2$, so that at full output $\alpha' = 0$. The fundamental voltage component is then given by

$$V_{DIL} = \left(1 - \frac{2\alpha'}{\pi} - \frac{\sin 2\alpha'}{\pi} \right) V \cos \omega_s t \quad (3)$$

and the total rms voltage by

$$V_{RMSL} = \frac{V}{\sqrt{2}} \left(1 - \frac{2\alpha'}{\pi} - \frac{\sin 2\alpha'}{\pi} \right)^{1/2} \quad (4)$$

The same relationships apply to the three-phase circuits, which are in effect triplicates of the single-phase circuit (Fig. 13.5.3a and 13.5.3b); more complex relationships exist for the remaining three-phase circuits.

The use of phase-delay control results in decreasing lagging displacement factor with increasing firing angle. Maximum displacement factor is obtained at full output, equaling the power factor of the given load. At a reduced power setting the power factor is less than the displacement factor; the ratio of the two equals the ratio of the fundamental line currents versus the total rms line currents. This ratio is less than unity because of the presence of harmonic currents.

The load voltages and currents and, more importantly, the line currents of phase-delay-controlled regulators have lower total rms distortion than those of integral-cycle-controlled regulators. Among the circuits shown, the delta regulator of Fig. 13.5.3b is most beneficial; since the triple n harmonics (those of orders which are integer multiples of 3) in its load currents are zero sequence, they do not flow in the supply lines and the circuit has both a better power factor and lower total line-current distortion than integral-cycle regulators or the phase-delay-controlled wye regulators with neutral.

For the wye regulator without neutral, the range of α is 0 to $7\pi/6$ rad, provided fully bilateral switches are used; for the British delta regulator and the wye regulator without neutral using thyristor-inverse diode switches, the range is 0 to $5\pi/6$ rad. When phase-delay regulators are used with inductive loads, the range of α used for control is reduced because current-zero crossings lag voltage-zero crossings and thus abrogate part of the delay obtained with resistive loads. The regulators most commonly used with inductive loads are the single-phase, wye with neutral and the delta, for which the range of α becomes ϕ to π , where ϕ is the load-phase angle.

STATIC VAR GENERATORS

The delta regulator with purely inductive loading finds extensive use in the *static VAR generator* (SVG) (Gyugyi et al., 1978, 1980). A basic SVG consists of three delta-connected inductors with phase-controlled switches ($\pi/2 \leq \alpha \leq \pi$) and three fixed capacitive branches which may be delta-or wye-connected. The

capacitive branches draw a fixed current from the supply, leading the voltage by $\pi/2$ rad. The fundamental current in the inductors is lagging the voltage by $\pi/2$ rad. Its amplitude can be varied, by phase controlling the switches, from the full inductor current to zero.

Hence the net reactive volt-ampere burden on the supply can be continuously controlled from the full capacitive VAR, when $\alpha = \pi$ and the inductor currents are zero, to the difference between the capacitive- and inductive-branch VARs when $\alpha = \pi/2$ and full inductor currents flow. This difference will be zero if inductive-branch VARs are made equal to capacitive-branch VARs and become an inductive burden if inductive VARs at full conduction exceed the capacitive VARs. Since the firing angle α can be varied on a half-cycle-to-half-cycle basis, extremely rapid changes in VAR supply (capacitive burden) or demand (inductive burden) can be accomplished.

SVGs can be used to supply shunt-reactive compensation on ac transmission and distribution systems, helping system stability and voltage regulation. They can also be used to provide damping of the subsynchronous resonances, which often prove troublesome during transient disturbances on series capacitor-compensated transmission systems, and to reduce the voltage fluctuations (flicker) produced by arc-furnace loads. In the latter application, their ability to accomplish dynamic load balancing is especially valuable.

An SVG which can provide control of reactive power supply or demand can obviously compensate for an unbalanced reactive load. It can also act as a Steinmetz balancer, providing the reactive power exchange between phases necessary to transform an unbalanced resistive load into a perfectly balanced and totally active (real) power load on the supply system.

This action can be explained as follows. Suppose a single-phase resistive load is connected between lines A and B of a three-phase system. Then the current it draws will be in phase with the AB voltage, and thus the A-line current created will lead the A-phase (line-to-neutral) voltage by $\pi/6$ rad and the B-line current will lag the B-phase voltage by $\pi/6$ rad.

If equal-impedance purely reactive loads are now connected to the BC and CA line pairs, capacitance on BC and inductive on CB, they create currents with the following phase relationships to the phase voltages:

In the A line, lagging by $2\pi/3$ rad

In the B line, leading by $2\pi/3$ rad

In the C line, one leading by $\pi/3$ rad and the other lagging by $\pi/3$ rad

The result in the C line is clearly an in-phase, wholly real current. If the impedances are of appropriate magnitude, their lagging and leading quadrature contributions in the A and B lines, respectively, can be made to cancel the lagging and leading quadrature currents created therein by the single-phase resistive load. The impedance required is $\sqrt{3}$ times the resistance. Obviously an SVG capable of providing either leading or lagging line-to-line loading on any of the line pairs can be used to balance a single-phase resistive load on any one line pair; by extension, it can be used to balance any unbalanced load. It can respond rapidly to changes in the degree of imbalance existing and thus dynamically balance the load despite the fluctuating imbalance typically created by an arc furnace.

In addition to a varying reactive fundamental current, an SVG operating other than at full or zero conduction in its reactive branches generates harmonic currents. Thus at least part of the capacitive branch is usually realized in the form of tuned harmonic filters to limit harmonic injection to the ac supply system. Maximum harmonic amplitudes relative to maximum fundamental are:

Harmonic order	3d	5th	7th	9th	11th	13th
Maximum amplitude percent	13.8	5.05	2.59	1.57	1.05	0.752

with diminishing amplitudes of the higher-order components.

When the SVG is in balanced operation, the triple n harmonics (3d and 9th in the table above) do not flow in the supply, being zero sequence. When operation is unbalanced in order to balance an unbalanced real load, positive and negative sequence components of the triple n harmonics develop and of course do flow in the supply unless filtering is provided for them.

SECTION 14

PULSED CIRCUITS AND WAVEFORM GENERATION

Pulsed circuits and waveform generation are very important to testing and identification in a whole range of electrical and electronic circuits and systems. There are essentially two types of such networks, those that are considered passive and the rest that can be lumped into active wave shaping (which includes those done digitally).

Passive circuits are lumped into linear and nonlinear. Linear are most commonly, single pole RC and RL networks. Nonlinear networks are usually designed around diodes with or without capacitors and inductors.

A common element used in waveform generation is the switch. Mechanical switches are cleaner giving better electrical characteristics; however, they do have serious limitations. Electronic switches can be compensated so that they can come close to the mechanical switches without the serious limitations such as contact bounce. In addition, electronic switches can be made smaller and are able to work at much higher frequencies.

Active networks are either analog or digital. Analog networks have been in use for a long period of time and still have many practical uses. Digital networks have advantages especially in the area of noise, speed, and accuracy and have successfully replaced most of the analog networks in most applications. C.A.

CHAPTER 14.1

PASSIVE WAVEFORM SHAPING

Paul G. A. Jespers

LINEAR PASSIVE NETWORKS

Waveform generation is customarily performed in active nonlinear circuits. Since passive networks, linear as well as nonlinear, enter into the design of pulse-forming circuits, this survey starts with the study of the transient behavior of passive circuits.

Among linear passive networks, the single-pole RC and RL networks are the most widely used. Their transient behavior in fact has a broad field of applications since the responses of many complex higher-order networks are dominated by a single pole; i.e., their response to a step function is very similar to that of a first-order system.

Transient Analysis of the RC Integrator

The step-function response of the RC circuit shown in Fig. 14.1.1a, after closing of the switch S , is given by

$$V(t) = E[1 - \exp(-t/T)] \quad (1)$$

where $T =$ time constant $= RC$. The inverse of T is called the cutoff pulsation ω_0 of the circuit.

The Taylor-series expansion of Eq. (1) yields

$$V(t) = E \frac{t}{T} \left(1 - \frac{t}{2!T} + \frac{t^2}{3!T^2} - \dots \right) \quad (2)$$

When the values of t are small compared with T , a first-order approximation of Eq. (2) is

$$V(t) \approx Et/T \quad (3)$$

In other words, the RC circuit of Fig. 14.1.1 behaves like an imperfect integrator. The relative error ϵ with respect to the true integral response is given by

$$\epsilon = -\frac{t}{2!T} + \frac{t^2}{3!T^2} - \frac{t^3}{4!T^3} + \dots$$

The theoretical step-function response of Eq. (1) and the ideal-integrator output of Eq. (3) are represented in Fig. 14.1.1b.

Small values of t with respect to T correspond in the frequency domain (Fig. 14.1.1c) to frequency components situated above ω_0 , that is, the transient signal whose spectrum lies to the right of ω_0 in the figure. In that case, the difference is small between the response curve of the RC filter and that of an ideal integrator

FIGURE 14.1.1 (a) RC integrator circuit; (b) voltage vs. time across capacitor; (c) attenuation vs. angular frequency.

FIGURE 14.1.2 (a) RC differentiator circuit; (b) voltage across resistor vs. time; (c) attenuation vs. angular frequency.

(represented by the -6 dB/octave line in the figure). The circuit shown in Fig. 14.1.1a thus approximates an integrator, provided either of the following conditions is satisfied: (1) the time under consideration is much smaller than T or (2) the spectrum of the signal lies almost entirely above ω_0 .

Transient Analysis of the RC Differentiator

When the resistor and the capacitor of the integrator are interchanged, the circuit (Fig. 14.1.2a) is able to differentiate signals. The step-function response (Fig. 14.1.2b) of the RC differentiator is given by

$$v(t) = E \exp(-t/T) \tag{4}$$

The time constant T is equal to the product RC , and its inverse ω_0 represents the cutoff of the frequency response of the circuit. As the values of t become large compared with T , the step-function response becomes more like a sharp spike; i.e., it increasingly resembles the delta function.

The response differs from the ideal delta function, however, because both its amplitude and its duration are always finite quantities. The area under the exponential pulse, equal to ET , is the important quantity in applications where such a signal is generated to simulate a delta function, as in the measurement of the impulse response of a system. These considerations may be transported in the frequency domain (Fig. 14.1.2a).

FIGURE 14.1.3 *RL* current-integrator circuit, the dual of the circuit in Fig. 14.1.1a.

FIGURE 14.1.4 *RL* current-differentiator circuit, the dual of the circuit in Fig. 14.1.2a.

FIGURE 14.1.5 *RL* voltage integrator.

FIGURE 14.1.6 *RL* voltage differentiator.

Transient Analysis of *RL* Networks

Circuits involving a resistor and an inductor are also often used in pulse formation. Since integration and differentiation are related to the functional properties of first-order systems rather than to the topology of actual circuits, *RL* networks may perform the same function as *RC* networks. The duals of the circuits represented in Figs. 14.1.1 and 14.1.2, respectively, are shown in Figs. 14.1.3 and 14.1.4 and exhibit identical functional properties. In the first case, the current in the inductor increases exponentially from zero to I with a time constant equal to L/R , while in the second case it drops exponentially from the initial value I to zero, with the same time constant. Similar behavior can be obtained regarding voltage instead of current by changing the circuit from Fig. 14.1.3 to that of Fig. 14.1.5 and from Fig. 14.1.4 to Fig. 14.1.6, respectively. This duality applies also to the *RC* case.

Compensated Attenuator

The compensated attenuator is a widely used network, e.g., as an attenuator probe used in conjunction with oscilloscopes. The compensated attenuator (Fig. 14.1.7) is designed to perform the following functions:

1. To provide remote sensing with a very high input impedance, thus producing a minimum perturbation to the circuit under test.
2. To deliver a signal to the receiving end (usually the input of a wide-band oscilloscope) which is an accurate replica of the signal at the input of the attenuator probe. These conditions can be met only by introducing substantial attenuation to the signal being measured, but this is a minor drawback since adequate gain to compensate the loss is usually available.

Diagrams of two types of oscilloscope attenuator probes are given in Fig. 14.1.9, similar to the circuit of Fig. 14.1.7. In both cases, the coaxial-cable parallels the input capacitance of the receiver end; C_p represents the sum of both capacitances.

FIGURE 14.1.7 Compensated attenuator circuit.

The shunt resistor R_p has a high value, usually $1\text{ M}\Omega$, while the series resistor R_s is typically $9\text{ M}\Omega$. The dc attenuation ratio of the attenuator probe therefore is 1:10, while the input impedance of the probe is 10 times that of the receiver.

At high frequencies the parallel and series capacitors C_p and C_s play the same role as the resistive attenuator. Ideally these capacitors should be kept as low as possible to achieve a high input impedance even at high frequencies. Since it is impossible to reduce C_p below the capacitance of the coaxial cable, there is no alternative other than

FIGURE 14.1.8 Voltage vs. time responses of attenuator, showing correctly compensated condition at $K = 1$.

to insert the appropriate value of C_s to achieve a constant attenuation ratio over the required frequency band. In consequence, as the frequency increases, the nature of the attenuator changes from resistive to capacitive. However, the attenuation ratio remains unaffected, and no signal distortion is produced. The condition that ensures constant attenuation ratio is given by

$$R_p C_p = R_s C_s \tag{5}$$

The step-function response of the compensated attenuator, which is illustrated in Fig. 14.1.8, clearly shows how distortion occurs when the above condition is not met. The output voltage $V(t)$ of the attenuator is given by

$$V(t) = \frac{C_s}{C_s + C_p} \left\{ 1 - (1 - K) \left[1 - \exp\left(-\frac{t}{T}\right) \right] \right\} E \tag{6}$$

where K represents the ratio of the resistive attenuation factor to that of the capacitive attenuation factor

$$K = \frac{R_p}{R_p + R_s} \bigg/ \frac{C_s}{C_p + C_s}$$

and

$$T = (R_p \parallel R_s) (C_s + C_p) \tag{7}$$

The \parallel sign stands for the parallel combination of two elements, e.g., in the present case $R_p \parallel R_s = R_p R_s / (R_p + R_s)$. Only when K is equal to 1, in other words when Eq. (5) is satisfied, will no distortion occur, as shown in Fig. 14.1.8.

In all other cases there is a difference between the initial amplitude of the step-function response (which is controlled by the attenuation ratio of the capacitive divider) and the steady-state response (which depends on the resistive divider only).

A simple adjustment to compensate the attenuator consists of trimming one capacitor, either C_p and C_s , to obtain the proper step-function response. Adjustments of this kind are provided in attenuators like those shown in Fig. 14.1.9.

Compensated attenuators may be placed in cascade to achieve variable levels of attenuation. The conditions imposed on each cell are like those enumerated above, but an additional requirement is introduced, namely, the requirement for constant input impedance. This introduces a different structure compared with the compensated attenuator, as shown in Fig. 14.1.10. The resistances R_p and R_s must be chosen so that the impedance is kept constant and equal to R . The capacitor C_s is adjusted to compensate the attenuator, while C_p provides the required additional capacitance to make the input susceptance equal to that of the load.

FIGURE 14.1.9 Coaxial-cable type of attenuator circuit: (a) series adjustment; (b) shunt adjustment.

Periodic Input Signals

Repetitive transients are typical input signals to the majority of pulsed circuits. In linear networks there is no difficulty in predicting the response of circuits to a succession of periodic step functions, alternatively positive and negative, since the principle of superposition holds. We restrict our attention here to two simple cases, the square-wave response of an RC integrator and an RC differentiator.

FIGURE 14.1.10 Compensated attenuator suitable for use in cascaded circuits.

Figure 14.1.11 represents, at the left, the buildup of the response of the RC integrator, assuming that the period τ of the input square wave is smaller than the time constant of the circuit T . On the right in the figure the steady-state response is shown. The triangular waveshape represents a fair approximation to the integral of the input square wave. The triangular wave is superimposed on a dc pedestal of amplitude $E/2$. Higher repetition rates of the input reduce the amplitude of the triangular wave without affecting the dc pedestal. When the frequency of the input square wave is high enough, the dc component is the only remaining signal; i.e., the RC integrator then acts like an ideal low-pass filter.

A similar presentation of the behavior of the RC differentiator is shown in Fig. 14.1.12a and b. The steady-state output in this case is symmetrical with respect to the zero axis because no dc component can flow through the series capacitor. When, as shown in Fig. 14.1.12b, no overlapping of the pulses occurs, the steady-state solution is obtained from the first step.

Pulse Generators

The step function and the delta function (Dirac function) are widely used to determine the dynamic behavior of physical systems. Theoretically the delta function is a pulse of infinite amplitude and infinitesimal duration but having a finite area (product of amplitude and time). In practice the question of the equivalent physical impulse arises. The answer involves the system under consideration as well as the impulse itself.

14.10 PULSED CIRCUITS AND WAVEFORM GENERATION

FIGURE 14.1.11 RC integrator with square-wave input of period smaller than RC : (a) initial buildup; (b) steady state.

FIGURE 14.1.12 RC differentiator with square-wave input: (a) period of input signal smaller than RC ; (b) input period longer than RC .

FIGURE 14.1.13 RC pulse-generator circuit with large series resistance R_1 .

FIGURE 14.1.14 Coaxial-cable version of RC pulse generator.

FIGURE 14.1.15 Use of mercury-wetted switch contacts in coaxial pulse generator.

The spectrum of the delta function has a constant amplitude over the whole frequency spectrum from zero to infinity. Other signals of finite area (amplitude \times time) have different spectral distributions. On a logarithmic scale of frequency, the spectrum of any finite-area transient signal tends to be constant between zero and a cutoff frequency that depends on the shape of the signal. The shorter the duration of the signal, the wider the constant-amplitude portion of the spectrum.

If such a signal is used in a system whose useful frequency band is located below the cutoff frequency of the signal spectrum, the system response is indistinguishable from its delta impulse response. Any transient signal with a finite area, whatever its shape, can thus be considered as a delta function relative to the given system, provided that the flat portion of its spectrum embraces the whole system's useful frequency range. A measure of the effectiveness of a pulse to serve as a delta function is given by the approximation of useful spectrum bandwidth $B = 1/\tau$, where τ represents the midheight duration of the pulse.

Very short pulses are used in various applications in order to measure their delta-function response. In the field of radio interference, for instance, the basic response curve of the CISPR receiver* is defined in terms of its response to regularly repeated pulses. In this case, the amplitude of the uniform portion of the pulse spectrum must be calibrated, i.e., the area under the pulse must be a known constant which is a function of a limited number of circuit parameters.

The step-function response of an RC differentiator provides such a convenient signal. Its area is given by the amplitude of the input step multiplied by the time constant RC of the circuit. Moreover, since the signal is exponential in shape, its -3-dB spectrum bandwidth is equal to 1/RC. In the circuit of Fig. 14.1.13, R_1 is much larger than R; when the switch S is open, the capacitor charges to the voltage E of the dc source. When the switch is closed, the capacitor discharges through R, producing an exponential signal of known amplitude and duration (known area).

A circuit based on the same principle is shown in Fig. 14.1.14. Here the coaxial line plays the role of energy storage source. If the line is lossless, its characteristic impedance is given by R_0 , the propagation delay is equal to τ , and the Laplace transform of the voltage drop across R is

$$V(p) = (1/p)E[1 + (R_0/R) \coth p\tau]^{-1} \tag{8}$$

When the line is matched to the load, Eq. (8) reduces to

$$V(p) = (1/2p)E(1 - e^{-p2\tau}) \tag{9}$$

which indicates that $V(t)$ is a square wave of amplitude $E/2$ and duration 2τ . The area of the pulse is equal to the product of E and the time constant τ . Both quantities can be kept reasonably constant. The bandwidth is larger than that of an exponential pulse of the same area (Fig. 14.1.13) by the factor π .

Very wide bandwidth pulse generators based on this principles use a coaxial mercury-wetted switch built into the line (Fig. 14.1.15) to achieve low standing-wave ratios. A bandwidth of several GHz can be obtained in this manner.

In coaxial circuits, any impedance mismatch causes reflections to occur at both ends of the line, replacing the desired square-wave signal by a succession of steps of decreasing amplitude. The cutoff frequency of the

*International Electrotechnical Commission (IEC), "Specification, de l'appareillage de mesure CISPR pour les frequences comprises entre 25 et 300 MHz," 1961.

spectrum is lowered thereby, and its shape above the uniform part can be drastically changed. Below cutoff frequency, however, the spectrum amplitude is given by $E\tau R/R_0$.

When the finite closing time of the switch is taken into account, it can be shown that only the width of the spectrum is reduced without affecting its value below the cutoff frequency. Stable calibrated pulse generators can also be built using electronic instead of mechanical switches.

NONLINEAR-PASSIVE-NETWORK WAVESHAPING

Nonlinear passive networks offer wider possibilities for waveshaping than linear networks, especially when energy-storage elements such as capacitors or inductors are used with nonlinear devices. Since the analysis of the behavior of such circuits is difficult, we first consider purely resistive nonlinear circuits.

Diode Networks without Storage Elements

Diodes provide a simple means for clamping a voltage to a constant value. Both forward conduction and avalanche (zener) breakdown are well suited for this purpose. Avalanche breakdown usually offers sharper nonlinearity than forward biasing, but consumes more power.

Clamping action can be obtained in many different ways. The distinction between series and parallel clamping is shown in Fig. 14.1.16. Clamping occurs in the first case when the diode conducts; in the second when it is blocked.

Since the diode is not an ideal device, it is useful to introduce an equivalent network that takes into account some of its imperfections. The complexity of the equivalent network is a trade-off between accuracy and ease of manipulation.

The physical diode is characterized by

$$I = I_s[\exp(V/V_T) - 1] \tag{10}$$

where I_s is the leakage current and $V_T = kT/q$, typically 26 mV at room temperature.

FIGURE 14.1.16 Diode clamping circuit and voltage vs. time responses: (a) shunt diode; (b) series diode.

FIGURE 14.1.17 Actual and approximate current-voltage characteristics of ideal and real diodes.

FIGURE 14.1.18 (a) DC restorer circuit; (b) input signal; (c) output signal.

The leakage current is usually quite small, typically 100 pA or less. Therefore, V must be at least several hundred millivolts, typically 600 mV or more, to attain values of forward current I in the range of milliamperes. A first approximation of the forward-biased real diode consists therefore of a series combination of the ideal diode and a small emf (Fig. 14.1.17). Moreover, to take into account the finite slope of the forward characteristic, a better approximation is obtained by inserting a small resistance in series.

Diode Networks with Storage Elements

There is no simple theory to represent the behavior of nonlinear circuits with storage elements, such as capacitors or inductances. Acceptable solutions can be found, however, by breaking the analysis of the circuit under investigation into a series of linear problems. A typical example is the dc restorer circuit hereafter.

The circuit shown in Fig. 14.1.18 resembles the RC differentiator but exhibits properties that differ substantially from those examined previously. The diode D is assumed to be ideal first to simplify the analysis of the circuit, which is carried out in two steps, i.e., with the diode forward- and reverse-biased. In the first step, the output of the circuit is short-circuited; in the second, the diode has no effect, and the circuit is identical to the linear RC differentiator.

When a series of alternatively positive and negative steps is applied at the input, after the first positive step is applied, no output voltage is obtained. The first positive step causes a large transient current to flow through the diode and charges the capacitor. Since D is assumed to be an ideal short circuit, the current will be close to a delta function as long as the internal impedance of the generator connected at the input is zero.

In practice, the finite series resistance of the diode must be added to the generator internal impedance, but this does not affect the load time constant significantly, since it is assumed to be much smaller than the time between the first positive step and the following negative step. This allows the circuit to attain the steady-state conditions between steps. When the input voltage suddenly returns to zero, the output voltage undergoes a large negative swing whose magnitude is equal to that of the input step. The diode is then blocked, and the capacitor discharges slowly through the resistor. If the time constant is assumed to be much larger than the period of the

14.14 PULSED CIRCUITS AND WAVEFORM GENERATION

input wave, the output voltage swings back to zero when the second positive voltage step is applied and only a small current flows through the forward-biased diode to restore the charge lost when the diode was under the reverse-bias condition.

If the finite resistance of the diode is taken into consideration, a series of short positive exponential pulses must be added to the output signal, as shown in the lower part of Fig. 14.1.18. The first pulse, which corresponds to the initial full charge on the capacitor, is substantially higher than the next pulse, but this is of little importance in the operation of the circuit.

An interesting feature of the dc restorer circuit lies in the fact that although no dc component can flow from input to output, the output signal has a well-defined nonzero dc level, although determined only by the amplitude of the negative steps (assuming, of course, that the lost charge between two steps is negligible). This circuit is used extensively in video systems to prevent the average brightness level of the image from being affected by its varying video content. In this case, the reference steps are the line-synchronizing pulses.

CHAPTER 14.2

SWITCHES

Paul G. A. Jespers

THE IDEAL SWITCH

An ideal switch is a two-pole device that satisfies the following conditions:

Closed-switch condition. The voltage drop across the switch is zero whatever the current flowing through the switch may be.

Open-switch condition. The current through the switch is zero whatever the voltage across the switch may be.

Mechanical switches are usually electrically ideal, but they suffer from other drawbacks; e.g., their switching rate is low, and they exhibit jitter. Moreover, bouncing of the contacts may be experienced after closing, unless mercury-wetted contacts are used. Electronic switches do not exhibit these effects, but they are less ideal in their electrical characteristics.

BIPOLAR-TRANSISTOR SWITCHES

The bipolar transistor approximates an open switch between emitter and collector when its base terminal is open or when both junctions are reverse-biased or even only slightly forward-biased. Inversely, under saturated conditions, the transistor resembles a closed switch with a small voltage drop in series, typically 50 to 200 mV. This drop may be considered negligible in many applications.

Static Characteristics

A more rigorous approach to the transistor static characteristics is based on the Ebers and Moll transport equations

$$\begin{bmatrix} I_E \\ I_C \end{bmatrix} = I_S \begin{bmatrix} -\frac{1}{\beta_F} - 1 & 1 \\ 1 & -1 - \frac{1}{\beta_R} \end{bmatrix} \begin{bmatrix} \exp(V_E/V_T) - 1 \\ \exp(V_C/V_T) - 1 \end{bmatrix} \quad (1)$$

where V_E , V_C = voltage drops across emitter and collector junctions, respectively (positive voltages stand for forward bias, negative for reverse bias); $V_T = kT/q$ (typically 26 mV at room temperature); I_S = saturation current; and β_F , β_R represent forward (I_C/I_B) and reverse (I_E/I_B) current gains, respectively, with $V_E > 0$, $V_C < 0$ in the first case and $V_E < 0$, $V_C > 0$ in the second.

14.16 PULSED CIRCUITS AND WAVEFORM GENERATION

The saturation current I_S governs the leakage current flowing through the transistor under blocked conditions. It is always exceedingly small, and since it usually amounts to 10^{-14} or 10^{-15} A, it is difficult to measure. A standard procedure is to draw the plot representing the collector current in log scale versus the emitter forward bias V_E in linear scale. To find the saturation current, one must extrapolate the part of the curve, which can be assimilated to a straight line with a slope of 60 mV/decade to the intercept with the vertical axis for which $V_E = 0$. The saturation current can also be obtained with emitter and collector terminals permuted.

The current gains β_F and β_R can be evaluated by means of the same experimental setup. An additional ammeter is required to measure I_B .

It is common practice to rewrite Eq. (1) so that the emitter and collector currents are expressed as functions of

$$I_F = I_S[\exp(V_E/V_T) - 1] \tag{2}$$

and

$$I_R = I_S[\exp(V_C/V_T) - 1] \tag{3}$$

With these definitions Eq. (1) can be expressed as

$$I_C = I_F - I_R - I_R/\beta_R \tag{4}$$

$$I_E = -I_F - (I_F/\beta_F) + I_R \tag{5}$$

Hence, the Ebers and Moll transport model is found. This is illustrated by the equivalent circuit of Fig. 14.2.1. The leakage currents of the two diodes D_1 and D_2 are given respectively by I_S/β_F and I_S/β_R . With this model, it is possible to compute the currents flowing through the transistor under any circumstance.

FIGURE 14.2.1 Equivalent circuit of the Ebers and Moll transport model of the bipolar transistor.

For instance, if the collector junction is reverse-biased and a small positive bias of, for example, +100 mV is established across the emitter-junction, the reverse current I_R is almost equal to $-I_S$ and I_F is equal to $I_S \exp(100/26)$ or $46.8 I_S$. Hence, from Eqs. (4) and (5), the collector current is found to be equal to $48I_S$, and the emitter current is approximately the same with opposite sign. With the assumption that I_S is equal to 10 pA, both I_C and I_E are essentially negligible. *A fortiori*, I_B as derived from Eqs. (4) and (5) is also small:

$$I_B = (I_F/\beta_F) + (I_R/\beta_R) \tag{6}$$

To drive current through the transistor, the voltage across one of the two junctions must reach at least 0.5 V, according to:

$$V_E = V_T \ln(I_F/I_S) \tag{7}$$

or

$$V_C = V_T \ln(I_R/I_S) \tag{8}$$

derived from Eqs. (2) and (3).

The transistor operates in the saturation region when it approximates a closed switch. The voltage drop between the emitter and collector terminals is then given by

$$V_{CE,sat} = V_T \ln \frac{n + (n + \beta_F)\beta_R}{n - 1} \tag{9}$$

where n represents the ratio $\beta_F I_B / I_C$, assumed larger than 1. For most transistors, this voltage drop lies between 50 and 200 mV. The inevitable resistance in series with the collector increases this voltage by a few tens of millivolts.

An interesting situation arises when I_C is almost equal to zero; e.g., when the bipolar transistor is used to set the potential across a capacitor. In this case, Eq. (9) becomes

$$V_{CE,sat} = V_T \ln(1 + 1/\beta_R) \quad (10)$$

Similarly, with interchanged emitter and collector terminals, the voltage drop is given by

$$V_{EC,sat} = V_T \ln(1 + 1/\beta_F) \quad (11)$$

Since β_F is normally much larger than β_R , $V_{EC,sat}$ may be smaller than 1 mV provided β_F is at least equal to 25. Consequently, inverted bipolar transistors are switches with a very small series voltage drop, provided that the current flowing through the transistor is kept small.

The two situations examined so far (open or closed switch) correspond in Fig. 14.2.2, respectively, to $I_B = 0$ and to the part of the curves closely parallel to the collector-current axis. The fact that all the curves have nearly the same vertical shape means that the series resistance of the saturated transistor is quite small. Since the characteristics do not coincide with the vertical coordinate axis, a small series emf must be considered, however, as previously stated.

A third region exists where the transistor plays the role of a current switch instead of a voltage switch. It concerns the switching from blocked conditions to any point within the active region or vice versa. Conceptually, the transistor may be compared to a controlled current

FIGURE 14.2.2 Typical common-emitter characteristics of the bipolar transistor. V_A is called the Early voltage.

source, which is switched on or off. However, because of the Early effect, the current is a function of the collector to emitter voltage. The Ebers and Moll model is inappropriate to describe this effect. A better expression of I_C is

$$I_C = I_S \exp(V_E/V_T)(1 + V_{CE}/V_A) \quad (12)$$

where V_A is called the *Early voltage*. Equation (12) is illustrated in Fig. 14.2.2. The finite output conductance of the transistor is given by I_C/V_A .

Dynamic Characteristics

The dynamic behavior of bipolar transistors suffers from a drawback called “charge storage in the base,” which takes place every time transistors are driven in or out of saturation. The phenomenon is related to the majority carriers supplementing the minority carrier in the base to guarantee neutrality. The question is how to remove these extra carriers when the transistor is supposed to desaturate. Zeroing the base current is not a satisfactory solution for the majority carriers can only recombine with minority carriers. This requires a lot of time for lifetimes in the base are generally large in order to maximize the current gain. A better technique is to reverse the polarity of the base current. The larger this current, the more rapidly the majority carriers disappear and the faster the transistor gets out of saturation. Current continues to flow, however, until one of the two junctions gets reverse biased (usually the collector junction). Only then the transistor enters the active region and the collector current may start to decrease. When all majority carriers are swept away, both junctions are reverse-biased and the impedance of the base contact unfolds from a low impedance to an open circuit. A quantitative analysis of the desaturation mechanism can be found in the CD-ROM together with an example.

Charge storage is generally associated with the base of bipolar transistors, although the same phenomenon takes place near the depleted region in the emitter neutral region also. The reason why this is not considered is related to the doping profile in the emitter comparatively to the base region. The emitter doping is much larger

FIGURE 14.2.3 A Schottky diode D prevents T from going into saturation.

FIGURE 14.2.4 Planar npn transistor and Schottky diode in integrated-circuit form.

than the base doping because it increases the emitter's efficiency, which controls the current gain (the emitter efficiency is the ratio of emitter-base current over base-emitter current).

Junction diodes suffer from the same drawback. The diffusion length in the less-doped region being much longer than the base width of a bipolar transistor, charge storage problems should be worse. This is not the case, however, as diodes are generally bipolar transistors with their base and collector terminals shorted, making their charge storage effects similar to those of bipolar transistors.

In order to reduce the delay between the control signal applied to the base and the moment the collector current begins to decay, several techniques have been developed. Two of these are reviewed hereafter.

The first takes advantage of Schottky diodes, which exploit field emission and, therefore, ignore charge storage phenomena. Schottky diodes exhibit a slightly smaller voltage drop under forward bias than junction diodes (of the order of 0.4 V instead of 0.7 V), which is currently exploited to prevent bipolar transistors from getting saturated. The idea is illustrated in Fig. 14.2.3, which represents a bipolar transistor whose collector junction is paralleled by a Schottky diode. When the transistor is nearing saturation, the Schottky diode starts conducting before the collector junction does. This prevents the transistor from entering saturation. The base current in excess to what is needed to sustain the actual collector current flows directly to ground through the series combination of the forward-biased Schottky diode and emitter junction. Figure 14.2.4 shows how the combination of a Schottky diode and a bipolar transistor can be implemented. The Schottky diode consists of the metal contact that overlaps the lightly doped collector, whereas in the base region the metal to the P-type semiconductor resumes to an Ohmic contact. Such combination is currently used in Schottky logic, a family of fast bipolar logic circuits.

The second way to avoid charge storage is to devise circuits that never operate in saturation. The switch shown in Fig. 14.2.5, which involves two transistors controlled by a pair of square waves with opposite polarities is a good example. When Q_1 is on, Q_2 is off or vice versa. Current is switched either left or right. Although the circuit looks like a differential pair, it operates in a quite different manner: the conducting transistor is in the common base configuration, while the other is blocked. Since the output current is taken from the collector of the common base transistor, the output impedance is very large. This means that the switch is a current-mode

FIGURE 14.2.5 A bipolar current switch.

switch instead of a voltage-mode switch. Very short switching times are feasible this way for none of the two transistors ever saturates. Emitter-coupled logic (ECL) takes advantage of this circuit configuration.

MOS SWITCHES

Insulated gate field-effects (IGFETs, also called MOS transistors) and junction field-effect transistors (JFETs) can be put to use in order to mimic switches. They resemble an ideal closed switch in series with a linear resistor when “on” and an open switch when “off.” The leakage current, however, is larger than with bipolar transistors.

Static Characteristics

When a field-effect transistor is turned on, its characteristics differ substantially from those of a bipolar switch. Since no residual emf in series with the switch is experienced, the transistor is comparable to a resistor whose conductance G is given by

$$G = \mu C_{\text{ox}} \frac{W}{L} (V_G - V_{T0} - \lambda V) \quad (13)$$

where μ is the mobility in the inversion layer, C_{ox} the gate oxide capacitance per unit area, V_G the gate-to-substrate voltage, V_{T0} the gate threshold voltage under zero bias, V the source or drain voltage, and λ a dimensionless factor that does take into account the so-called substrate effect (the value of λ lies somewhere between 1.3 and 1.5). The dependence on source and drain voltages of the conductance G represents a problem that impairs severely the performances of MOS switches. Consider, for instance, a MOS switch in series with a grounded capacitor to implement a simple sample-and-hold circuit. Since the MOS transistor is similar to a resistor when its gate voltage is high, the circuit may be assimilated to an RC network with a time constant that varies like the reciprocal of the difference in the right part of Eq. (13). Hence, when the input voltage V equals $(V_G - V_{T0})/\lambda$ the conductance becomes equal to zero and the switch resumes to an open circuit. In practice, V must be well below this limit to sample the input within a small enough time window. Single MOS switches are not favored therefore. For instance, in logic circuits, where the logic 1s and 0s are set by the power supply and ground, respectively, the logic high signal may be substantially corrupted and the speed reduced. CMOS switches are preferred therefore to single MOS switches. A typical CMOS transmission switch is shown in Fig. 14.2.6. It consists of the parallel combination of an

FIGURE 14.2.6 The complementary MOS switch.

N-MOS and a P-MOS transistor controlled by complementary logic signals. The idea is simply to counterbalance the decreasing conductance of the N-MOS transistor when the input goes from low to high by the increasing conductance of the P-MOS transistor. Thanks to the parallel combination, the series resistance is kept large and almost unchanged for any input voltage. The same holds true as long as the time is constant.

Dynamic Characteristics

MOS transistors ignore charge storage phenomena for they are unipolar devices. Their transient behavior is controlled by the parasitic capacitances associated with their gate, source, and drain. Source and drain are reverse-biased junctions, which exhibit parasitic capacitances with respect to the substrate. The gate capacitance relates to the inversion layer and to the regions overlapping source and drain. These capacitances control the dynamic behavior of the switch in conjunction with the parasitics associated to the elements connected to the MOS transistor terminals.

What happens with the inversion layer charge when the transistor is switched off is considered hereafter. Since charge cannot simply vanish, it must go somewhere, either to the source or drain or to both. This introduces generally a short spike in memoryless circuits that does not affect the performances significantly except at high frequency. In circuits that exhibit memory, like in the MOS sampling network discussed earlier, the impact is more serious. The part of the inversion layer charge left on the capacitive terminal is “integrated,” which leads to a DC offset.

The charge partition problem in memory circuits is illustrated by the simple circuit shown in Fig 14.2.7, which consists of a MOS switch between two capacitors C_1 and C_2 . We start from the situation where the voltages V_1 and V_2 across the capacitors are equal and no current is flowing through the transistor, supposed to be “on.” As soon as the gate voltage starts to decrease, the charge in the inversion layer tends to divide equally between MOS terminals for these are at the same potential. If the capacitors are not identical, a voltage difference starts to build up as soon as charge is being transferred. This causes current to flow in the MOS transistor,

FIGURE 14.2.7 The inversion layer charge divides between C_1 and C_2 after cutoff.

FIGURE 14.2.8 Fraction of the inversion layer charge left in C_2 after cutoff vs. the parameter B defined under Eq. (14).

which tend to reduce the voltage difference between the capacitors. This re-equilibration mechanism holds on as long as the gate voltage exceeds the effective threshold voltage although it is getting weaker and weaker as the transistor is nearing cut-off. When finally the MOS transistor is cut-off, a nonzero voltage difference is left over, which may be assimilated to an offset. The size of this offset is a function of several factors including the gate slewing-rate. It is obvious that an abrupt gate voltage step, which does not leave time for re-equilibration, will split the inversion layer charge equally between the two capacitors, whereas slow cut-off will tend to keep the voltages across the capacitors more alike.

The problem is addressed in Ref. 19. The fraction of the total inversion layer charge that is stored in capacitor C_2 versus the parameter B defined below is illustrated in Fig. 14.2.8:

$$B = (V_{\text{Gon}} - V_T) \cdot \sqrt{\frac{\beta}{aC_2}} \quad (14)$$

V_{Gon} is the gate voltage prior to switching, V_T the effective threshold voltage of the MOS transistor equal to $(V_{T0} + \lambda V_{\text{in}})$, β the well-known factor $\mu C_{\text{ox}} W/L$ and a the gate voltage slewing rate defined as $(V_{\text{Gon}} - V_{T0})$ divided by the fall time. Notice that fast switching yields small values of B , whereas long switching times lead to large values of B . When B is small the inversion layer charge divides equally. Voltage equalization tends to prevail when B is large, as can be found from the large differences experienced once the ratio C_2/C_1 departs from one. Let us consider, for instance, a MOS transistor with a β equal to 10^{-4} A/V^2 , a gate capacitance C_G of 0.1 pF, V_{Gon} and V_{T0} , respectively, equal to 5 and 0.7 V, a large capacitor C_1 to mimic a voltage generator and a load capacitance C_2 equal to 1 pF. For fall times between 1 ps and 1 ns, the factor B varies from 0.021 until 0.626. The offset voltage is large and varies little from 215 to only 200 mV since re-equilibration cannot take place in such a short time. A 10 ns fall time reduces the final offset to 125 mV, and 100 ns, 1 μs , and 10 μs fall times yield, respectively, 41, 13, and 4 mV offset. In any case, these are still large offsets in terms of analog signals. To get smaller offsets the switching times must be very long. Hence, switching noise cannot be avoided as such.

A second important problem is nonlinear distortion. Less time is needed to block the MOS transistor when the input voltage is close to V_{Gon} for the effective threshold voltage becomes quite large. The amount of charge stored in C_2 varies with the magnitude of the input signal and the offset is thus a nonlinear replica of the input.

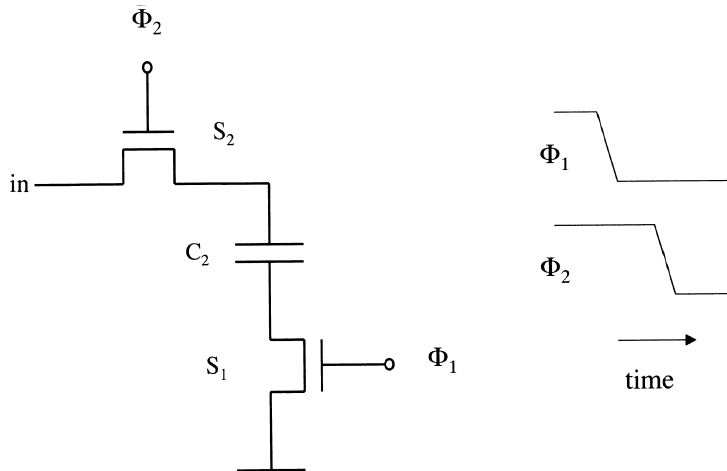

FIGURE 14.2.9 Switching noise nonlinearity can be lessened by means of the transistor S_2 in series with the storage capacitor.

This makes nonlinear distortion figures less than -70 dB hard to achieve unless a technique such as the one described hereafter is put to use.

In the circuit illustrated in Fig 14.2.9, the lower end of capacitor C_2 is tied to the ground by means of a second switch S_2 . During the acquisition time, both S_2 and S_1 are conducting. Sampling occurs when the switch S_2 opens, shortly before S_1 opens. Suppose switching times of both transistors are short enough to avoid charge re-equilibration. When S_2 opens, the charge in the inversion layer divides equally between C_2 and ground. When S_1 opens, since C_2 is already open-ended, the signal dependent charge of S_1 has no other way out than to flow back to the generator. Thus, C_2 stores only charge from S_2 , which is constant since the lower end of C_2 is tied always to ground. In fact, one exchanges a signal-dependent offset against a constant offset, which does not impair linearity. This offset moreover can be compensated easily by taking advantage of differential architectures that turn a constant offset into a common mode signal, which is ignored further on.

TRANSISTOR SWITCHES OTHER THAN LOGIC GATES

Transistor switches are extensively used in applications other than logic gates, covering a wide variety of both digital and analog applications. A typical illustration is the circuit converting the frequency of a signal into a proportional current, the so-called *diode pump*. This circuit (Fig. 14.2.10) consists of a capacitor C , two diodes D_1 and D_2 , and a switch formed by a transistor T_1 and a resistor R . The transistor is assumed to be driven periodically by a square-wave source, alternatively on and off.

FIGURE 14.2.10 Diode-pump circuit.

When T_1 is blocked, the capacitor C charges through the diode D_1 , while D_2 has no effect. As soon as the voltage across C has reached its steady-state value E_{cc} , T_1 may be turned on abruptly. The voltage with respect to ground at point A becomes negative, and D_1 is blocked, while D_2 is forward-biased. The capacitor thus discharges itself in the load (in Fig. 14.2.10 an ammeter, but it could be any other circuit element that does not exhibit storage), allowing V_A to reach 0 V before T_1 is again turned

off. The charge fed to the load thus amounts to CE_{cc} coulombs. If we suppose that this process is repeated periodically, the average current in the load is given by

$$I = fCE_{cc} \quad (15)$$

where f represents the switching repetition rate.

The diode-pump circuit provides a pulsed current whose average value is proportional to the frequency of the square-wave generator controlling the switching transistor T_1 . The proportionality would of course be lost if the load exhibited storage, e.g., if the load were a parallel combination of a resistor and a capacitor in order to obtain the average current. Using an operational amplifier, as shown in the right side of Fig. 14.2.10, circumvents the problem.

The requirements on the switching transistor in this application are different and in many respects more stringent than for logic gates. The transistor in a logic circuit provides a way of defining two well-distinguished states, logic 1 and 0. Nothing further is required whether these states approach an actual short circuit or an open circuit. In the diode-pump circuit, however, the actual switching characteristics are important, since the residual voltage drop across the saturated transistor of Fig. 14.2.10 influences the charge transfer from C to the load, thereby also introducing unwanted temperature sensitivity. The main difference lies in the fact that while T_1 is operated as a logical element, the purpose of the circuit actually is to deliver an analog signal.

There are many other examples where the characteristics of switching transistors influence the accuracy of given circuits or instruments. An even more critical problem pertains to amplitude gating, since this class of applications requires switches which correctly transfer analog signals without introducing too much distortion. Furthermore, positive and negative signals must be transmitted equally well, and noise introduced by the gating signals must be minimized.

Analog gating. A typical high-frequency gating network for analog signals is shown in Fig. 14.2.11. Gating is performed by means of the diode bridge in the center. All remaining circuitry controls the on-off switching.

In order to transmit the analog signal, the current sources Q bar and Q must, respectively, be on and off. The current $2I$ from transistor T_1 is split into two equal components, one that flows through T_3 , the other that flows vertically through T_4 and the bridge. The second forward biases all the diodes. Current, moreover, is injected horizontally from the signal source, left, to the output terminal, right. Those in- and out-currents representing the analog signal are equal since the sum of all currents injected in the bridge must necessarily be zero and the vertical current components though the bridge are balanced by the network. Voltage drops across the diodes are supposed to compensate each other.

When the path between source and load must be interrupted, the current sources Q and Q bar take opposite states. No current then flows through the bridge and the extra-currents supplied by T_2 and T_3 are diverted, respectively, through T_6 and T_5 . The two vertical nodes of the bridge are now connected to low impedance nodes so that the equivalent high-frequency network between in- and output terminals consist actually of two branches, each with two small parasitic capacitances representing series reverse-biased diodes short circuited in their middle to ground. This ensures an excellent separation between in- and output terminals making this type of gating network well suited for the sampling of high-frequency signals, like those used in sampling oscilloscopes.

Field-effect transistors also are extensively used to perform analog gating. A typical application is switched-capacitor filters. Figure 14.2.12a illustrates an elementary switched-capacitor network. In this circuit, the capacitor C is connected alternatively between the two terminals so that a charge $C(V_1 - V_2)$ is transferred at each cycle. Hence, if the repetition rate is f , the switched-capacitor network allows an average direct-current $C(V_1 - V_2)f$ to flow from one terminal to the other. It is thus equivalent to a resistor whose value is $1/Cf$.

If another capacitor C_o is connected at the output port, an elementary sampled-data RC circuit is built with a time constant equal to C_o/Cf . This time constant depends only on the clock frequency f and on the ratio of two capacitors. Hence, relatively large time constants can be achieved with good accuracy using very small capacitors and MOS transistor switches. In practice, MOS capacitors of a few picofarads match better than 0.1 percent. In addition, a slight modification (see Fig. 14.2.12b) of the circuit avoids the stray capacitance, which would otherwise affect the accuracy adversely. Hence, fully integrated switched-capacitor RC active filters can be designed to tight specifications, e.g., for telephone applications.

CHAPTER 14.3

ACTIVE WAVEFORM SHAPING

Paul G. A. Jespers

ACTIVE CIRCUITS

Linear active networks used currently for waveshaping take advantage of negative or positive feedback circuits to improve the performance. Of the linear negative feedback active wave-shaping circuits, the operational amplifier-integrator is widely used.

RC OPERATIONAL AMPLIFIER-INTEGRATOR

In Fig. 14.3.1 it is assumed that the operational amplifier has infinite input impedance, zero output impedance, and a high negative gain A . The overall transfer function is

$$\frac{A}{1 + p(1-A)T} \quad \text{where } T = RC \quad (1)$$

This function represents a first-order system with gain A and a cutoff frequency, which is approximately $|A|$ times lower than the inverse of the time constant T of the RC circuit. In Fig. 14.3.1b the frequency response of the active circuit is compared with that of the passive RC integrator. The widening of the spectrum useful for integration is clearly visible. For instance, an integrator using an operational amplifier with a gain of 10^4 and an RC network having a 0.1 s time constant has a cutoff frequency as low as 1.6 MHz.

In the time domain, the Taylor expansion of the amplifier-integrator response to the step function is

$$V(t) = E \frac{t}{T} \left[1 - \frac{t}{2!|A|T} + \frac{t^2}{3!(|A|T)^2} - \dots \right] \quad (2)$$

This shows that almost any desired degree of linearity of $V(t)$ can be achieved by providing sufficient gain.

SWEEP GENERATORS⁴

Sweep generators (also called time-base circuits) produce linear voltage or current ramps versus time. They are widely used in applications such as oscilloscopes, digital voltmeters, and television. In almost all circuits the linearity of the ramp results from charging or discharging a capacitor through a constant-current source. The difference between circuits used in practice rests in the manner of realizing the constant-current source. Sweep generators may also be looked upon as integrators with a constant-amplitude input signal. The latter point of view shows that RC operational amplifier-integrators provide the basic structure for sweep generation.

FIGURE 14.3.1 (a) Operational amplifier-integrator; (b) gain vs. angular frequency.

Circuits delivering a linear voltage sweep fall into two categories, the Miller time base and bootstrap time base. A simple Miller circuit (Fig. 14.3.2) comprises a capacitor C in a feedback loop around the amplifier formed by T_1 . Transistor T_2 acts like a switch. When it is on, all the current flowing through the base resistor R_B is driven to ground, keeping T_1 blocked, since the voltage drop across T_2 is lower than the normal base-to-emitter voltage of T_1 . The output signal V_{CE} of T_1 is thereby clamped at the level of the power-supply voltage E_{cc} , and the voltage drop across the capacitor C is approximately the same. When T_2 is turned off, it drives T_1 into the active region and

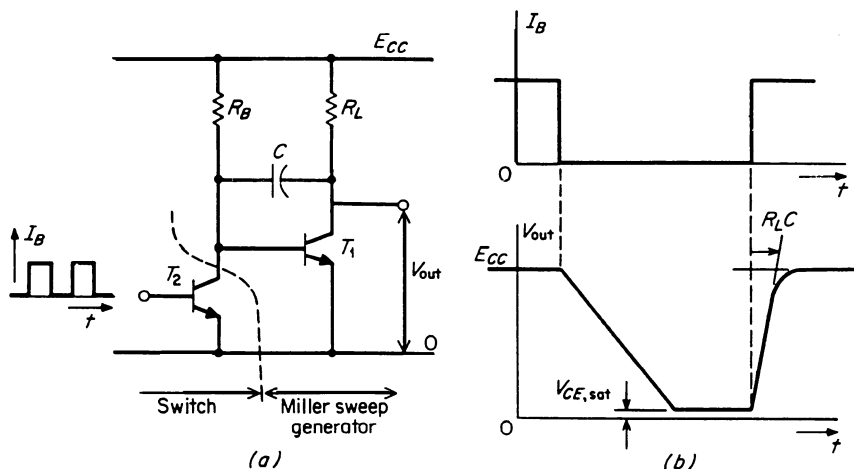

FIGURE 14.3.2 Miller sweep generator: (a) circuit; (b) input and output vs. time.

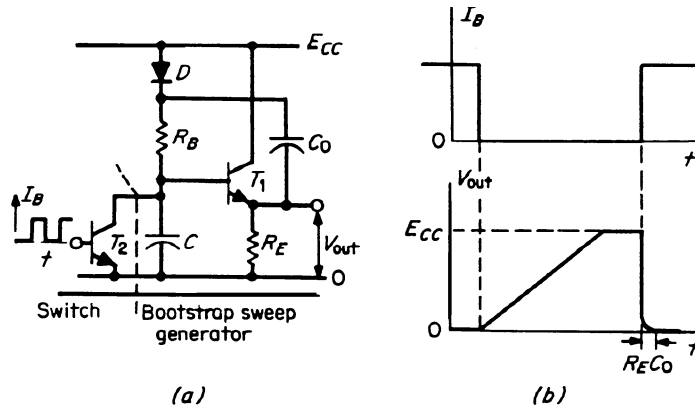

FIGURE 14.3.3 Bootstrap sweep generator: (a) circuit; (b) input and output vs. time.

causes collector current to flow through R_L . The resulting voltage drop across R_L is coupled capacitively to the base of T_1 , tending to minimize the base current; i.e., the negative-feedback loop is closed. The collector-to-emitter voltage V_{CE} of T_1 subsequently undergoes a linear voltage sweep downward, as illustrated in Fig. 14.3.2b.

The circuit behaves in the same manner as the RC operational amplifier above. Almost all the current flowing through R_B is derived through the feedback capacitor, and only a very small part is used for controlling the base of T_1 . The feedback loop opens when T_1 enters into saturation, and the voltage gain of the amplifier becomes small.

When T_2 is subsequently turned on again, blocking T_1 and recharging C through R_L and the saturated switch, the output voltage V_{CE} rises again according to an exponential with time constant $R_L C$.

Figure 14.3.3 shows a typical bootstrap time-base circuit. It differs from the Miller circuit in that the capacitor C is not a part of the feedback loop. Instead the amplifier is replaced by an emitter-follower delivering an output signal V_{out} which reproduces the voltage drop across the capacitor. C is charged through resistor R_B from a floating voltage source formed by the capacitor C_0 (C_0 is large compared with C).

First, we consider that the switch T_2 is on. Current then flows through the series combination of the diode D , the resistor R_B , and the saturated transistor T_2 . The emitter follower T_1 is blocked since T_2 is saturated. Moreover, the capacitor C_0 can charge through the path formed by the diode D and the emitter resistor R_E , and the voltage drop across its terminals is equal to E_{CC} . When T_2 is cut off, the current through R_B flows into the capacitor C , causing the voltage drop across its terminals to rise gradually, driving T_1 into the active region. Because T_1 is a unity-gain amplifier, V_{out} is a replica of the voltage drop across C .

Since C_0 acts as a floating dc voltage source, diode D is reverse-biased immediately. The current flowing through R_B is supplied exclusively by C_0 . Since $C_0 \gg C$, the voltage across R_B remains practically constant and equal to the voltage drop across C_0 minus the base-to-emitter voltage of T_1 .

Considering that the base current of T_1 represents only a small fraction of the total current flowing through R_B , it is evident that the charging of capacitor C occurs under constant-current and that therefore a linear voltage ramp is obtained as long as the output voltage of T_1 is not clamped to the level of the power-supply voltage E_{CC} .

The corresponding output waveforms are shown in Fig. 14.3.3b. After T_2 is switched on again, C discharges rapidly, causing V_{out} to drop, while the diode D again is forward-biased and the small charge lost by C_0 is restored. In practice, C_0 should be at least 100 times larger than C to ensure a quasi-constant voltage source.

More detailed analysis of the Miller and bootstrap sweep generators reveals that they are in fact equivalent. We redraw the Miller circuit as shown at the left of Fig. 14.3.4. Remembering that the operation of the sweep generator is independent of which output terminal is grounded, we ground the collector of T_1 and redraw the corresponding circuit. As shown at the right in the figure, this is a bootstrap circuit, so that the two circuits are equivalent.

Any sweep generator can be regarded as a simple loop (Fig. 14.3.5) comprising a capacitor C delivering a voltage ramp, a loading resistor R_B , and the series combination of two sources: a constant voltage source E_{cc} and a variable source whose emf E reproduces the voltage drop V across the capacitor. The voltage drop across

FIGURE 14.3.4 Equivalency of the Miller and bootstrap sweep generators.

R_B consequently remains constant and equal to E_{cc} making the loop current also constant. The voltage ramp consequently is given by

$$E = V = (E_{cc}/R_B C)t \tag{3}$$

Grounding terminal 1 yields the Miller network, while grounding terminal 2 leads to the bootstrap circuit.

Since linearity is one of the essential features of sweep generators, we consider the equivalent networks represented in Fig. 14.3.6. Starting with the Miller circuit, we determine the impedance in parallel with C

FIGURE 14.3.5 Basic loop of sweep-generator circuits.

$$|A|(R_B \parallel h_{11}) \tag{4}$$

where $|A|$ is the absolute value of the voltage gain of the amplifier

$$|A| = (h_{21}/h_{11})R_L$$

Next, considering the bootstrap circuit, we calculate the input impedance of the unity-gain amplifier to determine the loading impedance acting on C . This impedance is

$$R_L h_{21} R_B / (R_B + h_{11}) \tag{5}$$

which turns out to be the same as that given in Eq. (4); i.e., the two circuits are equivalent. To determine the degree of linearity it

is sufficient to consider the common equivalent circuit of Fig. 14.3.7 and to calculate the Taylor expansion of the voltage V

$$V = \frac{E_{CC}}{R_B C} t \left[1 - \frac{t}{2! |A| (R_B \parallel h_{11}) C} + \frac{t^2}{3! [|A| (R_B \parallel h_{11}) C]^2} - \dots \right] \tag{6}$$

FIGURE 14.3.6 Equivalent forms of (a) Miller and (b) bootstrap sweep circuits.

FIGURE 14.3.7 Common equivalent circuit of sweep generators.

FIGURE 14.3.8 Typical sample-and-hold circuit.

The higher the voltage gain $|A|$, the better the linearity. Thus, an integrated operational amplifier in place of T_1 leads to excellent performance in both the Miller and the bootstrap circuit. Voltage gains as high as 10,000 are easily obtained for this purpose.

SAMPLE-AND-HOLD CIRCUITS⁴

Sample-and-hold circuits are widely used to store analog voltages accurately over time ranging from microseconds to minutes. They are basically switched-capacitor networks, but since the analog voltage across the storage capacitor in the hold mode must be sensed under low impedance, a buffer amplifier is needed. Op-amps with FET input are commonly used for this purpose to minimize the hold-mode droop. The schematic of a widely used integrated circuit is shown in Fig. 14.3.8.

Storage and readout are achieved by the FET input op-amp in the hold mode. During the acquisition time, transistor S_2 is conducting, while S_1 is blocked. Current is supplied by the voltage-dependent current source to minimize the voltage difference between input and output terminals. As soon as S_1 and S_2 change their states, V_{out} ceases to follow V_{in} and remains unchanged.

The main requirements for sample-and-hold circuits are low hold-mode droop, short settling time in the acquisition mode, low offset voltage, and small hold-mode feedthrough. The hold-mode droop is dependent on the leakage current of the op-amp inverting node. Short settling times require high-slew-rate op-amps and large current-handling capabilities for both the current source and the op-amp. The offset voltage is determined by the differential amplifier which controls the current source. Finally, feedthrough is a result of imperfect isolation between the current source and the op-amp. For this reason, a double switch is preferred to a single series switch.

Another important feedthrough problem is related to the unavoidable gate-to-source or drain-overlap capacitance of the MOS switch S_2 . When the gate-control signal is switched off, some small charge is always transferred capacitively to the storage capacitor and a small voltage step is superimposed on the output terminal when the circuit enters the hold state. Minimization of this effect can be achieved by increasing the ratio of the storage capacitance to the switch-overlap capacitance. Since the latter cannot be made equal to zero, the storage capacitance must be chosen sufficiently large, but this inevitably lengthens the settling time. One means of alleviating the problem is to compensate the switching charge because of the control signal by injection of an equal and opposite charge on the inverting input node of the op-amp. This can be achieved by means of a dummy transistor controlled by the inverted signal.

NONLINEAR NEGATIVE FEEDBACK WAVEFORM SHAPING

The use of nonlinear devices with negative feedback accentuates the character of waveshaping networks. In many circumstances, this leads to an idealization of the nonlinear character of the devices considered. A good example of this is given by the ideal rectifier circuit.

The negative-feedback loop in the circuit shown in Fig. 14.3.9 is formed by two parallel branches. Each comprises a diode connected in such manner that if V_1 is positive, the current injected by resistor R_1 flows

14.30 PULSED CIRCUITS AND WAVEFORM GENERATION

through D_1 , and if V_1 is negative, through D_2 . A resistor R_2 is placed in series with D_1 , and the output voltage V_2 is taken at the node between R_2 and D_1 . Hence, V_2 is given by $-(R_2/R_1)V_1$ when V_1 is positive, independently of the forward voltage drop across D_1 .

FIGURE 14.3.9 The precision rectifier using negative feedback is almost an ideal rectifier.

consists of a current source delivering the current V_1/R_1 in parallel with an almost infinite resistor $|A|R$, where A represents the voltage gain of the op-amp. Hence, the current flowing through the branch formed by R_2 and D_1 is delivered by a quasi-ideal current source, and the voltage drop across R_2 is unaffected by the series diode D_1 . As for D_2 , it is required to prevent the feedback loop from being opened when V_1 is negative. If this could happen, the artificial ground at the input of the op-amp would be lost and V_2 would not be zero.

Other negative-feedback configurations leading to very high output impedances are equally powerful in achieving ideal rectification characteristics. For instance, the unity-gain amplifier used in instrumentation has wide linear ac measurement capabilities (Fig. 14.3.11).

When D_1 is forward-biased, the voltage V at the output of the op-amp adjusts itself to force the current flowing through D_1 and R_L to be exactly the same as through R_1 . This means that V may be much larger than V_2 , especially when V_2 (and thus also V_1) is of the order of millivolts. In fact, V exhibits approximately the same shape as V_2 plus an additional pedestal of approximately 0.6 to 0.7 V. Typical waveforms obtained with a sinusoidal voltage of a few tens of millivolts are shown in Fig. 14.3.10.

The quasi-ideal rectification characteristic of this circuit is readily understood by considering the Norton equivalent network seen from R_2 and D_1 in series.

POSITIVE FEEDBACK WAVEFORM SHAPING

Positive feedback is used extensively in bistable, monostable, and astable (free-running) circuits. Astable networks include free-running relaxation circuits whether self-excited or synchronized by external trigger pulses. Monostable and bistable circuits also exist, with one and two distinct stable states, respectively.

The degree to which positive feedback is used in harmonic oscillators differs substantially from that of astable, monostable, or bistable circuits. In an oscillator the total loop gain must be kept close to 1. It needs to compensate only for small losses in the resonating tank circuit. In pulsed circuits, positive feedback permits

FIGURE 14.3.10 Waveforms of circuit in Fig. 14.3.9.

FIGURE 14.3.11 Feedback rectification circuit used in precision measurements.

fast switching from one state to another, e.g., from cutoff to saturation and vice versa. Before and after these occur, the circuit is passive. Switching occurs in extremely short times, typically a few ns. After switching, the circuit evolves more slowly, approaching steady-state conditions.

It is common practice to call the switching time the *regeneration time* and the time needed to reach final steady-state conditions the *resolution time*. The resolution time may range from tens of nanoseconds to several seconds or more, depending on the circuit.

An important feature of triggered regenerative circuits is that their switching times are essentially independent of the steepness of the trigger-signal waveshape. Once instability is reached the transition occurs at a rate fixed by the total loop gain and the reactive parasitics of the circuit itself but independent of the rate of change of the trigger signal itself. Regenerative circuits, therefore, provide means of restoring short rise times.

Positive-feedback pulse circuits are necessarily nonlinear. The most conventional way to study their behavior is to take advantage of piecewise-linear analysis techniques.

Bistable Circuits⁵ (Collector Coupled)

Two cascaded common-emitter transistor stages implement an amplifier with a high positive gain. Connecting the output to the input (Fig. 14.3.12) produces an unstable network known as the *Eccles-Jordan bistable circuit* or *flip-flop*. Under steady-state conditions one transistor is saturated and the other is blocked.

Suppose the circuit of Fig. 14.3.12 has the value $R_L = 1 \text{ k}\Omega$, $R = 2.2 \text{ k}\Omega$, and $E_{cc} = 5 \text{ V}$. Suppose T_1 is at cutoff, and consider the equivalent network connected to the base of T_2 . It can be viewed as an emf of 5 V and series resistances of 3.2 k Ω . The base current of T_2 is given by

$$I_{B2} = (5 - 0.7)/3.2 = 1.34 \text{ mA} \quad (7)$$

T_2 being saturated, the collector current is equal to E_{cc}/R_L or 5 mA. A current gain of 4 would be sufficient to ensure saturation of T_2 . Hence the collector-to-emitter voltage across T_2 will be very small ($V_{CE,sat}$), and consequently T_1 will be blocked, as stated initially. The reverse situation, with T_1 saturated and T_2 cut off, is governed by identical considerations for reasons of symmetry. Two distinct stable states thus are possible.

When one of the transistors is suddenly switched from one state to the opposite, the other transistor automatically undergoes an opposite transition. At a given time both transistors conduct simultaneously, which increases the loop gain from zero to a high positive value. This corresponds to the regenerative phase, during which the circuit becomes active.

It is difficult to compute the regeneration time since the operating points of both transistors move through the entire active region, causing large variations of the small-signal parameters. Although determination of the regeneration time on the basis of a linear model is unrealistic and leads only to a rough approximation, we briefly examine this problem since it illustrates how the regeneration phase of unstable networks may be analyzed.

FIGURE 14.3.12 The Eccles-Jordan bistable circuit (flip-flop): (a) in the form of two cascaded amplifiers with output connected to input; (b) as customarily drawn, showing symmetry of connections.

FIGURE 14.3.13 Flip-flop circuit showing capacitances that determine time constants.

First, we introduce two capacitors in parallel with the two resistors R . These capacitors provide a direct connection from collector to base under transient conditions and hence increase the high-frequency loop again. The circuit can now be described by the network of Fig. 14.3.13, which consists of a parallel combination of two reversed transistors without extrinsic base resistances (for calculation convenience) and with two load admittances Y which combine the load and resistive input of each transistor. Starting from the admittance matrix of one of the transistors with its load, we equate the determinant of the parallel combination

$$\begin{vmatrix} p(C_\pi + C_{TC}) & -pC_{TC} \\ \frac{I}{V_T} - pC_{TC} & pC_{TC} + Y \end{vmatrix} \quad (8)$$

to zero to find the natural frequencies of the circuit. This leads to

$$pC_\pi + (I/V_T) + Y = 0 \quad (9)$$

and

$$p(C_\pi + 4C_{TC}) + Y - I/V_T = 0 \quad (10)$$

where C_π stands for the parallel combination of C_{TE} and the diffusion capacitance $\tau_F I/V_T$. Only Eq. (10) has a zero with a real positive pole, producing an increasing exponential function with time constant approximately equal to

$$\tau = (C_\pi + 4C_{TC}) V_T/I \quad (11)$$

Since the diffusion capacitance overrules the transition capacitances at high current, Eq. (11) reduces finally to τ_F . This yields extremely short switching times. For instance, a transistor with a maximum transition frequency f_T of 300 MHz and a τ_F equal to 0.53 ns, exhibits a regeneration time (defined as the time elapsing between 10 and 90 percent of the total voltage excursion from cutoff to saturation or vice versa) equal to $2.2\tau_F$, or 1.2 ns.

A more accurate but much more elaborate analysis, taking into account the influence of the extrinsic base resistance and nonlinear transition capacitances in the region of small-collector current, requires a computer simulation based on the dynamic large-signal model of the bipolar transistor. Nevertheless, Eq. (11) clearly pinpoints the factors controlling the regeneration time; the transconductance and unavoidable parasitic capacitances. This is verified in many other positive-feedback switching circuits.

We consider next which factors control the resolution time still with the same numerical data. We suppose T_1 initially nonconducting and T_2 saturated. The sudden turnoff of T_2 is simulated by opening the short-circuit switch S_2 in Fig. 14.3.14a. Immediately, V_{CE2} starts increasing toward E_{cc} . The base voltage V_{BE1} of T_1 consequently rises with a time constant fixed only by the total parasitic capacitance C_T at the collector of T_2 and base of T_1 times the resistor R_L . Hence this time constant is

$$\tau_1 = R_L C_T \quad (12)$$

This time is normally extremely short; e.g., a parasitic capacitance of 1 pF yields a time constant of 1 ns. The charge accumulated across C evidently cannot change, for C is much larger than C_T . So V_{BE1} and V_{CE2} increase at the same rate. This situation is illustrated in Fig. 14.3.14b. When V_{BE1} reaches approximately 0.7 V, T_1 starts conducting and a new situation arises, illustrated in Fig. 14.3.14 by the passage from (b) to (c). This is when regeneration actually takes place, forcing T_1 to go into saturation very rapidly. With the regeneration period neglected, case (c) is characterized by the time constant

$$\tau_2 = (R_L/R)C \quad (13)$$

For instance, if C is equal to 10 pF, τ_2 yields 7 ns. Although this time constant is much longer than τ_1 , it is still not the longest, for we have not yet considered the evolution of V_{BE2} .

FIGURE 14.3.14 Piecewise analysis of flip-flop switching behavior. Transistor T_2 is assumed to be on before (a). The opening of S_2 simulates cutoff. The new steady-state conditions are reached in (c).

It is considered in Fig. 14.3.15, where the saturated transistor T_1 is replaced by the closing of S_1 . The problem is the same as for the compensated attenuator. Since overcompensation is achieved, V_{BE2} undergoes a large negative-voltage swing almost equal to E_{CC} before climbing toward its steady-state value 0 V. The time constant of this third phase is given by

$$\tau_3 = RC \quad (14)$$

In the present case, τ_3 equals 22 ns.

The voltage variations versus time of the flip-flop circuit thus far analyzed are reviewed in Fig. 14.3.16 with the assumption that the regeneration time is negligible. Clearly C plays a double role. The first is favorable since it ensures fast regeneration and efficiently removes excess charges from the base of the saturated transistor, but the second is unfavorable since it increases the resolution time and sets an upper limit to the maximum repetition rate at which the flip-flop can be switched. The proper choice of

FIGURE 14.3.15 The longest time constant is experienced when T_1 is turned on. This is simulated by the closure of switch S_1 .

C as well as of R_L and R must take this fact into consideration. Small values of the resistances make high repetition rates possible at the price of increased dc power consumption.

INTEGRATED-CIRCUIT FLIP-FLOPS

The Eccles-Jordan circuit (Fig. 14.3.12) is the basic structure of integrated bistable circuits. The capacitor C is not present.

The integrated flip-flop can be viewed as two cross-coupled single-input NOR or NAND circuits. In fact, integrated flip-flops vary only in the way external signals act upon them for control purposes. A typical example is given in Fig. 14.3.17 with the corresponding logic-symbol representation. The triggering inputs are called *set* S and *reset* R terminals. Transistors T_3 and T_4 are used for triggering.

The truth for NOR and NAND bistable circuits are

R	S	NOR bistable			NAND bistable		
		Q_1	Q_2	Line	Q_1	Q_2	Line
0	0	Q	Q	1	1	1	5
0	1	1	0	2	1	0	6
1	0	0	1	3	0	1	7
1	1	0	0	4	Q	Q	8

FIGURE 14.3.16 Voltage variations vs. time of flip-flop circuit.

Lines 1 and 8 correspond to situations where the S and R inputs are both inactive, leaving the bistable circuit in one of its two possible states indicated in the tables above by the letters Q and \bar{Q} (Q may be either 1 or 0). If a specified output state is required, a pair of adequate complementary dc trigger signals is applied to the S and R inputs simultaneously.

For instance, if the output pair is to be characterized by $Q_1 = 1$ and $Q_2 = 0$, the necessary input combination, for NOR and NAND bistable circuits, is $S = 1$ and $R = 0$. Changing S back from 1 to 0 does not change anything in the output state in the NOR bistable. The same is true if S is made equal to 1 in the NAND bistable. In both cases, the flip-flop exhibits infinite memory of the stored state. The name *sequential circuit* is given to this class of networks as opposed to previous circuits, which are called combinational circuits.

Lines 4 and 5 must be avoided, for the passage from line 4 to line 1 or from line 5 to line 8 leads to uncertainty regarding the final state of the bistable circuit. In fact, the final transition is entirely out of the control of the input, since in both cases it results solely from small imbalances between transistor parasitics that allow faster switching of one or another inverter.

SYNCHRONOUS BISTABLE CIRCUITS⁴

Sequential networks may be either synchronous or asynchronous. The asynchronous class describes circuits in which the application of an input control signal triggers the bistable circuit immediately. This is true of the circuits thus far considered. In the synchronous class, changes of state occur only at selected times, after a clock signal has occurred.

Synchronous circuits are less sensitive to hazard conditions. Asynchronous circuits may be severely troubled by this effect, which results from differential propagation delays. These delays, although individually very small (typically of the order of a few nanoseconds), are responsible for introducing skew between signals that travel through different logic layers. Unwanted signal combinations may therefore appear for short periods and be interpreted erroneously.

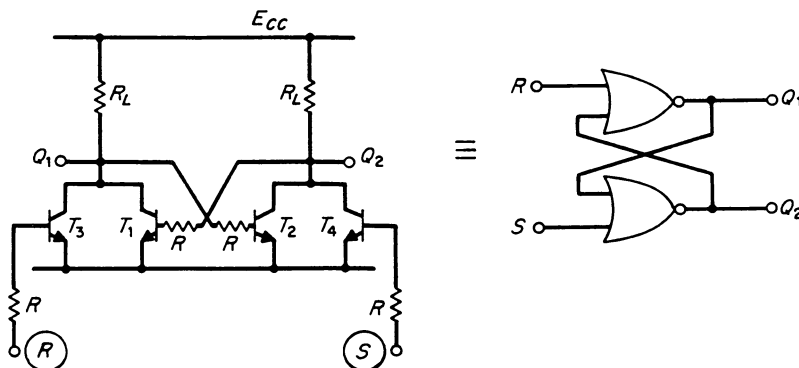

FIGURE 14.3.17 DC-coupled version of flip-flop, customarily used in integrated-circuit versions of this circuit.

FIGURE 14.3.18 Synchronous flip-flop.

Synchronous circuits do not suffer from this limitation because they conform to the control signals only when the clock pulse is present, usually after the transient spurious combinations are over. A simple synchronous circuit is shown in Fig. 14.3.18. The inhibition action provided by the absence of the clock signal is provided by a pair of input AND circuits. Otherwise nothing is changed with respect to the bistable network.

A difficulty occurs in cascading bistable circuits, to achieve time-division. Instead of each circuit controlling its closest neighbor, when a clock signal is applied, the set and reset signals of the first bistable jump from one circuit to the next, traveling throughout the entire chain in a time which may be shorter than the duration of the clock transition. To prevent this, a time delay must be introduced between the gating NAND circuits and the actual bistable network, so that changes of state can occur only after the clock signal has disappeared.

One approach is to take advantage of storage effects in bipolar transistors, but the so-called *master-slave* association, shown in Fig. 14.3.19, is preferred. In this circuit, intermediate storage is realized by an auxiliary clocked bistable network controlled by the complement of the clock signal. The additional circuit complexity is appreciable, but the approach is practical in integrated-circuit technology.

The master-slave bistable truth table can be found from that of the synchronous circuit in Fig. 14.3.18, which in turn can be deduced from the truth table given in the previous section. One problem remains, however, the forbidden 1,1 input pair, which is responsible for ambiguous states each time the clock goes to zero. To solve this problem, the *JK* bistable was introduced (see Fig. 14.3.20). The main difference is the introduction of a double feedback loop. Hence the *S* and *R* inputs become, respectively, *JQ* and *KQ*. As long as the *J* and *K* inputs are not simultaneously equal to 1, nothing in fact is changed with respect to the behavior of the *SR* synchronous circuit.

When *J* and *K* are both high, the cross-coupled output signals fed back to the input gates cause the flip-flop to toggle under control of the clock signal. The truth table then becomes

<i>J</i>	<i>K</i>	Q_{n+1}	Line
0	0	Q_n	1
1	0	1	2
0	1	0	3
1	1	\bar{Q}_n	4

Q_{n+1} stands for *Q* at the clock time $n + 1$ and Q_n for *Q* at clock time n . Lines 1 to 3 match the corresponding lines of the NOR bistable truth table. Line 4 indicates that state transitions occur each time the clock signal goes from high to low. The corresponding logic equation of the *JK* flip-flop, therefore, is

$$Q_{n+1} = J\bar{Q}_n + \bar{K}Q_n \quad (15)$$

FIGURE 14.3.19 Master-slave synchronous flip-flop.

FIGURE 14.3.20 JK Flip-flop.

When only one control signal is used, J , for instance, and K is obtained by negation of the J signal, a new type of bistable is found, which is called the D flip-flop. The name given to the J input is D . Since K is equal to J , Eq. (15) reduces to

$$Q_{n+1} = D \tag{16}$$

Hence, in this circuit the output is set by the input D after a clock cycle has elapsed. Notice that the flip-flop is insensitive to changes of D occurring while the clock is high.

D flip-flops without the master-slave configuration also exist, but their output state follows the D signal if changes occur while the clock is high. These bistables can be used to latch data. Several D flip-flops controlled by the same clock form a register for data storage. The clock signal then is called an enable signal.

Bistable Circuits, Emitter-Coupled Bistables (Schmitt Circuits)⁶

In the basic Schmitt circuit represented in Fig. 14.3.21 bistable operation is obtained by a positive-feedback loop formed by the common-base and common-collector transistor pair (respectively T_1 and T_2). The Schmitt circuit can be considered as a differential amplifier with a positive-feedback loop, which is a series-parallel association.

FIGURE 14.3.21 Emitter-coupled Schmitt circuit, showing positive-feedback loop.

Emitter-coupled bistables are fundamentally different from Eccles-Jordan circuits, since no transistor saturates in either of the two stable states. Storage effects therefore need not be considered.

The two permanent states are examined in Fig. 14.3.22. In each state, (a) as well as (b), one transistor operates in the common-collector configuration while the other is blocked. In Fig. 14.3.22a, the collector voltage V_{C1} of T_1 and base voltage V_{B2} of T_2 are given by

$$V_{C1} = E_{cc} \frac{R_1 + R_2}{R_1 + R_2 + R_c} \tag{17}$$

$$V_{B2} = E_{cc} \frac{R_1}{R_1 + R_2 + R_c} = V_h$$

FIGURE 14.3.22 Execution of transfer in Schmitt circuit: (a) with T_1 blocked; (b) with T_1 conducting.

When the other stable state (b) is considered,

$$V_{C1} = (E_{cc} - R_c I) \frac{R_1 + R_2}{R_1 + R_2 + R_c} \quad (18)$$

$$V_{B2} = (E_{cc} - R_c I) \frac{R_1}{R_1 + R_2 + R_c} = V_l$$

The situation depicted in Fig. 14.3.22 remains unchanged as long as the input voltage V_{B1} applied to T_1 is kept below the actual value V_h . In the other state (b), T_2 will be off as long as V_{B1} is larger than V_l . A range of input voltages between V_h and V_l thus exists where either of the two states is possible.

To alleviate the ambiguity, let us consider an input voltage below the smallest of the two possible values of V_{B2} so that the transistor T_1 necessarily is blocked. This corresponds to the situation of Fig. 14.3.22a. Now let the input voltage be gradually increased. Nothing will happen until V_{B1} approaches V_h . When the difference between the two base voltages is reduced to 100 mV or less, T_1 will start conducting and the voltage drop across R_c will lower V_{B2} . The emitter current of T_2 will consequently be reduced, and more current will be fed back to T_1 . Hence, an unstable situation is created, which ends when T_1 takes over all the current delivered by the current source and T_2 is blocked.

Now the situation depicted in Fig. 14.3.22b is reached. The base voltage of T_2 becomes V_l , and the input voltage may either continue to increase or decrease without anything else happening as long as V_{B1} has not reached V_l . When V_{B1} approaches V_l , another unstable situation is created causing the switching from (b) to (a). Hence, the input-output characteristic of the Schmitt trigger is as shown in Fig. 14.3.23 with a hysteresis loop.

FIGURE 14.3.23 Input-output characteristic of Schmitt circuit, showing rectangular hysteresis.

Schmitt triggers are suitable for detecting the moment when an analog signal crosses a given DC level. They are widely used in oscilloscopes to achieve time-base synchronization. This is illustrated in Fig. 14.3.24, which shows a periodic signal triggering a Schmitt circuit and the corresponding output waves. It is possible to modify the switching levels by changing the operating points of the

transistors electrically, e.g., by modifying the current delivered by the current source.

In many applications, the width of the hysteresis does not play a significant role. The width can be decreased, however, by increasing the attenuation of the resistive divider formed by R_1 and R_2 , but one should not go below 1 V because sensitivity to variations in circuit components or supply voltage may occur.

FIGURE 14.3.24 Trigger input and output voltage of Schmitt circuit; solid line delivered by a current source; broken line delivered by a resistor.

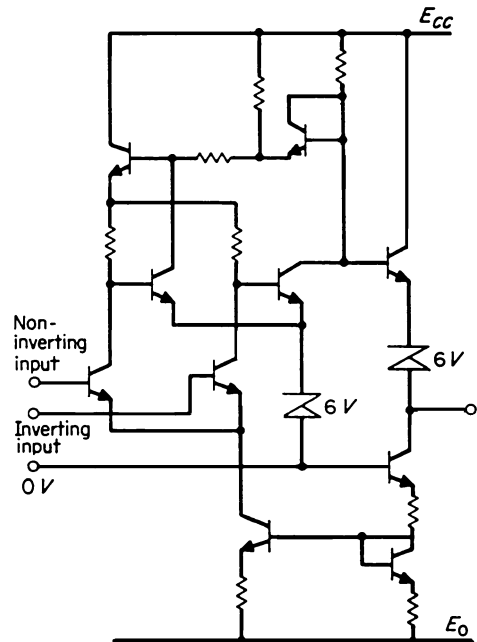

FIGURE 14.3.25 Bipolar integrated version of a comparator.

Furthermore, the increased attenuation in the feedback loop must be compensated for by a corresponding increase in the differential amplifier gain. Otherwise the loop gain may fall below 1, preventing the Schmitt circuit from functioning. A hysteresis of a few millivolts is therefore difficult to achieve.

A much better solution is to use *comparators* instead of Schmitt triggers when hysteresis must be avoided. A typical integrated comparator is shown in Fig. 14.3.25. It is a medium-gain amplifier (10^3 to 10^4) with a very fast response (a few nanoseconds) and an excellent slew rate. Comparators are not designed to be used as linear amplifiers like op-amps. Their large gain-bandwidth product makes them inappropriate for feedback configurations. They inevitably oscillate in any type of closed loop. In the open-loop configuration they behave like clipping circuits with an exceedingly small input range, which is equal to the output-voltage swing, usually 5 V, divided by the gain. The main difference compared with Schmitt triggers is the fact that comparators do not exhibit hysteresis. This makes a significant difference when considering very slowly varying input signals.

In the circuit of Fig. 14.3.21 the common-emitter current source can be replaced by a resistor. This solution introduces some common-mode sensitivity. The output signal does not look square, as shown in Fig 14.3.24 by the dashed lines. If unwanted, this effect can be avoided by taking the output signal at the collector of T_2 through an additional resistor, since the current flowing through T_2 is constant. An additional advantage of the latter circuit is that the output load does not interfere with the feedback loop.

INTEGRATED-CIRCUIT SCHMITT TRIGGERS

Basically a Schmitt trigger can always be implemented by means of an integrated differential amplifier and an external positive-feedback loop. If the amplifier is an op-amp, poor switching characteristics are obtained unless an amplifier with a very high slewing rate is chosen. If a comparator is considered instead of an op-amp, switching will be fast but generally the output signal will exhibit spurious oscillations during the transition period. The oscillatory character of the output signal is due to the trade-off between speed and stability which is typical of comparators compared with op-amps. Any attempt to create a dominant pole, in fact, inevitably would ruin their speed performance.

FIGURE 14.3.26 Precision integrated Schmitt trigger.

the circuit of Fig. 14.3.26 behaves like a Schmitt trigger with a hysteresis width $E_{cc}/3$ depending only on the resistive divider $3R$ and the offset voltages of the two comparators C_1 and C_2 . This circuit can therefore be considered as a precision Schmitt trigger and is widely used as such.

The integrated-circuit counterpart of the Schmitt trigger is shown in Fig. 14.3.26. It consists of two comparators connected to a resistive divider formed by three equal resistors R . Input terminals 2 and 6 are normally tied together. The output signals of the two comparators control a flip-flop. When the input voltage is below $E_{cc}/3$, the flip-flop is set. Similarly when the input voltage exceeds $2E_{cc}/3$, the circuit is reset.

The actual state of the flip-flop in the range between $E_{cc}/3$ and $2E_{cc}/3$ will depend on how the input voltage enters the critical zone. For instance, if the input voltage starts below $E_{cc}/3$ and is increased so that it changes the state of comparator C_2 but not that of comparator C_1 , both S and R are equal to $\bar{1}$ and the flip-flop remains set. The state changes only if the input voltage exceeds the limit $2E_{cc}/3$. Similarly, if the input voltage is lowered, setting the flip-flop will occur only when $E_{cc}/3$ is reached. Hence

Monostable and Astable Circuits (Discrete Components)⁴

Figures 14.3.27 and 14.3.28 show monostable and astable collector-coupled pairs, respectively. The fundamental difference between these circuits and bistable networks lies in the way DC biasing is achieved. In Fig. 14.3.27a, T_2 is normally conducting except when a negative trigger pulse drives this transistor into the cutoff region. T_1 necessarily undergoes the inverse transition, suddenly producing a large negative voltage step at the base of T_2 shown in Fig. 14.3.27b. V_{BE2} , however, cannot remain negative since its base is connected to the positive-voltage supply through the resistor R_1 . The base voltage rises toward E_{cc} , with a time constant R_1C . As soon as the emitter junction of T_2 becomes forward-biased, the monostable circuit changes its state again and the circuit remains in that state until another trigger signal is applied.

The time T between the application of a trigger pulse and the instant T_2 saturates again is given approximately by

$$T = \tau \ln 2 = 0.693 \tau \quad (19)$$

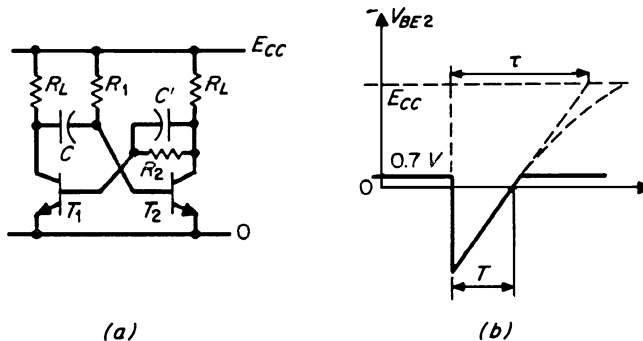

FIGURE 14.3.27 Monostable collector-coupled pair: (a) circuit; (b) output vs. time characteristics.

FIGURE 14.3.28 Astable (free-running) flip-flop: (a) circuit; (b) output vs. time characteristics.

where $\tau = R_1 C$. The supply voltage E_{CC} is supposed to be large compared with the forward-voltage drop of the emitter junction of T_2 for this expression to apply.

The astable collector-coupled pair, or free-running multivibrator (Fig. 14.3.28), operates according to the same scheme except that steady-state conditions are never reached. The base-bias networks of both transistors are connected to the positive power supply. The period of the multivibrator thus equals $2T$ if the circuit is symmetrical, and the repetition rate F , is given by

$$F_r = \frac{1}{2\tau \ln 2} \approx \frac{0.7}{RC} \quad (20)$$

INTEGRATED MONOSTABLE AND ASTABLE CIRCUITS⁷

The discrete component circuits discussed above are interesting only because of their inherent simplicity and exemplative value. Improved means to integrate monostable and astable are shown below.

The circuit shown in Fig. 14.3.29 is derived from the Schmitt trigger. It is widely used in order to implement high-frequency (100 MHz) relaxation oscillators. The capacitor C provides a short circuit between the emitters of the two transistors, closing the positive-feedback loop during the regeneration time. As long as one or the other of the two transistors is cut off, C offers a current sink to the current source connected to the emitter of the blocked transistor. The capacitor thus is periodically charged and discharged by the two current sources, and the voltage across its terminal exhibits a triangular waveform. The collector current of T_1 is either zero or $I_1 + I_2$, so that the resulting voltage step across R_C is $(R_B \parallel R_C)(I_1 + I_2)$. Since the base of T_2 is directly connected to the collector of T_1 , the same voltage step controls T_2 and determines the width of the input hysteresis, i.e., the maximum amplitude of the voltage sweep across C . The period of oscillation is computed from

FIGURE 14.3.29 Discrete-component emitter-coupled astable circuit.

$$T = C \left(\frac{1}{I_1} + \frac{1}{I_2} \right) (R_B \parallel R_C) (I_1 + I_2) \quad (21)$$

FIGURE 14.3.30 Waveforms of circuit in Fig. 14.3.29.

When, as is usual, both current sources deliver equal currents, the expression for T reduces to

$$T = 4(R_B \parallel R_C)C \tag{22}$$

T does not depend, in this case, on the amplitude of the current because changes in current in fact modify the amplitude and the slope of the voltage sweep across C in the same manner. A review of the waveforms obtained at various points of the circuit is given in Fig. 14.3.30.

Integrated monostable and astable circuits can be derived from the precision Schmitt trigger circuit shown in Fig. 14.3.26. The monostable configuration is illustrated in Fig. 14.3.31.

Under steady-state conditions, the flip-flop is set and the transistor T saturated. The input voltage V_{in} is kept somewhere between the two triggering levels $E_{cc}/3$ and $2E_{cc}/3$. To initiate the monostable condition, it is sufficient that V_{in} drops below $E_{cc}/3$ even for a very short time, in order to reset the flip-flop and prevent T from conducting. The current flowing through R_1 then charges C until the voltage V_C reaches the triggering level

FIGURE 14.3.31 Monostable precision Schmitt trigger: (a) circuit; (b) waveforms.

FIGURE 14.3.32 Astable precision Schmitt trigger: (a) circuit; (b) waveforms.

$2E_{cc}/3$. Immediately thereafter, the circuit switches to the opposite state and transistor T discharges C . The monostable circuit remains in that state until a new triggering pulse V_{in} is fed to the comparator C_2 . The waveforms V_{in} , V_C , and V_{out} are shown in Fig. 14.3.31b. This circuit is also called a *timer* because it provides constant-duration pulses, triggered by a short input pulse. A slight modification of the external control circuitry may change this monostable into a retriggerable timer.

The astable version of the precision Schmitt trigger is shown in Fig. 14.3.32. Its operation is easily understood from the preceding discussion. The capacitor C is repetitively discharged through R_2 in series with the saturated transistor T and recharged through $R_1 + R_2$. The voltage V_C therefore consists of two distinct exponentials clamped between the triggering levels $E_{cc}/3$ and $2E_{cc}/3$. The frequency is equal to $1.44/(R_1 + 2R_2)C$. Because of the precision of the triggering levels (10^{-3} to 10^{-4}) short-term frequency stability can be achieved.

CHAPTER 14.4

DIGITAL AND ANALOG SYSTEMS

Paul G. A. Jespers

INTEGRATED SYSTEMS

With the trend toward ever higher integration levels, an increasing number of ICs combine some of the circuits seen before in order to build large systems, digital as well as analog, or mixed, such as wave generators and A/D and D/A converters. Some of these are reviewed below.

COUNTERS^{4,7}

To count any number N of events, at least k flip-flops are required, such that

$$2^k \geq N \quad (1)$$

Ripple Counters

JK flip-flops with J and K inputs equal to 1 are *divide-by-2* circuits. Hence, a cascade of k flip-flops with each output Q driving the clock of the next circuit forms a divide-by- 2^k chain, or a binary counter (see Fig. 14.4.1). The main drawback of this circuit is its increasing propagation delay with k . When all the flip-flops switch, the clock signal must ripple through the entire counter. Hence, enough time must be allowed to obtain the correct count. Furthermore, the delays between the various stages of the counter may produce glitches, e.g., when parallel decoding is achieved.

Synchronous Binary Counters

Minimization of delay and glitches can be achieved by designing synchronous instead of asynchronous counters. In a synchronous counter all the clock inputs of the JK flip-flops are driven in parallel by a single clock signal. The control of the counter is achieved by driving the J input by means of the AND combination of all the preceding Q outputs, as shown in Fig. 14.4.2. In this manner, all state changes occur on the same trailing edge of the clock signal. The only remaining requirement is to allow enough time between clock pulses for the propagation through a single flip-flop and an AND gate. The drawback of course is increased complexity with the order k .

Divide-by- N Synchronous Counters

When the number N of counts cannot be expressed in binary form, auxiliary decoding circuitry is required. This is true also for counters that provide truncated and irregular count sequences. Their synthesis is based

FIGURE 14.4.1 Ripple counter formed by cascading flip-flops.

FIGURE 14.4.2 Synchronous counter.

on the so-called transition tables. The basic transition table of the JK flip-flop is derived easily from its truth table.

Q_n	Q_{n+1}	J	K	Line
0	0	0	×	1
0	1	1	×	2
1	0	×	1	3
1	1	×	0	4

Line 1, for instance, means that in order to maintain Q equal to 0 after a clock signal has occurred, the J input must be made equal to 0 whatever K may be (X stands for “don’t care”). This can be easily verified with the truth table (lines 1 and 3). Hence, the synthesis of a synchronous counter consists simply of determining the J and K inputs of all flip-flops that are needed to obtain a given sequence of states.

Once the J and K truth tables have been obtained, classical minimization procedures can be used to synthesize the counter. For instance, consider the design of a divide-by-5 synchronous counter for which a minimum of three flip-flops is required. First, the present and next states of the flip-flops are listed. Then the required J and K inputs are found by means of the JK transition table:

	Present state			Next state			JK inputs					
	Q_3	Q_2	Q_1	Q_3	Q_2	Q_1	J_3	K_3	J_2	K_2	J_1	K_1
0	0	0	0	0	0	1	0	×	0	×	1	×
1	0	0	1	0	1	0	0	×	1	×	×	1
2	0	1	0	0	1	1	0	×	×	0	1	×
3	0	1	1	1	0	0	1	×	×	1	×	1
4	1	0	0	0	0	0	×	1	0	×	0	×

Using Karnaugh minimization techniques, one finds

$$\begin{aligned}
 J_3 &= Q_1Q_2 & K_3 &= 1 \\
 J_2 &= Q_1 & K_2 &= Q_1 \\
 J_1 &= Q_3 & K_1 &= 1
 \end{aligned}$$

The corresponding counter is shown in Fig. 14.4.3. With this procedure it is quite simple to synthesize a decimal counter with four flip-flops. The same method also applies to the synthesis with D flip-flops.

Up-Down Counters

Upward and downward counters differ from the preceding ones only by the fact that an additional bit is provided to select the proper J and K controls for up or down count. The same synthesis methods are applicable.

Presetable Counters

Since a counter is basically a chain of flip-flops, parallel loading by any number within the count sequence is readily possible. This can be achieved by means of the set terminals. Hence, the actual count sequence can be initiated from any arbitrary number.

SHIFT REGISTERS³

Shift registers are chains of flip-flops connected so that the state of each can be transferred to its next left or right neighbor under control of the clock signal. Shift registers can be built with *JK* as well as *D* flip-flops. An example of a typical bidirectional shift register is shown in Fig. 14.4.4. Shift registers, such as counters, may be loaded in parallel or serial mode. This is also true for reading out.

FIGURE 14.4.3 Synchronous divide-by-5 circuit.

In MOS technology, dynamic shift registers can be implemented in a simple manner. Memorization of states occurs electrostatically rather than by means of flip-flops. The information is stored in the form of charge on the gate of an MOS transistor. The main advantage of MOS dynamic shift registers is area saving resulting from the replacement of flip-flops by single MOS transistors. A typical dynamic 2-phase shift register (Fig. 14.4.5) consists of two cascaded MOS inverters connected by means of series switches. These switches, T_3 and T_6 , are divid-

ed into two classes: *odd* switches controlled by the clock ϕ_1 , and *even* switches controlled by ϕ_2 .

The control signals determine two nonoverlapping phases. When ϕ_1 turns on the odd switches, the output signal of the first inverter controls the next inverter but T_6 prevents the information from going further. When ϕ_2 turns on, data are shifted one half cycle further. The signal jumps from one inverter to the next until it reaches the last stage.

FIGURE 14.4.4 Bidirectional shift register.

FIGURE 14.4.5 A 2-phase MOS dynamic shift register.

MULTIPLEXERS, DEMULTIPLEXERS, DECODERS, ROMS, AND PLAS³⁻⁸

A multiplexer is a combinatorial circuit that selects binary data from multiple input lines and directs them to a single output line. The selected input line is chosen by means of an address word. A representation of a 4-input multiplexer (MUX) is shown in Fig. 14.4.6 as well as a possible implementation. MOS technology lends itself to the implementation of multiplexers based on pass transistors. In the example illustrated by Fig. 14.4.7 only a single input is connected to the output through two conducting series transistors according to the $S_1 S_0$ code address.

Multiplexers may be used to implement canonical logic equations. For instance, the 4-input MUX considered above corresponds to the equation

$$y = x_0 \bar{S}_0 \bar{S}_1 + x_1 S_0 \bar{S}_1 + x_2 \bar{S}_0 S_1 + x_3 S_0 S_1 \tag{3}$$

FIGURE 14.4.6 A 4-input multiplexer (MUX) with a 2-bit ($S_1 S_0$) address.

FIGURE 14.4.7 (a) NMOS and (b) CMOS implementations of multiplexers.

Hence, logical functions of the variables S_0 and S_1 can be synthesized by means of multiplexers. For instance, an EXOR circuit corresponds to $x_0 = x_3 = 0$ and $x_1 = x_2 = 1$.

Demultiplexers (DEMUX) perform the inverse passage from a single input line to several output lines under the control of an address word. They implement logic functions that are less general than those performed by multiplexers because only minterms are involved. The symbolic representation of a 4-input DEMUX is shown in Fig. 14.4.8 with a possible implementation. The MUX represented in Fig. 14.4.7 may seem attractive for the purpose to achieve demultiplexation but one should not forget that when a given channel is disconnected, the data across the corresponding output remain unchanged. In a DEMUX, unselected channels should take a well-defined state, whether 0 or 1.

FIGURE 14.4.8 A 4-output demultiplexer (DEMUX).

A decoder is a DEMUX with a constant input. Decoders are currently used to select data stored in memories. Figure 14.4.9 shows a simple NMOS decoder. In this circuit, all unselected outputs are grounded while the selected row is at the logical 1. Any row may be viewed as a circuit implementing a minterm. For instance, the first row corresponds to

$$y_0 = \overline{S_1 + S_0} = \overline{S_1} \overline{S_0} \tag{4}$$

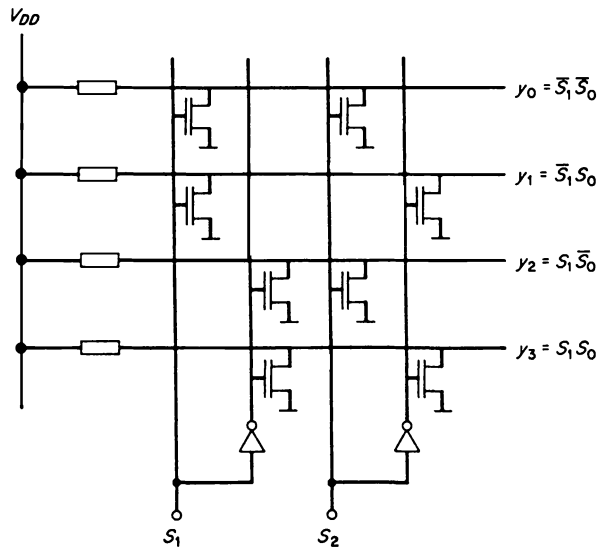

FIGURE 14.4.9 An NMOS decoder circuit.

FIGURE 14.4.10 A ROM memory.

When a decoder drives a NOR circuit, a canonical equation is obtained again. Figure 14.4.10 shows a decoder driving several NOR circuits which are implemented along vertical columns. This circuit is called a read-only memory (ROM). One can easily recognize an EXOR function (y_1) and its complement (y_0) in the example. The actual silicon implementation strictly follows the pattern illustrated by Fig. 14.4.10. Notice that the decoder block and ROM column block both have the same structure after turning them by 90° .

When a ROM is used to implement combinatorial logic, the number of outputs usually is restricted to only those minterms which are necessary to achieve the desired purpose. The ROM is then called a programmable logic array (PLA)

ROMs as well as PLAs are extensively used in integrated circuits because they provide the means to implement logic in a very regular manner. They contribute substantially to area minimization and lend themselves to automatic layout, reducing design time (silicon compilers).

A large number of functions can be implemented by means of the circuits described above: circuits converting the format of digital data, circuits coding pure binary into binary-coded decimal (BCD) or decimal data, and so forth. The conversion from a 4-bit binary-coded number into a 7-segment display by means of a PLA is illustrated by Fig. 14.4.11.

All the required OR functions are obtained by means of the right-plane decoder, while the left one determines the AND functions (they are called, respectively, OR-AND planes). In applications where multiple-digit displays are required, rather than repeating the circuit of Fig. 14.4.11 as many times as there are digits, a combination of MUX and DEMUX circuit and a single PLA can be used. An example is shown in Fig. 14.4.12.

The 4-input codes representing 4 digits are multiplexed in a quadruple MUX in order to drive a PLA 7-segment generator. Data appear sequentially on the seven common output lines connected to the four displays. Selection of a given display is achieved by a decoder driven by the same address as the MUX circuit. If the cyclic switching is done at a speed of 60 Hz or more, the human eye cannot detect the flicker.

MEMORIES³

Memories provide storage for large quantities of binary data. Individual bits are stored in minimum-size memory cells that can be accessed within two- or three-dimensional arrays. Read-only memories (ROMs) provide access only to permanently stored data. Programmable ROMs (PROMs) allow data modifications only during special write cycles, which occur much less frequently than readout cycles. Random access memories (RAMs) provide equal opportunities for read and write operations. RAMs store data in bistable circuits (flip-flops, SRAMs), or in the form of charge across a capacitor (DRAM).

Decimal display	Binary coded input				7 segment code						
	x_3	x_2	x_1	x_0	A	B	C	D	E	F	G

FIGURE 14.4.11 A 7-segment PLA driver.

Static Memories

Static memory cells are arrays of integrated flip-flops. The state of each flip-flop represents a stored bit. Read-out is achieved by selecting a row (word-line: WL) and a column (bit or bit-lines: BL) crossing each other over the chosen cell. Writing occurs in the same manner. A typical six-transistor MOS memory cell is shown in Fig. 14.4.13. The word-line controls the two transistors that connect the flip-flop to the read-write bus (BL and BLbar). In order to read out nondestructively the data stored in the cell, the read-write bus must be precharged. The inverter that is in the low-state discharges the corresponding bit-line. Writing data either confirms or changes the state of the flip-flop. When a change must happen, the high bit-line must overrule the corresponding low-state inverter, while the low bit-line simply discharges the output node of the high inverter. The second event takes less time than the first for the big differences between bus and inverter node capacitances. Bus capacitances are at least 10 times larger than cell node capacitances. The rapid discharge of the high inverter output node blocks the other half of the flip-flop before it has a chance to discharge the high bus. In order to prevent a read cycle from

FIGURE 14.4.12 A 4-digit, 7-segment multiplexed display.

becoming a write-cycle, it is important to equalize the voltages of the bit-lines prior to any attempt to read out. This is achieved by means of a single equalizing transistor on top of the read-write bus. This transistor shorts the two bit-lines for just long enough time to neutralize any bit-line voltage difference whatever the mean voltage may be. The pull-up circuitry precharging the read-write bus accommodates conflicting requirements. It must load the bit-lines as fast as possible but not counteract the discharge of the bit-line, which is tied to the low data during read out. Usually, the pull-up circuitry is clocked and driven by the same clock that controls the equalizing transistor.

Cell size and power consumption are the two key items that determine the performances and size of present memory chips which may count as much as several million transistors. Cell sizes have shrunk continuously until they are a few tens of microns square. Static power is minimized by using CMOS instead of resistively loaded inverters. Most of the power needed is to provide fast load and discharge cycles of the line capacitances. Therefore a distinction is generally made between standby and active conditions. The load-discharge processes imply short but very large currents. The design of memories (static as well as dynamic) has always been at the forefront of the most advanced technologies.

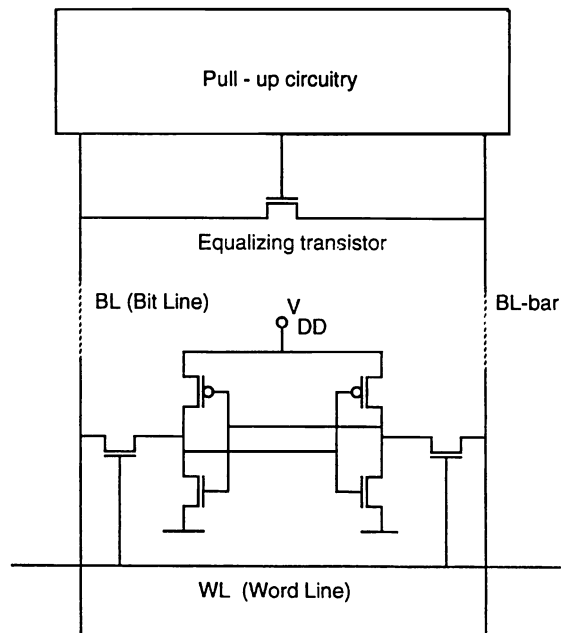

FIGURE 14.4.13 The basic six-transistor circuit of a static MOS memory cell.

FIGURE 14.4.14 The one-transistor MOS memory cell; (a) IC implementation; (b) equivalent circuit.

Dynamic Memories^{8,9}

The trend toward ever larger memory chips has led to the introduction of single transistor memory cells. Here the word-line controls the gate of the MOS switch that connects the single bit line to a storage capacitor (Fig. 14.1.14). Charge is pumped from (or fed back to) the bit-line by properly choosing the voltage of the bit-line. The actual data consist of charge (or absence of charge) stored in the capacitor in the inversion layer below a field plate. Typical storage capacitances are 100 to 50 fF. The useful charge is quite small, around 0.1 or 0.2 pC. In order to read data, this charge is transferred to the bit-line capacitance, which is usually one order of magnitude larger. The actual voltage change of the bit-line is thus very small, typically 100 to 200 mV. In order to restore the correct binary data, amplification is required. The amplifier must fulfill a series of requirements: It must fit in the small space between cells, be sensitive and respond very rapidly, but also distinguish data from inevitable switching noise injected by the overlap capacitance of the transistor in series with the storage capacitor. To solve this problem, dynamic memories generally use two bit-line output lines instead of a single one. Read-out of a cell always occurs in the same time as the selection of a single identical dummy cell. This compensates switching noises as far as tracking of parasitic capacitances of both switching transistors is achieved. The key idea behind the detection amplifier is the metastable state of a flip-flop. The circuit is illustrated in Fig. 14.4.15. Before read-out, the common source terminal is left open. Hence, assuming the bit-line voltages are the same, the flip-flop behaves like two cross-connected diode-connected transistors.

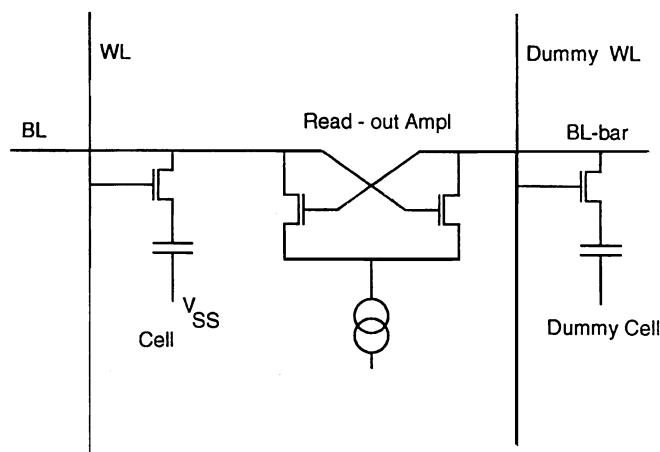

FIGURE 14.4.15 The readout amplifier of dynamic one-transistor-per-cell MOS memories consists of a flip-flop in the metastable state in order to enhance sensitivity and speed and to minimize silicon area.

The common source voltage adjusts itself to the pinch-off voltage of the transistors. After read-out has occurred, a small voltage imbalance is experienced between bit-lines. The sign of this imbalance is determined by the actual data previously stored in the cell. If then the common source node voltage is somewhat reduced, one of the two transistors becomes slightly conducting while the other remains blocked. The conducting transistor slightly discharges the bit-line with the lowest voltage, increasing the voltage imbalance. The larger this difference, the faster the common source node can be lowered without risk to switch-on of the second transistor. After a short time, the imbalance is large enough to connect the common source to ground. The final state of the flip-flop reproduces the content of the selected cell. Notice that data read during the read-out cycle are now available for rewriting in the cell. Permitting the transistor in series with the storage capacitor to conduct longer performs automatic rewriting. Because storage is likely to be corrupted by leakage current, this same procedure is repeated regularly, even when data are not demanded, in order to keep the memory active. Dynamic memories are the densest circuits designed. Memory sizes currently attain 16 Mbits, and 256 Mbits memories are being developed.

Commercially Available Memory Chips

Memory arrays usually consist of several square arrays packed on a single chip. In order to access data, the user provides an address. The larger the memory size, the longer the address. In order to reduce pin count, address words are divided in fields controlling less pins in a sequential manner. Many memories are accessed by a row address strobe (RAS) followed by a column address strobe (CAS), each one requiring only half of the total number of address bits. Memories represent a very substantial part of the semiconductor market. Besides RAMs (random access memories), a large share of nonvolatile memories is available comprising ROMs (read-only memories), programmable read-only memories (PROMs), and electrically alterable read-only memories (EAROMs), which are considered below.

RAM. Random access memories (RAMs) are either static or dynamic memory arrays like those described above. They are used to read and write binary data. Storage is warranted as long as the power supply remains on.

ROM. In read-only memories, the information is frozen. Information can only be read out. Access is the same as in RAMs. Memory elements are single transistors. Whether a cell is conducting or not has been determined during the fabrication process. Some MOS transistors have a thin gate oxide layer; others have a thick oxide layer, or some are connected to the access lines, while others are not.

PROM. The requirements for committing to a fixed particular memory content, inherent in the structure of ROMs, is a serious disadvantage in many applications. PROMs (programmable ROMs) allow the manufacturer or the user to program ROMs. Various principles exist:

- With mask programmable ROMs, a single mask is all the manufacturer needs to implement the client code.
- With fuse link programmable ROMs, the actual content is written in the memory by blowing a number of microfuses. This allows the customer to program the ROM, but the final stage is irreversible as in mask programmable ROMs.

EPROM. In electrically programmable ROMs the data are stored as shifts of the threshold voltages of the memory transistors. Floating-gate transistors are currently used for this purpose. Loading the gate occurs by hot electrons tunneling through the oxide from an avalanche junction toward the isolated gate. The charges trapped in the gate can only be removed by ultraviolet light, which provides the energy required to cross the oxide barrier.

EEPROM. Electrically erasable PROMs use metal-nitride-oxide-silicon transistors in which the charges are trapped at the nitride oxide interface. The memory principle is based on Fowler-Nordheim tunneling to move charges from the substrate in the oxide or vice versa. The electric field is produced by a control gate. EAROMs (electrically alterable ROMs) use the same principle to charge or discharge a floating gate with some additional features providing better yields.

DIGITAL-TO-ANALOG CONVERTERS (D/A OR DAC)¹⁰

Converting data from the digital to the analog domain may be achieved in a variety of ways. One of the most obvious is to add electrical quantities such as voltages, currents or charges following a binary weighted scale. Circuits illustrating this principle follow. They are of two kinds: first, converters aiming at integral linearity and, second, converters exchanging integral linearity for differential linearity.

FIGURE 14.4.16 Integral linearity converters. Switching is implemented by (a) MOS transistors and (b) bipolar circuits.

Integral Linearity Converters

A binary scale of voltages and currents is easily obtained by means of the well-known R - $2R$ network. In the circuit shown in Fig. 14.4.16a, binary weighted currents flowing in the vertical resistances are either dumped to ground or injected into the summing node of an operational amplifier. The positions of the switches reproduce the code of the digital word to be converted. Practical switches are implemented by means of MOS transistors. Their widths double going from left to right to keep the voltage drops constant between drains and sources. The resulting constant offset voltage can be compensated easily. Another approach, better suited for bipolar circuits, is illustrated in Fig. 14.4.16b. Here the currents are injected into the emitters of transistors whose outputs feed bipolar current switches performing the digital code conversion. To keep all emitters at the same potential, small resistors are placed between bases of the transistors. They introduce voltage drops of 18 mV ($UT \ln 2$) to compensate for the small base to emitter voltages changes resulting from the systematic halving of collector current going from left to right.

FIGURE 14.4.17 Capacitive D/A converter with charge integration op-amp.

The accuracy of R - $2R$ circuits is based on the matching of the resistances. It does not exceed 10 bits in practice, and may reach 12 bits when laser trimming is used.

Switched capacitors are used also to perform D/A conversion. Capacitors are easy to integrate and offer superior temperature characteristics compared to thin-film resistors. However, they suffer from several drawbacks and require special care in order to provide good matching. Integrated capacitors are sandwiches of metal-oxide-silicon layers (MOS technology) or polysilicon-oxide-polysilicon (double poly technology). The latter exhibit a highly linear behavior and extremely small temperature coefficient (typically 10 to 20 ppm/ $^{\circ}$ C). In order to improve geometrical tracking, any capacitor must be a combination of “unit” capacitors that represent the minimum-sized element available (typically 100 fF). MOS capacitors have relatively large stray capacitances to the substrate through their inversion layer, about 10 to 30 percent of their nominal value, depending on the oxide thickness. Doubly poly capacitors offer better figures, but their technology is more elaborate. Whatever choice is made, the circuits must be designed to be inherently insensitive to stray capacitance. This is the case for the circuit shown in Fig. 14.4.17.

In this circuit, a change of the position of a switch results in a charge redistribution among a weighted capacitor and the feedback capacitor C_0 . The transferred charge is stored on the feedback capacitor so that the output voltage stays constant, provided leakage currents are small (typically 10^{-15} A). The stray capacitors are illustrated in Fig. 14.4.17. They have no influence on the converter accuracy. Indeed, C_a and C_c are loaded and discharged according to position changes of switch S_3 , but the currents through those capacitors do not flow through the summing junction. On the other hand, C_b as well as C_d is always discharged and therefore do not influence the accuracy.

Another version of a capacitive D/A converter is shown in Fig. 14.4.18. In this network, changing the position of switches S_3 and S' produces a charge redistribution between the capacitor at the extreme left and the parallel combination of all other capacitors that represent a total of $8C$. Hence the upper node undergoes a voltage swing equal to $V_{ref}/2$. A binary scale of voltages consequently may be produced according to the various switches. Switch S' fixes the initial potential of the upper node and allows the discharge of all capacitors prior to conversion. There is no specific requirement that the upper node be connected to ground or to any fixed potential V_0 , provided V_{out} is evaluated against V_0 .

FIGURE 14.4.18 Capacitive D/A converter with unity-gain buffer.

FIGURE 14.4.19 Dynamic element matching converter principle.

Notice that the stray capacitance C_b degrades the converter accuracy, while C_a has no effect at all. Careful layout therefore is required to minimize C_b , unless this stray capacitance is included in the evaluation of the capacitor C at the extreme right. For this reason, only small numbers of bits should be considered. The unavoidable exponential growth of capacitances with the number of bits is relieved to some extent because the capacitance area increases as the square of dimensions.

Another widely used technique to perform D/A conversion is paralleling of many identical transistors controlled by a single base-to-emitter or gate-to-source voltage source. The output terminals are tied together in order to implement banks of binary weighted current sources. This requires $2^{(N+1)}$ transistors to make an N -bit converter, which is very efficient for transistors are the smallest on-chip devices available. Usually all the transistors are placed in an array and controlled by a row and column decoder, as in memories. One of the interesting features of this type of converter is its inherent monotonicity. Furthermore, if access to the individual transistors follows a pseudorandom pattern, many imperfections resulting from processing, such as an oxide gradient in the MOS process, have counterbalancing effects. Hence, an accuracy of 10 bits may be achieved with transistors whose standard deviation is much worse.

A converter¹¹ with excellent absolute accuracy is illustrated in Fig. 14.4.19. It is based on high-accuracy divide-by-2 blocks like those shown in the right part of the illustration. Each block consists of a Widlar circuit with equal resistances in the emitters of transistors T_1 and T_2 in order to split the current I approximately into two equal currents: I_1 and I_2 (1 percent tolerance). A double-throw switch is placed in series with the Widlar circuit in order to alternate I_1 and I_2 at the rate of the clock f . Provided the half clock periods t_1 and t_2 can be made equal within 0.1 percent, a condition that can easily be met, one obtains two currents whose averages I_3 and I_4 represent $I/2$ with an accuracy approaching 10^{-5} . This technique, known as the dynamic element matching method, has been successfully integrated in bipolar technology offering an accuracy of 14 bits without expensive element trimming. A band-gap current generator provides the reference current I_{ref} , which is compared to the right-side output current of the first divide-by-2 block. A high current-gain amplifier closes the feedback loop controlling the base terminals of T_1 and T_2 of the first block.

Segment Converters

In some applications, accuracy does not imply absolute linearity but rather differential linearity, which is very critical because errors between two successive steps larger than a half LSB cannot be tolerated. The difficulty occurs when changes of MSBs occur. To overcome the problem, segment converters were designed. The idea is to divide the full conversion scale into segments. A D/A converter with a maximum of 10 bits is used within segments. Passing from one segment to another is achieved in a smooth manner as in the circuit illustrated by Fig. 14.4.20.¹² In this circuit, the 10-bit segment converter is powered by one of the four bottom current sources. A 2-bit decoder,

FIGURE 14.4.20 Segment D/A converter.

which is controlled by the two MSBs, makes the appropriate connections. When the two MSBs are 00, current source I_1 is chosen and the three others are short-circuited to ground. When the MSB pattern changes to 01, the switches take the positions illustrated in the figure. Then I_2 supplies the 10-bit converter while I_1 is injected directly into the summing node of the op amp. Hence, no change occurs in the main current component. The differential linearity is entirely determined by the 10-bit converter. The price paid for this improvement is a degradation of absolute linearity. Small discrepancies among the four current sources introduce slope or gain changes between segments. The absolute linearity specifications thus do not reach the differential linearity specs of the converter.

Voltage segment converters can also be integrated. Instead of parallel current sources, series voltage sources are required. This is achieved by means of a chain of equal resistors dividing the reference voltage into segments. The D/A converter is connected along the chain by means of two unity-gain buffers in order not to affect input voltages. Passing from one segment to the next implies that the buffers are interchanged in order to avoid the degradation of the differential linearity, which could result from different offsets in the buffers. An integrated 16-bit D/A converter has been built along these lines.¹³

When a switched-capacitor D/A converter is embedded in a voltage segment converter, no buffer amplifiers are needed because no dc current drain is required. This property simplifies greatly the design of moderate accuracy converters and has been extensively used in the design of integrated codecs.

Codecs. Codecs are nonlinear converters used in telephony. To cover the wide dynamic range of speech satisfactorily with only 8 bits, steps of variable size must be considered: small steps for weak signals, and large steps when the upper limit of the dynamic range is approached. The four LSBs of a codec-coded word define a step size within a segment whose number is given by the three following bits. The polarity of the sample is given by the MSB. Going from one segment to the next implies doubling the step size in order to generate the nonlinear conversion law (μ law). In the codec circuit of Fig. 14.4.21,¹⁴ bottom plates are connected either in the middle of the resistive divider considered as an ac ground (position 1), or to V_{low} or V_{high} (position 2 plus switch S_1 or S_2) representing, respectively, the negative and positive reference voltage sources, or to a third position (position 3) connecting a single capacitor to an appropriate node of the resistive voltage divider. Hence, the resistive divider determines the step size (four LSBs), the capacitive divider defines the segment (three following bits), and switches S_1 or S_2 control the sign (MSB).

ANALOG-TO-DIGITAL (A/D) CONVERTERS (ADC)¹⁰

Some analog-to-digital converters are in fact D/A converters embedded in a negative feedback loop with appropriate logic (see Fig. 14.4.22). The analog voltage to be converted is sensed against the analog output of a D/A converter, which in turn is controlled by a logic block so as to minimize the difference sensed by the

FIGURE 14.4.21 Segment type codec.

comparator. Various strategies have been proposed for the logic block, depending on the type of D/A converter used. Most of the converters described previously have been implemented as ADCs in this manner. In particular, ladder and capacitive D/A converters are used in the so-called successive approximation D/A converter. In those devices, the logic block first sets the MSB; then the comparator determines whether the analog input voltage is larger or smaller than the half-reference voltage. Depending on the result, the next bit is introduced, leaving the MSB unchanged if the analog signal is larger and resetting the MSB in the opposite state. The algorithm is repeated until the LSB is reached.

Successive approximation ADCs are moderately fast, for conversion time is strictly proportional to the number of bits and is determined by the settling time of the op-amp. The algorithm implies that the analog input voltage remains unaltered during the conversion time; otherwise it may fail. To avoid this, a sample-and-hold (SH) circuit must be placed in front of the converter.

A capacitive A/D converter is shown in Fig. 14.4.23.¹⁵ The conversion is accomplished by a sequence of three operations. During the first, the unknown analog input voltage is sampled. The corresponding positions of the switches are as illustrated in Fig. 14.4.23a. The total stored charge is proportional to the input voltage V_{in} . In the second step, switch S_A is opened and the positions of all S_i switches are changed (Fig. 14.4.23b). The bottom plates of all capacitors are grounded, and consequently the voltage at the input node of the comparator

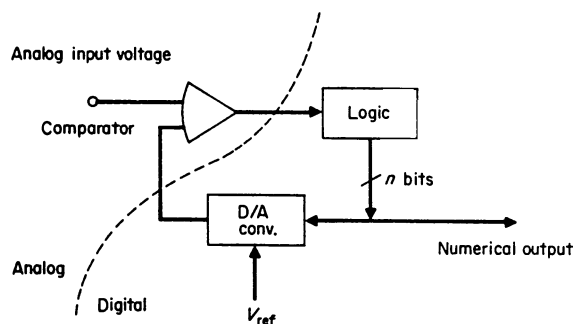

FIGURE 14.4.22 A D/A converter within a feedback loop forms an A/D converter.

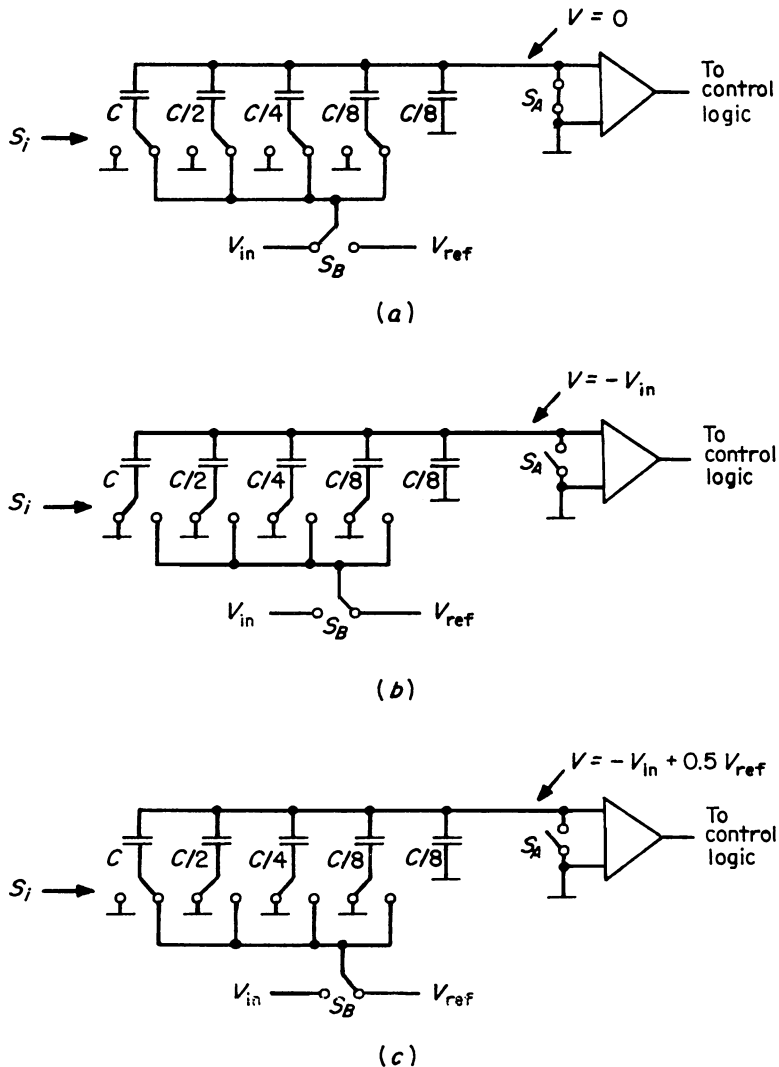

FIGURE 14.4.23 An integrated switched-capacitor A/D converter: (a) sample mode; (b) hold mode; and (c) redistribution mode.

equals $-V_{in}$. The third step is initiated when raising the bottom plate of the MSB capacitor from ground to the reference voltage V_{ref} (Fig. 14.4.23c). This is done by changing again the position of the MSB switch and connecting S_b to V_{ref} instead of V_{in} . The voltage at the input node of the comparator is thus increased by $V_{ref}/2$, so that the comparator's output is a logic 1 or 0, according to the sign of $(V_{ref}/2 - V_{in})$.

The circuit operates similarly to any successive approximations converter. That is, V is compared to $(V_{ref}/2 + V_{ref}/4)$ when the result of the previous operation is negative, or the MSB switch returns to its initial position and only the comparison with $V_{ref}/4$ is considered. After having carried out the same test until the LSB is reached, the conversion is achieved and the digital output may be determined from the position of the switches. The voltage of the common capacitive node is approximately equal to, or smaller than, the smallest incremental step.

FIGURE 14.4.24 A typical MOS comparator for an A/D converter.

Since this is almost negligible, the stray capacitance of the upper common node is practically discharged. It thus has no effect on the overall accuracy of the converter. Hence the problem in the circuit of Fig. 14.4.18 does not occur. The name “charge redistribution A/D converter” was given to this circuit because the charge stored during the first sequence is redistributed among only those capacitors whose bottom plates are connected to V_{ref} after the conversion algorithm is completed.

The design of comparators able to discriminate steps well below the offset voltage of MOS amplifiers is a problem deserving careful attention. An illustration of an MOS comparator is shown in Fig. 14.4.24.¹⁵ The amplifier comprises three parts: a double inverter, a differential amplifier, and a latch. The input-output nodes of the first inverter may be short-circuited by means of transistor T_0 to bias the gates and drains of the identical two first inverters at approximately half the supply voltage. This procedure occurs during the “sampling” phase of the converter and corresponds to the grounding of switch S_A in Fig. 14.4.23. As stated above in the comments concerning the circuit of Fig. 14.4.17, there is no necessity to impose zero voltage on this node during sampling; any voltage is suitable as long as the impedance of the voltage source is kept small. This is what occurs when T_0 is on, since the input impedance of the converter is then minimum because of the negative-feedback loop across the first stage. Once the double inverter is preset, T_0 opens and the output voltage of the second inverter is stored across the capacitor C_1 , momentarily closing switch S_1 . Then the floating input node of the comparator senses the voltage change resulting from charge redistribution during a test cycle and reflects the amplified signal at the output of the second inverter. Switch S_2 in turn samples the new output so that the differential amplifier sees only the difference between the two events. Any feed through noise from T_0 is ignored since it only affects the common mode of the voltages sampled on C_1 and C_2 . Hence, the overall offset voltage of this comparator is equal to the offset voltage of the differential amplifier divided by the gain of the double inverter input stage. Signals in the millivolt range can be sensed correctly regardless of the poor behavior of MOS transistors’ offset voltages.

FIGURE 14.4.25 The dual-slope A/D converter principle.

Since the polarities of both signals are opposite, the integrator provides an output ramp with opposite slope. It takes a time t_2 for the integrator output voltage to return from V_0 to zero. Hence

$$V_0 = -\frac{1}{RC} \int_0^{t_1} V_x dt \tag{5}$$

and

$$V_0 = (V_{ref}/RC)t_2 \tag{6}$$

Consequently, if V_x is a constant

$$V_x = -V_{\text{ref}} t_2 / t_1 \quad (7)$$

the time t_1 is determined by a counter. At the moment the counter overflows, switching of the input signal from V_x to V_{ref} occurs. The counter is automatically reset, and a new counting sequence initiated. When the integrator output voltage has returned to zero, the comparator stops the counting sequence. Thus the actual count is a direct measure of t_2 .

The dual-ramp converter has a number of interesting features. Its accuracy is not influenced by the value of the integration time constant RC ; neither is it sensitive to the long-term stability of the clock-frequency generator. The comparator offset can easily be compensated by autozeroing techniques. The only signal that actually controls the accuracy of the A/D converter is the reference voltage V_{ref} . Excellent thermal stability of V_{ref} can be achieved by means of band-gap reference sources.

Another interesting feature of the dual-ramp A/D converter is the fact that since V_x is integrated during a constant time t_1 , any spurious periodic signal with zero mean whose period is a submultiple of t_1 is automatically canceled. Hence, by making t_1 equal to an entire number of periods of the power supply one obtains excellent hum rejection.

DELTA-SIGMA CONVERTERS^{10,20}

Because the development of integrated systems is driven mainly by digital applications, mixed analog-digital circuits, especially converters, should be implementable equally well without loss of accuracy in digital technologies, even the most advanced ones. Short channels, however, do not just improve bandwidth, they also negatively affect other features, such as dynamic range and $1/f$ noise, because both supply voltage and gate area of the MOS transistors get even smaller. Therefore, a trade-off of speed and digital complexity for resolution in signal amplitude is needed.

Delta-Sigma converters illustrate this trend. Their object is to abate the quantization noise to enhance the signal-to-noise ratio (SNR) of the output data (quantization noise is the difference between the continuous analog data and their discrete digital counterpart). When the number of steps of a converter increases the quantization noise decreases. Similarly, if we enhance the SNR the resolution increases. Delta-Sigma converters take advantage of *oversampling* and *noise shaping* techniques to improve the SNR.

Oversampling refers to the Nyquist criterion, which requires a sampling frequency twice the baseband to keep the integrity of sampled signals. Oversampling does not improve the signal. Neither does it increase the quantization noise power, nor is it a way to spread the quantization noise power density over a large spectrum, thereby lessening its magnitude to keep the noise power unchanged. If we restrict the bandwidth of the over-sampled signal to the signal baseband in compliance with the Nyquist criterion, the amount of noise power left in the baseband is divided automatically by the ratio of the actual sampling frequency over the Nyquist frequency. We improve thus the SNR and consequently increase the resolution.

Noise shaping is the other essential feature of Delta-Sigma converters. It refers to the filtering step over-sampled data must undergo. The purpose is to further decrease the amount of noise left in the baseband by shifting a large part of the remaining quantization noise outside the baseband. During the step, the SNR is substantially improved.

Both A/D and D/A converters lend themselves to Delta-Sigma architectures. The same principles prevail, but their implementation differs. We consider both separately.

A/D Delta-Sigma Converters^{16,26}

In A/D converters, oversampling is done simply by increasing the sampling frequency of the analog input signal. Noise shaping is achieved by means of a nonlinear filter like the one illustrated in the upper part of Fig. 14.4.26. As stated already above, the goal is to shift most quantization noise out of the baseband. The noise shaper consists of a feedback loop similar to the linear circuit shown in the lower part. In the upper figure, the quantization noise is produced by the A/D converter. This converter is followed by a D/A converter, which is required because the difference between the continuous analog input signal and the discrete digital output signal delivered by the

FIGURE 14.4.26 Principle of sigma-delta converters.

A/D converter must be sensed in the analog domain. This difference is amplified and low-passed by means of the analog loop filter H . The idea is truly to minimize the signal fed to the amplifier as in the continuous circuit shown below. Consequently, the output signal becomes a replica of the input. This requires some caution, however, because matching continuous input data and discrete output data is not feasible. The situation is very different from the one illustrated in the lower part of Fig. 14.4.26 where the quantization noise is simulated by means of an independent analog continuous noise source. Clearly, if the loop gain is high, the signal outputted by the amplifier should be the sum of the input signal minus the noise in order to make u_a look like x_a . In the upper circuit, however, the amplifier senses steps whose magnitude is determined by the A/D and D/A quantizer. The signal delivered by the amplifier is an averaged image over time of the difference between the input and the discrete signal fed back. The latter tracks the input the best it can—thanks to the feedback loop. A look at the signals displayed in Fig. 14.4.27 confirms this statement. The figure represents output data of a third-order noise shaper with a 3-bit quantizer. The loop filter consists of three integrators in cascade. Their outputs are respectively illustrated in the three upper plots. The signal delivered by the third integrator is applied to the quantizer whose output is shown below. It is obvious that notwithstanding the poor resolution of the A/D converter, the noise shaper tracks the input sine wave pretty well by correcting its output data continuously.

Once the bandwidth of the signal outputted by the noise shaper has been restricted to the baseband, we get a signal whose SNR may be very high. To illustrate this, consider Fig. 14.4.28, which shows a plot of the signal-to-noise improvement that can be obtained with the linear circuit shown in Fig. 14.4.26. Although the actual noise shaper differs from its analog counterpart because the quantization noise is correlated with the input and the quantizer is a nonlinear device, results are comparable. Large SNR figures, 60 or 80 dB and even better, are readily achievable. It is obvious that large OSRs are not the only way to get high SNRs; these can also be obtained by increasing the order of the loop filters (assuming of course stability is achieved, which is not always easy in a nonlinear system). Another interesting feature that stems from the above figure is that A/D and D/A converters with few bits resolution only do not impair the resolution of the Delta-Sigma converter given the large SNRs noise shapers can achieve. Even a single-bit quantizer, notwithstanding its large amount of quantization noise, suffices.

In practice the above converters are parallel devices in order not to slow down needlessly the conversion rate. The A/D converter is a flash converter and the D/A converter a unit-elements converter. The accuracy of the A/D converter is not critical as it is a part of the forward branch and it does not control the overall accuracy like

FIGURE 14.4.27 Waveforms observed in a third-order noise shaper making use of a 3-bit quantizer.

FIGURE 14.4.28 Plot of the quantization noise attenuation vs. the oversampling rate (OSR) and the loop filter order. The case $n = 0$ corresponds to oversampling without noise shaping.

FIGURE 14.4.29 The generic Delta-Sigma A/D converter.

in any feedback loops. The D/A accuracy is more critical because it is located in the feedback branch and impairs the overall accuracy since the feedback loop minimizes only the difference between the oversampled input signal and the signal delivered by the D/A converter. This puts, of course, a heavy toll on the D/A converter unless we use a single-bit architecture. In single-bit quantizers, the A/D converter resumes to a comparator and the D/A converter to a device whose output can take only two states. No possibility exists that steps of unequal heights are found as in multi-bit D/As. This explains why single-bit quantizers are preferred generally to multi-bit. Multi-bit quantizers, however, are not evaded; they offer better alternatives for large bandwidth converters where the sampling frequency can be bound by the technology and the OSRs may take large values. To improve the performances of the D/A converter, randomization of their unit elements is generally recommended. This spreads the impairments of the unit elements mismatch over a large bandwidth. Without randomization, the same impairments produce harmonic distortion, which is a lot more annoying than white noise in terms of SNRs.

A generic A/D Delta-Sigma converter is shown in Fig. 14.4.29. Besides the noise shaper, two additional items are visible—an anti-alias filter at the input and a decimator at the output. The anti-alias filter is not specific to Delta-Sigma converters, but its implementation is much less demanding than in Nyquist converters. The reason therefore stems from the fact that the sampling frequency is much larger than the signal baseband so that a third- or second-order analog filter already is enough. At the output of the noise shaper, the decimator restricts the bandwidth to the baseband and lowers the sampling rate from oversampled to the Nyquist frequency. Since the signal inputted in the decimator is taken after the A/D converter, the decimator is in fact a digital filter. This is important for decimation is a demanding operation that cannot be done easily in the analog domain. The decimator is indeed supposed not only to restrict the bandwidth of the converted data but also to get rid of the large amounts of high-frequency noise lying outside the baseband. Therefore the decimator consists of two or three cascaded stages, an finite impulse response (FIR) filter and one or two accumulate-and-dump filters. The FIR filter takes care of the steep low-pass frequency characteristic that fixes the baseband, while the accumulate-and-dump filters attenuate the high-frequency noise. An illustration of the input-output signals of a fourth-order decimator fed by the third-order noise shaper considered in Fig. 14.4.27 is shown in Fig. 14.4.30. The signal from the noise shaper is shown in Fig. 14.4.27. The output of the decimator is illustrated below together with continuous analog input sine wave. The down-sampling rate in the example is equal to 8 and the effective number of bits (ENOB) of the decimated signal reaches 9.6 bits. In practice, resolutions of 16, even 24 bits, are obtained.

The resolution of Delta-Sigma converters is determined by the ENOB, which is derived from the relation linking quantization noise to number of bits:

$$\text{ENOB} = \frac{\text{SNR}_{\text{dB}} - 1.8}{6} \quad (8)$$

The SNR is measured by comparing the power of a full-scale pure sine wave to the quantization noise power taking advantage of the fast Fourier transform (FFT) algorithm. The measured noise consists of two

FIGURE 14.4.30 (Above) The quantizer output signal of Fig. 14.4.28. (Below) The same after decimation (order 4) compared to the input signal.

components—the actual quantization noise, which is a measure of the resolution, and the noise caused by the converter impairments. The first does not represent a defect; the second is unwanted and inevitable. The magnitude of this extra noise generally increases very rapidly when the input signal gets large because more and more nonlinear distortion tends to enter the picture. In order to avoid the impact of distortion on the ENOB evaluation, the SNR is evaluated generally as follows. The magnitude of the input signal is varied from a very low level, for instance, 60 dB below full scale, until full scale and the measured SNRs are plotted versus the magnitude of the input signal. As long as distortion does not prevail, the SNR varies like the power of the input signal, but beyond this it departs from ideal. The figure that must be considered in the above equation is the SNR obtained after extrapolating the linear portion of the SNR plot until full scale.

D/A Delta-Sigma Converters^{10,20}

The principles underlying A/D converters can be transposed in D/A Delta-Sigma converters (Fig. 14.4.31). Oversampling and noise shaping are applied concurrently but in a different way since the input data are digital words and the output is an analog signal. An interpolation step is needed first in order to generate additional samples interleaved with the input data. The output of the interpolator is then noise shaped before being applied to a low-resolution D/A converter whose analog output is filtered by means of a low-order analog low-pass filter. The quantization noise is evaluated and fed back to the loop filter before closing the feedback loop of the noise shaper. One of the differences with respect to A/D Delta-Sigma converters is the manner quantization noise is measured. All that is needed is to split the words delivered by the noise shaper in two fields—an MSB field and an LSB field. The MSB field, which consists of a few bits, or even a single-bit, controls the D/A converter, while the LSB field closes the feedback loop after the digital loop filter.

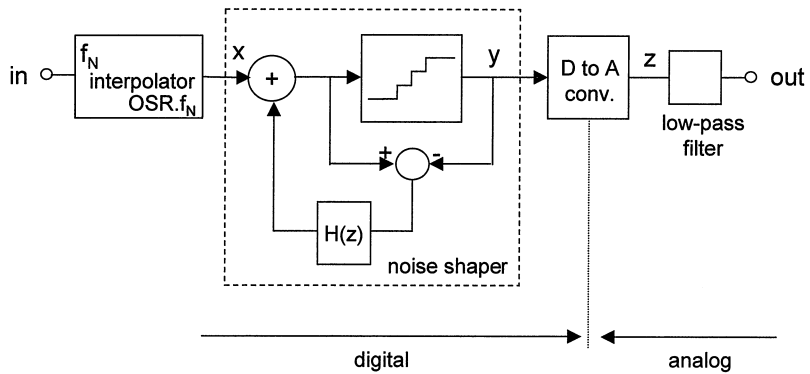

FIGURE 14.4.31 Block diagram of a Delta-Sigma D/A converter.

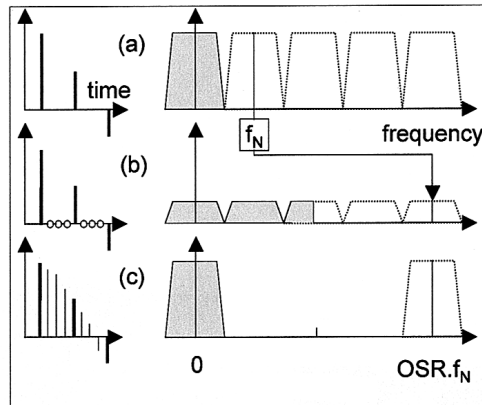

FIGURE 14.4.32 Interpolation (above) the principle (below) spectrum of a fourfold interpolated sine wave.

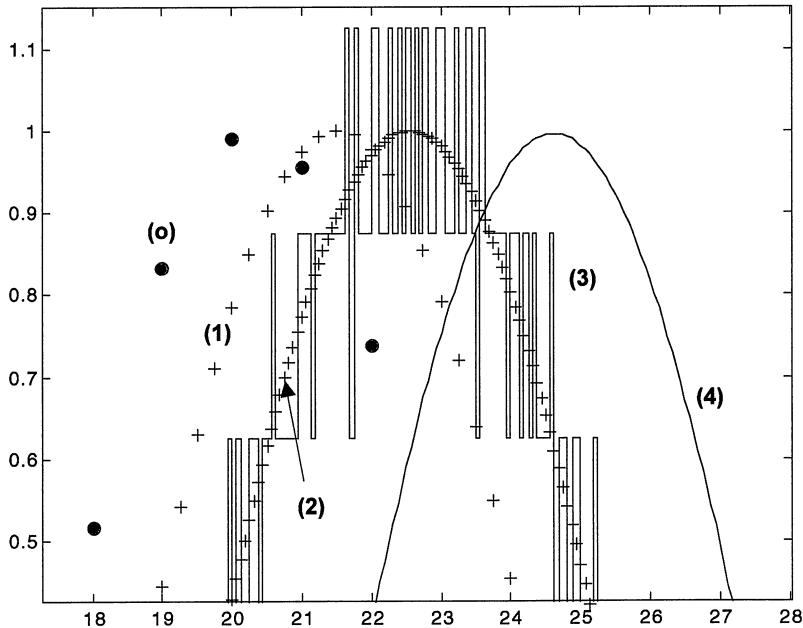

FIGURE 14.4.33 Timing of signals in a D/A Delta-Sigma converter: (0) the 13-bit digital input sine wave, (1) after a first fourfold interpolation, (2) after the second interpolation, (3) the noise shaped 3-bit signal, and (4) the analog output signal.

Interpolators are the counterpart of decimators. Instead of down-sampling they add data between samples as shown in the upper part of Fig. 14.4.32. In the figure, three zeros are placed between every sample. This multiplies already the sampling frequency by 4 but does not suffice because the spectrum of the resulting over-sampled signal is like the one shown in Fig. 14.4.32*b*. One must erase part of the spectrum and multiply the signal by 4 in order to get the correct spectrum shown under Fig. 14.4.32*c*. This is done by means of a digital filter with a sharp cutoff frequency at the edge of the baseband. In practice this filter consists of several cascaded filters like in the decimator. An FIR filter takes care of the sharp cutoff frequency, whereas one or two low-pass filters perform the rest. The FFT of a sine wave after a fourfold interpolator with a single FIR filter is shown in the lower part of Fig. 14.4.32. The fundamental ray that is reproduced three times lies approximately 80 dB below the quantization noise floor and does no harm.

A second more elaborate example is shown in Fig. 14.4.33. It illustrates the changes signals undergo versus time. The input is a 13-bit sine wave represented by large black dots. After a first interpolation, which multiplies the sampling frequency by 4, we get the data marked (1). A second interpolation by 4 yields data (2). The signal is then noise shaped. The three MSBs control the D/A converter whose analog output (3) consists of large steps that approximate the signal from the second interpolator. When the signal outputted by the D/A converter is filtered by means of a third-order low-pass, the continuous sine wave (4) is obtained, which is the actual output signal of the converter. With an SNR of nearly 80 dB, the 13-bit accuracy of the digital input signal is still met.

VIDEO A/D CONVERTERS¹⁰

Video applications require extremely short conversion times. Few of the previous converters meet the required speed. An obvious solution is full parallel conversion with as many comparators and reference levels as there are quantization steps. Fortunately, most video applications do not require accuracies higher than 8 bits, so 256 identical channels are sufficient. Only integrated circuits offer an economical solution in this respect.

FIGURE 14.4.34 A flash converter.

A typical parallel video converter, called a flash converter, is shown in Fig. 14.4.34.¹⁷ The architecture of the converter is simple. A string of 255 identical thin-film aluminum or polysilicon resistors is used in order to produce 2^8 reference levels. The input voltage V produces at the outputs of the comparators a vector which may be divided into two fields of 1s and 0s. An additional layer of logic transforms this vector into a new vector with 0s everywhere except at the boundary between the two fields. The new vector is further decoded to produce an 8-bit coded output. No sample-and-hold (SH) circuit is required since all comparators are synchronously driven by the same clock, but extremely fast comparators are required. An 8-bit resolution and a 5-MHz bandwidth imply binary decisions in a time as short as 250 ps. This is achieved by means of ECL logic drivers and storage flip-flops. Signal propagation across the chip also requires careful layout. The resistive divider impedance may not exceed 50 to 100 Ω . Another particular feature is the inevitable high-input capacitance, which results from the paralleling of many comparators.

The huge area and power consumption inherent to flash devices has stimulated the design of less greedy converters. Although these cannot compete with flash converters as far as speed is concerned, they offer conversion times short enough to comply with the requirements of a number of “fast” applications. Their principle comes to fragment the conversion process into several cycles, eventually two, during which strings of bits are evaluated by means of a subconverter. The process starts with the bits representing the MSB field. The other sets are evaluated one after another until the correct output word can be reconfigured by concatenating the individual segment codes. Each conversion step requires a single clock. This means, of course, that all subconverters must be fast devices, like flash converters. A 9-bit converter, for instance, operating by means of 3-bit segments requires three cycles for full conversion. Although only three clock cycles are required, the real conversion time is always much longer than three times what is needed for the 9-bit flash converter. Segmentation supposes indeed that some kind of analog memory be used in order to store intermediate results. Op-amps are thus required, which is a drawback with respect to flash converters, for the latter don’t need op-amps, and consequently ignore dominant poles.

The most stringent difference between flash converters and segmented A/D converters is the number of comparators. In a flash converter, the number of comparators increases exponentially with the number of bits.

FIGURE 14.4.35 A subranging converter.

In a segmented converter, less comparators are required. Not only is the area much smaller, but the power consumption is drastically reduced.

Figure 14.4.35 shows the implementation of a two-cycle segmented A/D converter called a *subranging converter*. The coarse A/D converter evaluates first the M_1 MSBs. For the remaining M_2 LSBs, an analog replica of the MSBs is subtracted from the analog input signal. This is done by means of the M_1 -bit wide D/A converter whose output is subtracted from the input signal. The difference, which is nothing but coarse conversion quantization noise, is fed to the fine A/D flash converter, which evaluates the LSBs. The output code word is obtained by concatenation of the M_1 and M_2 segment codes. The total number of comparators in this type of converter is drastically reduced. For instance, in a 10-bit converter taking advantage of two 5-bit segments, each flash converter requires 31 comparators, that is, a total of 62 comparators, which is very little compared to the 1023 comparators required by a true 10-bit flash converter. Naturally the coarse D/A converter, which is a unit-elements parallel device, and the sample-and-hold, which holds the input while A/D and D/A conversions take place, must be brought into the picture also. In any case, segmented converters save a lot of area and power.

The number of comparators can be decreased further if we consider the *recycling converter*²⁴ shown in Fig. 14.4.36. In this circuit the difference between the input and its coarse quantized approximation is fed back to the input, stored in the sample-and-hold device, and recycled through the A/D converter. Eventually a second cycle may be envisaged. Each cycle, a new set of lower rank bits is generated. The fine flash converter is not needed, but an interstage amplifier is required. Its purpose is to amplify the quantization noise so that it spans exactly over the full dynamic range of the A/D and D/A converters. If this were not the case, we would be forced to adapt continuously the resolution of the converters to cope with the decreasing magnitude of the difference signal.

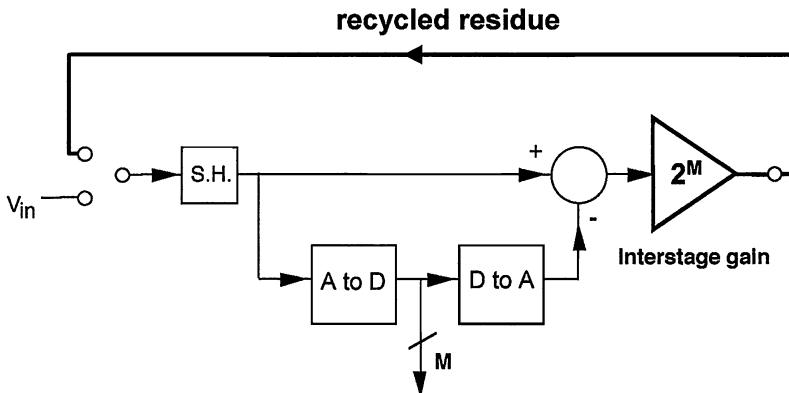

FIGURE 14.4.36 A recycling converter.

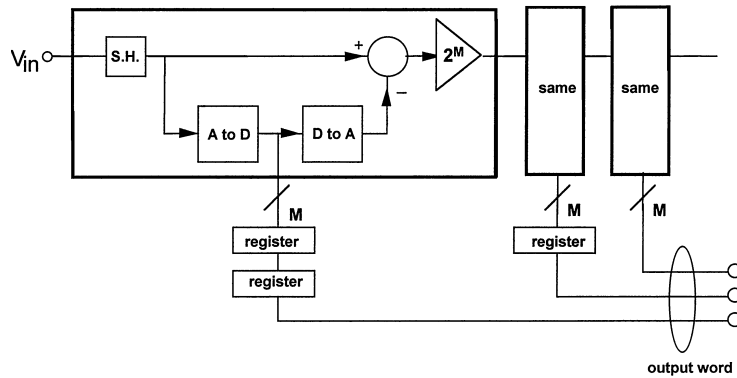

FIGURE 14.4.37 A pipelined converter.

Of course, it is useless to try to repeat this procedure over and over again because the errors generated in every new cycle pile up and corrupt the difference signal. It is very important to determine which sources of errors are important. The main ones are the interstage gain error, the D/A and the A/D nonlinearities. The A/D errors can easily be corrected by extending the dynamic range of both converters. Errors from the flash converter are corrected automatically during recycling. The other errors are more difficult to correct but one should not overlook the fact that they affect only bits generated after the first cycle.

The conversion time of recycling converters varies, of course, like the number of cycles. Pipelined converters offer a good means to keep the conversion time equal to a single cycle time, however, at the expense of area. Such a converter is shown in Fig. 14.4.37. The idea is simply to exchange time for space. In other words, we cascade blocks identical to the circuit of Fig. 14.4.36, but each circuit feeds its neighbor instead of recycling its own data. Every bloc thus deals with data that belong to different time samples. In order to reconfigure the correct output words, one must reshuffle the code segments in order to recover time consistency. This is done by means of registers.

Recycling and pipelined converters that operate with segments only 1-bit wide are currently designated *algorithmic converters*. They are not fast devices since they require as many cycles as number of bits to

FIGURE 14.4.38 A typical integrated wave generator that can deliver a square wave, a triangular wave, and a sine wave.

output code words. Algorithmic converters are similar to successive approximation converters although they operate differently.

FUNCTION GENERATORS

Integrated function generators consist generally of a free-running relaxation oscillator controlling a nonlinear shaping circuit. A typical block diagram of a function generator is shown in Fig. 14.4.38. The relaxation oscillator is a combination of a time-base generator and a Schmitt trigger. The time base in the present case is obtained by successive loading and discharging of a capacitor using two current sources. One is a constant current source I_1 and the other a controlled current source delivering a current step equal to $-2I_1$ or zero. Hence, the voltage across the capacitor C is a sawtooth.

The switching of the controlled current source is monitored by the logical output signal of the Schmitt trigger. This last circuit is in fact a precision Schmitt trigger. The oscillating voltage across C is obtained in the same manner. The output sawtooth signal is buffered and drives a network consisting of resistors and diodes which changes the sawtooth into a more or less sinusoidal voltage.

The advantage of function generators over RC or op-amp oscillators is their excellent amplitude stability versus frequency. Also frequency modulation can easily be achieved by changing the current delivered by the two current sources. This type of function generator can be frequency-swept over a wide dynamic range without spurious amplitude transients since no selective network is involved.

SECTION 15

MEASUREMENT SYSTEMS

Measurement circuits are critical in the analysis, design, and maintenance of electronic systems. For those who work in electronics, these circuits and systems become the eyes into the world of the electron that cannot be directly seen. The main objective of such systems is to not influence what is being measured or observed. This is accomplished by a range of types of measurement circuits. All of these are considered in this section.

A key element of systems that measure is how the measurement is actually made. Without an understanding of how the measurement is made, one cannot understand the limitations. It is possible to make a measurement and be off by several orders of magnitude. We look at the process of making measurements and what to look for so that one can have a level of confidence in the measurement.

Substitution and analog measurements have been an important mainstay of this field. Unlike measurements that involve some digital systems, the accuracy and precision of the measurements depend totally on the precision of elements used in the measurement systems. We look at a variety of measurement techniques using substitution and look at analog devices like ohmmeters. Digital instruments have many advantages especially when used in data acquisition systems.

An important component of measurement systems is the transducer. The transducer converts a physical quantity into an electrical signal that can be measured by a measurement system. Knowing the characteristics, especially its limitations, helps in understanding the precision with which measurements can be made. It is in the area of transducers and sensors that we have seen some of the most dramatic advances.

Bridge circuits gave us the first opportunity to actually make measurements without “loading” the circuit being measured. The accuracy of the measurements merely depended on the precision of the elements used in the bridge.

We need AC impedance measurements to develop the small signal characteristics of a circuit or system and to evaluate the stability of the circuit or system. These kinds of measurements are important in a variety of applications from the space station to how well your television works. C.A.

CHAPTER 15.1

PRINCIPLES OF MEASUREMENT CIRCUITS

Francis T. Thompson*

DEFINITIONS AND PRINCIPLES OF MEASUREMENT

Precision is a measure of the spread of repeated determinations of a particular quantity. Precision depends on the resolution of the measurement means and variations in the measured value caused by instabilities in the measurement system. A measurement system may provide precise readings, all of which are inaccurate because of an error in calibration or a defect in the system.

Accuracy is a statement of the limits that bound the departure of a measured value from the true value. Accuracy includes the imprecision of the measurement along with all the accumulated errors in the measurement chain extending from the basic reference standards to the measurement in question.

Errors may be classified into two categories, systematic and random. *Systematic errors* are those which consistently recur when a number of measurements are taken. Systematic errors may be caused by deterioration of the measurement system (weakened magnetic field, change in a reference resistance value), alteration of the measured value by the addition or extraction of energy from the element being measured, response-time effects, and attenuation or distortion of the measurement signal. *Random errors* are accidental, tend to follow the laws of chance, and do not exhibit a consistent magnitude or sign. Noise and environmental factors normally produce random errors but may also contribute to systematic errors.

The arithmetic average of a number of observations should be used to minimize the effect of random errors. The arithmetic average or mean X of a set of n readings X_1, X_2, \dots, X_n is

$$X = \sum X_i / n$$

The dispersion of these reading about the mean is generally described in terms of the standard deviation σ , which can be estimated for n observations by

$$s = \sqrt{\frac{\sum (X_i - X)^2}{n - 1}}$$

where s approaches σ as n becomes large.

*The author is indebted to I. A. Whyte, L. C. Vercellotti, T. H. Putnam, T. M. Heinrich, T. I. Pattantyus, and R. A. Mathias for suggestions and constructive criticism for Chap. 15.1.

15.4 MEASUREMENT SYSTEMS

A *confidence interval* can be determined within which a specified fraction of all observed values may be expected to lie. The *confidence level* is the probability of a randomly selected reading falling within this interval. Detailed information on measurement errors is given in Coombs (Chap. 15.5).

Standardization and calibration involve the comparison of a physical measurement with a reference standard. Calibration normally refers to the determination of the accuracy and linearity of a measuring system at a number of points, while standardization involves the adjustment of a parameter of the measurement system so that the reading at one specific value is in correspondence with a reference standard. The numerical value of any reference standard should be capable of being traced through a chain of measurements to a National Reference Standard maintained by the National Institute of Standards and Technology (formerly the National Bureau of Standards).

The range of a measurement system refers to the values of the input variable over which the system is designed to provide satisfactory measurements. The range of an instrument used for a measurement should be chosen so that the reading is large enough to provide the desired precision. An instrument having a linear scale, which can be read within 1 percent at full scale, can be read only within 2 percent at half scale.

The resolution of a measuring system is defined as the smallest increment of the measured quantity which can be distinguished. The resolution of an indicating instrument depends on the deflection per unit input. Instruments having a square-law scale provide twice the resolution of full scale as linear-scale instruments. Amplification and zero suppression can be used to expand the deflection in the region of interest and thereby increase the resolution. The resolution is ultimately limited by the magnitude of the signal that can be discriminated from the noise background.

Noise may be defined as any signal that does not convey useful information. Noise is introduced in measurement systems by mechanical coupling, electrostatic fields, and magnetic fields. The coupling of external noise can be reduced by vibration isolation, electrostatic shielding, and electromagnetic shielding. Electrical noise is often present at the power-line frequency and its harmonics, as well as at radio frequencies.

In systems containing amplification, the noise introduced in low-level stages is most detrimental because the noise components within the amplifier passband will be amplified along with the signal. The noise in the output determines the lower limit of the signal that can be observed.

Even if external noise is minimized by shielding, filtering, and isolation, noise will be introduced by random disturbances within the system caused by such mechanisms as the Brownian motion in mechanical systems, Johnson noise in electrical resistance, and the Barkhausen effect in magnetic elements. Johnson noise is generated by electron thermal agitation in the resistance of a circuit. The equivalent rms noise voltage developed across a resistor R at an absolute temperature T is equal to $\sqrt{4kTR \Delta f}$, where k is Boltzmann's constant ($1.38 \times 10^{-23} \text{ J/K}$) and Δf is the bandwidth in hertz over which the noise is observed.

The bandwidth Δf of a system is the difference between the upper and lower frequencies passed by the system (Chap. 15.2). The bandwidth determines the ability of the system to follow variations in the quantity being measured. The lower frequency is zero for dc systems, and their response time is approximately equal to $1/(3\Delta f)$. Although a wider bandwidth improves the response time, it makes the system more susceptible to interference from noise.

Environmental factors that influence the accuracy of a measurement system include temperature, humidity, magnetic and electrostatic influences, mechanical stability, shock, vibration, and position. Temperature changes can alter the value of resistance and capacitance, produce thermally generated emfs, cause variations in the dimensions of mechanical members, and alter the properties of matter. Humidity affects resistance values and the dimensions of some organic materials. DC magnetic and electrostatic fields can produce an offset in instruments which are sensitive to these fields, while ac fields can introduce noise. The lack of mechanical stability can alter instrument reference values and produce spurious responses. Mechanical energy imparted to the system in the form of shock or vibration can cause measurement errors and, if severe enough, can result in permanent damage. The position of an instrument can affect the measurements because of the influence of magnetic, electrostatic, or gravitational fields.

TRANSDUCERS, INSTRUMENTS, AND INDICATORS

Transducers are used to respond to the state of a quantity to be measured and to convert this state into a convenient electrical or mechanical quantity. Transducers can be classified according to the variable to be measured. Variable classifications include mechanical, thermal, physical, chemical, nuclear-radiation, electromagnetic-radiation, electrical, and magnetic, as detailed in Sec. 8.

Instruments can be classified according to whether their output means is analog or digital. Analog instruments include the d'Arsonval (moving-coil) galvanometer, dynamometer instrument, moving-iron instrument, electrostatic voltmeter, galvanometer oscillograph, cathode-ray oscilloscope, and potentiometric recorders. Digital-indicator instruments provide a numerical readout of the quantity being measured and have the advantage of allowing unskilled people to make rapid and accurate readings.

Indicators are used to communicate output information from the measurement system to the observer.

MEASUREMENT CIRCUITS

Substitution circuits are used in the comparison of the value of an unknown electrical quantity with a reference voltage, current, resistance, inductance, or capacitance. Various potentiometer circuits are used for voltage substitution, and divider circuits are used for voltage, current, and impedance comparison. A number of these circuits and the reference components used in them are described in Chap. 15.2.

Analog circuits are used to embody mathematical relationships, which permit the value of an unknown electrical quantity to be determined by measuring related electrical quantities. Analog-measurement techniques are discussed in Chap. 15.2, and a number of special-purpose measurement circuits are described in Chap. 15.4.

Digital instruments combine analog circuits with digital processing to provide a convenient means of making rapid and accurate measurements. Digital instruments are described in Chaps. 15.2 and 15.4. Digital processing using the computational power of microprocessors is discussed in Chap. 15.3.

Bridge circuits provide a convenient and accurate method of determining the value of an unknown impedance in terms of other impedances of known value. The circuits of a number of impedance bridges and amplifiers and detectors used for bridge measurements are described in Chap. 15.4.

Transducer amplifying and stabilizing circuits are used in conjunction with measurement transducers to provide an electric signal of adequate amplitude, which is suitable for use in measurement and control systems. These circuits, which often have severe linearity, drift, and gain-stability requirements, are described in Chap. 15.3.

CHAPTER 15.2

SUBSTITUTION AND ANALOG MEASUREMENTS

Francis T. Thompson

VOLTAGE SUBSTITUTION

The constant-current potentiometer, which is used for the precise measurement of unknown voltages below 1.5 V, is shown schematically in Fig. 15.2.1. For a constant current, the output voltage V_o is proportional to the resistance included between the sliding contacts. In this circuit all the current-carrying connections can be soldered, thereby minimizing contact-resistance errors. When the sliding contacts are adjusted to produce a null, V_o is equal to the unknown emf and no current flows in the sliding contacts. At null, no current is drawn from the unknown emf, and therefore the measured voltage is independent of the internal resistance of the source.

The circuit of a multirange commercial potentiometer is shown in Fig. 15.2.2. The instrument is standardized with the range switch in the highest range position as shown and switch S connected to the standard cell. The calibrated standard-cell dial is adjusted to correspond to the known voltage of the standard cell, and the standardizing resistance is adjusted to obtain a null on the galvanometer. This procedure establishes a constant current of 20 mA through the potentiometer. The unknown emf is connected to the emf terminals, and switch S is thrown to the emf position. The unknown emf can be read to at least five significant figures by adjusting the tap slider and the 11-turn $5.5\text{-}\Omega$ potentiometer for a null on the galvanometer. The range switch reduces the potentiometer current to 2 or 0.2 mA for the 0.1 and the 0.01 ranges, respectively, thereby permitting lower voltages to be measured accurately. Since the range switch does not alter the battery current (22 mA), the instrument remains standardized on the lower ranges. When making measurements, the current should be checked using the standard cell to ensure that the current has not drifted from the standardized value. The Leeds and Northrup Model 7556-B six-dial potentiometer operates in a similar manner and provides an accuracy of $\pm(0.001$ percent of reading + $0.1\ \mu\text{V})$.

The constant-resistance potentiometer of Fig. 15.2.3 uses a variable current through a fixed resistance to generate a voltage for obtaining a null with the unknown emf. The constant-resistance potentiometer is used primarily for measurements in the millivolt and microvolt range.

The microvolt potentiometer, or low-range potentiometer, is designed to minimize the effect of contact resistance and thermal emfs. Thermal shielding is used to minimize temperature differences. The galvanometer is connected to the circuit through a special Wenner thermo-free reversing key of copper and gold construction to eliminate thermal effects in the galvanometer circuit.

A typical microvolt potentiometer circuit consisting of two constant-current decades and a constant-resistance element is shown in Fig. 15.2.4. The constant-current decades use Diesselhorst rings, in which the constant current entering and leaving the ring divides two paths. The IR drop across the resistance in the isothermal shield increases in 10 equal increments as the dial switch is rotated. The switch contacts are in the constant-current

FIGURE 15.2.1 Constant-current potentiometer.

supply circuit, and therefore the effects of their IR drops and thermal emfs are minimized. A 100-division millimeter associated with the constant-resistance element provides nearly three additional decades of resolution. Readings to 10 nV are possible with this type of potentiometer.

The direct-current comparator potentiometer used for precise measurement of unknown voltages below 2.1 V is shown in Fig. 15.2.5. Feedback from the zero-flux detector winding is used to adjust the current supply for ampere-turn balance between the primary and secondary windings as in the dc-comparator ratio bridge of Chap. 15.4.

Standardization on the 1X range is obtained in a two-step procedure. First, the external standard cell and galvanometer are connected in series across resistor EH by the selector switch, and the constant current source is adjusted for zero galvanometer deflection. This transfers the standard cell voltage across resistor EH. Second, the seven measuring dials are set to the known standard voltage, and the selector switch is used to connect the galvanometer across the opposing voltages AD and EH. Trimmer turns n_s are used to obtain zero galvanometer deflection. This results in the standard cell voltage being generated across resistor AD with the dials set to the known standard cell value, and therefore calibration of the 1X range.

The unknown emf is measured on the 1X range by using the selector switch to connect the unknown emf and the voltage generated across resistor AD in series opposition across the galvanometer. The seven

FIGURE 15.2.2 K2 potentiometer. (Leeds and Northrup)

measuring dials are adjusted to obtain zero deflection. Specified measurement accuracies are $\pm(0.5 \text{ ppm of reading} + 0.05 \mu\text{V})$ on the 1X range ($2.111111 \text{ V full scale}$), $\pm(1 \text{ ppm of reading} + 0.01 \mu\text{V})$ on the 0.1X range, and $\pm(2 \text{ ppm of reading} + 0.005 \mu\text{V})$ on the 0.01X range.

DIVIDER CIRCUITS

The volt box (Fig. 15.2.6) is used to extend the voltage range of a potentiometer. The unknown voltage is connected between 0 and an appropriate terminal, for example, $\times 100$. The potentiometer is connected between the 0 and P output terminals. When the potentiometer is balanced, it draws no current, and therefore the current drawn from the source flows through the resistor between terminals 0 and P . The unknown voltage is equal to the potentiometer reading multiplied by the selected tap multiplier. Unlike the potentiometer, the volt box does load the voltage source. Typical resistances range from about 200 to 1000 Ω/V . The higher resistance values minimize self-heating and do not load the source as heavily. Errors due to leakage currents, which could flow through the insulators supporting the resistors, are minimized by using a guard circuit (see Chap. 15.4).

FIGURE 15.2.3 Constant-resistance potentiometer.

Decade voltage dividers provide a wide range of precisely defined, and very accurate voltage ratios. The Kelvin-Varley vernier decade circuit is shown in Fig. 15.2.7. The slide arms in the first three decades are arranged so that they always span two contacts. The shunting effect of the second gang resistance across the slide arms of the first decade is equal to $2R$, thereby giving a net resistance of R between

resistance across the slide arms of the first decade is equal to $2R$, thereby giving a net resistance of R between

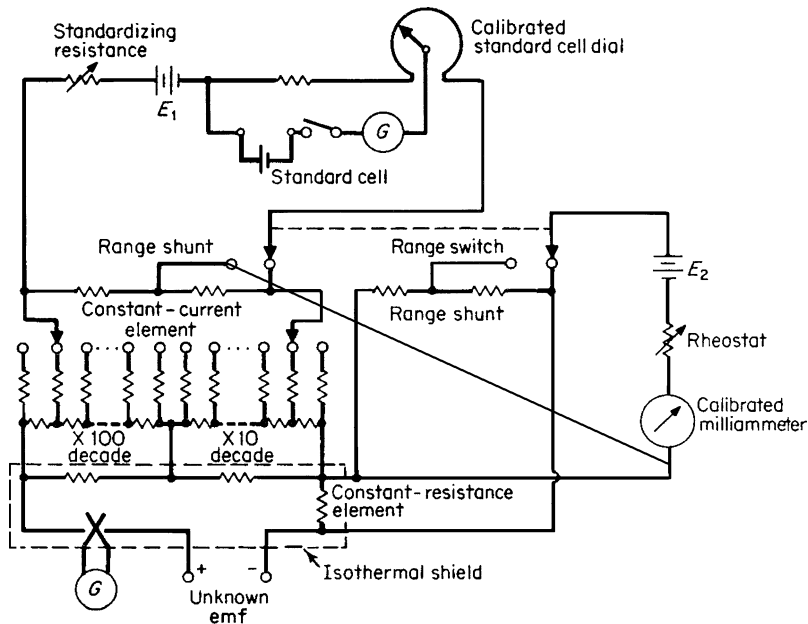

FIGURE 15.2.4 Microvolt potentiometer.

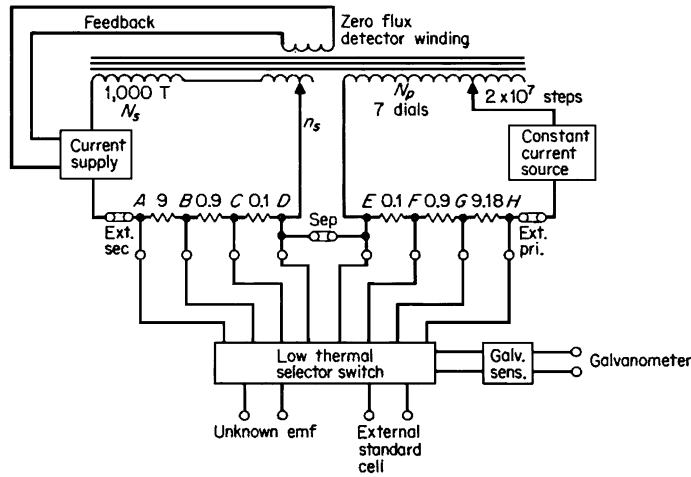

FIGURE 15.2.5 Direct-current comparator potentiometer.

the slide-arm contacts. With no current drawn from the output, the resistance loading on the input is equal to $10R$ and is independent of the slide-arm settings. In each of the first three decades, 11 resistors are used, while only 10 resistors are used in the final decade, which has a single sliding contact. Potentiometers with six decades have been constructed using the Kelvin-Varley circuit.

DECADE BOXES

Decade resistor boxes contain an assembly of resistances and switches, as shown in Fig. 15.2.8. The power rating of each resistance step is approximately constant; therefore, each decade has a different maximum current rating, which should not be exceeded. Boxes having four to seven decades are available with accuracies of 0.02 percent. Two typical seven-decade boxes provide resistance values from 0 to 1,111,111 Ω in 0.1- Ω steps and values from 0 to 11,111,110 Ω in 1- Ω steps. The accuracy at higher frequencies is affected by skin effect, series inductance, and shunt capacitance. The equivalent circuit of a resistance decade is shown in Fig. 15.2.9,

FIGURE 15.2.6 Volt-box circuit.

where ΔL is the undesired incremental inductance added with each resistance step ΔR . Silver contacts are used to obtain a zero resistance R_o , as low as 1 m Ω /decade at dc. Zero inductance values L_o as low as 0.1 μ H/decade are obtainable. The shunt capacitance for the configuration of Fig. 15.2.8 is a function of the highest decade in use, i.e., not set at zero. The shunt capacitance with the low terminal connected to the shield is typically 10 to 15 pF for the highest decade in use plus an equal value for each higher decade not in use.

Some applications, e.g., the determination of small inductances at audio frequency and the determination of resistance at radio frequency by the substitution method, require that the equivalent series inductance of the resistance box remain constant, independent of the resistance setting. In the inductively compensated decade resistance box small copper-wound coils each having an inductance equal to the inductance of an individual resistance unit are selected by the decade switch so as to maintain a constant total inductance.

Decade capacitor units generally consist of four capacitances which are selectively connected in parallel by a four-gang 11-position switch (Fig. 15.2.10). The individual capacitors and their associated switch are shielded to

FIGURE 15.27 Decade voltage divider.

ensure that the selected steps add properly. *Decade capacitor boxes* are available with six-decade resolution, which provides a range of 0 to 1.11111 μF in increments of 1 pF and with an accuracy of 0.05 percent. Air capacitors are used in the 1- and 10-pF decades, and silver-mica capacitors in the higher ranges. Polystyrene capacitors are used in some less-precise decade capacitors.

Decade inductance units can be constructed using four series-connected inductances of relative units 1, 2, 3, 4 or 1, 2, 2, 5. A four-gang 11-position switch is used to short-circuit the undesired inductances. Care must be

FIGURE 15.28 Decade resistance box.

FIGURE 15.2.9 Equivalent circuit of a resistance decade. (General Radio Co.)

FIGURE 15.2.10 Capacitor decade.

taken to avoid mutual coupling between the inductances. *Decade inductance boxes* are available with individual decades ranging from 1 mH to 10 H total inductance. A commercial single-decade unit consists of an assembly of four inductors wound on molybdenum-Permalloy dust cores and a switch which enables consecutive values to be selected. Typical units have an accuracy of 1 percent at zero frequency. The effective series inductance of a typical decade unit increases with frequency. The inductance is also a function of the ac current and any dc bias current. The Q of the coils varies with frequency.

ANALOG MEASUREMENTS

Ohmmeter circuits provide a convenient means of obtaining an approximate measurement of resistance.

The basic series-type ohmmeter circuit of Fig. 15.2.11a consists of an emf source, series resistor R_1 and d'Arsonval milliammeter. Resistor R_2 is used to compensate for changes in battery emf and is adjusted to provide full-scale meter deflection ($0\text{-}\Omega$ indication) with terminals X_1 and X_2 short-circuited. No deflection (infinite resistance indication) is obtained with X_1 and X_2 open-circuited. When an unknown resistor R_x is connected

FIGURE 15.2.11 Series-type ohmmeters: (a) basic circuit; (b) commercial circuit (Simpson Electric Co.)

across the terminals, the meter deflection varies inversely with the unknown resistance. With the range switch in the position shown, half-scale deflection is obtained when the external resistance is equal to $R_1 + R_2 R_M / (R_2 + R_M)$. A multirange meter can be obtained using current-shunting resistors R_3 and R_4 . A typical commercial ohmmeter circuit (Fig. 15.2.11*b*) having midscale readings of 12 Ω , 1200 Ω , and 120 k Ω uses an Ayrton shunt for range selection and a higher battery voltage for the highest resistance range.

FIGURE 15.2.12 Shunt-type ohmmeter. (Triplet Electrical Instrument Co.)

In the shunt-type ohmmeter the unknown resistor R_x is connected across the d'Arsonval milliammeter, as shown in Fig. 15.2.12*a*. The variable resistance R_1 is adjusted for full-scale deflection (infinite-resistance indication) with terminals X_1 and X_2 open-circuited. The ohm scale, with 0 Ω corresponding to zero deflection, is the reverse of the series-type ohmmeter scale. The resistance range can be lowered by switching a shunt resistor across the meter. With the range switch selecting shunt resistor R_2 , half-scale deflection occurs when R_x is equal to the parallel combination of R_1 , R_M , and R_2 . The shunt-type ohmmeter is therefore most suited to low-resistance measurements.

The use of a high-input impedance amplifier between the circuit and the d'Arsonval meter permits the shunt-type ohmmeter to be used for high- as well as low-resistance measurements. A commercial ohmmeter (Fig. 15.2.12*b*) uses a field-effect-amplifier input stage which draws negligible current.

The amplifier gain is adjusted to provide full-scale deflection with terminals X_1 and X_2 open-circuited. Half-scale deflection occurs when R_x is equal to the total selected tap resistance.

Voltage-drop (or fall-of-potential) methods for determining resistance involve measuring the current flowing through the resistor with an ammeter, measuring the voltage drop across the resistor with a voltmeter, and calculating the resistance using Ohm's law. The circuit of Fig. 15.2.13*a* should be used for low-resistance measurements since the current drawn by the voltmeter V/R_V will be small with respect to the total current I . The circuit of Fig. 15.2.13*b* should be used for high-resistance measurements since the resistance of the ammeter R_A will be small with respect to the unknown resistance R_x . An accuracy of 1 percent or better can be obtained using 0.5 percent accurate instruments if the voltage source and instrument ranges are selected to provide readings near full scale.

Resonance methods can be used to measure the inductance, capacitance, and Q factor of components at radio frequencies. In Fig. 15.2.14, resistors R_1 and R_2 couple the oscillator voltage e to a series-connected known capacitance and an unknown inductance represented by effective inductance L' and effective series resistance r' . Resistor R_2 is chosen to be small with respect to resistance r' , thereby minimizing the effect of source resistance of the injected voltage.

FIGURE 15.2.13 Fall-of-potential method: (a) for low resistances; (b) for high resistances.

FIGURE 15.2.14 Inductance measurement.

A circuit containing reactive components is in resonance when the supply current is in phase with the applied voltage. The series circuit of Fig. 15.2.14 is in resonance when the inductive reactance X_L is equal to the capacitive X_C , which occurs when

$$\omega^2 = \omega_0^2 = 1/L'C$$

where $X_L = \omega L'$, $X_C = 1/\omega C$, $\omega = 2\pi f$, $\omega_0 = 2\pi f_0$, f_0 = resonant frequency (Hz), L' = effective inductance (H), and C = capacitance (F).

If L' , r' , C , and e are constant and the oscillator frequency ω is adjusted until the voltage read across C by the FET input voltmeter is maximum, the frequency ω will be slightly less than the resonant frequency ω_0 :

$$\omega^2 = \frac{1}{L'C} - \frac{(r' + R_s)^2}{2L'^2} = \omega_0^2 \left(1 - \frac{1}{2Q^2} \right)$$

where $R_s = R_1 R_2 / (R_1 + R_2)$ and $Q^* = \omega_0 L' / (r' + R_s)$. If $Q^* \geq 10$, ω and ω_0 will differ by less than 0.3 percent. The ratio m of the voltage across C to the voltage across R_2 can be measured while operating at ω . If $R_s \ll r'$, the value of the effective Q of the unknown inductance is related to m by

$$m = \frac{2Q'^2}{\sqrt{4Q'^2 - 1}} \quad Q' = \sqrt{\frac{m}{2(m - \sqrt{m^2 - 1})}}$$

where $Q' = \omega_0 L' / r'$ and $m = V_C / V_{R2}$ measured at ω . The values of m and Q' are nearly equal for high values of Q' ; the difference is less than 0.4 percent for $Q' > 10$. If R_s is not small with respect to r' , its value affects the determination of Q' only indirectly through its effect on ω . If $R_s = r$ and $Q' \geq 10$, the determination of Q' by the above equation is in error by less than 1 percent.

If ω , L' , r' , and e are constant and the capacitance C is adjusted until the voltage across it is maximum, the capacitance value C will be slightly less than the capacitance value C_R needed for resonance at the frequency ω :

$$C = \frac{1}{\omega^2 L'} \left(\frac{1}{1 + 1/Q^{*2}} \right) = C_R \frac{1}{1 + 1/Q^{*2}}$$

where $\omega = \omega_0$, $Q^* = \omega_0 L' / (r' + R_s)$, and $R_s = R_1 R_2 / (R_1 + R_2)$. For $Q^* \geq 10$, C differs from C_R by less than 1 percent. If $R_s \ll r'$, the value of the effective Q of the unknown inductance is related to m by

$$m = \sqrt{Q'^2 + 1} \quad Q' = \sqrt{m^2 - 1}$$

where $Q' = \omega L' / r'$, $m = V_C / V_{R2}$, $\omega = \omega_0 = 2\pi f_0$, and f_0 is the resonant frequency in hertz for L and C_R .

The circuit of Fig. 15.3.14 can be used to find the value of an unknown capacitance if a stable inductance of known value is available. Similar circuits are used in Q meters (see Chap. 15.4). Discussions of series resonance, parallel resonance, and Q factor are given in Refs. 3, 12, and 13.

FIGURE 15.2.15 Equivalent circuit of inductance.

FIGURE 15.2.16 Loosely coupled tuned circuit.

Lead lengths should be kept short when making measurements at high frequencies, and the capacitance of the voltmeter must be added to capacitor C if it is not negligible.

The self-capacitance C_0 of an inductance is generally not negligible and can cause discrepancies in measurements. An inductance can be represented by the equivalent circuit of Fig. 15.2.15, where C_0 is the self-capacitance, L is the true inductance, and r is the true series resistance. The self-capacitance causes the effective inductance L' and the effective series resistance r' of the equivalent unknown inductance as measured in the circuit of Fig. 15.2.14 to differ somewhat from L and r , that is

$$r' = r \left(\frac{C + C_0}{C} \right)^2 \quad \text{and} \quad L' = L \frac{C + C_0}{C}$$

The value of C_0 can be measured with the aid of a Q meter (Chap. 15.4) having a calibrated variable capacitance.

The bandwidth of a tuned circuit can be determined by measuring the frequencies f_1 and f_2 at which the capacitor voltage in Fig. 15.2.16 is 0.707 times the maximum capacitor voltage. The oscillator, which maintains a constant voltage, is loosely coupled to the tuned circuit. The bandwidth Δf is equal to the difference $f_2 - f_1$ and is a function of the resonant frequency f_0 and the Q of the tuned circuit: $\Delta f = f_0/Q$.

The circuit Q of a tuned circuit for sinusoidal excitation is defined as $2\pi(\text{maximum stored energy})/(\text{energy dissipated per cycle})$. Circuit Q can be measured directly using the circuit of Fig. 15.2.16. In this circuit the self-capacitance C_0 appears directly in parallel with the tuning capacitor C . The bandwidth is determined as explained above, and the Q is equal to $f_0/(f_2 - f_1)$. If the circuit of Fig. 15.2.14 is used, the self-capacitance no longer appears in parallel with the tuning capacitor C and the effective Q is measured. The real Q can be calculated if the self-capacitance C_0 is known; $Q = Q'(C + C_0)/C$, where Q' is the effective Q .

DIGITAL INSTRUMENTS

Digital multimeters provide a convenient means of making rapid and accurate measurements of voltage, current, and resistance. These instruments rely on the accuracy of A/D converters (see Chap. 15.3) and built-in precision voltage references. Many contain microprocessor-based intelligence and can be incorporated in automated-measurement and data-collection systems by means of the IEEE-488 bus (see Chap. 15.3). A typical block diagram is shown in Fig. 15.2.17. The performance is largely dependent on the A/D converter. Low-cost handheld units use a single-chip $3\frac{1}{2}$ -digit A/D converter, while high-accuracy $5\frac{1}{2}$ - and $6\frac{1}{2}$ -digit meters use microprocessor-controlled discrete A/D converters. Typical performance specifications are given in Table 15.2.1. Unlike analog meters that have accuracies specified in terms of full scale, accuracy figures for digital meters are given in percent of the reading plus the number of counts of the least significant digit. Therefore, a 5.00 V reading on a $3\frac{1}{2}$ -digit meter with a specified accuracy of $\pm(0.1 \text{ percent} + 1 \text{ digit})$ would be accurate to $\pm 0.3 \text{ percent}$ or $\pm 0.015 \text{ V}$.

The input resistance R_{in} of the meter can introduce an error in the measurement of an unknown voltage V_x by loading the unknown as shown in Fig. 15.2.18. The voltage V_m indicated by the meter is equal to $V_x R_{in} / (R_{in} + R_x)$.

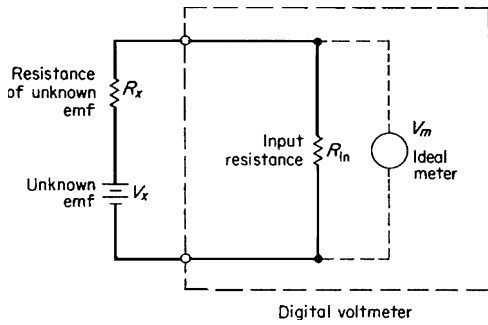

FIGURE 15.2.18 Effect of loading.

For example, if a meter having a 10-M Ω input resistance is used to measure an unknown emf having an equivalent resistance of 100 K Ω , the meter will read 99 percent of the correct value.

Resistance measurements rely on the accuracy of an internal current reference, shown as I_r in Fig.15.2.19. For an ideal meter with infinite input resistance R_{in} , the unknown resistance R_x is equal to V_m/I_r and the meter is calibrated to read the resistance value directly. For finite values of R_{in} , the indicated resistance value of R_x is equal to the parallel resistance of R_x and R_{in} , which can introduce a significant error in the measurement of high-value unknown resistances. The resistance of the leads connecting the unknown resistance to the meter of Fig. 15.2.19 can introduce an error in the measure-

ment of low-value resistances. This problem is overcome in high-precision meters by using separate terminals and leads to connect the precision current reference to the unknown resistance. In this case the voltage measurement leads carry only the current drawn by the input resistance R_{in} .

Digital electrometers are highly refined dc multimeters which provide exceptionally high input resistance and sensitivity. The block diagram of a typical microcomputer-controlled digital electrometer is shown in Fig. 15.2.20. Performance depends on the high-input-resistance, low-offset-current JFET preamp and operational amplifier as well as the A/D converter. A state-of-the-art 4 $^{1/2}$ -digit autoranging meter* provides voltage ranges from 200 mV to 200 V, current ranges from 2 pA (2×10^{-12} A) to 20 mA, resistance ranges from 2 k Ω to 200 G Ω ($200 \times 10^9 \Omega$), and Coulomb ranges from 200 pC to 200 nC. Specified accuracies for the most-sensitive ranges are $\pm(0.05$ percent + 4 counts) for voltage, $\pm(1.6$ percent + 66 counts) for current, $\pm(0.20$ percent + 4 counts) for resistance, and $\pm(0.4$ percent + 4 counts) for charge. The input impedance is greater than $200 \times 10^{12} \Omega$ in parallel with 20 pF, and the input bias current is less than 5×10^{-15} A at 23 $^{\circ}$ C. A bipolar 100-V, 0.2 percent-accuracy voltage source programmable in 50-mV steps and a 1-nA to 100- μ A decade current source are built into the meter. Two techniques may be used to measure resistance or generate $I - V$ curves: The decade current source can be used to force a known current through the unknown impedance with the voltage measured by the high-input-impedance voltmeter, or the voltage source can be applied across the unknown with the resulting current measured by the current meter. The latter method is preferred for characterizing voltage-dependent materials.

FIGURE 15.2.19 Effect of loading.

*Keithley Model 617 Electrometer.

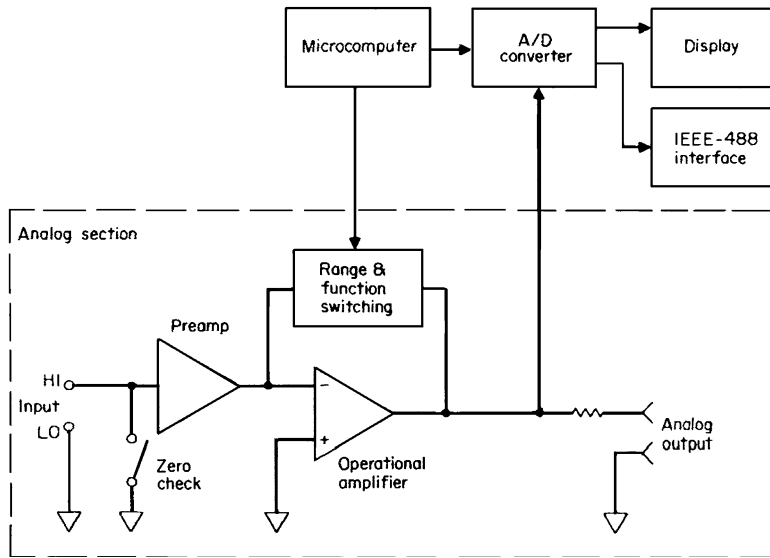

FIGURE 15.2.20 Typical digital electrometer.

A triaxial input cable, Fig. 15.2.21, is used with the electrometer to minimize input lead leakage and cable capacitance problems. The outer shield connected to the LO input can be grounded. The inner shield is driven by electrometer unity gain low-impedance output which maintains the guard voltage essentially equal to the high-impedance input signal HI. Insulator leakage through r becomes negligible since there is essentially no voltage difference between the center conductor and the guard.

Digital nanovoltmeters are digital voltmeters that are optimized for nanovolt measurements. A state-of-the-art meter uses a JFET input amplifier to obtain an input resistance of $10^9 \Omega$ and a 5-nF input capacitance. Voltage ranges of 2 mV to 1000 V are available. Specified accuracy for a 24-h period is $\pm (0.006 \text{ percent} + 5 \text{ counts})$ when properly zeroed. A special connector having a low thermoelectric voltage is used for the 200-mV and lower ranges.

FIGURE 15.2.21 Guard shield minimizes input leakage.

CHAPTER 15.3

TRANSDUCER-INPUT MEASUREMENT SYSTEMS

Francis T. Thompson

Transducers are used to convert the quantity to be measured into an electric signal. Transducer types and their input and output quantities are discussed in Sec. 8.

TRANSDUCER SIGNAL CIRCUITS

Amplifiers are often required to increase the voltage and power levels of the transducer output and to prevent excessive loading of the transducer by the measurement system. The design of the amplifier is a function of the performance specifications, which include required amplification in terms of voltage gain or power gain, frequency response, distortion permissible at a given maximum signal level, dynamic range, residual noise permissible at the output, gain stability, permissible drift (for dc amplifiers), operating-temperature range, available supply voltage, permissible power consumption and dissipation, reliability, size, weight, and cost.

Capacitive-coupled amplifiers (ac amplifiers) are used when it is not necessary to preserve the dc component of the signal. AC amplifiers are used with transducers that produce a modulated carrier signal. Low-level amplifiers increase the signal from millivolts to several volts. The two-stage class A capacitor-coupled transistor amplifier of Fig. 15.3.1 has a power gain of 64 dB and a voltage gain of approximately 1000. Design information, an explanation of biasing, and equations for calculating the input impedance and various gain values are given in Walston and Miller (see Chap. 15.5). An excellent ac amplifier can be obtained by connecting a coupling capacitor in series with resistor R_1 of the operational amplifier of Fig. 15.3.4. The capacitor should be selected so that $C > 1/2\pi fR_1$, where f is the lowest signal frequency to be amplified. Class B transformer-coupled amplifiers, which are often used for higher power-output stages, are also discussed in Walston and Miller (see Chap. 15.5).

Direct-coupled amplifiers are used when the dc component of the signal must be preserved. These designs are more difficult than those of capacitive-coupled amplifiers because changes in transistor leakage currents, gain, and base-emitter voltage drops can cause the output voltage to change for a fixed input voltage, i.e., cause a dc-stability problem. The dc stability of an amplifier is determined primarily by the input stage since the equivalent input drift introduced by subsequent stages is equal to their drift divided by the preceding gain. Balanced input stages, such as the differential amplifier of Fig. 15.3.2, are widely used because drift components tend to cancel. By selecting a pair of transistors, Q_1 and Q_2 , which are matched for current gain within 10 percent and base-to-emitter voltage within 3 mV, the temperature drift referred to the input can be held to within $10 \mu\text{V}/^\circ\text{C}$. Transistor Q_3 acts as a constant-current source and thereby increases the ability of the amplifier to reject common-mode input voltages. For applications where the generator resistance r_g is

FIGURE 15.3.1 Two-stage cascaded common-emitter capacitive audio amplifier.

FIGURE 15.3.2 Differential amplifier.

greater than 50 kΩ, current offset becomes dominant, and lower overall drift can be obtained by using field-effect transistors in place of the bipolar transistors Q_1 and Q_2 . Voltage drifts as low as $0.4 \mu\text{V}/^\circ\text{C}$ can be obtained using integrated-circuit operational amplifiers (see Table 15.3.1).

Operational amplifiers are widely used for amplifying low-level ac and dc signals. They usually consist of a balanced input stage, a number of direct-coupled intermediate stages, and a low-impedance output stage. They provide high open-loop gain, which permits the use of a large amount of gain-stabilizing negative feedback. High-gain bipolar and JFET transistors are often used in the balanced input stage. The bipolar input provides lower voltage offset and offset voltage drift while the JFET input provides higher input impedance, lower bias current, and lower offset current as can be seen in Table 15.3.1 which compares the typical specifications of three high-performance operational amplifiers. The chopper-stabilized CMOS operational amplifier provides the low offset and bias currents of FET transistors while using internal chopper stabilization to achieve excellent offset voltage characteristics. With input voltages, e_1 , e_2 , and e_{cm} equal to zero, the output of the amplifier of Fig. 15.3.3 will have an offset voltage E_{os} defined by

$$E_{os} = V_{os} \frac{R_1 + R_2}{R_1} + I_{b1} R_2 - I_{b2} \frac{R_3 R_4 (R_1 + R_2)}{R_1 (R_3 + R_4)}$$

TABLE 15.3.1 Operational Amplifier Comparison

Typical parameter (except where noted)	Temp.	Bipolar input (Harris 5130)	JFET input (Harris 5170)	Chopper-stabilized CMOS (Siliconix 7652)
Input characteristics				
Offset voltage	25°C	10 μV	100 μV	0.7 μV

FIGURE 15.3.3 Operational amplifier.

where I_{b1} and I_{b2} are bias currents that flow into the amplifier when the output is zero and V_{os} is the input offset voltage that must be applied across the input terminals to achieve zero output. The input bias current specified for an operational amplifier is the average of I_{b1} and I_{b2} . Since the bias currents are approximately equal, it is desirable to choose the parallel combination of R_3 and R_4 equal to the parallel combination of R_1 and R_2 . For this case, $E_{os} = V_{os}(R_1 + R_2)/R_1 + I_{os}R_2$, where the offset current $I_{os} = I_{b1} - I_{b2}$.

In the ideal case, where V_{os} and I_{os} are zero, the output voltage E_0 as a function of signal voltage e_1 and e_2 and common-mode voltage e_{cm} is

$$E_0 = -e_1 \frac{R_2}{R_1} + e_2 \frac{R_4(R_1 + R_2)}{R_1(R_3 + R_4)} + e_{cm} \frac{R_4(R_1 + R_2) - R_2(R_3 + R_4)}{R_1(R_3 + R_4)}$$

Maximum common-mode rejection can be obtained by choosing $R_4/R_3 = R_2/R_1$, which reduces the above equation to $E_0 = R_2(e_2 - e_1)/R_1$. The common-mode signal is not entirely rejected in an actual amplifier but will be reduced relative to a differential signal by the common-mode rejection ratio of the amplifier. Minimum drift and maximum common-mode rejection, which are important when terminating the wires from a remote transducer, can be obtained by selecting $R_3 = R_1$ and $R_4 = R_2$.

Where common-mode voltages are not a problem, the simple inverting amplifier (Fig. 15.3.4) is obtained by replacing e_{cm} and e_2 with short circuits and combining R_3 and R_4 into one resistor, which is equal to the parallel equivalent of R_1 and R_2 . The input impedance of this circuit is equal to R_1 .

Similarly, the simple noninverting amplifier (Fig. 15.3.5) is obtained by replacing e_{cm} and e_1 with short circuits. The voltage follower is a special case of the noninverting amplifier where $R_1 = \infty$ and $R_2 = 0$. The input impedance of the circuit of Fig. 15.3.5 is equal to the parallel combination of the common-mode input impedance of the amplifier and impedance $Z_{id}[1 + (AR_1)/(R_1 + R_2)]$, where Z_{id} is the differential-mode amplifier input impedance and A is the amplifier gain. Where very high input impedances are required, as in electrometer circuits, operational amplifiers having field-effect input transistors are used to provide input resistances up to $10^{12} \Omega$.

FIGURE 15.3.4 Inverting amplifier.

FIGURE 15.3.5 Noninverting amplifier.

An ac-coupled amplifier can be obtained by connecting a coupling capacitor in series with the input resistor of Fig. 15.3.4. The capacitor value should be selected so that the capacitive reactance at the lowest frequency of interest is lower than the amplifier input impedance R_1 .

Operational amplifiers are useful for realizing filter networks and integrators. Other applications include absolute-value circuits, logarithmic converters, nonlinear amplification, voltage-level detection, function generation, and analog multiplication and division. Care should be taken not to exceed the maximum supply voltage and maximum common-mode voltage ratings and also to be sure that the load resistance R_L is not smaller than that permitted by the rated output.

The charge amplifier is used to amplify the ac signals from variable-capacitance transducers and transducers having a capacitive impedance such as piezoelectric transducers. In the simplified circuit of Fig. 15.3.6a, the current through C_s is equal to the current through C_1 , and therefore

$$C_s \frac{de_s}{dt} + e_s \frac{dC_s}{dt} = -C_1 \frac{de_o}{dt}$$

For the piezoelectric transducer, C_s is assumed constant, and the gain $\delta e_o / \delta e_s = -C_s / C_1$. For the variable-capacitance transducer, e_s is constant, and the gain $de_o / dC_s = -e_s / C_1$. A practical circuit requires a resistance across C_1 to limit output drift. The value of this resistance must be greater than the impedance of C_1 at the lowest frequency of interest. A typical operational amplifier having field-effect input transistors has a specified maximum input current of 1 nA, which will result in an output offset of only 0.1 V if a 100-M Ω resistance is used across C_1 . It is preferable to provide a high effective resistance by using a network of resistors, each of which has a value of 1 M Ω or less.

The effective feedback resistance R' in the practical circuit of Fig. 15.3.6b is given by $R' = R_3(R_1 + R_2)/R_2$, assuming that $R_3 > 10R_1R_2/(R_1 + R_2)$. Output drift is further reduced by selecting $R_4 = R_3 + R_1R_2/(R_1 + R_2)$. Resistor R_5 is used to provide an upper frequency rolloff at $f = 1/2\pi R_5 C_s$, which improves the signal-to-noise ratio.

Amplifier-gain stability is enhanced by the use of feedback since the gain of the amplifier with feedback is relatively insensitive to changes in the open-loop amplifier gain G provided that the loop gain GH is high. For example, if the open-loop gain G changes by 10 percent from 100,000 to 90,000 and the feedback divider gain H remains constant at 0.01, the closed-loop gain $G/(1 + GH) \approx 99.9$ changes only 0.011 percent.

If a high closed-loop gain is required, simply decreasing the value of H will reduce the value of GH and thereby reduce the accuracy. The desired accuracy can be maintained by cascading two or more amplifiers, thereby reducing the closed-loop gain required from each amplifier. Each amplifier has its own individual feedback, and no feedback is applied around the cascaded amplifiers. In this case, it is unwise to cascade more stages than needed to achieve a reasonable value of GH in each individual amplifier, since excessive loop gain will make the individual stages more prone to oscillation and the overall system will exhibit increased sensitivity to noise transients.

Chopper amplifiers are used for amplifying dc signals in applications requiring very low drift. The dc input signal is converted by a chopper to a switched ac signal having an amplitude proportional to the input signal and a phase of 0 or 180° with respect to the chopper reference frequency, depending on the polarity of the input signal. This ac signal is amplified by an ac amplifier, which eliminates the drift problem, and then is converted back into a proportional dc output voltage by a phase-sensitive demodulator.

The frequency response of a chopper amplifier is theoretically limited to one-half the carrier frequency. In practice, however, the frequency response is much lower than the theoretical limit. High-frequency components in the input signal exceeding the theoretical limit are removed to avoid unwanted beat signals with the chopper frequency.

FIGURE 15.3.7 Chopper amplifier.

The chopper amplifier of Fig. 15.3.7 consists of a low-pass filter to attenuate high frequencies, an input chopper, an ac amplifier, a phase-sensitive demodulator, and a low-pass output filter to attenuate the chopper ripple component in the output signal. The frequency response of this amplifier is limited to a small fraction of the chopper frequency.

The frequency-response limitation of the chopper amplifier can be overcome by using the chopper amplifier for the dc and low-frequency signals and a separate ac amplifier for the higher-frequency signals, as shown in Fig. 15.3.8. Simple shunt field-effect-transistor choppers Q_1 and Q_2 are used for modulation and detection, respectively. Capacitor C_T is used to minimize spikes at the input to the ac amplifier.

A CMOS auto-zeroed operational amplifier, which contains a built-in chopper amplifier, has typical specifications of $0.7 \mu\text{V}$ input offset voltage, $0.01 \mu\text{V}/^\circ\text{C}$ average offset voltage drift, and 15 pA input bias current (see Table 15.3.1).

Modulator-demodulator systems avoid the drift problems of dc amplifiers by using a modulated carrier which can be amplified by ac amplifiers (Fig. 15.3.9). Inputs and outputs may be either electrical or mechanical.

The varactor modulator (Fig. 15.3.10) takes advantage of the variation of diode-junction capacitance with voltage to modulate a sinusoidal carrier. The carrier and signal voltages applied to the diodes are small, and the diodes never reach a low-resistance condition. Input bias currents of the order of 0.01 pA are possible. For zero signal input, the capacitance values of the diodes are equal, and the carrier signals coupled by the diodes cancel. A dc-input signal will increase the capacitance of one diode while decreasing the capacitance of the other and thereby produce a carrier imbalance signal which is coupled to the ac amplifier by capacitor C_2 . A phase-sensitive demodulator, such as field-effect transistor Q_2 of Fig. 15.3.8, may be used to recover the dc signal.

The magnetic amplifier and second-harmonic modulator can also be used to convert dc-input signals to modulation on a carrier, which is amplified and later demodulated. Mechanical-input modulators include ac-driven potentiometers, linear variable differential transformers, and synchros. The amplified ac carrier can be converted directly into a mechanical output by a two-phase induction servomotor.

FIGURE 15.3.8 Chopper-stabilized dc amplifier.

FIGURE 15.3.9 Modulator-demodulator system.

FIGURE 15.3.10 Basic varactor modulator.

FIGURE 15.3.11 Analog integrator.

Integrators are often required in systems where the transducer signal is a derivative of the desired output, e.g., when an accelerometer is used to measure the velocity of a vibrating object. The output of the analog integrator of Fig. 15.3.11 consists of an integrated signal term plus error terms caused by the offset voltage V_{os} and the bias currents I_{b1} and I_{b2}

$$e_0 = \frac{1}{R_1 C} \int e_1 dt + \frac{1}{R_1 C} \int (V_{os} + I_{b1} R_1 - I_{b2} R_2) dt$$

These error terms will cause the integrator to saturate unless the integrator is reset periodically or a feedback path exists, which tends to drive the output toward a given level within the linear range. In the accelerometer integrator, accurate integration may not be required below a given frequency, and the desired stabilizing feedback path can be introduced by incorporating a large effective resistance across the capacitor using the technique shown in Fig. 15.3.6b.

Digital processing of analog quantities is frequently used because of the availability of high-performance analog-to-digital (A/D) converters, digital-to-analog (D/A) converters, microprocessors, and other special digital processors. The analog input signal (Fig. 15.3.12) is converted into a sequence of digital values by the A/D converter. The digital values are processed by the microprocessor (see “The microprocessor”) or other digital processor, which can be programmed to provide a wide variety of functions including linear or nonlinear gain characteristics, digital filtering, integration, differentiation, modulation, linearization of signals from nonlinear transducers, computation, and self-calibration. The Texas Instruments TMS 320 series of digital processors are specially designed for these applications.

The digital output may be used directly or converted back into an analog signal by the D/A converter. Commercial A/D converter modules are available with 15-bit resolution and 17- μ s conversion times using the successive-approximation technique (Analog Devices AD 376, Burr Brown ADC 76). Monolithic integrated-circuit A/D converters are available with 12-bit resolution and 6- μ s conversion times (Harris HI-774A). An 18-bit D/A converter with a full-scale current output of 100 mA and a compliance voltage range of ± 12 V has been

FIGURE 15.3.12 Digital processing of analog signals.

built at the National Bureau of Standards (Schoenwetter). It exhibits a settling time to $1/2$ least significant bit (2 ppm) of less than $20 \mu\text{s}$. Commercial 16- and 18-bit D/A converters are available with 2-mA full-scale outputs (Analog Devices DAC1136/1138, Burr Brown DAC 70).

The application of A/D converters, D/A converters, and sample-and-hold (S/H) circuits requires careful consideration of their static and dynamic characteristics.

The microprocessor is revolutionizing instrumentation and control. The digital processing power that previously cost many thousands of dollars has been made available on a silicon integrated-circuit chip for only a few dollars. A microcomputer system (Fig. 15.3.13) consists of a microprocessor central processing unit (CPU), memory, and input-output ports. A typical microprocessor-based system consists of the 8051 microprocessor, which provides 4 kbytes of read-only memory (ROM), 128 bytes of random-access memory (RAM), 2 timers and 32 input-output lines, and a number of additional RAM and ROM memory chips as needed for a particular application. The microprocessor can provide a number of features at little incremental cost by means of software modification. Typical features include automatic ranging, self-calibration,

self-diagnosis, data conversion, data processing, linearization, regulation, process monitoring, and control. Instruments using microprocessors are described in Chaps. 15.2 and 15.4.

Instrument systems can be automated by connecting the instruments to a computer using the IEEE-448 general purpose interface bus (Santoni). The bus can connect as many as 14 individually addressable instruments to a host computer port. Full control capability requires the selection of instruments that permit bus control of front panel settings as well as bus data transfers.

Voltage comparators are useful in a number of applications, including signal comparison with a reference, positive and negative signal-peak detection, zero-crossing detection, A/D successive-approximation converter systems, crystal oscillators, voltage-controlled oscillators, magnetic-transducer voltage detection, pulse generation, and square-wave generation. Comparators with input offset voltages of 2 mV and input offset currents of 5 nA are commercially available.

Analog switches using field-effect-transistor (FET) technology are used in general-purpose high-level switching ($\pm 10 \text{ V}$), multiplexing, A/D conversion, chopper applications, set-point adjustment, and bridge circuits. Logic and schematic diagrams of a typical bilateral switch are shown in Fig. 15.3.14. The switch provides the required isolation between the data signal and the control signal. Typical switches provide zero offset voltage, on resistance of 35Ω , and leakage current of 0.04 nA. Multiple-channel switches are commercially available in a single package.

Output Indicators. A variety of analog and digital output indicators can be used to display and record the output from the signal-processing circuitry.

CHAPTER 15.4

BRIDGE CIRCUITS, DETECTORS, AND AMPLIFIERS

Francis T. Thompson

PRINCIPLES OF BRIDGE MEASUREMENTS

Bridge circuits are used to determine the value of an unknown impedance in terms of other impedances of known value. Highly accurate measurements are possible because a null condition is used to compare ratios of impedances.

The most common bridge arrangement (Fig. 15.4.1) contains four branch impedances, a voltage source, and a null detector. Galvanometers, alone or with chopper amplifiers, are used as null detectors for dc bridges; while telephone receivers, vibration galvanometers, and tuned amplifiers with suitable detectors and indicators are used for null detection in ac bridges. The voltage across an infinite-impedance detector is

$$V_d = \frac{(Z_1 Z_3 - Z_2 Z_x)E}{(Z_1 + Z_2)(Z_3 + Z_x)}$$

If the detector has a finite impedance Z_5 , the current in the detector is

$$I_d = \frac{(Z_1 Z_3 - Z_2 Z_x)E}{Z_5(Z_1 + Z_2)(Z_3 + Z_x) + Z_1 Z_2(Z_3 + Z_x) + Z_3 Z_x(Z_1 + Z_2)}$$

where E is the potential applied across the bridge terminals.

A null or balance condition exists when there is no potential across the detector. This condition is satisfied, independent of the detector impedance, when $Z_1 Z_3 = Z_2 Z_x$. Therefore, at balance, the value of the unknown impedance Z_x can be determined in terms of the known impedances Z_1 , Z_2 , and Z_3 :

$$Z_x = Z_1 Z_3 / Z_2$$

Since the impedances are complex quantities, balance requires that both magnitude and phase angle conditions be met: $|Z_x| = |Z_1| \cdot |Z_3| / |Z_2|$ and $\theta_x = \theta_1 + \theta_3 - \theta_2$. Two of the known impedances are usually fixed impedances, while the third impedance is adjusted in resistance and reactance until balance is attained.

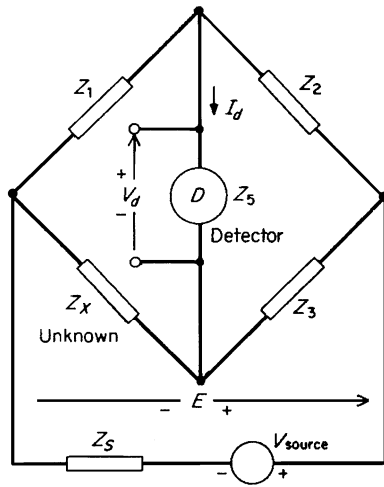

FIGURE 15.4.1 Basic impedance bridge.

$E\delta/4$ when the phase angles θ_3 and θ_x are equal; $\Delta V_d = E\delta/2$ when the phase angles θ_3 and θ_x are in quadrature; and ΔV_d is infinite when $\theta_3 = -\theta_x$, as is the case with lossless reactive components of opposite sign. In practice, the value of the adjustable impedance must be sufficiently large to ensure that the resolution provided by the finest adjusting step permits the desired precision to be obtained. This value may not be compatible with the highest sensitivity, but adequate sensitivity can be obtained for an order-of-magnitude difference between Z_3 and Z_x or Z_1 and Z_2 , especially if a tuned-amplifier detector is used.

Interchanging the source and detector can be shown to be equivalent to interchanging impedances Z_1 and Z_3 . This interchange does not change the equation for balance but does change the sensitivity of the bridge. For a fixed applied voltage E higher sensitivity is obtained with the detector connected from the junction of the two high-impedance arms to the junction of the two low-impedance arms.

The source voltage must be carefully selected to ensure that the allowable power dissipation and voltage ratings of the known and unknown impedances of the bridge are not exceeded. If the bridge impedances are low with respect to the source impedance Z_s , the bridge-terminal voltage E will be lowered. This can adversely affect the sensitivity, which is proportional to E . The source for an ac bridge should provide a pure sinusoidal voltage since the harmonic voltages will usually not be nulled when balance is achieved at the fundamental frequency. A tuned detector is helpful in achieving an accurate balance.

Balance Convergence. The process of balancing an ac bridge consists of making successive adjustments of two parameters until a null is obtained at the detector. It is desirable that these parameters do not interact and that convergence be rapid.

The equation for balance can be written in terms of resistances and reactances as

$$R_x + jX_x = (R_1 + jX_1)(R_3 + jX_3)/(R_2 + jX_2)$$

Balance can be achieved by adjusting any or all of the six known parameters, but only two of them need be adjusted to achieve the required equality of both magnitude and phase (or real and imaginary components). In a ratio-type bridge, one of the arms adjacent to the unknown, either Z_1 and Z_3 , is adjusted. Assuming that Z_1 is adjusted, then to make the resistance adjustment independent of the change in the corresponding reactance, the ratio $(R_3 + jX_3)/(R_2 + jX_2)$ must be either real or imaginary but not complex. If this ratio is equal to the real number k , then for balance $R_x = kR_1$ and $X_x = kX_1$. In a product-type bridge, the arm opposite the unknown Z_2

The sensitivity of the bridge can be expressed in terms of the incremental detector current ΔI_d for a given small per-unit deviation δ of the adjustable impedance from the balance value. If Z_1 is adjusted, $\delta = \Delta Z_1/Z_1$ and

$$\Delta I_d = \frac{Z_3 Z_x E \delta}{(Z_3 + Z_x)^2 [Z_5 + Z_1 Z_2 / (Z_1 + Z_2) + Z_3 Z_x / (Z_3 + Z_x)]}$$

when Z_5 is the detector impedance.

If a high-input-impedance amplifier is used for the detector and impedance Z_5 can be considered infinite, the sensitivity can be expressed in terms of the incremental input voltage to the detector ΔV_d for a small deviation from balance

$$\Delta V_d = Z_3 Z_x E \delta / (Z_3 + Z_x)^2 = Z_1 Z_2 E \delta / (Z_1 + Z_2)^2$$

where $\delta = \Delta Z_1/Z_1$ and ΔZ_1 is the deviation of impedance Z_1 from its balance value Z_1 . Maximum sensitivity occurs when the magnitudes of Z_3 and Z_x are equal (which for balance implies that the magnitudes of Z_1 and Z_2 are equal). Under this condition, $\Delta V_d =$

$E\delta/4$ when the phase angles θ_3 and θ_x are equal; $\Delta V_d = E\delta/2$ when the phase angles θ_3 and θ_x are in quadrature; and ΔV_d is infinite when $\theta_3 = -\theta_x$, as is the case with lossless reactive components of opposite sign. In practice, the value of the adjustable impedance must be sufficiently large to ensure that the resolution provided by the finest adjusting step permits the desired precision to be obtained. This value may not be compatible with the highest sensitivity, but adequate sensitivity can be obtained for an order-of-magnitude difference between Z_3 and Z_x or Z_1 and Z_2 , especially if a tuned-amplifier detector is used.

Interchanging the source and detector can be shown to be equivalent to interchanging impedances Z_1 and Z_3 . This interchange does not change the equation for balance but does change the sensitivity of the bridge. For a fixed applied voltage E higher sensitivity is obtained with the detector connected from the junction of the two high-impedance arms to the junction of the two low-impedance arms.

The source voltage must be carefully selected to ensure that the allowable power dissipation and voltage ratings of the known and unknown impedances of the bridge are not exceeded. If the bridge impedances are low with respect to the source impedance Z_s , the bridge-terminal voltage E will be lowered. This can adversely affect the sensitivity, which is proportional to E . The source for an ac bridge should provide a pure sinusoidal voltage since the harmonic voltages will usually not be nulled when balance is achieved at the fundamental frequency. A tuned detector is helpful in achieving an accurate balance.

Balance Convergence. The process of balancing an ac bridge consists of making successive adjustments of two parameters until a null is obtained at the detector. It is desirable that these parameters do not interact and that convergence be rapid.

The equation for balance can be written in terms of resistances and reactances as

$$R_x + jX_x = (R_1 + jX_1)(R_3 + jX_3)/(R_2 + jX_2)$$

Balance can be achieved by adjusting any or all of the six known parameters, but only two of them need be adjusted to achieve the required equality of both magnitude and phase (or real and imaginary components). In a ratio-type bridge, one of the arms adjacent to the unknown, either Z_1 and Z_3 , is adjusted. Assuming that Z_1 is adjusted, then to make the resistance adjustment independent of the change in the corresponding reactance, the ratio $(R_3 + jX_3)/(R_2 + jX_2)$ must be either real or imaginary but not complex. If this ratio is equal to the real number k , then for balance $R_x = kR_1$ and $X_x = kX_1$. In a product-type bridge, the arm opposite the unknown Z_2

FIGURE 15.4.2 Linearized convergence locus.

is adjusted for balance, and the product of Z_1Z_3 must be either real or imaginary to make the resistance adjustment independent of the reactance adjustment.

Near balance, the denominator of the equation giving the detector voltage (or current) changes little with the varied parameter, while the numerator changes considerably. The usual convergence loci, which consist of circular segments, can be simplified to obtain linear convergence loci by assuming that the detector voltage near balance is proportional to the numerator, $Z_1Z_3 - Z_2Z_x$. Values of this quantity can be plotted on the complex plane. When only a single adjustable parameter is varied, a straight-line locus will be produced as shown in Fig. 15.4.2. Varying the other adjustable parameter will produce a different straight-line locus. The rate of convergence to the origin (balance condition) will be most rapid if these two loci are perpendicular, slow if they intersect at a small angle, and zero if they are parallel. The cases of independent resistance and reactance adjustments described above correspond to perpendicular loci.

RESISTANCE BRIDGES

The Wheatstone bridge is used for the precise measurement of two-terminal resistances. The lower limit for accurate measurement is about $1\ \Omega$, because contact resistance is likely to be several milliohms. For simple galvanometer detectors, the upper limit is about $1\ \text{M}\Omega$, which can be extended to 10^{12} by using a high-impedance high-sensitivity detector and a guard terminal to substantially eliminate the effects of stray leakage resistance to ground.

The Wheatstone bridge (Fig. 15.4.3) although historically older, may be considered as a resistance version of the impedance bridge of Fig. 15.4.1, and therefore the sensitivity equations are applicable. At balance

$$R_x = R_1R_3/R_2$$

Known fixed resistors, having values of 1, 10, 100, or $1000\ \Omega$, are generally used for two arms of the bridge, for example, R_2 and R_3 . These arms provide a ratio R_3/R_2 , which can be selected from 10^{-3} to 10^3 . Resistor R_1 , typically adjustable to $10,000\ \Omega$ in 1- or $0.1\text{-}\Omega$ steps, is adjusted to achieve balance. The ratio R_3/R_2 should be chosen so that R_1 can be read to its full precision. The magnitudes of R_2 and R_3 should be chosen to maximize the sensitivity while taking care not to draw excessive current.

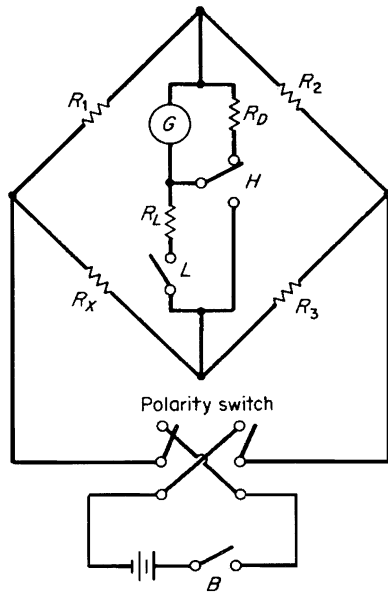

FIGURE 15.4.3 Wheatstone bridge.

FIGURE 15.4.4 Kelvin double bridge. $A + B$ is typically $1000\ \Omega$ and $\alpha + \beta$ is typically $1000\ \Omega$.

An alternate arrangement using R_1 and R_2 for the ratio resistors and adjusting R_3 for balance will generally provide a different sensitivity.

The battery key B should be depressed first to allow any reactive transients to decay before the galvanometer key is depressed. The low-galvanometer-sensitivity key L should be used until the bridge is close to balance. The high-sensitivity key H is then used to achieve the final balance. Resistance R_D provides critical damping between the galvanometer measurements. The battery connections to the bridge may be reversed and two separate resistance determinations made to eliminate any thermoelectric errors.

The Kelvin double bridge (Fig. 15.4.4) is used for the precise measurement of low-value four-terminal resistors in the range $1\ \mu\Omega$ to $10\ \Omega$. The resistance to be measured X and a standard resistance S are connected by means of their current terminals in a series loop containing a battery, an ammeter, an adjustable resistor, and a low-resistance link l . Ratio-arm resistances A and B and α and β are connected to the potential terminals of resistors X and S as shown. The equation for balance is

$$X = S \frac{A}{B} + \frac{\beta l}{\alpha + \beta + l} \left(\frac{A}{B} - \frac{\alpha}{\beta} \right)$$

If the ratio α/β is made equal to the ratio A/B , the equation reduces to $X = S(A/B)$.

The equality of the ratios should be verified after the bridge is balanced by removing the link. If $\alpha/\beta = A/B$, the bridge will remain balanced. Lead resistances r_1 , r_2 , r_3 , and r_4 between the bridge and the potential terminals of the resistors may contribute to ratio imbalance unless they have the same ratio as the arms to which they are connected. Ratio imbalance caused by lead resistance can be compensated by shunting α or β with a high resistance until balance is obtained with the link removed.

In some bridges a fixed standard resistor S having a value of the same order of magnitude as resistor X is used. Fixed resistors of 10 , 100 , or $1000\ \Omega$ are used for two arms, for example, B and β , with B and β having equal values. Bridge balance is obtained by adjusting tap switches to select equal resistances for the other two arms, for example, A and α , from values adjustable up to $1000\ \Omega$ in $0.1\text{-}\Omega$ steps. In other bridges, only decimal ratio resistors are provided for A , B , α , and β , and balance is obtained by means of an adjustable standard having nine steps of $0.001\ \Omega$ each and a Manganin slide bar of $0.0011\ \Omega$.

FIGURE 15.4.5 Comparator ratio bridge.

The battery connection should be reversed and two separate resistance determinations made to eliminate thermoelectric errors.

The dc-comparator ratio bridge (Fig. 15.4.5) is used for very precise measurement of four-terminal resistors. Its accuracy and stability depend mainly on the turns ratio of a precision transformer. The master current supply is set at a convenient fixed value I_x . The zero-flux detector maintains an ampere-turn balance, $I_x N_x = I_s N_s$, by automatically adjusting the current I_s from the slave supply as N_x is manually adjusted. A null reading on the galvanometer is obtained when $I_s R_s = I_x R_x$. Since the current ratio is precisely related to the turns ratio, the unknown resistance $R_x = N_x R_s / N_s$. Fractional turn resolution for N_x can be obtained by diverting a fraction of the current I_x as obtained from a decade current divider through an additional winding on the transformer. Turns ratios have

been achieved with an accuracy of better than 1 part in 10^7 . The zero-flux detector operates by superimposing a modulating mmf on the core using modulation and detector windings in a second-harmonic modulator configuration. The limit sensitivity of the bridge is set by noise and is about $3 \mu\text{A}$ turns.

Murray and Varley bridge circuits are used for locating faults in wire lines and cables. The faulted line is connected to a good line at one end by means of a jumper to form a loop. The resistance r of the loop is measured using a Wheatstone bridge. The loop is then connected as shown in Fig. 15.4.6 to form a bridge in which one arm contains the resistance R_x between the test set and the fault and the adjacent arm contains the remainder of the loop resistance. The galvanometer detector is connected across the open terminals of the loop, while the voltage supply is connected between the fault and the junction of fixed resistor R_2 and variable resistor R_3 . When balance is attained

$$R_x = rR_3 / (R_2 + R_3)$$

where r is the resistance of the loop. Resistance R_x is proportional to the distance to the fault. In the Varley loop of Fig. 15.4.7, variable resistor R_1 is adjusted to achieve balance and

$$R_x = \frac{rR_3 - R_1R_2}{R_2 + R_3}$$

where r is the resistance of the loop.

FIGURE 15.4.7 Varley loop circuit.

INDUCTANCE BRIDGES

General. Many bridge types are possible since the impedance of each arm may be a combination of resistances, inductances, and capacitances. A number of popular inductance bridges are shown in Fig. 15.4.8. In the balance equations L and M are given in henrys, C in farads, and R in ohms; ω is 2π times the frequency in hertz. The Q of an inductance is equal to $\omega L/R$, where R is the series resistance of the inductance.

The symmetrical inductance bridge (Fig. 15.4.8a) is useful for comparing the impedance of an unknown inductance with that of a known inductance. An adjustable resistance is connected in series with the inductance having the higher Q , and the inductance and resistance values of this resistance are added to those of the associated inductance to obtain the impedance of that arm. If this series resistance is adjusted along with the known inductance to obtain balance, the resistance and reactance balances are independent and balance convergence is rapid. If only a fixed inductance is available, the series resistance is adjusted along with the ratio R_3/R_2 until balance is obtained. These adjustments are interacting, and the rate of convergence will be proportional to the Q of the unknown inductance. Care must be taken to avoid inductive coupling between the known and unknown inductances since it will cause a measurement error.

The Maxwell-Wien bridge (Fig. 15.4.8b) is widely used for accurate inductance measurements. It has the advantage of using a capacitance standard which is more accurate and easier to shield and produces practically no external field. R_2 and C_2 are usually adjusted since they provide a noninteracting resistance and inductance balance. If C_2 is fixed and R_2 and R_1 or R_3 are adjusted, the balance adjustments interact and balancing may be tedious.

Anderson's bridge (Fig. 15.4.8c) is useful for measuring a wide range of inductances with reasonable values of fixed capacitance. The bridge is usually balanced by adjusting r and a resistance in series with the unknown inductance. Preferred values for good sensitivity are $R_1 = R_2 = R_3/2 = R_x/2$ and $L/C = 2R_x^2$. This bridge is also used to measure the residuals of resistors using a substitution method to eliminate the effects of residuals in the bridge elements.

Owen's bridge (Fig. 15.4.8d) is used to measure a wide range of inductance values in terms of resistance and capacitance. The inductance and resistance balances are independent if R_3 and C_3 are adjusted. The bridge can also be balanced by adjusting R_1 and R_3 .

This bridge is useful for finding the incremental inductance of iron-cored inductors to alternating current superimposed on a direct current. The direct current can be introduced by connecting a dc-voltage source with a large series inductance across the detector branch. Low-impedance blocking capacitors are placed in series with the detector and the ac source.

Hay's bridge (Fig. 15.4.8e) is similar to the Maxwell-Wien bridge and is used for measuring inductances having large values of Q . The series $R_2 C_2$ arrangement permits the use of smaller resistance values than the parallel arrangement. The frequency-dependent $1/Q_x^2$ term in the inductance equation is inconvenient since the dials cannot be calibrated to indicate inductance directly unless the term is neglected, which causes a 1 percent error for $Q_x = 10$.

$$R_X = R_1 R_3 / R_2$$

$$L_X = L_1 R_3 / R_2$$

(a)

$$L_X = R_1 R_3 C_2$$

$$R_X = R_1 R_3 / R_2$$

(b)

$$R_X = R_1 R_3 / R_2$$

$$L = R_1 R_3 C (1 + r/R_1 + r/R_2)$$

(c)

$$R_X = R_1 C_2 / C_3$$

$$L_X = R_1 R_3 C_2$$

(d)

$$R_X = R_1 R_3 / (R_2 Q_X^2 + R_2)$$

$$L_X = R_1 R_3 C_2 / (1 + 1/Q_X^2)$$

$$Q_X = \omega L_X / R_X = 1 / (\omega R_2 C_2)$$

(e)

$$M_X = M_S R_3 / R_2$$

$$L_X = (L_1 + L_S) R_3 / R_2$$

$$R_X = R_1 R_3 / R_2$$

(f)

FIGURE 15.4.8 Inductance bridges: (a) symmetrical inductance bridge; (b) Maxwell-Wien bridge; (c) Anderson's bridge; (d) Owen's bridge; (e) Hay's bridge; (f) Campbell's bridge.

This bridge is also used for determining the incremental inductance of iron-cored reactors, as discussed for Owen's bridge.

Campbell's bridge (Fig. 15.4.8f) for measuring mutual inductance makes possible the comparison of unknown and standard mutual inductances having different values. The resistances and self-inductances of the primaries are balanced with the detector switches to the right by adjusting L_1 and R_1 . The switches are thrown to the left, and the mutual-inductance balance is made by adjusting M_s . Care must be taken to avoid coupling between the standard and unknown inductances.

CAPACITANCE BRIDGES

Capacitance bridges are used to make precise measurements of capacitance and the associated loss resistance in terms of known capacitance and resistance values. Several different bridge circuits are shown in Fig. 15.4.9. In the balance equations R is given in ohms and C in farads, and ω is 2π times the frequency in hertz. The loss angle δ of a capacitor may be expressed either in terms of its series loss resistance r_s , which gives $\tan \delta = \omega C r_s$, or in terms of the parallel loss resistance r_p , in which case, $\tan \delta = 1/\omega C r_p$.

$$R_x = R_1 R_3 / R_2$$

$$C_x = C_1 R_2 / R_3$$

(a)

$$R_x = R_3 (1 + \omega^2 R_1^2 C_1^2) / (\omega^2 R_1 R_2 C_1^2)$$

$$C_x = C_1 R_2 / [R_3 (1 + \omega^2 R_1^2 C_1^2)]$$

(b)

$$R_x = C_2 R_3 / C_1$$

$$C_x = C_1 R_2 / R_3$$

(c)

$$C_1 = C_2 + N_b C_5$$

$$\delta_1 = \delta_2 \frac{C_2}{C_1} + N_b \delta_5 \frac{C_5}{C_1} - N_a C_3 / [R \omega C_1 (C_3 + C_4)]$$

(d)

FIGURE 15.4.9 Capacitance bridges: (a) series-resistance-capacitance bridge; (b) Wien bridge; (c) Schering's bridge; (d) transformer bridge.

The Series RC bridge (Fig. 15.4.9a) is a resistance-ratio bridge used to compare a known capacitance with an unknown capacitance. The adjustable series resistance is added to the arm containing the capacitor having the smaller loss angle δ .

The Wien bridge (Fig. 15.4.9b) is useful for determining the equivalent capacitance C_x and parallel loss resistance R_x of an imperfect capacitor, e.g., a sample of insulation or a length of cable.

An important application of the Wien bridge network is its use as the frequency-determining network in RC oscillators.

Schering's bridge (Fig. 15.4.9c) is widely used for measuring capacitance and dissipation factors. The unknown capacitance is directly proportional to known capacitance C_1 . The dissipation factor $\omega C_1 R_x$ can be measured with good accuracy using this bridge. The bridge is also used for measuring the loss angles of high-voltage power cables and insulators. In this application, the bridge is grounded at the R_2/R_3 node, thereby keeping the adjustable elements R_2 , R_3 , and C_2 at ground potential.

The transformer bridge is used for the precise comparison of capacitors, especially for three-terminal shielded capacitors. A three-winding toroidal transformer having low leakage reactance is used to provide a stable ratio, known to better than 1 part in 10^7 . In Fig. 15.4.9d capacitors C_1 and C_2 are being compared, and a balance scheme using inductive-voltage dividers a and b is shown. It is assumed that $C_1 > C_2$ and loss angle $\delta_2 > \delta_1$. In-phase current to balance any inequality in magnitude between C_1 and C_2 is injected through C_5 while quadrature current is supplied by means of resistor R and current divider $C_3/(C_3 + C_4)$. The current divider permits the value of R to be kept below 1 M Ω . Fine adjustments are provided by dividers a and b . N_a is the fraction of the voltage E_1 that is applied to R , while N_b is the fraction of the voltage E_2 applied to C_5 , δ_1 is the loss angle of capacitor C_1 and $\tan \delta_1 = \omega C_1 r_1$, where r_1 is the series loss resistance associated with C_1 . The impedance of C_3 and C_4 in parallel must be small compared with the resistance of R .

The substitution-bridge method is particularly valuable for determining the value of capacitance at radio frequency. The *shunt-substitution method* is shown for the series RC bridge in Fig. 15.4.10. Calibrated adjustable standards R_s and C_s are connected as shown, and the bridge is balanced in the usual manner with the unknown capacitance disconnected. The unknown is then connected in parallel with C_s , and C_s and R_s are readjusted to obtain balance. The unknown capacitance C_x and its equivalent series resistance R_x are determined by the rebalancing changes ΔC_s and ΔR_s in C_s and R_s , respectively: $C_x = \Delta C_s$ and $R_x = \Delta R_s (C_{s1}/C_x)^2$, where C_{s1} is the value of C_s in the initial balance.

FIGURE 15.4.10 Substitution measurement.

In *series substitution* the bridge arm is first balanced with the standard elements alone, the standard elements having an impedance of Z_{s1} , and then the unknown is inserted in series with the standard elements. The standard elements are readjusted to an impedance Z_{s2} to restore balance. The unknown impedance Z_x is equal to the change in the standard impedance, that is, $Z_x = Z_{s1} - Z_{s2}$.

Measurement accuracy depends on the accuracy with which the changes in the standard values are known. The effects of residuals, stray capacitance, stray coupling, and inaccuracies in the impedances of the other three bridge arms are minimal, since these effects are the same with and without the unknown impedance. The proper handling of the leads used to connect the unknown impedance can be important.

FACTORS AFFECTING ACCURACY

Stray Capacitance and Residuals. The bridge circuits of Figs. 15.4.8 and 15.4.9 are idealized since stray capacitances which are inevitably present and the residual inductances associated with resistances and connecting leads have been neglected. These spurious circuit elements can disturb the balance conditions and

FIGURE 15.4.11 Stray capacitances in unshielded and ungrounded bridge.

FIGURE 15.4.12 Bridge with shields and ground.

result in serious measurement errors. Detailed discussions of the residuals associated with the various bridges are given in Souders.

Shielding and grounding can be used to control errors caused by stray capacitance. Stray capacitances in an ungrounded, unshielded series RC bridge are shown schematically by C_1 through C_{12} in Fig. 15.4.11. The elements of the bridge may be enclosed in the grounded metal shield, as shown schematically in Fig. 15.4.12. Shielding and grounding eliminate some capacitances and make the others definite localized capacitances which act in a known way as illustrated in Fig. 15.4.13. The capacitances associated with terminal D shunt the oscillator and have no adverse effect. The possible adverse effects of the capacitance associated with the output diagonal EF are overcome by using a shielded output transformer. If the shields are adjusted so that $C_{22}/C_{21} = R_a/R_b$, the ratio of the bridge is independent of frequency. Capacitance C_{24} can be taken into account in the calibration of C_s , and capacitance C_{23} can be measured and its shunting effect across the unknown impedance can be calculated. Shielding, which is used at audio frequencies, becomes more necessary as the frequency and impedance levels are increased.

Guard circuits (Fig. 15.4.14) are often used at critical circuit points to prevent leakage currents from causing measurement errors. In an unguarded circuit surface leakage current may bypass the resistor R and flow through the detector G , thereby giving an erroneous reading. If a guard ring surrounds the positive terminal

FIGURE 15.4.13 Schematic circuit of shielded and grounded bridge.

FIGURE 15.4.14 Leakage current in guarded circuit. (Leeds and Northrup)

post (as in the circuit of Fig. 15.4.14), the surface leakage current flows through the guard ring and a noncritical return path to the voltage source. A true reading is obtained since only the resistor current flows through the detector.

Coaxial leads and twisted-wire pairs may be used in connecting impedances to a bridge arm in order to minimize spurious-signal pickup from electrostatic and electromagnetic fields. It is important to keep lead lengths short, especially at high frequencies.

BRIDGE DETECTORS AND AMPLIFIERS

Galvanometers are used for null decision in dc bridges. The permanent-magnet moving-coil d'Arsonval galvanometer is widely used. The suspension provides a restoring torque so that the coil seeks a zero position for zero current. A mirror is used in the sensitive suspension-type galvanometer to reflect light from a fixed source to a scale. This type of galvanometer is capable of sensitivities on the order of $0.001 \mu\text{A}$ per millimeter scale division but is delicate and subject to mechanical disturbances. Galvanometers for portable instruments generally have indicating pointers and use taut suspensions which are less sensitive but more rugged and less subject to disturbances. Sensitivities are typically in the range of $0.5 \mu\text{A}$ per millimeter scale division. Galvanometers exhibit a natural mechanical frequency which depends on the suspension stiffness and the moment of inertia. Overshoot and oscillatory behavior can be avoided without an excessive increase in response time if an external resistance of the proper value to produce critical damping is connected across the galvanometer terminals.

Null-detector amplifiers incorporating choppers or modulators (see Chap. 15.3) are used to amplify the null output signal from dc bridges to provide higher sensitivity and permit the use of rugged, less-sensitive microammeter indicators. Null-detector systems such as the L&N 9838 are available with sensitivities of 10 nV per division for a $300\text{-}\Omega$ input impedance. The Guideline 9460A nanovolt amplifier uses a light-beam-coupled amplifier that can provide 7.5-mm deflection per nV when used with a sensitive galvanometer. The input signal polarity to this amplifier may be reversed without introducing errors because of hysteresis or input offset currents. This reversal-capability is useful to balance out parasitic or thermal emfs in the measured circuit.

Frequency-selective amplifiers are extensively used to increase the sensitivity of ac bridges. An ac amplifier with a twin-T network in the feedback loop provides full amplification at the selected frequency but falls off rapidly as the frequency is changed. Rectifiers or phase-sensitive detectors are used to convert the amplified ac signal into a direct current to drive a dc microammeter indicator. The General Radio 1232-A tuned amplifier and null detector, which is tunable from 20 Hz to 20 kHz with fixed-tuned frequencies of 50 and 100 kHz, provides a sensitivity better than $0.1 \mu\text{V}$. Cathode-ray-tube displays using Lissajous patterns are also used to indicate the deviation from null conditions. Amplifier and detector circuits are described in Chap. 15.3.

MISCELLANEOUS MEASUREMENT CIRCUITS

Multifrequency LCR meters incorporate microprocessor control of ranging and decimal-point positioning, which permits automated measurement of inductance, capacitance, and resistance in less than 1 s. Typical of the new generation of microprocessor instrumentations is the General Radio 1689 Digibridge, which automatically measures a wide range of L , C , R , D , and Q values from 12 Hz to 100 kHz with a basic accuracy of 0.02 percent. This instrument compares sequential measurements rather than obtaining a null condition and therefore is not actually a bridge.

Similar performance is provided by the Hewlett-Packard microprocessor-based 4274A (100 Hz to 100 kHz) and 4275A (10 kHz to 10 MHz) multifrequency LCR meters, which measure the impedance of the device under test at a selected frequency and compute the value of L , C , R , D , and Q as well as the impedance, reactance, conductance, susceptance, and phase angle with a basic accuracy of 0.1 percent.

FIGURE 15.4.15 Q meter. (Hewlett-Packard)

The Q meter is used to measure the quality factor Q of coils and the dissipation factor of capacitors; the dissipation factor is the reciprocal of Q . The Q meter provides a convenient method of measuring the effective values of inductors and capacitors at the frequency of interest over a range of 22 kHz to 70 MHz.

The simplified circuit of a Q meter is shown in Fig. 15.4.15, where an unknown impedance of effective inductance L' and effective resistance r' is being measured. A sinusoidal voltage e is injected by the transformer secondary in series with the circuit containing the unknown impedance and the tuning capacitor C . The transformer secondary has an output impedance of approximately 1 m Ω . Unknown capacitors can be measured by connecting them between the HI and GND terminals while using a known standard inductor for L' .

Either the oscillator frequency or the tuning-capacitor value is adjusted to bring the circuit to approximate resonance, as indicated by a maximum voltage across capacitor C . At resonance $X_{L'} = X_C$ where $X_{L'} = 2\pi fL'$, $X_C = 1/2\pi fC$, L' is the effective inductance in henrys, C is the capacitance in farads, and f is the frequency in hertz. The current at resonance is $I = e/R$, where R is the sum of the resistances of the unknown and the internal circuit. The voltage across the capacitor C is $V_C = IX_C = eX_C/R$, and the indicated circuit Q is equal to V_C/e . In practice, the injected voltage e is known for each Q -range attenuator setting and the meter is calibrated to indicate the value of Q . Corrections for residual resistances and reactances in the internal circuit become increasingly important at higher frequencies (see Chap. 15.2). For low values of Q , neglecting the difference between the resonance and the approximate resonance achieved by maximizing the capacitor voltage may result in an unacceptable error. Exact equations are given in Chap. 15.2.

The rf impedance analyzer is a microprocessor-based instrument designed to measure impedance parameter values of devices and materials in the rf and UHF regions. The basic measurement circuit consists of a signal source, an rf directional bridge, and a vector voltage ratio detector as shown in Fig. 15.4.16. The measurement source produces a selectable 1-MHz to 1-GHz sinusoidal signal using frequency synthesizer techniques. The unknown impedance Z_x is connected to a test port of an rf directional bridge having resistor values Z equal to the 50- Ω characteristic impedance of the measuring circuit. The test-channel and reference-channel signal frequencies are converted to 100 kHz by the sampling i.f. converters in order to improve the accuracy of vector ratio detection. The vector ratio of the test channel and reference channel i.f. signals is detected for both the real and imaginary component vectors. The vector ratio, which is equal to e_2/e_1 , is proportional to the reflection coefficient Γ , where $\Gamma = (Z - Z_x)/(Z + Z_x)$. The microprocessor computes values of L , C , D , Q , R , X , θ , G , and B from the real and imaginary components Γ_x and Γ_y of the reflection coefficient Γ . The basic accuracy of the magnitude of Γ is better than 1 percent, while that of other parameters is typically better than 2 percent.

The twin-T measuring circuit of Fig. 15.4.17 is used for admittance measurements at radio frequencies. This circuit operates on a null principle similar to a bridge circuit, but it has an advantage in that one side of the oscillator and detector are common and therefore can be grounded. The substitution method is used with this circuit, and therefore the effect of stray capacitances is minimized. The circuit is first balanced to a null condition

FIGURE 15.4.16 Rf impedance analyzer. (Hewlett-Packard)

with the unknown admittance $G_x + jB_x$ unconnected.

$$G_L = \omega^2 RC_1 C_2 (1 + C_o / C_3)$$

$$L = 1 / [\omega^2 (C_b + C_1 + C_2 + C_1 C_2 / C_3)]$$

The unknown admittance is connected to terminals a and b , and a null condition is obtained by readjusting the variable capacitors to values C'_a and C'_b . The conductance G_x and the susceptance B_x of the unknown are proportional to the changes in the capacitance settings:

$$G_x = \omega^2 RC_1 C_2 (C'_a - C_a) / C_3 \quad B_x = \omega (C_b - C'_b)$$

Measurement of Coefficient of Coupling. Two coils are inductively coupled when their relative positions are such that lines of flux from each coil link with turns of the other coil. The mutual inductance M in henrys

can be measured in terms of the voltage e induced in one coil by a rate of change of current di/dt in the other coil; $M = -e_1/(di_2/dt) = -e_2/(di_1/dt)$. The maximum coupling between two coils of self-inductance L_1 and L_2 exists when all the flux from each of the coils links all the turns of the other coil; this condition produces the maximum value of mutual inductance, $M_{max} = \sqrt{L_1 L_2}$. The coefficient of coupling k is defined as the ratio of the actual mutual inductance to its maximum value; $k = M/\sqrt{L_1 L_2}$.

The value of mutual inductance can be measured using Campbell's mutual-inductance bridge. Alternately, the mutual inductance can be measured using a self-inductance bridge. When the coils are connected in series with the mutual-inductance emf aiding the self-inductance emf (Fig. 15.4.18a), the total inductance $L_a = L_1 + L_2 + 2M$ is measured. With the coils connected with

FIGURE 15.4.17 Twin-T measuring circuit. (General Radio Co.)

FIGURE 15.4.18 Mutual inductance connected for self-inductance measurement: (a) aiding configuration; (b) opposing configuration.

the mutual-inductance emf opposing the self-inductance emf (Fig. 15.4.18b), inductance $L_b = L_1 + L_2 - 2M$ is measured. The mutual inductance is $M = (L_a - L_b)/4$.

Permeameters are used to test magnetic materials. By simulating the conditions of an infinite solenoid, the magnetizing force H can be computed from the ampere-turns per unit length. When H is reversed, the change in flux linkages in a test coil induces an emf whose time integral can be measured by a ballistic galvanometer. The *Burrows permeameter* (Fig. 15.4.19) uses two magnetic specimen bars, S_1 and S_2 , usually 1 cm in diameter and

FIGURE 15.4.19 Burrows permeameter.

30 cm long, joined by soft-iron yokes. High precision is obtainable for magnetizing forces up to 300 Oe. The currents in magnetizing windings M_1 and M_2 and in compensating windings A_1 , A_2 , A_3 , and A_4 are adjusted independently to obtain uniform induction over the entire magnetic circuit. Windings A_1 , A_2 , A_3 , and A_4 compensate for the reluctance of the joints. The reversing switches are mechanically coupled and operate simultaneously. Test coils a and c each have n turns, while each half of the test coil b has $n/2$ turns. Coils a and b are connected in opposing polarity to the galvanometer when the switch is in position b , while coils a and c are opposed across the galvanometer for switch position c .

Potentiometer P1 is adjusted to obtain the desired magnetizing force, and potentiometers P2 and P3 are adjusted so that no galvanometer deflection is obtained on magnetizing current reversal with the switches in either position b or c . This establishes uniform flux density at each coil. The switch is now set at position a and the galvanometer deflection d is noted when the magnetizing current is reversed.

The values of B in gauss and H in oersteds can be calculated from

$$H = \frac{0.4\pi NI}{l} \quad B = 10^8 \frac{dkR}{2an} - \frac{A-a}{a} H$$

where N = turns of coil M_1
 I = current in coil M_1 (A)
 l = length of coil M_1 (cm)
 d = galvanometer deflection
 k = galvanometer constant
 R = total resistance of test coil a circuit
 a = area of specimen (cm²)
 A = area of test coil (cm²)
 n = turns in test coil a

The term $(A - a)H/a$ is a small correction term for the flux in the space between the surface of the specimen and the test coil.

Other permeameters such as the Fahy permeameter, which requires only a single specimen, the Sandford-Winter permeameter, which uses a single specimen of rectangular cross section, and Ewing's isthmus permeameter, which is useful for magnetizing forces as high as 24,000 G, are discussed in Harris.

The frequency standard of the National Institute of Standards and Technology (formerly the National Bureau of Standards) is based on atomic resonance of the cesium atom and is accurate to 1 part in 10^{13} . The second is defined as the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyper-fine levels of the ground state of the atom of cesium 133. Reference frequency signals are transmitted by the NIST radio stations WWV and WWH at 2.5, 5, 10, and 15 MHz. Pulses are transmitted to mark the seconds of each minute. In alternate minutes during most of each hour, 500- or 600-Hz audio tones are broadcast. A binary-coded-decimal time code is transmitted continuously on a 100-Hz subcarrier. The carrier and modulation frequencies are accurate to better than 1 part in 10^{11} .

These frequencies are offset by a known and stable amount relative to the atomic-resonance frequency standard to provide "Coordinated Universal Time" (UTC), which is coordinated through international agreements by the International Time Bureau. UTC is maintained within ± 0.9 s of the UT1 time scale used for astronomical measurements by adding leap seconds about once per year to UTC, depending on the behavior of the earth's rotation.

Quartz-crystal oscillators are used as secondary standards for frequency and time-interval measurement. They are periodically calibrated using the standard radio transmissions.

Frequency measurements can be made by comparing the unknown frequency with a known frequency, by counting cycles over a known time interval, by balancing a frequency-sensitive bridge, or by using a calibrated resonant circuit.

Frequency-comparison methods include using Lissajous patterns on an oscilloscope and heterodyne measurement methods. In Fig. 15.4.20, the frequency to be measured is compared with a harmonic of the 100-kHz reference oscillator. The difference frequency lying between 0 and 50 kHz is selected by the low-pass filter and

FIGURE 15.4.20 Heterodyne frequency-comparison method.

compared with the output of a calibrated audio oscillator using Lissajous patterns. Alternately, the difference frequency and the audio oscillator frequency may be applied to another detector capable of providing a zero output frequency.

Digital frequency meters provide a convenient and accurate means for measuring frequency. The unknown frequency is counted for a known time interval, usually 1 or 10 s, and displayed in digital form. The time interval is derived by counting pulses from a quartz-crystal oscillator reference. Frequencies as high as 50 MHz can be measured by using scalars (frequency dividers). Frequencies as high as 110 GHz are measured using heterodyne frequency-conversion techniques. At low frequencies, for example 60 Hz, better resolution is obtained by measuring the period $T = 1/f$. A counter with a built-in computer is available, which measures the period at low frequencies and automatically calculates and displays the frequency.

A frequency-sensitive bridge can be used to measure frequency to an accuracy of about 0.5 percent if the impedance elements are known. The Wien bridge of Fig. 15.4.21 is commonly used, R_3 and R_4 being identical slide-wire resistors mounted on a common shaft. The equations for balance are $f = 1/2\pi \sqrt{R_3 R_4 C_3 C_4}$ and $R_1/R_2 = R_4/R_3 + C_3/C_4$.

In practice, the values are selected so that $R_3 = R_4$, $C_3 = C_4$, and $R_1 = 2R_2$. Slide wire r , which has a total resistance of $R_1/100$, is used to correct any slight tracking errors in R_3 and R_4 . Under these conditions $f = 1/2\pi R_4 C_4$. A filter is needed to reject harmonics if a null indicator is used since the bridge is not balanced at harmonic frequencies.

Time intervals can be measured accurately and conveniently by gating a reference frequency derived from a quartz-crystal oscillator standard to a counter during the time interval to be measured. Reference frequencies of 10, 1, and 0.1 MHz, derived from a 10-MHz oscillator, are commonly used.

Analog frequency circuits that produce an analog output proportional to frequency are used in control systems and to drive frequency-indicating meters. In Fig. 15.4.22, a fixed amount of charge proportional to $C_1(E - 2d)$, where d is the diode-voltage drop, is withdrawn through diode D_1 during each cycle of the input. The current

FIGURE 15.4.21 Wien frequency bridge.

FIGURE 15.4.22 Frequency-to-voltage converter.

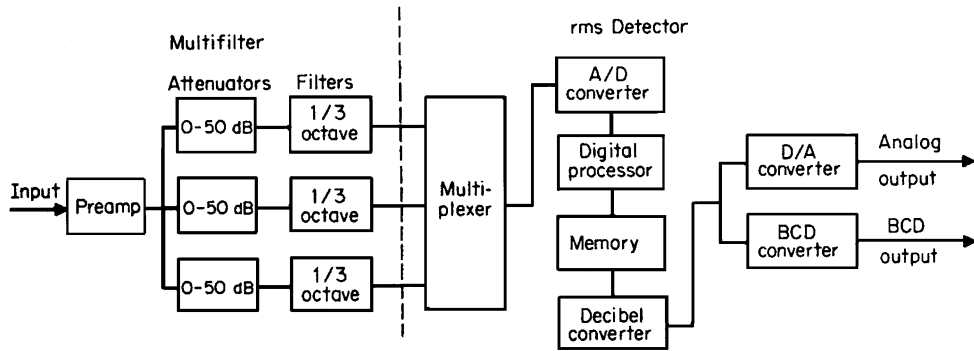

FIGURE 15.4.23 Real-time analyzer using 30 attenuators and filters. (General Radio Co.)

through diode D_1 , which is proportional to frequency, is balanced by the current through resistor R , which is proportional to e_{out} . Therefore, $e_{\text{out}} = fRC_1(E - 2d)$. Temperature compensation is achieved by adjusting the voltage E with temperature so that the quantity $E - 2d$ is constant.

Frequency analyzers are used for measuring the frequency components and analyzing the spectra of acoustic noise, mechanical vibrations, and complex electric signals. They permit harmonic and intermodulation distortion components to be separated and measured. A simple analyzer consists of a narrow-bandwidth filter, which can be adjusted in frequency or swept over the frequency range of interest. The output amplitude in decibels is generally plotted as a function of frequency using a logarithmic frequency scale. Desirable characteristics include wide dynamic range, low distortion, and high stop-band attenuation. Analog filters that operate at the frequency of interest exhibit a constant bandwidth, for example, 10 Hz. The signal must be averaged over a period inversely proportional to the filter bandwidth if the reading is to be within given confidence limits of the long-time average value.

Real-time frequency analyzers are available which perform $1/3$ -octave spectrum analysis on a continuous real-time basis. The analyzer of Fig. 15.4.23 uses 30 separate filters each having a bandwidth of $1/3$ octave to achieve the required speed of response. The multiplexer sequentially samples the filter output of each channel at a high rate. These samples are converted into a binary number by the A/D converter. The true rms values for each channel are computed from these numbers during an integration period adjustable from $1/8$ to 32 s and stored in the memory. The rms value for each channel is computed from 1,024 samples for integration periods of 1 to 32 s.

Real-time analyzers are also available for analyzing narrow-bandwidth frequency components in real time. The required rapid response time is obtained by sampling the input waveform at 3 times the highest frequency of interest using an A/D converter and storing the values of a large number of samples in a digital memory. The frequency components can be calculated in real time by a microprocessor using fast Fourier transforms.

Time-compression systems can be used to preprocess the input signal so that analog filters can be used to analyze narrow-bandwidth frequency components in real time. The time-compression system of Fig. 15.4.24 uses a recirculating digital memory and a D/A converter to provide an output signal having the same waveform as the input with a repetition rate which is k times faster. This multiplies the output-frequency spectrum by a factor of k and reduces the time required to analyze the signal by the same factor. The system operates as follows. A new sample is entered into the circulating memory through gate A during one of each k shifting periods. Information from the output of the memory recirculates through gate B during the remaining $k - 1$ periods. Since information experiences k shifts between the addition of new samples in a memory of length $k - 1$, each new sample p is entered directly behind the previous sample $p - 1$, and therefore the correct order is preserved. $(k - 1)/n$ seconds is required to fill an empty memory, and thereafter the oldest sample is discarded when a new sample is entered.

FIGURE 15.4.24 Time-compression system.

Frequency synthesizers/function generators provide sine wave, square wave, triangle, ramp, or pulse voltage outputs, which are selectable over a wide frequency range and yet have the frequency stability and accuracy of a crystal oscillator reference. They are useful for providing accurate reference frequencies and for making measurements on filter networks, tuned circuits, and communications equipment. High-precision units feature up to 11-decade digital frequency selection and programmable linear or logarithmic frequency sweep. A variety of units are available, which cover frequencies from a fraction of a hertz to tens of gigahertz.

Many synthesizers use the indirect synthesis method shown in Fig. 15.4.25. The desired output frequency is obtained from a voltage-controlled oscillator, which is part of a phase-locked loop. The selectable frequency divider is set to provide the desired ratio between the output frequency and the crystal reference frequency. Fractional frequency division can be obtained by selecting division ratio R alternately equal to N and $N + 1$ for appropriate time intervals.

Time-domain reflectometry is used to identify and locate cable faults. The cable-testing equipment is connected to a line in the cable and sends an electrical pulse that is reflected back to the equipment by a fault in the cable. The original and reflected signals are displayed on an oscilloscope. The type of fault is identified by the shape of the reflected pulse, and the distance is determined by the interval between the original and reflected pulses. Accuracies of 2 percent are typical.

A low-frequency voltmeter using a microprocessor has been developed that is capable of measuring the true rms voltage of approximately sinusoidal inputs at voltages from 2 mV to 10 V and frequencies from 0.1 to 120 Hz. A combination of computer algorithms is used to implement the voltage- and harmonic-analysis functions. Harmonic distortion is calculated using a fast Fourier transform algorithm. The total autoranging, settling, and measurement time is only two signal periods for frequencies below 10 Hz.

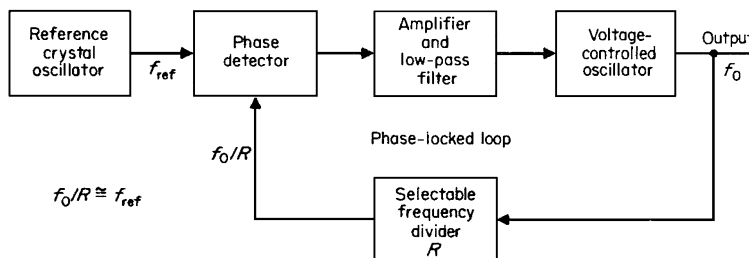

FIGURE 15.4.25 Indirect frequency synthesis.

CHAPTER 15.5

AC IMPEDANCE MEASUREMENT

Ramon C. Lebron

The generation of Impedance Gain and Phase versus frequency plots of an electrical circuit (passive or active) is extremely important to characterize small signal behavior and evaluate stability. In space dc power distribution systems, such as the International Space Station power system, each of the power system components and dc-to-dc converters has to meet strict input and output impedance requirements over a specific frequency range to ensure end-to-end system stability.

Figures 15.5.1 and 15.5.2 show the technique used to measure ac impedance. This test can be performed with the device under test (DUT) operating at rated voltage and rated load. The network analyzer output provides a sinusoidal signal with a frequency that will vary over the desired range. The signal is amplified and fed into the primary of an audio isolation transformer. Figure 15.5.1 shows the method of ac voltage injection by connecting the transformer secondary in series with the power source. The voltage and current amplifiers are ac coupled and the network analyzer is set to generate the magnitude and phase plot of Channel 2 (ac voltage) divided by Channel 1 (ac). Therefore the impedance magnitude plot is $|Z| = |V_{ac}|/|I_{ac}|$ and the impedance phase plot is $\theta_Z = \theta_{vac} - \theta_{iac}$ for the required frequency values.

Figure 15.5.2 shows the method of ac injection where a capacitor and a resistor are connected in series with the secondary of the transformer. The transformer and RC series combination is connected in parallel with the terminals of the DUT to inject a small ac into the DUT. The network analyzer performs the same computations for $|Z|$ and θ_Z at the desired frequency range. The voltage injection method is used for high-impedance measurements such as the input impedance of a dc-to-dc converter, and the current injection method is better suited for low-impedance measurements such as the output impedance of a dc-to-dc converter.

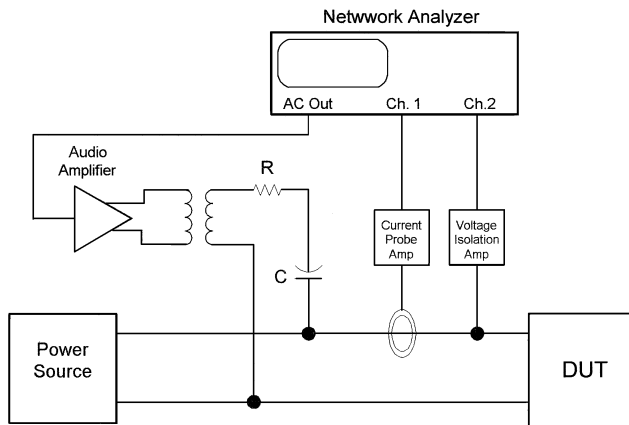

FIGURE 15.5.2 Impedance measurement with current injection method.

SECTION 16

ANTENNAS AND WAVE PROPAGATION

An antenna can be thought of as the control unit between a source and some medium that will propagate an electromagnetic wave. In the case of a wire antenna, it can be seen as a natural extension of the two-wire transmission line, and, in a similar way, a horn antenna can be considered a natural extension of the waveguide that feeds the horn.

The radiation properties of antennas are covered in Chap. 16.1. They include gain and directivity, beam efficiency, and radiation impedance. Depending on the antenna application, certain parameters may be more important. For example, in the case of receiving antennas that measure noise signals from an extended source, beam efficiency is an important measure of its performance.

Chapter 16.2 examines the various types of antennas, including simple wire antennas, waveguide antennas useful in aircraft and spacecraft applications, and low-profile microstrip antennas.

Finally, Chap. 16.3 treats the propagation of electromagnetic waves through or along the surface of the earth, through the atmosphere, and by reflection or scattering from the ionosphere or troposphere. More details of propagation over the earth through the nonionized atmosphere and propagation via the ionosphere are covered on the accompanying CD-ROM. D.C.

CHAPTER 16.1

PROPERTIES OF ANTENNAS AND ARRAYS

William F. Croswell

ANTENNA PRINCIPLES

The radiation properties of antennas can be obtained from source currents or fields distributed along a line or about an area or volume, depending on the antenna type. The magnetic field \mathbf{H} can be determined from the vector potential as

$$\mathbf{H} = \frac{1}{\mu} \nabla \times \mathbf{A} \quad (1)$$

To determine the form of \mathbf{A} first consider an infinitesimal dipole of length L and current I aligned with the z axis and placed at the center of the coordinate system given in Fig. 16.1.1.

$$A = z[\mu IL \exp(-jkr)]/4\pi r \quad (2)$$

where $k = 2\pi/\lambda$, and r is the radial distance away from origin in Fig. 16.1.1. From Eqs. (1) and (2) and Maxwell's equations, the fields of a short current element are

$$\begin{aligned} H_\phi &= \frac{jkL \sin\theta}{4\pi r} \left(1 + \frac{1}{jkr}\right) \exp(-jkr) \\ E_\theta &= \frac{jkL\eta \sin\theta}{4\pi r} \left(1 + \frac{1}{jkr} - \frac{1}{k^2 r^2}\right) \exp(-jkr) \\ E_r &= \frac{IL\eta}{2\pi r} \cos\theta \left(1 + \frac{1}{jkr}\right) \exp(-jkr) \end{aligned} \quad (3)$$

when $\eta = \sqrt{\mu/\epsilon}$ and $\epsilon =$ permittivity of source medium.

By superposition, these results can be generalized to the vector of an arbitrary oriented volume-current density \mathbf{J} given by

$$A(x, y, z) = \frac{\mu}{4\pi} \int_{V'} \mathbf{J}(x', y', z') \frac{\exp(-jkR)}{R} dx' dy' dz' \quad (4)$$

For a surface current, the volume-current integral Eq. (4) reduces to a surface integral of $\mathbf{J}_s[\exp(-jkR)]/R$, and for a line current reduces to a line integral of $\mathbf{I}[\exp(-jkR)]/R$. The fields of all physical antennas can be

FIGURE 16.1.1 Spherical coordinate system with unit vectors.

FIGURE 16.1.2 Equivalent aperture plane for far-field calculations: $\mathbf{M} = 2\mathbf{E}_s \times \hat{\mathbf{n}}$, $\mathbf{J} = 2\hat{\mathbf{n}} \times \mathbf{H}_s'$, and $\mathbf{J} = \mathbf{n} \times \mathbf{H}_s'$, $\mathbf{M} = \mathbf{E}_s' \times \hat{\mathbf{n}}$.

obtained from the knowledge of \mathbf{J} alone. However, in the synthesis of antenna fields the concept of a magnetic volume current \mathbf{M} is useful, even though the magnetic current is physically unrealizable. In a homogeneous medium the electric field can be determined by

$$\mathbf{E} = \frac{1}{\epsilon} \nabla \times \mathbf{F} \quad F = \frac{\epsilon}{4\pi} \int_{V'} M(x', y', z') \frac{\exp(-jkR)}{R} dx' dy' dz' \quad (5)$$

Examples of antennas that have a dual property are the thin dipole in free space and the thin slot in an infinite ground plane. The fields of an electric source \mathbf{J} can be determined using Eqs. (1) and (5) and Maxwell's equations. From the far-field conditions and the relationships between the unit vectors in the rectangular and spherical coordinate systems, the far fields of an electric source \mathbf{J} are

$$\begin{aligned} \eta H_{\theta}^J &= \frac{-jnk \exp(-jkr)}{4\pi r} \int_{V'} (J_{x'} \cos \theta \cos \phi \\ &+ J_{y'} \cos \theta \sin \phi - J_{z'} \sin \theta) \exp[jk(x' \sin \theta \cos \phi \\ &+ y' \sin \theta \sin \phi + z' \cos \theta)] dx' dy' dz' \end{aligned} \quad (6)$$

$$\begin{aligned} -\eta H_{\phi}^J = E_{\phi}^J &= \frac{j\eta k \exp(-jkr)}{4\pi r} \int_{V'} (J_{x'} \sin \phi \\ &- J_{y'} \cos \phi) \exp[jk(x' \sin \theta \cos \phi \\ &+ y' \sin \theta \sin \phi + z' \cos \theta)] dx' dy' dz' \end{aligned} \quad (7)$$

In a similar manner the radiated far fields from a magnetic current \mathbf{M} are

$$\begin{aligned} \eta H_{\phi}^M = E_{\theta}^M &= \frac{-jk \exp(-jkr)}{4\pi r} \int_{V'} (M_{y'} \cos \phi \\ &- M_{x'} \sin \phi) \exp[jk(x' \sin \theta \cos \phi \\ &+ y' \sin \theta \sin \phi + z' \cos \theta)] dx' dy' dz' \end{aligned} \quad (8)$$

$$\begin{aligned} \eta H_{\theta}^M = E_{\phi}^M = & \frac{-jk \exp(-jkr)}{4\pi r} \int_{V'} (M_{x'} \cos \phi \cos \theta \\ & + M_{y'} \sin \phi \cos \theta - M_{z'} \sin \theta) \exp [jk(x' \sin \theta \cos \phi \\ & + y' \sin \theta \sin \phi + z' \cos \theta)] dx' dy' dz' \end{aligned} \quad (9)$$

Currents and Fields in an Aperture

For aperture antennas such as horns, slots, waveguides, and reflector antennas, it is sometimes more convenient or analytically simpler to calculate patterns by integrating the currents or fields over a fictitious plane parallel to the physical aperture than to integrate the source currents. Obviously, the fictitious plane can be chosen to be arbitrarily close to the aperture plane. If the integration is chosen to be an infinitesimal distance away from the aperture plane, the fields to the right of s' in Fig. 16.1.2 can be found using either of the equivalent currents

$$\mathbf{M}_{s'} = 2\mathbf{E}_{s'} \times \hat{\mathbf{n}} \quad (10a)$$

$$\mathbf{J}_{s'} = 2\hat{\mathbf{n}} \times \mathbf{H}_{s'} \quad (10b)$$

$$\mathbf{J}_{s'} = \hat{\mathbf{n}} \times \mathbf{H}_{s'} \quad \text{and} \quad \mathbf{M}_{s'} = -\hat{\mathbf{n}} \times \mathbf{E}_{s'} \quad (10c)$$

The combined electric and magnetic current given in Eq. (10c) is the general Huygens' source and is generally useful for aperture problems where the electric and magnetic fields are small outside the aperture: In limited cases, the waveguide without a ground plane, a small horn, and a large tapered aperture can be approximated this way.

Far Fields of Particular Antennas

From the field equations stated previously or coordinate transformations of these equations, the far-field pattern of antennas can be determined when the near-field or source currents are known. Approximate forms of these fields or currents can often be estimated, giving good pattern predictions for practical purposes.

Electric Line Source

Consider an electric line source (current filament) of length L centered on the z' axis of Fig. 16.1.1 with a time harmonic-current $I(z')e^{j\omega t}$. The fields of this antenna are, from Eq. (6),

$$E_{\theta} = \frac{jk \sin \theta \exp(-jkr)}{4\pi r} \int_{-L/2}^{L/2} I(z') \exp[-jkz' \cos \theta] dz' \quad E_{\phi} = 0$$

For the short dipole where $kL \ll 1$ and $I(z') = I_0$

$$E_{\theta} = [j\eta k L I_0 \exp(-jkr) \sin \theta] / 4\pi r$$

which agrees with Eq. (3).

Electric Current Loop

The far fields of an electric current loop of radius a , centered in the xy plane of Fig. 16.1.1, which has a current flowing on it can be obtained by returning to the vector potential \mathbf{A} and deriving the expressions similar to Eqs. (6) and (7) using a potential $A_{\phi} = A_r$. The resulting field is

16.6 ANTENNAS AND WAVE PROPAGATION

$$E_{\theta} = \frac{-j\eta \exp(-jkr) \cos\theta}{4\pi r} \int_0^{2\pi} I(\phi') \sin(\phi - \phi') \exp[jka \cos(\phi - \phi') \sin\theta] d\phi'$$

$$E_{\phi} = \frac{-jk \exp(-jkr) \cos\theta}{4\pi r} \int_0^{2\pi} I(\phi') \cos(\phi - \phi') \exp[jka \cos(\phi - \phi') \sin\theta] d\phi'$$

The fields for the constant current loop. $I(z') = I_0$ with a radius $a \ll \lambda$, are

$$E_{\phi} = (k^2 a^2 \eta / r) I_0 \exp(-jkr) \sin\theta$$

Note that $E_{\theta} = 0$. The field of the small loop is similar to the field produced by a constant magnetic current source of length L , where $L \ll \lambda$.

Elementary Huygens' Source

Assume that constant electric and magnetic current sources $J_x = J_0$ and $M_y = M_0$ of equal length $L \ll \lambda$ are simultaneously placed at the origin of Fig. 16.1.1. If the currents are adjusted such that $\eta J_0 L = M_0 L$, the far fields of this source are

$$E_{\theta} = \frac{-jk \exp(-jkr)}{4\pi r} \cos\phi(1 + \cos\theta) J_0 L$$

$$E_{\phi} = \frac{jk \exp(-jkr)}{4\pi r} \sin\phi(1 + \cos\theta) J_0 L$$

The unique feature of this fictitious source compared with the electric or magnetic current element alone is the obliquity factor $(1 + \cos\theta)$, which tends to cancel the far-field radiation pattern in the region $\pi/2 \leq \theta \leq \pi$ due to its cardioid shape. Aperture antennas have field distributions which can be constructed from Huygens' source elements having the patterns described above.

Aperture in Infinite Ground Plane

With the equivalent current $\mathbf{M}_s = -2\mathbf{z} \times \mathbf{E}_s$, the far field of a waveguide aperture opening onto an infinite ground plane can be obtained by integrating the aperture field since the tangential electric field is zero on the ground plane. From the magnetic current and Eqs. (6) to (9), the far-field patterns of the dominant-mode circular and rectangular waveguides can be derived.

Simple Arrays

Consider a linear array of radiating elements which, for simplicity, are assumed to be equally spaced at a distance d apart, as illustrated in Fig. 16.1.3. The field at a large distance away from the m th element can be written

$$E_m = f_m(\theta, \phi) \frac{\exp(-jkr)}{r} \exp(jk_m d \cos\theta) \quad (11)$$

By superposition the field of an array of N elements is given by

$$E_N = \frac{-\exp(-jkr)}{r} \sum_{m=1}^N f_m(\theta, \phi) \exp[-j(m-1)kd \cos\theta] \quad (12)$$

If the element at the origin is chosen as a reference. If each element has an identical pattern, $f_m(\theta, \phi) = a_m E(\theta, \phi)$ and

$$E_n(\theta, \phi) = E(\theta, \phi), f(\varphi)$$

$$f(\varphi) = \sum_{m=1}^N a_m \exp j\varphi \tag{13}$$

where a_m is a complex number representing the excitation current (voltage in the case of slots) for the m th element and $\varphi = -(m - 1)kd \cos \theta$. The function $f(\varphi)$ is commonly called the *array factor* or *array polynomial*, and the factorization process given in Eq. (13) is called *pattern multiplication*.

Uniform Linear Array

Suppose the array of point sources in Fig. 16.1.3 is fed uniformly in amplitude and has a phase shift δ between adjacent elements. Here $a_m = e^{-jm\delta}$ and $\varphi = kd \cos \theta - \delta$, and consequently $|f(\theta, \phi)|^2$ is as follows:
General:

FIGURE 16.1.3 Geometry of a linear array of equally spaced elements.

$$|f(\theta, \phi)|^2 = \left| \frac{\sin^2[(N/2)(kd \cos \theta - \delta)]}{N^2 \sin^2[(kd/2) \cos \theta - \delta]} \right| \tag{14}$$

Broadside $\delta = 0$:

$$|f(\theta, \phi)|^2 = \left| \frac{\sin^2[(N/2)(kd \cos \theta)]}{N^2 \sin^2[(kd/2) \cos \theta]} \right| \tag{15}$$

End fire $\delta = kd$:

$$|f(\theta, \phi)|^2 = \left| \frac{\sin^2[(Nkd/2)(\cos \theta - 1)]}{N^2 \sin^2[kd/2(\cos \theta - 1)]} \right| \tag{16}$$

Owing to the ϕ rotational symmetry in Eq. (14), the pattern of the line source has rotational symmetry about the z axis. As the cone angle of the pattern decreases with scan angle from broadside, the pattern directivity remains constant at the value N regardless of scan angle. By choosing the phase shift between elements so that $\delta = kd + 2.94/N$ the sharpest pattern in the end-fire direction ($\theta = 0$) is obtained. In this case

$$|f(\theta, \phi)|^2 = \left| \frac{\sin^2[(Nkd/2)(k \cos \theta - k')]}{N^2 \sin^2[(d/2)(k \cos \theta - k')]} \right| \tag{17}$$

where $k' = k + 2.94/Nd$. This phase condition, which is determined graphically, is called the *Hansen-Woodward condition* for superdirectivity. This extra directivity may be several decibels in practical antennas.

Circular Arrays

Consider an array of N equally spaced elements about a circle of radius a in the xy plane of Fig. 16.1.1. If the azimuthal location of the m th element is $\phi_m = 2\pi m/N$, then for an element excitation of the form $a_m = A_{mn} e^{j\alpha_m}$ the array factor is given by

$$f(\theta, \phi) = \sum_{m=1}^N A_m \exp\{j[\alpha_m + ka \sin\theta \cos(\phi - \phi_m)]\} \quad (18)$$

For arrays having a large number of elements, $|A_m| = \text{const}$, the array-factor pattern in the xy plane can be approximated by

$$|f(\theta, \phi = \pi/2)| \approx |J_0[2ka \sin 1/2(\phi - \phi_0)]|$$

which is a directional beam with a maximum of $\phi = \phi_0$. If the pattern of each antenna in the circular array is of the form $F(\phi) = \sum_{m=0}^{\infty} A_m \cos^m \phi$, the pattern of a uniformly excited circular array of N such elements is approximately given by

$$\Phi(\theta, \phi) \approx N \sum_{m=0}^M A_m (-i)^m \frac{d^m}{dz^m} [J_0(z) + 2j^N J_m(z) \cos N\phi] \quad (19)$$

where $M < N$ and $Z = ka \sin\theta$. A design curve for determining the number of sources N required in a circular array of circumference Z to produce an omnidirectional pattern with 0.5 dB ripple or less is given in Ref. 1.

Planar Arrays

Now consider a planar array of equally spaced elements in the yz plane of Fig. 16.1.3, where the elements in the y direction are a distance d from the elements on the axis. With the origin as a phase reference, the array factor is given by

$$f(\theta, \phi) = \sum_{n=1}^N \sum_{m=1}^M a_{mn} \exp[jk(nd \cos\theta + md \sin\theta \sin\phi)] \quad (20)$$

where the excitation coefficient $a_{mn} = A_{mn} \exp[jk(m\delta_y + n\delta_z)]$. If $A_{mn} = 1$ and $\delta_y = \delta_z = 0$, the array has a pattern maximum at broadside and has the array factor

$$|f(\theta, \phi)|^2 = \left| \frac{\sin^2(Nkd/2) \cos\theta}{N^2 \sin[(kd/2) \cos\theta]} \right| \left| \frac{\sin^2(Mkd/2) \cos\theta \sin\phi}{M^2 \sin^2[(kd/2) \cos\theta \sin\phi]} \right| \quad (21)$$

The pattern in the two principal planes of the uniformly excited array is identical in form to the linear array in the same plane. As the array is scanned from broadside, the pattern broadens and becomes asymmetrical.

Gain and Directivity

Antennas that are several wavelengths or larger in dimension have far-field patterns for which most of the radiated energy is restricted to narrow angular regions. Several useful measures of how the pattern is concentrated are gain, directivity, effective area, and beam efficiency. The beam efficiency is important for low-noise

communication systems, microwave radiometry, and radio-astronomy antennas. The definitions of directional directivity $D(\theta, \phi)$, directivity D , gain G , and directional $G(\theta, \phi)$ are:

$$G(\theta, \phi) = N_A(1 - |\Gamma|^2)[D(\theta, \phi)] = N_A(1 - |\Gamma|^2) \left[4\pi \frac{\text{power radiated in direction } (\theta, \phi)}{\text{total power radiated by antenna}} \right]$$

$$G = N_A(1 - |\Gamma|^2)[D = N_A(1 - |\Gamma|^2) \left(4\pi \frac{\text{maximum power radiated by antenna}}{\text{total power radiated by antenna}} \right)]$$

The term N_A is the antenna efficiency related to I^2R losses, and Γ is the reflection coefficient as seen at the antenna input terminals. In equation form

$$D(\theta, \phi) = \frac{4\pi |E(\theta, \phi)|^2}{\int_0^{2\pi} \int_0^\pi |E(\theta, \phi)|^2 \sin\theta \, d\theta \, d\phi} \quad (22)$$

where $E(\theta, \phi)$ = electric field of the antenna, and

$$D = \frac{4\pi |E(\theta, \phi)|^2 \max}{\int_0^{2\pi} \int_0^\pi |E(\theta, \phi)|^2 \sin\theta \, d\theta \, d\phi} \quad (23)$$

An example of the directivity of two-dimensional arrays is given in Fig. 16.1.4. The element pattern is of the form $2J_1(c_\theta)/c_\theta$ which approximates the elements such as slots and dipoles. Other calculations for different element patterns are given in Eqs. (2) and (3).

Beam Efficiency

In addition to the gain of an antenna, the beam efficiency is a very useful parameter for judging the quality of receiving antennas intended for measurement of noise signals from an extended source. The beam efficiency is a measure of the ability of an antenna to discriminate between the received signal in the main beam and unwanted signals received through the side lobes in other directions. Assuming that the antenna aperture is in the xy plane in Fig. 16.1.1, the beam efficiency is defined as

$$BE = \frac{\text{power radiated in a cone angle } \theta_1}{\text{total power radiated by the antenna}} = \frac{\int_0^{2\pi} \int_0^{\theta_1} |E(\theta, \phi)|^2 \sin\theta \, d\theta \, d\phi}{\int_0^{2\pi} \int_0^\pi |E(\theta, \phi)|^2 \sin\theta \, d\theta \, d\phi} \quad (24)$$

Beam efficiency varies significantly dependent on the shape of the aperture and the aperture distribution. Calculations for circular apertures with a symmetrical distribution $f(p) = [1 - (p/a)^2]N$ are given in Fig. 16.1.5. This distribution approximates the aperture field of parabolic antennas. Calculations for square apertures with field distribution $f(x) = \cos^n(x/a)$ are given in Fig. 16.1.5. Further beam efficiencies for circular apertures with different field distributions are given in Eqs. (4) and (5).

Antenna Temperature

An antenna located on the earth and pointing at an angle (θ, ϕ) to the sky will receive noise from all directions. The amplitude of this noise as seen at the antenna terminals will depend on the noise source (warm earth, cosmic noise,

FIGURE 16.1.4 Directivities for uniformly excited $M \times N$ arrays with the element pattern of $2J_1(C\theta)/C\theta$ (after Ref. 2): (a) $c = 1.5$, (b) $c = 2$.

water vapor, radio stars, and so forth), the antenna orientation, and the operating frequency and polarization. The equivalent received noise power in a receive matched to the antenna terminal impedance by a lossless transmission line is

$$P_n = kTB \tag{25}$$

where k = Boltzmann's constant
 T = temperature (K)
 B = bandwidth (Hz)

Noise power for a fixed bandwidth may be thought of an equivalent temperature. Consequently, if it is assumed that the various noise sources that make up the antenna noise environment have an equivalent temperature $T(\theta, \phi)$ the apparent antenna temperature is given by

$$T_A = \frac{\int_0^{2\pi} \int_0^\pi G(\theta, \phi) T(\theta, \phi) \sin\theta \, d\theta \, d\phi}{\int_0^{2\pi} \int_0^\pi G(\theta, \phi) \sin\theta \, d\theta \, d\phi} \tag{26}$$

The most important natural emitter of noise at microwave frequencies is the ground at 377 K compared with the sky temperature at a few degrees. Therefore, antennas that have low side and back lobes will have low apparent antenna temperatures T_A .

FIGURE 16.1.5 Beam efficiencies of rectangular apertures (RA) and circular apertures (CA) with various aperture distributions.

If the antenna has losses and is not matched to the receiver for maximum power transfer, the antenna temperature will be higher than predicted by Eq. (26). The contribution due to the particular mismatch and losses of every component must be analyzed for each particular receiving system in detail. An outline of an excellent method of analysis is available.⁶ For a receiving system with no mismatch loss, the apparent temperature T_a is given by

$$T_a = (1 - L)T_A + LT_0 \tag{27}$$

where T_A is the antenna temperature given by Eq. (27) and T_0 is the physical temperature of lossy device.

Friis Transmission Formula

Assume that there is a source antenna and an antenna under test located at a distance r apart such that

$$r \geq 2(d_t)^2/\lambda \tag{28}$$

where d_t is the maximum aperture dimension of the antenna under test. The distance specified by Eq. (28) is the so-called *far-field distance*. The far-field distance is commonly specified as the distance where the phase front of a spherical wave over a planar aperture will not exceed $\pi/8$ rad. For special purposes, such as

the measurement of deep nulls or extremely precise side-lobe levels, the far-field distance may have to be extended further; curves using other criteria are available.⁷ The power received at the terminals of one antenna located in the far field of a second antenna can be expressed as a fraction of the transmitted power as

$$P_R = P_T \{ \lambda / 4\pi r \}^2 N_{AT} N_{AR} D_T(\theta_T, \phi_T) D_R(\theta_R, \phi_R) (1 - |\Gamma_r|^2) (1 - |\Gamma_r|^2) |\rho_R \cdot \rho_T|^2 \quad (29)$$

where N_{AT} , N_{AR} are loss efficiencies of antennas and $D_T(\theta_T, \phi_T)$, $D_R(\theta_R, \phi_R)$ are directivities of antennas in the direction one antenna is pointing toward the other. $|\Gamma_T|^2$ and $|\Gamma_R|^2$ are the reflected power due to mismatch of the antenna terminals and $|\rho_R \cdot \rho_T|^2$ is the polarization loss. The term in brackets in Eq. (29) is the so-called free-space loss, which is a result of spherical spreading of the energy radiated by an antenna. In the far field all antennas appear as a spherical wave emanating from a point source located at the phase center of the antenna, where the phase center may be a function of the observation angle.

Polarization

Consider a plane wave propagating in the z direction, which has an arbitrary plane polarization with an axial ratio r_A is defined as the ratio of the major to minor axis of the ellipse referenced to a coordinate system (Fig. 16.1.6). The field expression for this arbitrary plane-polarized wave is

FIGURE 16.1.6 Polarization ellipse.

$$E = C [x(r_a \cos \phi + j \sin \phi) + y(r_a \sin \phi - j \cos \phi)] \exp(-jkz)$$

When the z -phase dependence is neglected except for the sign, the normalized fields of two different plane-polarized waves with the wave number 2 propagating in the negative z direction (two antennas pointing at one another) are given by

$$E_1 = E_{1p1} = E_1 \frac{x(r_1 \cos \phi_1 + j \sin \phi_1) + y(r_1 \sin \phi_1 - j \cos \phi_1)}{\sqrt{r_1^2 + 1}} \quad (30)$$

$$E_2 = E_{2p2} = E_2 \frac{x(r_2 \cos \phi_2 + j \sin \phi_2) + y(r_2 \sin \phi_2 - j \cos \phi_2)}{\sqrt{r_2^2 + 1}} \quad (31)$$

A chart of polarization loss between two elliptically polarized waves with arbitrary axial ratio is given in Fig. 16.1.7. Table 16.1.1 enables the calculation of polarization loss between plane-polarized waves for three different configurations, and for the general case.

Radiation Impedance

The complex Poynting vector $P = \mathbf{E} \times \mathbf{H}^*$ can be integrated over a closed surface about an antenna to give

$$\iint_s \mathbf{E} \times \mathbf{H}^* \cdot ds = 4j\omega(W_m - W_f) + \mathbf{P}_s = \mathbf{VI}^* \quad (32)$$

FIGURE 16.1.7 Polarization loss between two elliptically polarized waves.

Where $W_m - W_f =$ time-average net reactive power stored within the volume enclosed by S' and $P_s =$ net real power flow through S' . As a result, the real power can be related to a radiation resistance and the reactive power to a radiation reactance by equating this total complex power to an equivalent voltage V and current I at a defined set of terminals. This radiation impedance, which is a lumped-circuit-element description of an antenna, is defined at a specific set of terminals or terminal plane which may be the aperture of a waveguide antenna. The simplest term to determine in Eq. (32) is the radiated power P_s and the corresponding radiation resistance R_r . This is true because the surface S' may be chosen in the far field of the antenna, where fields with only $1/r$ dependence are important. The radiation reactance is determined by choosing S' close to the antenna and integrating fields where $1/r^2$ and $1/r^3$ terms are important. A convenient surface to choose for these calculations is a sphere of radius r surrounding the antenna.

TABLE 16.1.1 Polarization Loss Between Plane-Polarized Waves

Type	ρ_1	ρ_2	$ \rho_1 \cdot \rho_2 ^2$
Linear to linear $r_1 = r_2 \rightarrow \infty$	$x \cos \phi_1 + y \sin \phi_1$	$x \cos \phi_2 + y \sin \phi_2$	$\cos^2(\phi_1 - \phi_2)$
Linear to circular ($r_1 = 1, \phi = 0$ to π)	$\frac{x \pm jy}{\sqrt{2}}$	$x \cos \phi_2 + y \sin \phi_2$	$\frac{1}{2}$
Circular to circular	$\frac{x+jy}{\sqrt{2}}$	$\frac{x+jy}{\sqrt{2}}$	1
$r_1 = r_2 = 1$ $\phi_1 = 0$ or η $\phi_2 = 0$ or η	$\frac{x+jy}{\sqrt{2}}$	$\frac{x+jy}{\sqrt{2}}$	0
General case	$\frac{x(r_1 \cos \phi_1 + j \sin \phi_1)}{\sqrt{r_1^2 + 1}} + \frac{y(r_1 \sin \phi_1 + j \cos \phi_1)}{\sqrt{r_1^2 + 1}}$	$\frac{x(r_2 \cos \phi_2 - j \sin \phi_2)}{\sqrt{r_2^2 + 1}} + \frac{y(r_2 \cos \phi_2 + j \sin \phi_2)}{\sqrt{r_2^2 + 1}}$	$\frac{(1+r_1^2+r_2^2+r_1^2r_2^2+4r_1r_2)+(1+r_1^2r_2^2-r_1^2-r_2^2)\cos^2(\phi_1-\phi_2)}{2(r_1^2+1)(r_2^2+1)}$

Radiation Resistance of Short Current Filament

The far fields of a current filament from Eq. (3) are

$$E_{\theta} = \frac{jkI_0\eta L \sin\theta \exp(-jkr)}{4\pi r} \quad H_{\phi} = \frac{jkI_0 L \sin\theta \exp(-jkr)}{4\pi r} \quad (33)$$

When these fields are used, P_s from Eq. (33) is given by

$$P_s = \int_0^{2\pi} \int_0^{\pi} E_{\theta} H_{\phi}^* \sin\theta r^2 d\theta d\phi = \frac{\eta\pi I_0^2}{3} \left(\frac{L}{\lambda}\right) = I_0^2 R_r \quad (34)$$

Array Impedance

The pattern expressions given earlier for arrays have neglected coupling between elements in the array. Mutual coupling will not only affect the input impedance of each element input terminal as a function of scan angle but will also change the pattern of each element in a manner dependent on the element location in the array. The determination of the mutual and self-impedance of an element in an array and the effect of these changes on array patterns is a specialized problem. In general, however, arrays of antennas radiating into a linear medium will have to satisfy the same equations as any linear system with n pairs of terminals, or

$$V_1 = Z_{11}I_1 + Z_{12}I_2 + \cdots + Z_{1n}I_n \quad V_n = Z_{n1}I_1 + Z_{n2}I_2 + \cdots + Z_{nn}I_n \quad (35)$$

Input Impedance as a Function of Scan Angle

As a first approximation a large array can be treated as large continuous aperture. Wheeler⁹ has shown that the impedance of a large aperture approximation in an array may be thought of as an impedance sheet whose normalized impedance and reflection coefficient vary as

$$\eta_{aperture} = (1 - \sin^2\theta \cos^2\phi) / \cos\theta \quad (36)$$

which results in

$$|\Gamma| = \tan^2(\theta/2) \quad (37)$$

for $\phi = 0^\circ$ or $\pi/2$. This simple impedance-sheet concept acts as an upper bound on the input-impedance variation of the central element of a large array as a function of scan angle. Perhaps this model inspired the erroneous description of the scan-angle reflection peak as related to a surface wave for uncoated arrays. An indication of the accuracy of this simple bound is given in Fig. 16.1.8 from dipole calculations by Allen.¹⁰ It should be noted that the reflection peak is the result of a null in the element pattern of each element in the infinite array at the scan angle corresponding to the reflection peak. For waveguide arrays the addition of fences in between waveguides will extend the scan-angle range to wider angles by filling in the reflection null in the element patterns. The impedance variation as a function of scan angle, for infinite arrays, can be obtained using waveguide simulators.^{11,12}

CHAPTER 16.2

TYPES OF ANTENNAS

William F. Croswell

WIRE ANTENNAS

Analysis of Wire Antennas

The development of wire antennas has been extensive, since such antennas are simple to construct. The classical analysis of wire antennas such as dipoles, loops, and loaded-wire antennas has been developed by Hallen and R. W. P. King and his students; a good summary of theoretical and experimental results, including specific impedance curves and design data, is given in Ref. 1. The unfortunate drawback of this analysis method is that each new wire-antenna configuration presents another analytical problem which must be solved before design computations can be made. A systematic method of solving wire-antenna problems using computerized matrix methods has been developed by extending the analysis of scattering by wire objects by Richmond²⁻⁵ and Harrington.⁶⁻⁹ These matrix analysis methods have been applied to wire antennas to determine the input impedance, current distribution, and radiation patterns by subdividing any particular wire antenna into segments and determining the mutual coupling between any one segment and all other segments. The method therefore can treat any arbitrary wire configuration, including loading and arrays, the limitation being the storage capacity of available digital computers and the patience of the programmer. In the last 10 years, these numerical methods have been extended to include wire antenna near obstacles such as towers and mounted on aircraft and missiles.

Wire Antennas over Ground Planes

The wire antenna mounted over a ground plane forms an image in the ground plane such that its pattern is that of the real antenna and the image antenna and the impedance is one-half of the impedance of the antenna and its image when fed as a physical antenna in free space. For example, the quarter-wave monopole mounted on an infinite ground plane has an impedance equal to one-half the free-space impedance of the half-wave dipole. The advantage of the ground-plane-mounted wire antenna is that the coaxial feed can be used without disrupting the driving-point impedance. In practice an antenna mounted on a 2- to 3-wavelength ground plane has about the same impedance as the same antenna mounted on an infinite ground plane. The finite-ground-plane edges produce pattern ripples whose depth and angular extent depend on the ground-plane size.

V Dipole

The V dipole is constructed by bending a wire dipole antenna into a V. The impedance of the half-wave V-dipole antenna has been calculated as a function of the V angle, as given in Fig. 16.2.1. Note that the V dipole is equivalent to the bent-wire monopole antenna over a ground plane. The effect of bending the dipole is to tune

FIGURE 16.2.1 Impedance of a V-dipole antenna as a function of V angle, $h/a = 1000 n$ – arm length = $\lambda/4$, a = wire radius. (Courtesy of J. E. Jones)

it, giving another practical tuning method in addition to adjusting its length. The patterns of the V dipole (vertical polarization) are nearly identical to those of the straight dipole for φ angles as small as 120° . With decreasing tilt angle this antenna excites a horizontal polarized field component which tends to fill in the pattern, making the antenna a popular communication antenna for aircraft.

Bent Dipole

Another form of the dipole antenna that has practical application, particularly for ground-plane or airplane applications, is the bent-wire dipole formed by bending the wire 90° some distance out from the feed point. The impedance of the bent wire is given in Fig. 16.2.2 for the free-space and ground-plane case. Note that this antenna can also be tuned by adjusting the lengths perpendicular and parallel to the driving point. The radiation pattern in the plane of this antenna is nearly omnidirectional for values of $H_1 \leq 0.10$, after which the pattern approaches that of the vertical half-wave dipole. Other forms of this antenna can be constructed, including loading to reduce the effective length.

Loop Antenna

Another useful classical antenna is the loop antenna. As stated earlier, many investigators have erroneously designated this antenna as a magnetic dipole when indeed it is just another form of the wire antenna.

FIGURE 16.2.2 Impedance of half-wave bent-dipole antenna, $H_1 + H_2 = \lambda/4$. (Courtesy of J. E. Jones)

FIGURE 16.2.3 Admittance of the loop antenna. (Courtesy of J. E. Jones)

The admittance of the loop antenna can be computed using the matrix method by approximating the loop with a polygon having the same electrical length. The admittance of a 12-sided polygon, which is identical to the admittance of a loop of the same length, has been computed and is given in Fig. 16.2.3. These results have been verified in the ground-plane case experimentally.¹⁰ Indeed the square loop or any other multisided loop with the same electrical-perimeter length has approximately the same admittance as the circular loop. Another method of improving the impedance of a loop is to add turns or load the loop with discrete lumped capacitances. The patterns and impedance of loop antennas mounted on aircraft structures have been studied.

Wire Antennas near Ground Planes

Although the impedance of wire antennas mounted on ground planes several wavelengths in dimension for practical purposes is similar to the impedance of the same antenna mounted on an infinite ground plane, the patterns of wire antennas on finite ground planes strongly depend on the ground-plane size. In recent years, the geometrical theory of diffraction (GTD) has been successfully applied to such problems.^{11–16} These published results and the method of analysis are of great interest to antenna engineers since the geometry is the practical one of interest.

Loop above a Finite Ground Plane

The loop above a finite ground plane is an antenna commonly used as an array element in VHF omnirange stations located near all airports as an aircraft landing aid. Since the pattern of the small loop is symmetrical in azimuth, the elevation pattern of a loop over a finite circular ground plane can be computed using a pair of closely spaced line sources fed out of phase and located over a finite-width conducting strip.¹⁴ The geometry of the line-source pair a distance d above a ground plane $2x_0$ in width is shown in Fig. 16.2.4.

The pattern of this antenna has a null at $\phi = 90^\circ$ and a maximum value at some angle above the ground plane, which depends on the spacing d and the ground-plane size $2x_0$. The value of the field along the ground-plane edge ($\phi = 0$) is also of interest to the antenna designer. The variation of these field parameters is given in Fig. 16.2.5.

Horizontal Dipole over a Finite Ground Plane

The GTD method can be applied to the horizontal dipole over a finite ground plane,¹⁵ the geometry of which is shown in Fig. 16.2.6. Also shown in Fig. 16.2.6 is the geometry of the same dipole placed over a cylinder. The

FIGURE 16.2.4 Linear array of line sources and its diffraction mechanism, a two-element array above a ground plane. (Adapted from Balanis¹⁴).

purpose of this antenna design is to minimize the ripple or field variation in the pattern above the ground plane and simultaneously achieve a low back-lobe level. These field parameters are plotted as a function of ground-plane size and dipole spacing in Fig. 16.2.7. Also plotted in Fig. 16.2.7 are similar design curves for the dipole spaced the same parametric distances above a perfectly conducting cylinder having a diameter equal to the finite-ground-plane width. These calculations were made by programming available formulas. The cylinder curvature allows one to obtain a better back-lobe level for a given pattern variation or ripple in the forward region. Experimentally, it has been determined that the rear part of the metal cylinder can be substantially removed with little effect.

FIGURE 16.2.5 Variations of the maximum field strength and the field strength at the angle of the ground-plane edge as a function of line-source spacing and ground-plane size. (Adapted from Balanis¹⁴)

FIGURE 16.2.6 Radiation mechanism of dipole near finite ground plane and circular conducting cylinder. (a) ground plane; (b) circular cylinder. (From Balanis and Cockrell¹⁵)

WAVEGUIDE ANTENNAS

General Considerations

The waveguide antenna, which consists of a dominant-mode-fed waveguide opening onto a conducting ground plane, is very useful for many applications such as a feed for reflector antennas or a flush-mounted antenna for aircraft or spacecraft. For flush-mounting purposes it is sometimes desirable or necessary to cover the ground plane with dielectric layers to protect the aperture from the external environment or in some instances to put dielectric plugs in the feed-waveguide section. The impedance properties of waveguide antennas have been studied extensively both theoretically and experimentally, particularly for the rectangular waveguide, the circular waveguide, and the coaxial waveguide or so-called annular slot. For unloaded apertures, the assumptions of the single-mode trial field in the impedance variational solution has proved adequate for practical purposes. The impedance of these antennas is relatively independent of ground-plane size so long as the ground plane is 2λ in dimension or greater. However, the radiation pattern of the waveguide antenna mounted on finite ground

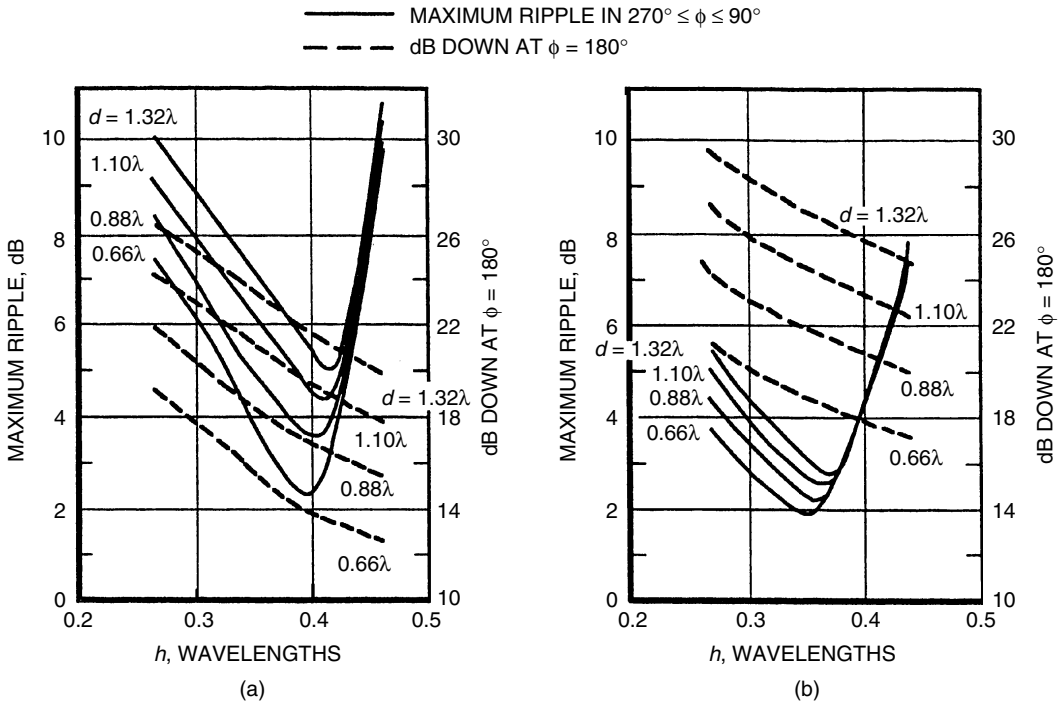

FIGURE 16.2.7 Variations of maximum ripple in $270^\circ \leq \phi \leq 90^\circ$ region and radiation $\phi = 180^\circ$ as functions of dipole position h near (a) the ground plane and (b) circular conducting cylinder. (From Balanis and Cockrell¹⁵)

planes is very dependent on the ground-plane size. The effects of diffraction by ground-plane edges can be treated by the GTD in a manner similar to that used for wire antennas above a finite ground plane.

Aperture Admittance of Rectangular Waveguides

Calculations have been made assuming the dominant mode as a trial function. These calculations are compared with measured results in Fig. 16.2.8, where the waveguide flange was used as a ground plane. (Note that the X-band flange was 1.62 by 1.62 in. and the S-band flange was 6.42 by 6.42 in.) Other measurements were made with up to 10λ ground planes with similar results, as given in Fig. 16.2.8. Calculations of the aperture admittance of square waveguides are given in Fig. 16.2.9. Note that the square waveguide aperture is more nearly matched to the characteristics admittance of the waveguide than the rectangular one. This is also true for the circular aperture.

Aperture Admittance of Circular Waveguides

Calculations for the circular waveguide radiating both into free space and into dielectric slabs have been performed and compared with measurements.¹⁸⁻¹⁹ Calculations for a 1.5 in.-diameter waveguide operating at C band are given in Fig. 16.2.10. Note that the circular waveguide is nearly matched when radiating into free space. Like that of the rectangular waveguide, the aperture admittance of the 2λ ground-plane antenna closely approximates the infinite-ground-plane model.

FIGURE 16.2.8 Aperture admittance of a square waveguide.

Patterns of Waveguides on Finite Ground Planes

The design of waveguide antennas on finite ground planes can also be treated by the geometrical theory of diffraction in a manner similar to that for the wire antennas above a finite groundplane. Edge or diffraction effects will primarily occur only in the *E*-plane (*yz* plane) of the circular or rectangular waveguide.

FIGURE 16.2.9 Measured and computed aperture admittance of a circular waveguide. (From Bailey and Swift¹⁹)

FIGURE 16.2.10 *E*-plane radiation patterns of a TE₀₁-mode-excited rectangular aperture opening onto a finite ground plane vs. aperture size in wavelengths. Ground-plane size = 4λ .

FIGURE 16.2.11 *E*-plane radiation patterns of a TE₁₁-mode-excited circular aperture opening onto a finite ground plane vs. aperture size in wavelengths. Ground-plane size = 4λ .

A summary of calculations for waveguides with different aperture sizes is given in Fig. 16.2.11. The radiation patterns differ for different ground-plane sizes. It should be noted that no diffractions occur in the *E* plane for a 1λ -wide rectangular aperture or a 1.22λ -diameter circular aperture. Indeed, for these aperture dimensions the *E*- and *H*-plane patterns are nearly identical.

The impedance properties of thin-slot antennas are relatively independent of ground-plane size.

Patterns of Narrow Slots in Cylinders

The radiation pattern of a thin circumferential waveguide fed slot on a cylinder is about the same as a similar slot on an infinite ground plane if the cylinder $C = ka$ is greater than about 8.0 to 9.0. The pattern of the axial slot on a cylinder is quite sensitive to the mounting cylinder size, as shown in Fig. 16.2.12.

HORN ANTENNAS

The horn antenna may be thought of as a natural extension of the dominant-mode waveguide feeding the horn in a manner similar to the wire antenna, which is a natural extension to the two-wire transmission line. The most common type of horns are the *E*-plane sectoral, *H*-plane sectoral, and pyramidal horn, formed by expanding the walls of the TE₀₁-mode-fed rectangular waveguide or the conical horn formed by expanding the wall of the TE₁₁-mode-fed circular waveguide. Early work concerned the determination of the forward radiation patterns, directivity, and approximate impedance of sectoral, pyramidal, and conical horns, including comprehensive experimental studies.^{21–30} An excellent summary of this work is given by Compton and Collin.³¹ In later work, the input impedance, wide-angle side lobes, and back lobes of certain horn antennas have been determined to a high precision using the GTD.^{32–36} The remainder of this chapter on horn antenna will follow the work by Milligan⁸⁹ and his chapter on horn antennas.

FIGURE 16.2.12 Radiation patterns of an axial infinitesimal slot on a cylinder vs. cylinder circumference Ka in wavelengths. Note that the vertical scale for each pattern is displaced 5 dB for clarity.

The general geometry of the waveguide fed horn is given in Fig. 16.2.13. The general phase error in the aperture is given by

$$S = \frac{\Delta}{\lambda} = \frac{W^2}{8\lambda R} \tag{1}$$

Sectoral and Pyramid Horns

The general geometry for the pyramidal horn is given in Fig. 16.2.14. For the E plane and H plane of the sectoral horn, or the E and H planes of the pyramidal horn, the quadratic phase error can be expressed as

$$S_E = \frac{a^2}{8\lambda R_E}, \quad S_H = \frac{b^2}{8\lambda R_H} \tag{2a,b}$$

The quadratic phase error change the TE_{10} mode excited horn aperture radiation pattern that is dependent on the amount of phase error S_E and/or S_H . Universal patterns for the sectoral and pyramidal horn are given in Figs. 16.2.15 and 16.2.16.

FIGURE 16.2.13 General geometry of a waveguide horn. (Adapted from Milligan,⁸⁹ p. 180)

FIGURE 16.2.14 The geometry of a pyramidal horn. (Adapted from Milligan,⁸⁹ p. 181)

FIGURE 16.2.15 Universal pattern of a pyramidal horn, *E* plane. (Adapted from Milligan,⁸⁹ p. 182)

The gain of pyramidal and sectoral horns has been determined to accuracies of about ± 0.4 dB even for frequencies as high as 38 GHz.³⁷ The most common gain standard is the pyramidal horn, which has a gain equal to

$$\text{Gain}_{\text{dB}} = 10(1.008) + \log a_{\lambda} b_{\lambda} - (L_E - L_H) \tag{3}$$

where a_{λ}, b_{λ} are aperture dimensions in wavelengths and L_e, L_h are the loss due to phase error in *E* and *H* planes of horn as given in Fig. 16.2.17. Gain curves for other horns and an excellent summary of horn-design information are given by Jakes³⁸ and Compton and Collin.³¹

Conical Horns

The conical horn formed as an extension of the circular waveguide excited in the TE_{11} mode has been thoroughly studied by King.²⁹ The radiation patterns of his antenna can be obtained by integrating the dominant TE_{11} -mode field, with quadratic phase error (Fig. 16.2.17). As in rectangular-waveguide-fed horns, the fields outside the aperture are neglected, and therefore, the wide-angle side lobes and back lobes will be computed incorrectly with such a procedure. The universal radiation patterns of conical horns excited by a circular

FIGURE 16.2.17a Loss correction for phase error in sectoral and pyramidal horns. (From Jakes³⁸)

FIGURE 16.2.17b Loss correction for phase error in conical horns. (From Jakes³⁸)

FIGURE 16.2.18 *E*-plane universal pattern of a TE_{11} mode excited conical horn. (After Milligan,⁸⁹ p. 192)

waveguide excited in the TE_{11} dominant mode are given in Figs. 16.2.18 and 16.2.19 for various values of quadratic phase error. Care must be used in exciting this horn since any feed asymmetry may excite the TM_{01} mode in the feed waveguide.

The gain of the conical horn has been determined to be

$$\text{Gain}_{\text{dB}} = 20 \log C\lambda - L \tag{4}$$

where C is the circumference of horn aperture and L is the gain loss due to phase error given by curve in Fig. 16.2.17. It should be carefully noted that the gain given by Eqs. (3) and (4) neglects the losses in the conducting walls of the entire horn and the VSWR.

FIGURE 16.2.19 H-plane universal pattern of a TE_{11} mode excited conical horn. (After Milligan,⁸⁹ p. 193)

Corrugated Horns

The conical horn can have undesired pattern ripples, particularly in the E plane. Such patterns are undesirable for horn feeds used in high-efficiency parabolic antennas. The most commonly used horn feed is the corrugated conical horn described³⁹ in Fig. 16.2.20. The teeth in these horns generally are between $\lambda/4$ and $\lambda/2$ deep, although the best operating band is about 1.5 to 1. These horns convert the dominant waveguide feed TE_{11} mode into the hybrid HE_{11} which tend to make the E -plane pattern similar to the H-plane pattern. Therefore, the narrow angle corrugated horn (10 dB beamwidth, less than 74°) has a very symmetrical pattern in the ϕ plane as given in Fig. 16.2.21. The so-called scalar horn is of sufficiently wide angle that the phase center is at the horn throat. This horn is particularly useful for wideband applications.⁴⁰

FIGURE 16.2.20 (a) Corrugated horn and (b) Scalar horn. (After Milligan⁸⁹ and Thomas³⁹)

REFLECTOR ANTENNAS

The theory commonly used for the direct-fed parabolic antenna is that of Silver,⁴¹ using physical optics. As outlined by Silver, this theory is adequate to predict the gain, radiation pattern, and the level of the first few side lobes of the secondary pattern, neglecting blockage and scattering by feed struts. The effect of feed-strut blockage can be estimated using geometrical optics;⁴² however, an analysis of the diffraction of struts using a more rigorous formulation is necessary to improve the quantitative understanding of the problem. The radiation-pattern characteristics of the offset-fed parabola have been determined approximately using an extension of Silver's formulation to include this geometry.^{43–44}

The spherical reflector is a good design for a scanning reflector antenna—thanks to its geometrical symmetry; however, a point source at the focal region will not produce a set of parallel rays from the secondary reflector. To correct this spherical-aberration error a line-source feed is employed.^{45–46} By phasing this line source, the beam can be scanned to other positions.

FIGURE 16.221 Universal pattern of a conical corrugated horn, HE₁₁ mode. (After Milligan⁸⁹)

Another way of feeding the parabolic reflector antenna is to use a subreflector in the focal region of the parabola and illuminate the subreflector from the parabolic surface. The principal advantages of the Cassegrain system or other methods of folded optics are the increase in effective f/d ratio and the simple mechanical location of the feed so that cooled receivers used with such antennas can be serviced in a more practical manner. The chief disadvantage is the aperture blockage of the subreflector, which restricts the application of this principle to large aperture. The Cassegrain antenna has been analyzed extensively, and computer programs are available. This design effort resulted in the design and construction of the 210-ft dish antenna⁴⁷⁻⁵⁶ used in the worldwide space-receiving network. In order to achieve all-weather operating capability a precision 120 ft Cassegrain dish under a 150-ft radome has been constructed at Millstone Hill, Massachusetts. The radome produces about 1- to 2.8-dB loss in the microwave to millimeter-wavelength region.⁵⁸

Besides ground-based antennas, special reflector types for use as erectable spacecraft antennas have been developed. Analysis of the gored reflector⁵⁹ is available, as is the design of conical-reflector antenna.⁶⁰

Performance of Symmetric Parabolic Antennas

The purpose of this section is to present a brief summary of the performance of symmetric parabolic antennas in terms of geometric and performance parameters. The information follows the excellent work of Knop⁶¹ and Milligan.⁸⁹ Consider the geometry given in Fig. 16.2.22. This figure depicts a feed located at the focal point of a symmetric parabola. The feed illuminates the reflecting surface, so that the secondary radiation pattern is obtained by integrating the surface current until the edge of the dish is reached. (This edge field or edge taper is a design parameter that affects the secondary pattern and gain performance.) Assuming that the feed pattern is symmetrical in both the *E* and *H* planes, a set of universal design curves can be generated as given in Fig. 16.2.23. These data are presented as a function of edge taper in dB. The data plotted in Fig. 16.2.24 is defined in the following manner:

- η_B = beam efficiency, which is the percent of the horn energy captured by the parabolic dish antenna
- η_A = total aperture efficiency
- $\eta_{A_I} = \eta_A / \eta_B$ = aperture illumination efficiency
- $2\theta_3 D / \lambda$, degrees = product of the aperture diameter in wavelengths, multiplied by the full half power beamwidth in degrees ($2\theta_3$)
- FSL, dB down = first sidelobe level in dB down from the main lobe peak
- $U_{FSL} = \pi(D/\lambda)\sin\theta_{FSL}$ = universal angle at which the first sidelobe occurs.

Other performance parameters are given in Fig. 16.2.23. For example:

- (a) amount of phase error loss due to axial defocus $\pm DZ/\lambda$ for various *f/D* ratios
- (b) phase error loss for phase center differential for different *f/D* ratios

FIGURE 16.2.22 Geometry of a symmetric parabolic dish antenna. (After Knop⁶¹)

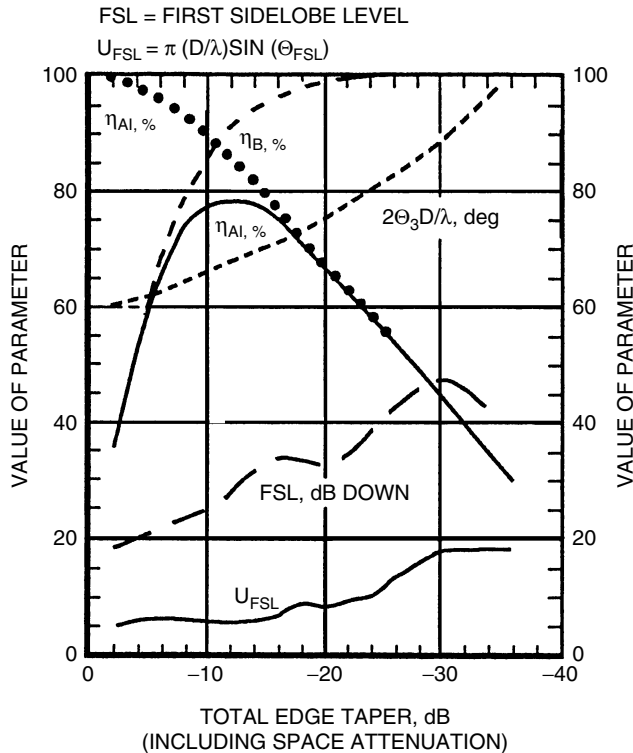

FIGURE 16.2.23 Universal performance curves for a symmetric parabolic dish antenna fed with a feed having symmetrical radiation pattern. (After Knop⁶¹)

- (c) scan loss versus beamwidths of scan for different f/D ratios
- (d) beam deviation factor as a function of f/D ratio.

The most important performance parameter, the gain loss as a function of the surface roughness, is given in Fig. 16.2.25.

LOG-PERIODIC ANTENNAS

The Frequency Independent Antenna

The frequency independent antenna is specified only by angles. It was suggested by Rumsey⁶² in 1954. The simplest form of such antennas is the equiangular spiral,⁶³ although early models with the frequency-independent idea included the tapered helix.⁶⁴⁻⁶⁵ All antenna shapes that are completely specified by angles must extend to infinity; thus any physically realizable frequency-independent antenna has bandwidth limitations because of end effects. A simple modification of the frequency-independent antenna is the logarithmically periodic antenna,⁶⁶ whose properties vary periodically with the logarithm of the frequency. This modification tends to minimize the end effect, although the impedance will vary as a function of frequency; such variations are sometimes small. From these early designs a number of log-periodic antennas have been developed, including conical log spirals,⁶⁷ the log-periodic V,⁶⁸ the log-periodic dipole,⁶⁹⁻⁷⁰ and the log-periodic Yagi-Uda array.⁷¹

FIGURE 16.2.24 Performance parameters for a symmetrical parabola dish antenna: (a) Gain loss due to phase error caused by axial defocusing; (b) Gain loss due to the difference between E -plane and H -plane phase errors; (c) Gain loss due to feed scan; and (d) the beam deviation factor vs. f/D ratio.

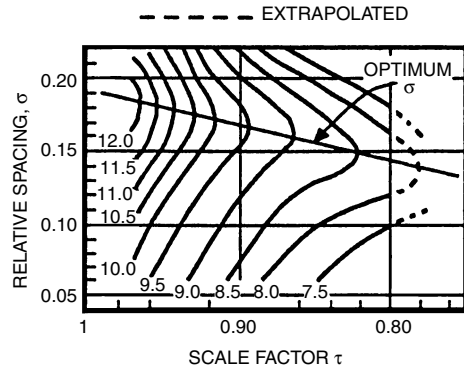

FIGURE 16.2.27 Constant-directivity contours in decibels versus τ and σ . Optimum indicates maximum directivity for a given value of τ . $Z_0 = 100 \Omega$, $h/a = 100$, $Z_T = 100 \Omega$.

Log-Periodic Dipole Design

One of the most popular antennas of this type is the log-periodic dipole antenna, which has the geometry depicted in Fig. 16.2.26. This antenna can be fed either by using alternating connections to a balanced line, as indicated in Fig. 16.2.26, or by a coaxial line running through one of the feeders from front to back. A simple procedure determined by Carre⁷⁰ which can be used for designing this antenna is outlined here. The number of elements is primarily determined by τ , and the antenna size is determined by boom length, which depends primarily on σ . The procedure is as follows:

1. An estimate of τ and σ based on the desired gain can be obtained from Fig. 16.2.27.
2. The bandwidth of the structure B_s is given by $B_s = B B_{ar}$ where B is the operating bandwidth and B_{ar} is determined in Fig. 16.2.28 using the parameter $\tan \alpha = (1 - \Gamma)/4\sigma$.
3. The length of the first elements is always made $\lambda_{max}/2$, so that the boom length L between the largest and smallest elements can be found from $L/\lambda_{max} = 1/4(1 - 1/B_s) \cot \alpha$.
4. The number of elements required is given by $N = 1 + [(\log B_s)/\log(1/\tau)]$.

By several iterations of this design procedure a minimum boom length can be obtained. The relative feeder impedance of the design can be found using available data.⁷⁰

SURFACE-WAVE ANTENNAS

General Description

A wide class of *surface-wave antennas* has been devised, e.g., the Yagi, backfire, helix, cigar, and polyrod antenna. The surface-wave nomenclature is related to the idea that these antennas, if infinite in length, will support a wave that travels along the structure at a velocity slower than the velocity of light in free space. Data for the phase velocity along such antenna structures are available.⁷²⁻⁷⁴ If the parameters of the antenna structure are chosen so

FIGURE 16.2.28 Bandwidth of active region B_{ar} vs. for several values of, for $Z_0 = 100 \Omega$, $h/a = 125$. (From Carrel⁷⁰)

FIGURE 16.2.29 Relative phase velocity $c/v = \lambda/\lambda_z$ for maximum-gain surface-wave antennas as a function of relative antenna length $1/\lambda$. HW = Hansen-Woodward condition; EP = Ehrenspeck-Poehler experimental values; 100 percent = idealized perfect excitation. (From Zuckel⁷⁵)

that the resultant phase velocity causes the Hansen-Woodward condition to be met on the finite length of the antenna, an increased or supergain condition occurs. The relative phase velocity $c/v = \lambda/\lambda_z$ to maximize the gain as a function of antenna length is given in Fig. 16.2.29. A typical phase-velocity variation as a function of specific antenna parameters is given in Fig. 16.2.30 for the Yagi. Choosing particular antenna parameters so that the optimum phase-velocity conditions are met will result in a good first-cut design. Improved designs require extensive parametric experimental studies where the antenna elements are varied about the initial dimensions. An estimate of how much gain can be expected from surface-wave antennas is given in Fig. 16.2.31. An excellent summary of surface-wave antenna design and literature has been compiled by Zucker.^{75,76}

FIGURE 16.2.30 Relative phase velocity on a Yagi antenna (data from Ehrenspeck and Poehler and Frost); δ = diameter of wire element, s = spacing between elements, and h = half length of element. (From Zucker⁷⁶)

5349-042 (M)

FIGURE 16.2.31 Gain and beam width of surface-wave antenna as a function of a relative antenna length $1/\lambda$. For gain (in decibels above an isotropic source) use right-hand coordinate; for beam width left-hand coordinate. Solid lines are optimum values; dashed lines are for low-side-lobe and broadband design. (From Zucker⁷⁶)

The surface-wave antenna is a misnomer since surface waves do not exist on finite antennas. Consequently, aside from the use of the general concepts mentioned above, most surface-wave antennas are designed experimentally because of the importance of the feed radiation and end effects.

Use of Feed Shields

Nearly all surface-wave antennas suffer from side-lobe and beam asymmetry if not fed from special launchers. For example, the helix mounted on a flat ground plane has pattern asymmetry and poor axial ratio (about 3 dB) on axis.⁷⁷ Short helices in particular have been found to exhibit this property. A way to improve this helix performance is to use a conical feed shield and to taper the beginning and end turns as in the helicoid antenna.⁷⁸ The feed shield that improves the performance of the cigar antenna is a conical horn⁷⁹ or a square cavity or bucket.⁸⁰

MICROSTRIP ANTENNAS

General Considerations

In many applications where low-profile antennas are required and bandwidths less than a few percent are acceptable microstrip antennas may have the desired characteristics. Microstrip antennas are constructed on a thin dielectric sheet over a ground plane using printed-circuit-board and photo-etching techniques. The most common board is dual-copper-coated Teflon-fiberglass as it allows the microstrip antenna to be curved to conform to the shape of the mounting surface. The antenna itself may be square, rectangular, round, elliptical, and the like; the two most common elements (rectangular and round) are illustrated in Fig. 16.2.32. Circular-polarized radiation can be obtained by exciting the square or round element at two feed points 90° apart and in phase quadrature. Circular polarization can also be obtained over a limited frequency range by making the element slightly rectangular ($W/L \approx 1.03$) or slightly elliptical (eccentricity ≈ 0.2) and using a single feed point on the 45° diagonal.

Resonant Frequency

The frequency response for the basic elements (rectangular or round) is similar to a resonant tuned circuit or cavity. When viewed as a thin cavity, the rectangular element should be resonant when the length is equal to a half wavelength, and the round element should be resonant when the radius is equal to 0.293 wavelength; however, owing to fringing fields at the edges of the element, the actual resonant size is smaller by a few percent, that is, $L_e = 0.5\lambda_e$ and $\alpha_e = 0.23\lambda_e$ where the effective length L_e and effective radius α_e are given by

$$L_e = L + 0.824h[(\epsilon_e + 0.3)/(\epsilon_e - 0.258)][(\alpha L + 0.262h)/(\alpha L + 0.813h)] \quad (5)$$

$$\alpha_e = a[1 + 2h(\pi\alpha\epsilon_r)^{-1} \ln(9.246a/h)]^{1/2} \quad (6)$$

where $\alpha = W/L$, and

$$\epsilon_e = 0.5(\epsilon_r + 1) + 0.5(\epsilon_r - 1)(1 + 12h/\alpha L)^{-1/2} \quad (7)$$

The resonant size (for minimum VSWR) decreases for an increase in the thickness h , as shown in Fig. 16.2.33 for the square ($W = L$) and in Fig. 16.2.34 for the round element. The resonant length of the rectangular element also decreases with an increase in the width.⁸¹ A TE-excited strip provides a lower bound on the resonant length of rectangular elements with a large width-to-length ratio.

FIGURE 16.2.32 (a) Coaxial-fed microstrip antennas; (b) line-fed microstrip antennas.

Bandwidth

The bandwidth of microstrip antennas is determined primarily by the thickness of the dielectric, increasing with an increase in thickness, as shown in Fig. 16.2.35 for square and round elements on Teflon-fiberglass with coaxial feed probes. The data in Fig. 16.2.35 can be used to select a board thickness to meet the bandwidth requirement, and the resonant size of the element is then determined for this thickness by using the effective length or radius described earlier.

FIGURE 16.2.33 Resonant size of square microstrip antenna.

FIGURE 16.2.34 Resonant diameter of round microstrip antenna.

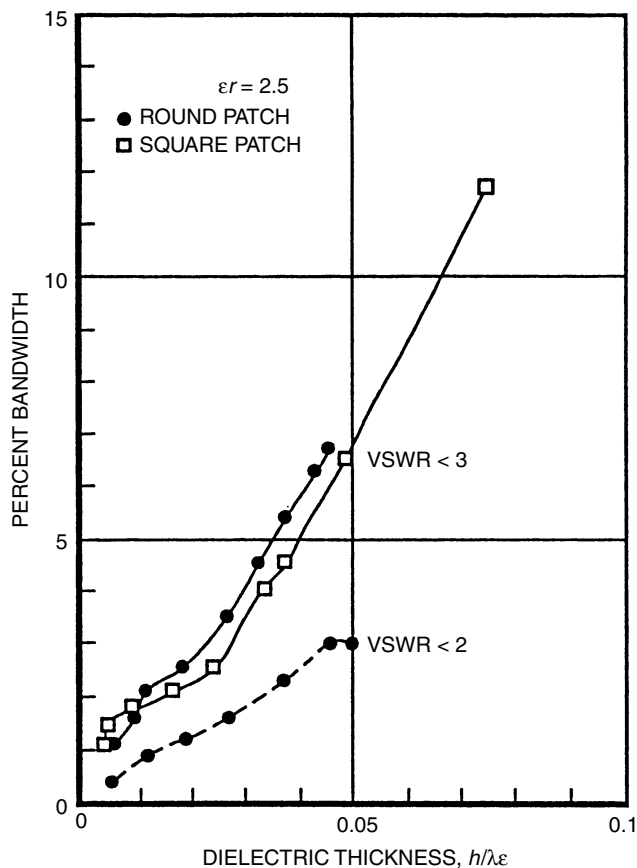

FIGURE 16.2.35 Measured bandwidth for coaxial-fed microstrip antenna.

Impedance

The resonant input impedance for a feed line connected at the edge of a microstrip antenna is about $120\ \Omega$ for the rectangular and about $300\ \Omega$ for the round element. A quarter-wave section with a characteristic impedance of $77.5\ \Omega$ or $122.5\ \Omega$ can be inserted in the microstrip feed line to match the rectangular or round element to $50\ \Omega$. In coaxial probe-fed microstrip antennas, the resonant input impedance varies from zero to the center of the element to about $120\ \Omega$ (rectangular) or $240\ \Omega$ (round) to the edge; therefore, a probe position can always be found, which matches the antenna to the $50\ \Omega$ coaxial feed. The exact probe position for a $50\ \Omega$ match depends on the thickness of the dielectric; however, it has been found that a coaxial probe positioned $L/4$ from the edge of a rectangular element or $a/3$ from the center of a round element will usually yield an input impedance quite close to $50\ \Omega$. Approximate analytical models are also available^{81–86} for calculating the impedance of microstrip antennas.

Radiation Patterns

The radiation patterns of round or rectangular microstrip elements can be found from a complementary-waveguide-fed aperture of the same size as the effective size of the microstrip antenna⁸⁷ or from slots located around the perimeter of the element.⁸⁸

CHAPTER 16.3

FUNDAMENTALS OF WAVE PROPAGATION

Richard C. Kirby, Kevin A. Hughes

INTRODUCTION: MECHANISMS, MEDIA, AND FREQUENCY BANDS

This chapter deals with radio waves propagated through or along the surface of the earth, through the atmosphere, and by reflection or scattering from the ionosphere or troposphere. The particular propagation mechanism around which a given application is designed depends on the distance to be spanned, the type of information to be transmitted or the service to be provided, and the reliability required. Other propagation mechanisms can affect the performance of the system or lead to interference with and from other systems, depending on frequency and distance.

Over a line-of-sight path within the nonionized atmosphere, transmission is much as through free space, though atmospheric refraction causes bending, reflection, scattering, and possibly fading. At frequencies above about 10 GHz, there may be attenuation because of rainfall and absorption by air and water vapor. The conductivity and permittivity (dielectric constant) of the earth are markedly different from those of the atmosphere. A wave mainly diffracted along the surface of the ground encounters increasing loss with increasing frequency. Very low frequency waves are propagated with little attenuation over thousands of kilometers. At high frequencies, losses along the ground become so great that the usefulness of the ground wave is limited to short distances. At medium and high frequencies, ionospheric reflections permit radio communication to great distances. At frequencies much above 30 MHz, ionospheric reflections are not dependable, and most communications depend on line-of-sight propagation or tropospheric scattering beyond the horizon.

Because of the dependence of propagation characteristics on frequency, much of the discussion of these sections will be in terms of frequency bands, and abbreviations such as VLF for very low frequencies and VHF for very high frequencies will be used.

The International Telecommunication Union (ITU) has defined nine frequency bands designated by integer band numbers; for example, 1 MHz is the approximate midband of band 6, and so on, as listed in Table 16.3.1.

Certain frequency bands, however, are sometimes unofficially designated by letter rather than by the abbreviations given in Table 16.3.1. Since there is no standard correspondence between the letters and the frequency bands concerned, it is advisable that their use be clarified by reference to the approximate limits of the band or to a frequency within the band. For information, letter designations used essentially in the areas of radar and space communications, are given in Table 16.3.2.

Propagation characteristics are discussed according to somewhat different bands, such as 10 to 150 kHz and 150 to 1500 kHz, corresponding to bands of relatively homogeneous propagation characteristics.

References 1 to 6 are basic texts on electromagnetic wave propagation. References 7 to 22 are comprehensive texts on tropospheric and ionospheric radiowave propagation which, in some cases, adopt a systems approach in describing the particular propagation mechanisms of concern. Recent results of theoretical and experimental radio science worldwide are outlined in Ref. 23.

TABLE 16.3.1 Frequency Bands Defined by ITU

ITU band number*	Frequency range (lower limit exclusive, upper limit inclusive)	Corresponding metric subdivision	Abbreviation
4	3–30 kHz	Myriametric waves	VLF
5	30–300 kHz	Kilometric waves	LF
6	300–3000 kHz	Hectometric waves	MF
7	3–30 MHz	Decametric waves	HF
8	30–300 MHz	Metric waves	VHF
9	300–3000 MHz	Decimetric waves	UHF
10	3–30 GHz	Centimetric waves	SHF
11	30–300 GHz	Millimetric waves	EHF
12	300–3000 GHz (3 THz)	Decimillimetric waves	

*Band number N extends from 0.3×10^N to 3×10^N Hz.

The emphasis here is mainly descriptive, key formulas indicating the behavior of parameters and references to significant publications providing material for engineering calculations. Maxwell’s uniform plane-wave equations are cited only to show the role of the electrical constants and the vector relationships of electric and magnetic field and power flux.

Wave Propagation in Homogeneous Media

Electromagnetic radiation is composed of two mutually dependent vector fields, electric and magnetic. The electric field is characterized by the vectors **E**, electric field strength in volts per meter, and **D**, dielectric displacement in coulombs per square meter. The magnetic field is characterized by **H**, the magnetic field strength in ampere-turns per meter (or amperes per meter) and **B**, flux density, in webers per square meter. The vector current density **J** is in amperes per square meter.

The relationship between the members of the various pairs of field vectors is characterized by the constitutive parameters, or *electrical constants*, of the medium:

$$\begin{aligned} \epsilon &= \text{permittivity (dielectric constant), F/m} \\ \sigma &= \text{conductivity, S/m} \quad \mu = \text{permeability, H/m} \end{aligned} \tag{1}$$

In some cases these constants are functions of the coordinate. Locally, however, they are always considered to be constant. Nearly always the time factor in these sections is $\exp(+i\omega t)$, where ω is the angular frequency $2\pi f$ (f in hertz) and t the time. The *electric field*, then, is the real part of $E \exp i\omega t$.

TABLE 16.3.2 Unofficial Letter Designations for Certain Bands (Recomm. ITU-R V.431)

Letter symbols	Radar (GHz)		Space radiocommunications	
	Spectrum regions	Examples	Nominal designations	Examples (GHz)
L	1–2	1.215–1.4 2.3–2.5	1.5 GHz band 2.5 GHz band	1.525–1.710
S	2–4	2.7–3.4		
C	4–8	5.25–5.85	4/6 GHz band	3.7–4.2 5.925–6.425
X	8–12	8.5–10.5 13.4–14.0	— 11/14 GHz band	10.7–13.25
Ku	12–18	15.3–17.3	12/14 GHz band	14.0–14.5
K	18–27	24.05–24.25	20 GHz band	
Ka	27–40	33.4–36.0	30 GHz band	20–30 (approx.)

To explain very basic notation,* a short outline of plane electromagnetic waves in a homogeneous medium is given.

Ohm's law in the complex form is

$$\mathbf{J} = (\sigma + i\epsilon\omega)\mathbf{E} \quad (2)$$

where \mathbf{J} is the current density vector and \mathbf{E} is the electric field vector.

The analogous relation for magnetic quantities is

$$\mathbf{B} = \mu\mathbf{H} \quad (3)$$

In source-free media the above vector quantities are related by

$$\text{curl } \mathbf{E} = -i\mu\omega\mathbf{H} \quad (4)$$

and

$$\text{curl } \mathbf{H} = (\sigma + i\epsilon\omega)\mathbf{E} \quad (5)$$

These are Maxwell's equations.

For a homogenous medium

$$\text{curl curl } \mathbf{E} = \text{grad div } \mathbf{E} - \text{div grad } \mathbf{E} = -i\mu\omega(\sigma + i\epsilon\omega)\mathbf{E} \quad (6)$$

Since $\text{div } \mathbf{E} = 0$,

$$(\nabla^2 - \gamma^2)\mathbf{E} = 0 \quad (7)$$

where $\nabla^2 = \text{div grad} = \text{Laplacian operator}$ (which operates on the rectangular components of \mathbf{E}) and $\gamma^2 = i\mu\omega(\sigma + i\epsilon\omega)$. The quantity γ is called the *propagation constant*.

As a simple illustration of the role of the electrical constants of the medium, the field of a wave is assumed to vary only in the z direction in space (time factor $\exp i\omega t$ understood), and the electric field is assumed to have only an x component E_x . For this case Eq. (7) reduces to

$$\left(\frac{d^2}{dz^2} - \gamma^2 \right) E_x = 0 \quad (8)$$

and the solutions are $\exp(+\gamma z)$ and $\exp(-\gamma z)$ or, in general,

$$E_x = A \exp \gamma z + B \exp(-\gamma z) \quad (9)$$

where A and B are constants. The magnetic field then has only a y component given by

$$H_y = -\frac{1}{i\mu\omega} \frac{\partial E_x}{\partial z} = -\eta^{-1} [A \exp(+\gamma z) - B \exp(-\gamma z)] \quad (10)$$

where

$$\eta = \left(\frac{i\mu\omega}{\sigma + i\epsilon\omega} \right)^{1/2} \quad (11)$$

η is defined as the *characteristic impedance* of the medium for plane-wave propagation. Remembering that the time factor is $\exp i\omega t$, we see that the term $B \exp(-\gamma z)$ is a wave traveling in the positive z direction with diminishing amplitude and the term $A \exp \gamma z$ is a wave traveling in the negative z direction with diminishing amplitude.*† The electric and magnetic fields are both transverse to the direction of propagation and orthogonal to each other.

*From Wait³ by permission.

†The geometry of subsequent paragraphs uses a different convention for x , y , and z directions, shown in figures.

16.50 ANTENNAS AND WAVE PROPAGATION

Such radiation is termed *plane-polarized*. It is by convention designated as *horizontal* or *vertical* according to the orientation of the plane containing the \mathbf{E} vector.

The quantity η is equal to the complex ratio of the electric and magnetic field components in the x and y directions, respectively, for plane waves in an unbounded homogeneous medium, i.e.,

$$H_y = (i\omega\epsilon/r)E_x = E_x/\eta, \quad H_x = (-r/i\omega\mu)E_y = -E_y/\eta \quad (12)$$

For a perfect dielectric ($\sigma = 0$)

$$\eta = \sqrt{\mu/\epsilon} \quad \text{and} \quad r = ik \quad (13)$$

where $k = \omega\sqrt{\mu\epsilon} = 2\pi/\lambda$ and λ is the wavelength.

The velocity of this wave is

$$v = 1/\sqrt{\mu\epsilon} \quad (14)$$

v is called the *phase velocity* of the wave. It represents the velocity of propagation of phase and does not necessarily coincide with the velocity with which the energy of a wave of signal is propagated, known as the group velocity. In fact, v may exceed free-space wave velocity without violating relativity in any way.

The wavelength is defined as the distance the wave propagates in one period.

$$\lambda = \frac{2\pi}{\omega\sqrt{\mu\epsilon}} = \frac{v(\text{m/s})}{f(\text{Hz})} \quad \text{m} \quad (15)$$

For free space

$$\epsilon = \epsilon_0 = 8.854 \times 10^{-12} \text{ F/m}, \quad \mu = \mu_0 = 4\pi \times 10^{-7} \text{ H/m}, \quad \sigma = 0 \quad (16)$$

Then

$$\gamma = ik = i\omega\sqrt{\mu_0\epsilon_0} = i2\pi/\lambda$$

The *velocity of the wave for free space* is

$$v_0 = 1/\sqrt{\mu_0\epsilon_0} \approx 3 \times 10^8 \text{ m/s} \quad (17)$$

The *characteristic impedance of free space* is

$$\eta_0 = \sqrt{\mu_0/\epsilon_0} \approx 120\pi \Omega \approx 4\pi v_0 \times 10^{-7} \Omega \quad (18)$$

Energy flow in the electromagnetic field is described by the Poynting vector

$$\mathbf{P} = \mathbf{E} \times \mathbf{H}^* \quad (19)$$

where the complex representation of the time-periodic quantities is implied and the asterisk denotes the complex conjugate. The *real part* of the Poynting vector represents the average power flow over a cycle of the time variation per unit area in the direction of transmission.

$$\mathbf{P}_{\text{av}} = 1/2 \text{ Re} (\mathbf{E} \times \mathbf{H}^*) = E^2/2\eta_0 \quad \text{W/m}^2 \quad (20)$$

\mathbf{P}_{av} is called the *power flux density* or *field intensity*. Note that \mathbf{E} and \mathbf{H} are peak values.

The permeability and permittivity of any medium relative to free space are called the *relative permeability* and *relative permittivity*. These are usually the values given in tables of physical constants; they are dimensionless and designated by μ_r and ϵ_r , respectively.

Polarization of the Wave. *Polarization* is a term characterizing the orientation of the field vector in its travel. In radio, polarization usually refers to the electric vector. In the simplest case E_z and H_z (field components in the direction of propagation) are zero, and \mathbf{E} and \mathbf{H} lie in a plane transverse to the direction of propagation and orthogonal to each other. Such a plane wave is *elliptically polarized* when the electric vector \mathbf{E} describes an ellipse in the plane perpendicular to the direction of propagation over one cycle of the wave.

When the amplitudes of the rectangular components are equal and their phases differ by some odd integral multiple of $\pi/2$, the polarization ellipse becomes a circle and the wave is *circularly polarized*. It is customary to describe as *right-handed* circularly polarized a clockwise rotation of \mathbf{E} when viewed in the direction of propagation; counterclockwise rotation is *left-handed* polarization.*

An important case for many radio problems is that in which the polarization is a straight line. The wave is then *linearly polarized*. In *horizontal polarization* the electric vector lies in a plane parallel to the earth's surface.

To obtain maximum transfer of power between two antennas the polarization should match. If the transmitting antenna is horizontally polarized, the receiving antenna must likewise be horizontally polarized. If the transmitting antenna is elliptically polarized with a given degree of ellipticity and a specified direction of rotation, the receiving antenna should have the proper direction of rotation and degree of ellipticity in order to maximize the path antenna gain.

It should be noted that in the process of propagation, except through free space, the polarization may be altered. This can be caused by reflections from surfaces and, for frequencies at SHF and above, by hydrometers in the neutral atmosphere such as rain. Passage through the ionosphere in the presence of magnetic field is likely to impart elliptical polarization to a plane-polarized incident wave and rotation of the major axis. For MF or HF ionospheric propagation, the downcoming wave may be randomly polarized.

Reflection

Most problems in wave propagation involve reflection from a boundary between media of different refractive properties, often between air and the ground or between air and the ionosphere. In general, such a boundary may involve dissipative media (finite conductivity), curvature, finite dimensions, roughness, and stratification.

FIGURE 16.3.1 Geometry of reflection and transmission.

The *complex index of refraction* for a conducting medium is

$$n^2 = [i\omega\mu(\sigma + i\omega\epsilon)]/[i\omega\mu_0(i\omega\epsilon_0)] \tag{21}$$

When $\sigma = 0$,

$$n = \sqrt{\mu_r\epsilon_r} \quad \text{where } \mu_r = \mu/\mu_0, \epsilon_r = \epsilon/\epsilon_0$$

For many applications $\mu = 1$ and $\sigma = 0$, and the index of refraction is simply the square root of ϵ_r .

Figure 16.3.1 illustrates Snell's law for refraction of plane waves at an infinite plane interface. The angle ϕ between the direction of propagation and the normal to the boundary is called the *angle of incidence*. The angle ψ between the direction of propagation and the boundary, called the *grazing angle*

*Right- and left-hand polarization are sometimes misinterpreted with regard to the direction of viewing; the definition given here corresponds to the International Radio Regulations, Geneva, 1990.

or *Elevation angle*, is often more convenient. If the medium containing the incident wave is lossy, the angle of incidence is complex and can be defined in various ways.³ At the boundary, the tangential components of \mathbf{E} and \mathbf{H} must be continuous; the phase of the reflected wave is in step with the phase of the incident wave to satisfy this requirement.

Snell's law of refraction for the direction of the transmitted wave toward C is

$$n_1 \sin \phi_1 = n_2 \sin \phi_2 \quad \text{or} \quad n_1 \cos \psi_1 = n_2 \cos \psi_2 \quad (22)$$

The *penetration depth* δ , or the depth at which the transmitted wave E_t has attenuated to $1/e$ of its incident value (for a conducting medium where $\sigma \gg \omega\epsilon$), is

$$\delta = \frac{1}{\sqrt{\omega\mu\sigma/2}} \quad \text{m} \quad (23)$$

Ground Reflection, Reflection Coefficients, Fresnel Zones

A wave incident on a plane surface can be resolved into two components, one polarized normal and the other parallel to the plane of incidence. The reflection coefficients for the two components differ, and consequently the polarization of the reflected wave depends on the angle of incidence. Consider an air-earth boundary, taking the media to be nonmagnetic; for the case where the \mathbf{H} vector is parallel to the ground surface the complex reflection coefficient¹ is

$$\mathbf{R}_v = \frac{(\epsilon_r - i60\sigma\lambda)\sin\psi - (\epsilon_r - \cos^2\psi - i60\sigma\lambda)^{1/2}}{(\epsilon_r - i60\sigma\lambda)\sin\psi + (\epsilon_r - \cos^2\psi - i60\sigma\lambda)^{1/2}} \quad (24)$$

where σ = conductivity (S/m)

ψ = grazing angle (Fig. 16.3.1)

ϵ_r = relative permittivity of earth to air or free space

$\epsilon_r - i60\sigma\lambda$ is referred to as the *complex permittivity*.

If E is parallel to the ground surface and H is in the plane of incidence,

$$\mathbf{R}_h = \frac{\sin\psi - (\epsilon_r - \cos^2\psi - i60\sigma\lambda)^{1/2}}{\sin\psi + (\epsilon_r - \cos^2\psi - i60\sigma\lambda)^{1/2}} \quad (25)$$

These are reflection coefficients for vertical and horizontal polarization, respectively. Curves of values for a range of ϵ and σ are given in Ref. 1.

An important property for vertical polarization is that there exists an angle of incidence for which the reflection coefficient approaches zero (for purely dielectric media it equals zero). This is the *Brewster angle*, also called the *polarizing angle*, given by

$$\phi_0 = \tan^{-1} \sqrt{\epsilon_1/\epsilon_2} \quad (26)$$

It is equal to the angle of incidence for which the reflected and refracted (transmitted) rays are at right angles. If the incidence occurs at the Brewster angle, the reflected wave is polarized entirely in the direction normal to the plane of incidence.

Wave tilt is a property frequently used to determine the electrical constants of the earth. For waves traveling at nearly grazing incidence along the surface of the earth, wave tilt may be interpreted geometricaly as the angle between the normal to the wavefront and the tangent to the earth's surface. Wave tilt is

defined to be the ratio of the horizontal to the vertical component of the electric field in the air just above the ground:

$$W = \mathbf{E}_h / \mathbf{E}_v \tag{27}$$

Wave tilt is related to the electrical constants of a homogeneous earth by

$$W = \frac{\sqrt{\mu_1 / \epsilon_{1c}}}{\sqrt{\mu / \epsilon_0}} \sqrt{1 - \frac{\mu_0 \epsilon_0}{\mu_1 \epsilon_{1c}}} \tag{28}$$

The subscript 1 refers to earth constants and 0 refers to free space; $\epsilon_{1c} = \text{complex permittivity} = \epsilon_1 - i\sigma_1/\omega$.

This procedure assumes that $\mu_0 = \mu_1$, generally a valid assumption; if it is not, μ_1 must be determined by some other procedure.

An important consideration in many propagation problems is the interference pattern generated by vector addition of the fields corresponding to the direct ray from an antenna to a point within line of sight plus the ground-reflected ray. In fact, the ground acts as a partial reflector and as a partial absorber, and the resultant field strength at a receiving point is given by

$$E_R = E_1 \left[\underbrace{1}_a + \underbrace{R e^{i\Delta}}_b + \underbrace{(1 - R) A e^{i\Delta} + \dots}_c \right] \tag{29}$$

Term *a* corresponds to the direct wave while term *b* represents the reflected wave with *R* as the reflection coefficient and Δ the phase difference (in radians) corresponding to the path difference between the direct and reflected rays.

Term *c* corresponds to the surface wave, with the attenuation factor *A* a function of frequency, polarization, and electrical constants of the ground. The surface wave is particularly important at medium and low frequencies.

Using the notation in Fig. 16.3.2a the phase difference Δ may be written as

$$\Delta = 4\pi h_1 h_2 / \lambda d \quad \text{rad} \tag{30}$$

for a wavelength λ and for grazing angles less than about 0.5 rad, Eq. (29) may be written:

$$E_R = E_1 \frac{4\pi h_1 h_2}{\lambda d} \tag{31}$$

omitting any contribution from the surface wave.

FIGURE 16.3.2 Geometry of ground reflection, image antennas, and Fresnel zones for plane earth: (a) ray paths; (b) Fresnel zone and ellipsoid.

The received field strength at a given distance will therefore display maxima and minima around the free-space value (corresponding to the direct wave alone) as the height of either antenna is altered. The angle at which maxima and minima occur are given by

$$\sin \psi = n\lambda/4h_1 \quad \text{maxima for } n \text{ odd, minima for } n \text{ even} \quad (32)$$

For the first maximum to occur at a specified elevation ψ_1 ,

$$h_1 = \lambda/(4 \sin \psi_1) \quad (33)$$

In Fig. 16.3.2a the ray reflections are shown as though they occurred at a point. Actually, the surface of the earth is illuminated over a wide region corresponding to the radiation patterns of the two antennas and, in accordance with Huygens' principle, reradiates elementary wavelets in all directions. In any particular direction, as toward R , these elementary wavelets arrive with strength and phase such that the waves from an elliptical zone in the neighborhood of the ray reflection add nearly in phase. From successive ring areas, similarly bounded by larger ellipses, the waves alternately cancel and add.

These zones of physical reflection are called *Fresnel zones*, since they are closely related to the Fresnel zones of diffraction theory.^{5,10} Most of the energy can be thought of as being reflected from the first Fresnel zone; it is defined, with the aid of Fig. 16.3.2b, for reflection paths between points such as T and R , as the area from which all the reradiated elementary wavelets arrive, according to geometric optics, within half wavelength of the phase of the direct ray. Thus the length of the geometric ray path at the edge of the n th Fresnel zone is n half wavelengths greater than the geometric ray path.

From Fig. 16.3.2b, the boundary of the first Fresnel zone is defined as the locus of points A such that $TA + AR$ differs by half a wavelength from TR . This locus is an ellipsoid of revolution with foci at T' and R . The minor axis of the first Fresnel zone has the same dimension as the diameter of the first Fresnel ellipsoid, which can be easily shown to be $\sqrt{\lambda d}$, where d is the length of the propagation path. The length of the major axis will depend on the antenna heights h_1 and h_2 and is given by

$$L = \frac{d\sqrt{1+4h_1h_2/\lambda d}}{1+(h_1+h_2)^2/\lambda d} \quad (34)$$

For a well-developed ground reflection, the ground should be flat over an area that includes at least the first Fresnel zone. The degree of flatness depends on the wavelength and angle of incidence; assuming that phase-path changes less than $\lambda/16$ are unimportant, Rayleigh's criterion limits height deviations in terrain from a smooth surface to a magnitude less than $\Delta h = \lambda/(16 \sin \psi)$ over the area of the first Fresnel zone for waves incident at angle ψ . Methods allowing for surface roughness, finite conductivity, and divergence owing to the spherical shape of the earth are outlined on the accompanying CD-ROM under "Propagation Over the Earth Through the Nonionized Atmosphere."

The general topic of reflection from the surface of the earth and a description of the influence-reflected signals have on the performance of telecommunication systems is given in Refs. 7 and 8.

Diffraction and Scattering

The spherical shape of the earth and irregularities of terrain give rise to *diffraction* as an important part of the ground wave and as a mechanism for propagation beyond the optical horizon. Diffraction is included in the methods for calculation given on the accompanying CD-ROM under "Propagation Over the Earth Through the Nonionized Atmosphere."

Scattering takes place from the rough surface of the earth and from small-scale irregularities in the index of refraction of the atmosphere or the ionosphere. It is analogous to scattering of light, although the radio problem is complicated by the wide range of relationships of radio wavelength to size of irregularity.

Scattering is discussed on the accompanying CD-ROM (Tropospheric forward scattering under "Propagation Over the Earth Through the Nonionized Atmosphere," and ionospheric scattering under "Propagation Via the Ionosphere").

Reciprocity

Reciprocity in wave propagation means that the source and receiver can be interchanged, with the transmission loss and phase unaffected by direction of propagation. In most radio-wave-propagation problems, with the notable exception of those involving an ionized medium with magnetic field, such reciprocity obtains. The refraction index of the ionosphere depends on magnetic field effects; the direction of propagation of the wave affects attenuation, phase, and bending, and the medium is called *anisotropic*. Thus, especially at very low and medium frequencies propagated via the ionosphere, reciprocity does not obtain. Reciprocity does not in any case imply the same signal-to-noise ratio in both directions. The noise environment may be very different at the transmitting and receiving locations.

Transmission Loss; Free-Space Attenuation; Field Strength; Power Flux Density

The concept of transmission loss for radio links consisting of a transmitting antenna, a receiving antenna, and the intervening propagation medium is addressed and defined in *Recomm. ITU-R P.341*.⁶⁹

In general terms, the transmission loss on a radio link between a transmitter and a receiver is defined by the ratio between the power supplied by the transmitter and the power available at the receiver input. The transmission loss depends on several factors such as the losses in the antennas or in the transmission feed lines, the attenuation in the propagation medium, the losses because of faulty adjustment of the impedance or polarization, and so forth. As a consequence there are several definitions employed to characterize transmission loss and its components.

The *system loss* (L_s) on a radio link is the ratio, usually expressed in decibels, of the radio-frequency power input to the terminals of the transmitting antenna p_t , and the resultant radio-frequency signal power available at the terminals of the receiving antenna p_a . The available power is the maximum real power that a source can deliver to a load, i.e., the power that would be delivered to the load if the impedances were conjugately matched. The system loss may be expressed by*

$$L_s = 10 \log(p_t/p_a) = P_t - P_a \quad \text{dB} \quad (35)$$

and as defined here excludes losses in feeder lines but includes all losses in radio-frequency circuits associated with the antennas, such as ground losses, dielectric losses, antenna loading coil losses, and terminating resistor losses.

The *transmission loss* (L) on a radio line is the ratio, usually expressed in decibels, between the power radiated by the transmitting antenna and the power that would be available at the receiving antenna output if there were no loss in the radio-frequency circuits, assuming that the antenna radiation diagrams are retained. The transmission loss may be expressed by

$$L = L_s - L_{tc} - L_{rc} \quad \text{dB} \quad (36)$$

where L_{tc} and L_{rc} are the losses, expressed in decibels, in the transmitting and receiving antenna circuits, respectively, excluding the dissipation associated with antenna radiation, i.e., L_{tc} and L_{rc} may be expressed by $10 \log (r'/r)$, where r' is the resistive component of the antenna circuit and r is the radiation resistance.

The *basic transmission loss* (L_b) on a radio link is the transmission loss that would occur if the antennas were replaced by isotropic antennas with the same polarization as the real antennas, the propagation path being retained, but the effects of obstacles close to the antennas being disregarded. An isotropic antenna is one that radiates (or receives radio energy equally in (or from) all directions. In determining the basic transmission loss, any local features, such as the ground or nearby structures, which affect the power gain and directivity of the antenna, but which do not affect the overall propagation path, are assumed to be removed. The effect of the local ground is included in computing the antenna gain, but not in L_b . For instance, in the case of ionospheric propagation using an antenna near the ground which has a strong influence on the effective gain for the sky-wave path,

*Capital letters are used to denote quantities in decibels.

the ground is removed for the calculation of L_b , so as to maintain the gain in the desired direction. In the case of a tropospheric propagation path involving diffraction over a distance obstacle, that obstacle is not removed in estimating L_b .

The *free-space basic transmission loss* (L_{bf}) is the transmission loss that would occur if the antennas were replaced by isotropic antennas located in a perfectly dielectric, homogeneous, isotropic, and unlimited environments, the distance between the antennas being retained. At a distance d very much greater than the wavelength λ , the power flux density (field intensity), expressed in watts per square meter, is simply $p'_i/4\pi d^2$ since the power p'_i is radiated uniformly in all directions. The effective absorbing area of the isotropic receiving antenna is $\lambda^2/4\pi$, and the available power at the terminals of the loss-free isotropic receiving antenna is given by

$$p'_a = \frac{\lambda^2}{4\pi} \frac{p'_i}{4\pi d^2} \quad (37)$$

Consequently, the free-space *basic transmission loss* can be expressed by

$$L_b = 20 \log \frac{4\pi d}{\lambda} \quad \text{dB} \quad (38)$$

d and λ are expressed in the same units.

A practical form of this equation is

$$L_b = 32.45 + 20 \log f_{\text{MHz}} + 20 \log d_{\text{km}} \quad \text{dB} \quad (39)$$

In many cases, it is important to know the *loss relative to free space* (L_m) on a radio link which is the difference between the basic transmission loss and the free-space basic transmission loss, expressed in decibels, and may be expressed by

$$L_m = L_b - L_{bf} \quad \text{dB} \quad (40)$$

The loss relative to free space may be divided into losses of different types, such as

- Absorption loss (ionospheric, atmospheric gases or precipitation)
- Diffraction loss as for ground waves
- Effective reflection or scattering loss, as for ionospheric propagation and including the results of any focusing or defocusing because of curvature of a reflection layer
- Polarization coupling loss, which can arise from any polarization mismatch between the antennas for the particular ray path considered
- Aperture to medium coupling loss or antenna gain degradation, which may be a result of the presence of substantial scatter phenomena on the path
- Effect of wave interference between the direct ray and rays reflected from the ground, other obstacles, or atmospheric layers

For broadcasting and mobile services, where characteristics and locations of receiving installations vary, it is convenient to calculate the electric *field strength* at some distance from the transmitter. The rms field strength e (V/m) of a plane wave of wavelength λ (m) is related to the power p'_a (W) available from an ideal loss-free isotropic receiving antenna by

$$e = (480 \pi^2 p'_a / \lambda^2)^{1/2} \quad (41)$$

It then follows from Eq. (37) that the field strength produced by a transmitter having an *equivalent isotropically radiated power* (EIRP) of p_i (W), at the distance d (m) sufficiently large for the wavefront to be considered plane, is given by

$$e = (30 p'_i / d^2)^{1/2} \quad (42)$$

or in more practical units,

$$e(\text{mV/m}) = 173[p'_t (\text{kW})]^{1/2} / d (\text{km}) \quad (43)$$

In decibels, the equivalent expression is

$$E [\text{dB}(\mu\text{V/m})] = 105 - 20 \log d (\text{km}) + P'_t \quad (44)$$

where p_t is the EIRP in dB(kW).

In the above expressions, the EIRP includes the gain of the transmitting antenna with respect to an isotropic antenna. Often it is more convenient to express antenna gain with respect to a standard antenna other than an isotope, and an appropriate conversion must be made in order to determine the EIRP. For example, if the gain is given with respect to a half-wave dipole, the gain must be multiplied by 1.64 or, in decibels, be increased by 2.1 dB to obtain the EIRP. Alternatively, the following formula may be used

$$E \approx 7(p''_t)^{1/2} / d \quad (45)$$

where E is the field strength in V/m, d is the distance in m, and p''_t is the effective radiated power (ERP), which includes the transmitter gain with respect to a half-wave dipole.

Similarly, the antenna gain may be expressed with respect to a short vertical monopole above a perfectly conducting ground plane. In this case, the gain must be multiplied by 3 or, in decibels, be increased by 4.8 dB to obtain the EIRP.

For microwave and satellite services, power flux density is a convenient term. The *power flux density* is given by the characteristic relations of a plane wave

$$p = e^2 / \eta \quad \text{W/m}^2 \quad (46)$$

where η is the characteristic impedance of the medium in which the measurement is made ($\eta_0 = 120\pi$ in free space). In free space

$$p = e^2 / 120\pi \quad \text{and} \quad p = 4\pi p_a / \lambda^2 \quad (47)$$

where p_a is available power received by an isotropic antenna in the field.

The relations between field strength, power flux density, and available power in the receiving antenna are outlined below.

The absorbing area of a receiving antenna with gain g_r relative to an isotropic antenna can be written

$$a_e = \lambda^2 g_r r_f / 4\pi r \quad (48)$$

where λ = wavelength in medium

r = radiation resistance of antenna

r_f = radiation resistance of antenna in free space

Combining the above two equations, we find the following formula for the available power p'_a from a lossless receiving antenna:

$$p'_a = e^2 \lambda^2 g_r r_f / 4\pi \eta r = v^2 / 4r \quad (49)$$

The v in this equation denotes the open-circuit voltage induced in the receiving antenna. The field strength is related to the open-circuit voltage by

$$v = e \sqrt{\lambda^2 g_r r_f / \pi \eta_0} = el \quad (50)$$

Field-strength meters usually are calibrated in terms of the effective length l of the antenna.

The relation between the available power p_a from the receiving antenna (neglecting losses) and the field strength e can be expressed in decibels as

$$E = 10 \log[4\pi\eta_0 p_a \times 10^{12} / \lambda^2 g_r] = P_a + 20 \log f - G_r + 107.22 \text{ dB } (\mu\text{V/m}) \quad (51)$$

where f is in megahertz.

For field strength E in decibels referred to 1 $\mu\text{V/m}$, referred to 1 kW radiated from a half-wave dipole over perfectly conducting earth, propagation loss is

$$L_p = 139.4 - G_r + 20 \log f - E \text{ dB} \quad (52)$$

If the reference radiation is a short electric dipole, the constant becomes 136.0.

Power Fading and Time-Variant Multipath Fading

Random variations appear in the signal received via various transmission media, especially at frequencies above about 100 kHz when propagation is by the troposphere or ionosphere. Such variation is usually of two types: one is *attenuation*, or *power fading*, which may be quite slow (minute to minute, hour to hour, and so forth) and is associated with comparatively large-scale changes in the medium, such as absorption; the other is *variable-multipath* or *phase-interference fading*.

Power fading is usually allowed for in the power margin designed into the system. Phase-interference fading, on the other hand, affects not only the amplitude but also the variable phase-vs.-frequency characteristic of the channel, limiting coherence bandwidth and introducing extraneous fluctuation in received-signal parameters. Alleviation of the effects of variable multipath is possible by diversity techniques, signal design, and signal receiving, processing, and detection operations.

The amplitude probability distribution of the fading envelope is usually determined from samples of duration much shorter than the shortest fade duration; observation intervals over which statistical averages are taken are about 1000 times the reciprocal of the nominal fading rate. The fit of experimental distributions of envelope fading to the Rayleigh distribution is often excellent for ionospheric and tropospheric scatter propagation, and similarly to a Nakagami-Rice⁸ distribution for situations where a specular component is mixed with scattered components. (See also Recomm. ITU-R PN. P.1057).

It is often necessary, however, to consider the combination of long-term (power) fading, represented by a log-normal distribution, with short-term variations, represented by a Rayleigh distribution. The distribution of instantaneous values over a long period can be obtained from the Rayleigh law, whose mean is itself a random variable having a log-normal distribution.

A description of the fundamental properties of the most common probability distribution used in the statistical study of radio-wave propagation is given in Recomm. ITU-R PN. P.1057.

Most theoretical treatments of communication performance in the presence of variable multipath fading resulting from several signal components have been carried out for channels characterized by Rayleigh envelope distribution. The probability density function is given by

$$p(V) = (2V/v^2) \exp[-(V/v)^2] \quad (53)$$

where V is the fluctuating envelope and v^2 is the mean square value of V over distribution. For the Rayleigh fading channel, the probability that the received signal envelope will fall at or below some specified value of V is given by the cumulative distribution

$$p(V \leq V') = \int_0^{V'} \frac{2V}{v^2} \exp\left[-\left(\frac{V}{v}\right)^2\right] dV = 1 - \exp\left[-\left(\frac{V'}{v}\right)^2\right] \quad (54)$$

The Rayleigh probability distribution function Eq. (54) is often used in the form

$$p(V \leq V') = 1 - \exp[-0.693(V'/V_M)^2] \quad (55)$$

where V_M is the median value, about 1.6 dB below the rms value. *Fading rate* is important to certain systems. One measure of fading rate is the number of times per second (hertz) the carrier envelope crosses its median with a positive or negative slope. Another measure is the width of the received carrier-envelope spectral density.

It is also important to obtain information on fade durations; the effect of a large number of very short fades is quite different from that of a few long-duration fades, the former being serious for digital links, the latter for analog links. The rate of change of fade is important in the design of switching systems for diversity reception.

For some time, design concern (besides its emphasis on the amplitude variation) has centered on the dispersion and multipath characteristics of the medium, in terms of linear time-variant amplitude and phase- and frequency-distortion parameters, often referred to as *multiplicative noise*, which cannot be overcome by power increase.

A more comprehensive characterization is in terms of the *system function* or *impulse function*. This approach relates the response and excitation of a channel at its input and output terminals.^{12,24,25}

The expressions for output are formulated in terms of operations on the input time function $x(t)$ or the spectral function (Fourier transform) $X(\omega)$, to produce the output function $y(t)$ or $Y(\omega)$. Each path is characterized by a system function $h(t, \tau)$ that operates on the replica of $x(t)$ traversing it; t is the time at which the observation is made, and τ is the delay or transit time for the path. The spread of delays between the input and output is determined by the system function $h(t, \tau)$, which can be called the *delay-spread system function*. For any particular elemental path x in a distribution of paths that covers some range of delays, the output for a range of delay $\Delta\tau$ centered on τ is given by $h(t, \tau)x(t - \tau) \Delta\tau$, and the total output of the channel is the sum of all such weighted and delayed contributing paths, namely.

$$y(t) = \int_{-\infty}^{\infty} x(t - \tau)h(t, \tau) d\tau \quad (56)$$

For a Fourier transformable input $x(t)$, the output can be expressed in terms of the input spectral function $X(i\omega)$:

$$x(t) = \int_{-\infty}^{\infty} X(i\omega)\exp(i\omega t)d(\omega/2\pi) \quad (57)$$

Here we characterize the channel by stating that it modifies the contribution to the structure of $x(t)$ from spectral components in the range $\Delta\omega$ centered at ω by multiplying it by the transfer function $H(i\omega, t)$. The total channel response to $x(t)$ is then

$$x(t) = \int_{-\infty}^{\infty} H(i\omega, t)X(i\omega)\exp(i\omega t)d(\omega/2\pi) \quad (58)$$

which is the limit of the sum of the channel responses to the components of $x(t)$ from various infinitesimally wide spectral elements. The time-variant, *frequency-dependent transfer function* $H(i\omega, t)$ can be shown to be the *Fourier transform over the delay-spread variable* τ of the *delay-spread function* $h(t, \tau)$.

The randomness of the channel with time is reflected in the treatment of the system functions $h(t, \tau)$ and $H(i\omega, t)$ as sample functions of processes that are random over the space of the time variable t . The autocorrelation function of the channel response process is given by an inverse Fourier transform operation on the product of the spectral density function of the input process and the autocorrelation function of the time-variant, frequency-dependent transfer function $H(i\omega, t)$ of the channel. Further transformations produce a combined time-shift and frequency-shift correlation function and a so-called *scattering function* $S(\tau_0, f_0)$, which has the physical significance of a function that determines the weighting of the signal power as a function of the time delay τ_0 and Doppler shift f_0 incurred in transmission.

On the basis of the above functions, a set of transmission parameters for random time-variant linear filters is defined.²⁵

1. The *multipath spread* or *delay spread* is determined by the relative delays of the component paths, or the "duration" of $h(t, \tau)$ over the delay variable τ .
2. The *coherence bandwidth*, the bandwidth over which correlation of amplitude fading (or coherence of phase for some applications) remains to a desired degree is usually defined in terms of specified degradation of error rate, distortion, or other parameter.

3. *Diversity bandwidth* is the frequency separation between two sinusoidal inputs which results in a specified decorrelation of the fluctuating responses, usually taken to be a correlation coefficient of $1/e$.
4. The *fading rate*, *fading bandwidth*,* *frequency smear*, or *Doppler spread* is a measure of the bandwidth of the received signal when the input to the channel is a stable single-frequency signal.
5. The *diversity time* (or decorrelation time) is a measure of the time separation between input signals to yield correlation of less than $1/e$ between the envelopes of the responses.

These parameters are not all independent; the coherence bandwidth and delay spread are inversely proportional to each other, as are fading bandwidth and decorrelation time.

Most channel characteristics can be measured. The delay-spread response $h(t, \tau)$ can be measured directly by transmitting very short, widely spaced pulses; each received replica will correspond to one path, which can be resolved to examine the relative amplitudes and delays. The amplitude characteristic of the frequency-dependent transfer function $|H(\omega, t)|$ can be measured for short intervals by transmitting a constant-amplitude test signal with repetitive linear sweep covering the desired frequency range. The envelope of the received signal will give a very close approximation to $|H(\omega, t)|$.

Diversity techniques for counteracting short-term fading are used extensively for HF ionospheric communication, forward scatter systems, microwave line-of-sight systems, and Earth-space systems, where high reliability is required. The most common mechanism is to use *spaced antennas*, taking advantage of the fact that fading at one antenna tends to be independent of the signal fluctuation received on another antenna; provision is made to switch between signals or to combine two or more of them. Depending on the propagation mechanism, other kinds of useful diversity include *frequency*, *angle of arrival*, *polarization*, and *time*. Line-of-sight links frequently employ vertical space diversity where vertical separation of the antennas is found to be more effective than horizontal spacing. A simple, generally effective design procedure for this so-called height diversity gives the required vertical spacing between the centers of the antennas as

$$\Delta h = 0.3\sqrt{\lambda d} \quad (59)$$

where the path length d , wavelength λ , and the spacing Δh are all in the same units. A more thorough treatment is found in Recomm. ITU-R P.530.⁶⁹

At frequencies affected by rain, i.e., above about 10 GHz, route diversity is used in which the spacing between the terminals is sufficiently large so that rain affecting one route is unlikely to affect the other.

The performance of a diversity system may be quantified by two parameters, *diversity gain* or *diversity advantage*. The diversity gain of a system is the ratio of the power output at a given time percentage to the corresponding power that would be obtained from a single channel. The diversity advantage is the ratio of the time percentage for which a given fade level is exceeded for a single channel to that for a diversity system. Both parameters may be obtained from cumulative distributions of fade statistics.

Recommendations ITU-R P.530 and 618⁶⁹ give expressions for diversity improvement under different propagation conditions for line-of-sight and Earth-space links, respectively, with further discussion given elsewhere.^{7,8,14}

The outline of fading and diversity improvement given here has assumed *flat* (nonfrequency-selective) fading and Gaussian (white) noise. References 11, 14, and 25 discuss frequency-selective fading for the various types of system. Non-Gaussian noise effects are considered in the next paragraph.

Noise: Signal-to-Noise Ratio

Several types of radio noise must be considered in any design, though, in general, one type will be the dominant factor. In broad categories, the noise can be divided into two types: noise internal to the receiving system and noise external to the receiving antenna.

The *noise of the receiving system* is often the controlling noise in systems operating above about 300 MHz. This type of noise is a result of antenna losses, transmission-line losses, and the circuit noise of the receiver itself and has the characteristics of thermal (i.e. white) noise and thus is Gaussian in nature.¹⁰

**Fading bandwidth* is also often used in the same sense as diversity bandwidth, or coherence bandwidth, above.

The second of the broad categories, *external radio noise*, can be subdivided further into natural and artificial sources. Natural sources of radio noise are: (1) atmospheric, (2) galactic, (3) solar noise from antennas pointing at the sun, (4) precipitation (blowing snow or dust), (5) corona, and (6) noise reradiating from any absorbing medium through which the wanted radio signal passes. Very low noise systems used in space communications can be limited by such absorption by clouds, water vapor, and oxygen. Such *sky noise* has the Gaussian characteristic of receiver noise. Examples of artificial noise sources are: (1) power lines or generating equipment, (2) automotive ignition systems, (3) fluorescent lights, (4) switching transients, and (5) electrical equipment in general. Unlike internal noise, external noise is generally non-Gaussian, being impulsive in nature.

Noise power is generally the most significant single parameter in relating the interference value of the noise to system performance. This parameter, however, is seldom sufficient in the case of impulsive noise, and a more detailed statistical description of the received-noise waveform is generally required.

A useful parameter for expressing the noise power external to the antenna is the effective antenna noise factor f_a which is defined by

$$f_a = p_n / K t_0 b = t_a / t_0 \tag{60}$$

where p_n = noise power available from an equivalent loss-free antenna (W)

K = Boltzmann's constant, 1.38×10^{-23} J/K

t_0 = reference temperature, taken as 288 K

b = effective receiver noise bandwidth, Hz

t_a = effective antenna temperature in the presence of external noise

The noise factor f_a is commonly given as the corresponding noise figure F_a , which is given by $F_a = 10 \log f_a$ (dB).

Figure 16.3.3 shows the median value of the *available noise-power*, F_a (dB above Kt_0), from various sources. While the solar noise, galactic noise, and sky noise are Gaussian, the atmospheric and artificial noises are very impulsive.

Based on measurements from a worldwide network of stations, Recomm. ITU-R P.372⁶⁹ gives detailed estimates of F_a for atmospheric noise as a function of geographic location, season, frequency, and time. Additional data are also provided on noise variability and character which include the standard deviation of F_a , upper and lower deciles of F_a with standard deviations, and estimates of V_d , the ratio of the rms envelope voltage to the average noise envelope voltage. The values of F_a are for a lossless short vertical antenna over a perfectly conducting ground plane; they are related to the vertical rms field strength by

$$E_n = F_a - 95.5 + 20 \log f_{\text{MHz}} + 10 \log b \tag{61}$$

where E_n is the rms noise field strength [dB(μ V/m)] in bandwidth b (Hz), and F_a is the noise figure for the center frequency, f_{MHz} .

Estimates of the noise-power spectral density from artificial noise expected in business, residential, rural, and quiet rural areas have been developed from measurements.²⁷⁻²⁹ These expected values are the means of a number of location medians, with variation from location to location in each type of area and temporal variation indicated. Generally the noise below 20 MHz is associated with power lines. At 20 MHz and above, automotive electrical systems, especially ignition systems, are the dominant sources in all but rural locations. Median values of artificial noise power expressed in terms of F_a are given in Recomm. ITU-R P.372⁶⁹ for different categories of environment, of which curve 3 and 4 in Fig. 16.3.3 are examples.

Impulsive atmospheric or artificial noise disturbs communications in a way quite different from Gaussian noise. Figure 16.3.4 shows the amplitude probability distribution of Gaussian noise and a sample of atmospheric noise. The parameter V_d is the ratio in decibels of the rms voltage to the average voltage and is commonly used as an *impulsive index*. The two distributions are plotted relative to their rms level; i.e., both noises shown have the same energy or power. The probability distribution of the noise envelope determines the performance of most basic digital receivers, as indicated by the two error-rate curves for a binary coherent phase-shift-keying system.

Digital receivers are frequently designed for optimum performance in white Gaussian noise. Their performance in impulsive artificial or atmospheric noise can be summarized as follows, with comparisons made on the basis of equal noise power:

FIGURE 16.3.3 Median radio noise spectral density from various sources. Curve 1 = atmospheric noise, summer, 2000 to 2400 h. Washington, D.C., omnidirectional antenna near ground; curve 2 = atmospheric noise, winter 0800 to 1200 h. Washington, D.C., omnidirectional antenna near ground; curve 3 = artificial noise, business area, omnidirectional antenna near ground; curve 4 = artificial noise, quiet rural areas, omnidirectional antenna near ground; curve 5 = quiet sun, isotropic (0 dB gain) antenna; curve 6 = disturbed sun, isotropic (0 dB gain) antenna; curve 7 = sky noise, narrow-beam antenna (degrees from vertical); curve 8 = galactic noise, omnidirectional antenna near ground.

FIGURE 16.3.4 Comparison of noise distribution and error probabilities for Gaussian and non-Gaussian noise (same noise power, coherent phase-shift keying).

1. For constant signal, at high signal-to-noise (S/N) ratio, impulsive noise causes more errors than Gaussian noise; at lower S/N ratio, Gaussian noise causes more errors.
2. For Rayleigh-fading signals, Gaussian noise causes more errors at all S/N ratios; flat-fading cases do arise, for which impulsive noise will cause more errors than Gaussian noise; for diversity reception, impulsive noise is more harmful.
3. While pairing of errors in differentially coherent phase-shift keying (DCPSK) becomes more unlikely as the S/N ratio increases, pairing of errors increases as the noise becomes more impulsive.
4. For systems with time-bandwidth products in the order of unity, the standard matched filter-receiver is also optimum for impulsive noise.
5. Noise-suppression schemes, such as wide-band limiting and smear-desmear, are not particularly effective at high S/N ratios.
6. Receivers especially designed to reject a particular type of impulsive noise perform substantially better than receivers using the “standard” noise-suppression techniques.

CCIR Report 340-4 (Geneva, 1983) CCIR Atlas of ionospheric characteristics (deleted)		
CCIR: Handbook of Curves for Radio Wave Propagation over the Surface of the Earth (Geneva, 1991)		

The performance of analog voice systems in impulsive noise can be summarized as follows:

1. For a given articulation index, a much lower S/N ratio is required for impulsive noise than for Gaussian noise.
2. Various forms of limiting in AM systems (pre-i.f. limiting, i.f. limiting, postdetection limiting) are quite effective in further reducing the required S/N ratio when the noise is impulsive.

As mentioned above, noise power is also generated from atmospheric gases, clouds, and rain. Recomm. ITU-R P.372⁶⁹ discusses radio emission at frequencies above about 50 MHz from natural sources, not only in the atmosphere but also from extraterrestrial sources and from the surface of the earth. This topic is discussed on the accompanying CD-ROM under “Propagation Over the Earth Through the Nonionized Atmosphere.”

Minimum external noise levels to be expected at terrestrial receiving sites owing to natural and artificial noise sources are also specified in Recomm. ITU-R P.372.⁶⁹ With such data, the appropriate minimum receiver noise figure can be determined so that a terrestrial receiving system can be designed to be almost limited by external noise. Finally, Recomm. ITU-R F.339⁶⁹ gives ratios of required signal energy to noise power spectral density for various systems operating in the presence of atmospheric noise.

Ionspheric Modification by High-Power Radio Transmissions

High-power radio waves can modify the ionospheric plasma by classical ohmic heating, which changes the density and distribution of the ionization, and by generating parametric instabilities which in turn leads to field-aligned ionospheric irregularities (see Recomm. ITU-R P.532, Table 16.3.3).⁶⁹ At HF, ionospheric modification experiments generally use purpose-built transmitters, operating close to the *F*-region critical frequency, to modify the upper ionosphere (150–400 km). The ionosphere can also be appreciably modified by oblique high-power transmission at frequencies considerably in excess of the critical frequency. However, transmitters operating over the range from VLF to UHF can give rise to modifications in all regions of the ionosphere, with the resulting modified region having an effect on other radio signals passing through it. In particular, the scattering properties of ionospheric irregularities, artificially produced in the *F*-region, have been used to establish communications up to UHF between two points on the earth’s surface. Such experiments demonstrate the interference potential to existing services from such mechanisms.

SECTION 17

TELECOMMUNICATIONS

Telecommunication systems and applications deal with the actual technology by which devices communicate with each other. This includes transmission systems, switching systems, local area networks (LANs), wide area networks (WANs), broadband systems, cellular and mobile communication systems, and wireless digital communications. It is interesting to note that in areas of the world where the infrastructure for wire-based communication systems does not exist, it seems that development of such systems will be skipped and they will go directly to wireless.

Future trends dictate that we must communicate more information much faster, much more reliably, and send more transmissions over the same system. We will continue to see wireless technology becoming the dominant communication system. A very good example is the increase in ways of wireless connection to the Internet such as cell phones and PDAs. Clearly, security will also be a dominant force in determining how we communicate. Such security will need to be achieved without degrading the communication process and without making communicating more difficult.

Chapter 17.5, *Wireless Networks*, deals with technologies that combine Internet access with cell phone communication, with picture and email transmission, and walkie-talkie communication. These technologies must allow us to communicate and use information seamlessly, across a wide variety of devices and platforms.

In Chap. 17.6, we look at data networks and the Internet. LANs, metropolitan area networks (MANs), and WANs must be able to cope with the explosion in volume of information communicated at extremely high speeds over hard wire, fiber, and wireless systems.

This explosion in wireless technology and all the resulting capabilities it enables requires more and more sophisticated micro-miniaturized circuits and systems, thus becoming a major driver for MEMS technology. This is fully covered in Chap. 17.8. C.A.

CHAPTER 17.1

TRANSMISSION SYSTEMS

A. B. Brown, Jr., Virgil I. Johannes

INTRODUCTION

A. B. Brown, Jr.

Service Networks

Communication entails the transfer of information from one point to another; the information may be in any of several forms, including voice, data, video, and facsimile. The facilities used for any particular form of service are known as a *service network*. A service network is made up of *terminals*, through which the information enters and leaves the network; *transmission facilities*, which provide the transfer of information from place to place, and *switching*, which connects the appropriate transmission facilities to cause the information to be delivered to the desired place. Some service networks do not include terminals, and some do not include switching. Terminals are of many types, including telephones, teletypewriters, facsimile terminals, and computer ports.

Interfaces

The boundary of the service network, where the user interacts with it (as by means of some piece of terminal equipment) or connects equipment to it is the *interface*. If the interface is digital, the use of digital transmission and switching obviates the need for digital-to-analog (D/A) and analog-to-digital (A/D) conversion of the signals. Contemporary networks with digital interfaces are used for digitally encoded video or voice as well as for high-speed data. Some older networks are used only for data.

Codes and Protocols

Communication of digital data is usually done in the form of characters, each of which is represented as a sequence of bits. Less commonly, the signals may be a bit stream generated and interpreted by the terminal equipment. The number of bits per character and the correspondence between the bit sequence and the character represented is called a *code*. Several codes have been used at various times for telegraphic and computer communications, starting with the Morse dot-dash codes used by telegraphers. The most common standard code at the present time is International Alphabet no. 5 (known in the United States as the American Standard Code for Information Interchange, ASCII). Other codes have been in use for older types of transmission equipment (teletypewriters), and some codes have been introduced by individual manufacturers.

In coded transmission, two methods of maintaining synchronism between the transmitting and receiving points are commonly used. In *start-stop transmission*, the interval between characters is represented by a steady 1 signal; the transmission of a single 0 bit signals the receiving terminal that a character is starting. The information bits follow the start bit and are followed by the stop pulse. It is the same as the signal between

characters and has a minimum length that is part of the specification of the terminal: 1.0, 1.42, 1.5, or 2.0 b are commonly used. In the synchronous method, the bits are sent at a uniform rate; if there is no character ready to be sent when it is time to send one, a synchronous idle pattern is used to maintain the timing. The synchronous method is used at higher speeds.

Protocols are standard procedures for the operations of communication; their purpose is to coordinate the equipment and processes at interfaces and at the ends of the communication channel. The International Telegraph and Telephone Consultative Committee (CCITT) recommendations in the X series, which apply to public data networks, include X.1, speeds; X.2, user options; X.20, interface for start-stop transmission services; X.21, interface for synchronous operation; X.22, multiplex interface for synchronous terminals; X.24, definitions of interface circuits; and X.121, international numbering plan for public data networks. Additional recommendations apply to packet networks.

Network Planning Objectives

The objectives that form the basis of network planning are derived from the service the network is to provide. There may, however, be different objectives for a network corresponding to different intended uses by the customers. For example, most of the objectives of the public telephone network are derived from the needs of voice communication; however, some objectives, e.g., the limits on delay distortion and impulse noise, concern its use for data communication. In turn, network objectives are the bases for the design objectives of the facilities which will compose the network. In practice networks evolve while they are in service, usually with more stringent objectives to meet the rising expectations of the users and with improved performance made possible by improved technology and designs. Thus, additions to the network may be designed according to objectives different from those of the earlier parts.

Packet Networks

Among the data networks provided up to the mid-1960s, both the circuit-switched and message-switched types were in use. In the first, a channel was assigned full time for the duration of a call. In the second, a message or section of a serial message was transmitted to the next switch if a path (loop or trunk) was available; if not, it was stored until a path became available. The use of trunks between the message switches was often very efficient. In many circuit-switched applications, however, data were transmitted only a fraction of the time the circuit was in use. In order to make more efficient use of facilities and to make it possible to charge users only according to the amount of data transmitted, packet networks were developed. In a packet network, a message from one terminal to another is divided into *packets* of some definite maximum length, often 128 octets (corresponding to bytes in a computer) of data; the packets are sent from the origination point to the destination individually. Each packet contains a header, which provides the network with necessary information to handle the packet. The packets transmitted by one terminal to another are interleaved on the facilities between the packets transmitted by other users to their addresses, so that the idle time of one source can be used by another. At the destination switching center, the message is reassembled and formatted before delivery to the called station. In general, a network has an internal protocol to control the movement of data within the network. The internal speed of the network is in general higher than any of the terminal speeds, so that there is a change of speed from source to network and from network to destination.

The same physical interface circuit can be used for communication with more than one other terminal or computer at the same time by the use of *logical channels*. At any given time, each logical channel is used for communication with some particular addressee; each packet includes the identification of its logical channel, and the packets for the various logical channels are interleaved on the physical-interface circuit.

Three methods of handling messages are in common use. *Datagrams* are one-way messages sent from an originator to a destination; the packets are delivered independently, not necessarily in the order they were sent. Delivery and nondelivery notifications may be provided. In *virtual calls*, packets may be exchanged between two users of the network; at the destination they are delivered to the addressee in the same order as they were originated. *Permanent virtual circuits* also provide for exchange of packets between two users of the network; each assigns a logical channel, by arrangement with the provider of the network, for exchange of packets with the other. No setup or clearing of the channel is then needed. Some packet networks support terminals that are not capable of formulating the data in packets, by means of a packet assembler and disassembler included in the network.

Other packet networks have been set up since ARPANET (the earliest major packet network in the United States) to provide packet communication service to commercial users, in the United States, Canada, France, Spain, Japan, and elsewhere. An early commercial network in the United States provides service at speeds up to 56 kb/s. The service is either common-user or with closed user groups; the latter service prevents communication into or out of a given group of stations, the equivalent of a private network. The network is arranged in a hierarchy of switching nodes, the higher nodes being redundantly connected by 56-kb/s trunks. The transit delay for a packet is less than 200 ms. The network operates in the virtual call mode.

Protocols for packet networks are the subject of several Recommendations of the CCITT. Recommendations X.3, X.28, and X.29 cover start-stop mode terminal handling; X.25 covers the interface for packet-mode data terminal equipment, X.75 covers the interface for packet-network interconnection, and X.244 covers exchange of protocol identification during virtual call establishment.

In early packet networks, routing of each packet in a message was independent; each packet carried the address of its destination, as well as a number to permit arranging the packets in the proper order at the destination. Later networks use a *virtual circuit*, which is set up at the beginning of a call and which contains the routing information for all the packets of that call. The packets after the first contain the designation of the virtual circuit. In some networks, the choice of route is based on measurements, received from all other nodes, of the delay to every other node in the network. It is sufficient for a node to measure and transmit to the other nodes the delay to nodes to which it is directly connected.

Integrated Service Digital Networks (ISDNs)

An ISDN uses a single digital transmission network to provide a wide variety of services, such as voice, text, facsimile, videotex, and video, both switched and nonswitched, and both circuit- and packet-made. See Chap. 17.4.

TRANSMISSION SYSTEM OPERATIONS

Virgil I. Johannes

Transmission System Principles

Transmission Systems. A telecommunications transmission link can be either a *loop*, which connects a subscriber with a switch, or a *trunk*, which connects two switches. A loop may consist of a *feeder* portion, connecting the switch at the central office with a terminal near the subscriber, and a *distribution* portion connecting the terminal to the subscriber. Transmission can be at voice frequency over wire pairs, or a number of voice-frequency channels can be multiplexed together using frequency-division techniques (analog carrier) or time-division techniques (digital carrier). The multiplexed signal can then be transmitted over guided wave media, such as wire and optical fibers, or through free space, as in radio systems.

Digital carrier provides higher quality transmission than analog, as the signal can be completely regenerated when necessary without the addition of noise and distortion that is characteristic of analog carrier. Digital carrier over fiber-optic cables is also more economical than analog carrier on cable. As a result, new carrier systems being installed throughout the world are almost exclusively digital, and in the United States at least, most analog carrier systems have been removed from service, leaving only vestiges of a once ubiquitous analog carrier network.

Transmission at voice frequency is commonly used in loops, and for some short trunks between analog switches, such as the 1A ESS, as the cost of converting the signal to and from digital form can be avoided. Loops to customers with digital PBX (Private Branch Exchanges) are often digital carrier, and there is increasing use of digital carrier on loops longer than 3 to 5 km. In this latter technique, signals are converted to and from digital form in equipment near the customer, and the final connection to the customer is at voice frequency over wire pair. Direct digital connection to the residential and small business customer is not widely available, but there are a few installations, and many proposals, both technical and regulatory, for bridging this "last mile." These include use of wire pairs from the central office to provide a 144 kb/s digital link, in connection with the ISDN, "fiber to the home" schemes with much higher capacity, and "fiber to the curb" schemes in which the feeder portion of the loop is fiber, while the distribution part is copper.

Voice-Band Transmission and Analog Carrier. Voice-band (200 to 3500 Hz) transmission over a pair of wires in a cable is widely used for loops, and for trunks between nearby switches. For lengths of a few miles or more, the cable is often *loaded* to improve voice-band performance.

In a loop, wire gauge and loading are normally selected to keep the loop resistance below 1300 Ω , which permits proper operation of the supervisory and transmission circuits. Loops up to about 3 mi can be 26-gauge pairs. Loops up to 5 mi can be 24-gauge, and longer loops are often of mixed gauges with the thinner wire closer to the exchange. An alternative approach (*long-route design* or *unigauge*) is to use 26-gauge only (up to 2800 Ω loops) and compensate for the additional resistance with audio gain, equalization, and increased signaling power at the office.

Voice-band trunks were once widely used among local and tandem offices but with digital switches, digital carrier connection is generally preferred. Voice-band trunks are still used for shorter connections among analog switches. Such trunks can be either two-wire, in which both directions of transmission are carried on a single wire pair, or four-wire, preferred for longer trunks, in which the two directions of transmission are carried on separate pairs. Use of amplifiers (repeaters) along the transmission path to compensate for the loss of longer cables is now rare, any gain required being included in a terminal near the switch, which also incorporates any other functions required, such as two-wire to four-wire conversion, and equalization of the frequency response. Voice-band trunks are typically designed to have a loss of about 6 dB (after any amplification) between local offices, and less for tandem office connections.

Typical analog carrier transmission involves single-sideband suppressed-carrier modulation of a voice-band signal, thus shifting the signal to a higher frequency. Such shifted signals, each typically occupying a 4-kHz bandwidth, are then combined into groups of 12 or 24 voice channels, and then further modulated and combined into 300 or 600 channel mastergroups. Short haul systems that carry groups, and long-haul systems carrying many mastergroups on a single coaxial, microwave radio, or satellite facility, while no longer being installed, are still in service in some areas, mostly outside North America. The SG submarine cable system, for example, carries 4200 two-way voice circuits in a single coaxial cable with dielectric diameter of 1.7 in. and has been in service across the Atlantic since 1976.

Digital Transmission Formats and Hierarchies

The first telecommunications digital transmission system, (T1) put into service in the United States in 1962, was designed to carry 24 voice channels over distances up to 50 miles. Each voice channel was sampled 8000 times per second, and each sample represented by an 8-bit byte, thus occupying 64 kb/s. The line signal was assembled by taking 1 byte from each channel in sequence (for a total of 192 bits) and then adding a single bit, the framing bit, to make a 193-bit frame, with a line rate of 1.544 Mb/s. At the receiving end, the framing bit was used to identify the other bytes so that they could be associated with the appropriate voice channel. In this initial design, an alarm was given, and the system was taken out of service, if more than 1 percent of the received framing bits failed to match the transmitted 1-0 pattern for about 300 ms. T1 systems were point-to-point, independent of each other, and the exact line rate of each system was determined by its own crystal clock, with an accuracy of about ± 50 ppm. This system became widespread within a few years in the United States, Canada, and Japan. Subsequently, a similar system, with 8 kHz sampling, and 8 bits per sample, but carrying 30 channels at a line rate of 2.048 MHz, and differing in coding technique as well, was developed extensively in Europe. These are referred to as *primary rate* systems.

TABLE 17.1.1 Hierarchical Rates in the Plesiochronous Digital Hierarchy—kb/s

North America	Japan	Europe
64	64	64
1544	1544	2048
6312	6312	8448
44736	32064	34368
	97728	139264

As the use of the primary rate systems increased, higher bit-rate systems were developed for longer distances and more economical transmission. The line signals for these higher rate systems are assembled from the primary rate signals in one or more steps using bit-by-bit time division multiplexing, and pulse stuffing. Two separate hierarchies of rates, each based on one of the two primary rates, along with rules for multiplexing and demultiplexing have been

standardized. These are shown in Table 17.1.1, along with a variant used only in Japan. In the United States, transmission systems at rates other than the hierarchical rates are more the rule than the exception, and the

6.312 Mb/s rate is little used. Higher rate signals for transmission are assembled from whatever number of DS-1 or DS-3 signals may be appropriate for the application at hand, using the pulse-stuffing technique. Thus the existing U.S. network has transmission systems carrying one, two, and four primary rate signals, in which the standardized primary rate signals appear only at the ends, as well as systems operating at various multiples of 44.736 Mb/s in which again the standardized signals appear only at the ends. The termination of these non-hierarchical rate systems in standardized signals allows for ready interconnection and rearrangement. All these rates and variations in both hierarchies are sometimes referred to, in the aggregate, as the *plesiochronous digital hierarchy* (PDH), in reference to the derivation of the various rates from independent timing sources that are not necessarily synchronized.

While systems above the primary rate generally include parity check bits for monitoring of the performance, the primary rate systems were initially monitored by examining the signal for violations of the line code and these violations (but not the errors!) disappear when the signal is multiplexed to a higher rate. To provide some means of determining the end-to-end performance of a DS-1 signal that may be multiplexed and demultiplexed many times between source and destination, newer DS-1 sources use the 193rd bit not only for framing, but also for error detection using a cyclical redundancy check code. A similar provision has been added to the 2.048 Mb/s signal. Even with these additions, the provisions for monitoring, maintenance, and network control provided in the PDH are not well suited to the worldwide digital network, and the existence of two separate hierarchies makes interconnection cumbersome.

In 1988, a new set of rates and multiplexing rules for higher bit-rate systems was standardized by the CCITT.* This new hierarchy includes a single set of rates intended for worldwide use, to transport signals from either of the two older hierarchies. There is also extensive provision of additional bits for monitoring and network operation. Recognizing the present availability of synchronized timing sources, the new hierarchy is nominally synchronous (hence the name, *synchronous digital hierarchy*, or SDH) although there is provision for small frequency variations, to account for the possibility that synchronism among parts of the network may be lost from time to time. In the United States, this hierarchy is part of a more extensive set of standards, referred to as the Synchronous Optical Network (SONET). SONET is intended also to encourage use of line systems and a standardized set of optical interfaces at the established rates of the hierarchy. The lowest rate envisioned is 51.84 Mb/s, appropriate for carrying a DS-3 signal.

Media for Transmission

Paired Cable. Paired telephone cables have been described earlier. Trunk and loop cables are similar, except that to reduce loss trunk cables often use thicker wire and therefore include fewer pairs (900-pair cable with 22 gage pairs is typical). The performance of carrier systems on paired cable is generally limited by crosstalk. Near-end crosstalk is more significant than far-end crosstalk. Some trunk cables are available with an internal shield (screen) to separate the directions of transmission and thus reduce near-end crosstalk, and in some applications a separate cable is used in each direction (two-cable operation).

Coaxial Cable, Waveguide. Coaxial cable for telecommunication trunks has been made with as many as 22 coaxial tubes, stranded and sheathed as for paired cable, and often including some wire pairs for maintenance. Tube diameters have ranged from 2.9 mm (in Europe), through 0.375 in. (once widespread in the United States), to 1.7 in. (for single tube submarine cable). Such cables were widely used for medium- and long-haul transmission before the advent of optical fiber, and many remain in service outside the United States. Circular waveguide systems operating at mm wavelengths had been used in some experimental installations before being obsoleted by optical fiber. (See also Chap. 17.3.)

Optical-Fiber Cables. Optical fibers for telecommunications are covered in Chap. 17.3 and they are typically about 125 μm thick and are made of very pure silica with dopants added to control the index of refraction. They consist of a doped silica glass core with a glass cladding having a 0.3 to 1 percent lower index of refraction, which

*International Consultative Committee on Telephone and Telegraph, recently renamed the Standards Sector of the ITU (International Telecommunications Union). The CCITT formerly issued its standards in the form of "Recommendations" every four years in volumes identified by their color. Current practice is to issue or revise individual Recommendations from time to time.

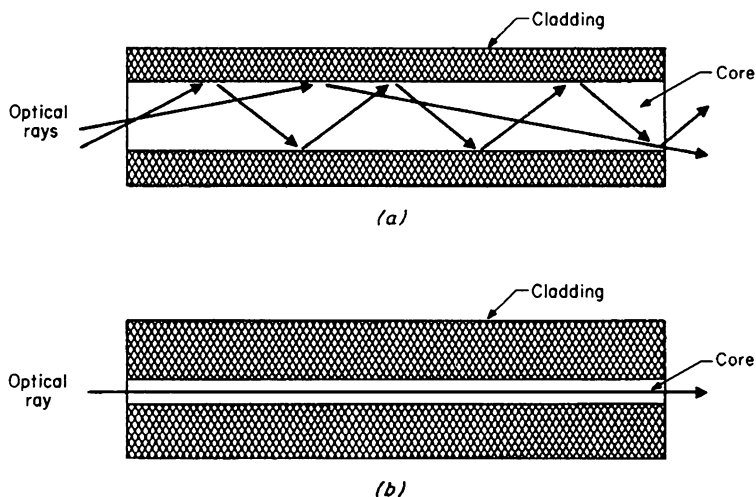

FIGURE 17.1.1 Optical fibers: (a) Multimode fiber; (b) single-mode fiber. (From Paul S. Henry, "Introduction to Lightwave Transmission," *IEEE Commun. Mag.*, Vol. 23, No. 5, p. 13. © 1985 IEEE. Used by permission)

serves to confine the light within the fiber. If the core is thick enough ($50\ \mu\text{m}$), light at the wavelengths used (0.8 to $1.55\ \mu\text{m}$) will propagate in several modes, as shown in the multimode fiber of Fig. 17.1.1a. A thinner core ($0.85\ \mu\text{m}$) can restrict propagation to a single mode as shown in Fig. 17.1.1b. Single-mode fibers are more difficult to splice and couple, but usually have lower loss because of lower dopant concentration in the core.

Radio and Free Space. Microwave frequency bands allocated to telecommunications within the United States are shown in Table 17.1.2. (Except for mobile applications there is little present use of other frequency bands.) At these frequencies propagation is line-of-sight, so is limited by the curvature of the earth. At typical relay tower spacings of 15 to 30 mi, the free space loss is about 140 dB in the 4- and 6-GHz bands. With antenna gains of about 40 dB, the normal loss from antenna input to output is about 60 dB. Loss well above the normal can occur because of propagation effects, as discussed in Sec. 16. At frequencies above 10 GHz, the additional attenuation resulting from heavy rainfall is often the limiting factor. Path lengths 10 to 15 mi in the 11-GHz band, and 1 to 3 mi in the 18-GHz band are typical. The deployment of microwave systems is often limited by the need to avoid interference with existing systems using the same frequencies. These same microwave bands are used for satellite links.

Rainfall and other propagation problems have mitigated against the use of optical, or near optical, wavelengths in free-space transmission.

TABLE 17.1.2 Selected United States Common-Carrier Microwave Frequency Allocations

Band, GHz	Allotted frequencies, MHz	Bandwidth, MHz
2	2,110–2,130	20
	2,160–2,180	20
4	3,700–4,200	500
6	5,925–6,425	500
11	10,700–11,700	1,000
18	17,700–19,700	2,000
30	27,500–29,500	2,000

Voice Encoding, Circuit Multiplication, Echo Control

Voice Encoding. To prepare a voice signal for digital transmission or switching, it is band-limited to about 3500 Hz and sampled at 8 kHz; each sample is encoded into 8-b PCM, producing a 64-kb/s signal. The quantization of the signal to one of $2^8 = 256$ levels that is inherent in the coding process produces noise, termed *quantizing noise* or *quantizing distortion*, in the decoded signal. (This is the major impairment suffered by a voice signal transmitted digitally.)

FIGURE 17.1.2 Logarithmic compression characteristics. (Copyright 1982, Bell Telephone Laboratories, Inc. Reprinted by permission)

To improve the signal-to-distortion ratio at small-signal levels, a logarithmic encoding law is employed in order to use a greater portion of the available levels for weak signals. In this way, a certain *percentage* change in the instantaneous signal corresponds closely to a change of one encoding level, and the signal-to-distortion ratio is approximately constant over a wide range of talker volume. This process can be thought of as compressing the signal in amplitude according to one of the curves of Fig. 17.1.2 and then performing a linear A/D conversion. In current practice, however, a piecewise linear approximation to the logarithmic curve is incorporated in the coder proper and, of course, in the decoder as well. The two approximations in current use (A-law in Europe, μ -law in North America and Japan) are shown in Table 17.1.3. Both meet the CCITT requirement of 33-dB signal-to-quantizing-distortion ratio for sine waves from 0 to -30 dBm0, with overload point at

about 3 dBm0. Idle channel noise for the μ -law coder is specified as less than 23 dBm0. (In this, as in other sine-wave specifications of coders, exact submultiples of the 8-kHz sampling frequency are excluded.) In the μ -law code, the all-zero code word is not used, slightly increasing the quantizing noise.

Some coding schemes for voice which use less than 64 kb/s found use in special applications even prior to the CCITT standardizing a 32-kb/s ADPCM (adaptive differential pulse code modulation) method. In differential PCM, the *difference* between sampled values of the voice signal is coded rather than the values themselves. The adaptive feature, an improvement on the logarithmic coding law, changes the code in accord with a complex algorithm dependent on past signal amplitudes. A major problem in finding an acceptable 32-kb/s coding method was providing acceptable performance for voice-band data signals from data modems. This is even more of a problem with 16-kb/s coding, and along with decreasing cost of high-capacity transmission systems, and increasing nonvoice traffic on the network, has limited the application of these lower bit-rate coding schemes.

TABLE 17.1.3 CCITT Recommended Coding Laws for Voice

Name	Basic law $0 \leq x \leq 1$	Parameter value	Segments in linear approximation	Primary multiplex rate, Mb/s
μ law	$y = \frac{\ln(1 + \mu x)}{\ln(1 + \mu)}$	$\mu = 255^*$	15	1.544
A law	$\frac{1 + \ln A x }{1 + \ln A} \quad \frac{1}{A} \leq x \leq 1$ $\frac{A x }{1 + \ln A} \quad 0 \leq x \leq \frac{1}{A}$	$A = 87.6$	13	2.048

* $\mu = 100$ was used in original T1 system.

Circuit Multiplication, Time-Assignment Speech Interpolation. In a typical telephone conversation, only one party is talking at a time, so each direction of transmission is idle half the time. When pauses are also taken into account, the actual utilization is about 40 percent. Equipment taking advantage of this phenomenon to increase the number of voice channels carried by a transmission link is widely used on long distance international transmission links on submarine cable and satellite. It was first introduced on analog submarine cable systems, and termed TASI (time assignment speech interpolation), as the analog channels available were assigned to various talkers as they became active. The TASI systems achieved a 2:1 increase in capacity in practice. Similar systems, sometimes called DSI (digital speech interpolation) have been deployed on digital satellite links as well, with similar results. The combination of interpolation techniques with a code conversion from the 64 kb/s PCM signal to 32 kb/s ADPCM allows an increase of as much as 5:1 in capacity for digital voice applications. (The signal is restored to 64 kb/s at the receiving end.) This combined function is referred to as *circuit multiplication*, and is in general used on satellite and intercontinental submarine cable digital links.

Circuit multiplication introduces some slight degradations to voice signals, introduced by the conversion to and from ADPCM, the finite time to recognize the beginning of speech (processing clip), and the occasional need for more channels than are available. (The effect of the latter can be mitigated by reducing the number of bits for all conversations, rather than cutting off some conversations for short intervals.) Circuit multiplication equipment must detect nonvoice signals, and pass them without alteration, as they would not be restored correctly. This detection may be based on the 2000–2200 Hz tone emitted by voice-band data modems.

Echo Control. If the round trip delay is less than 45 ms, acceptable echo performance can be achieved by designing all trunks to have a loss that increases the return loss of the echo. Voice-band and other analog trunks were traditionally assigned losses in the range of 0.5 to 8.9 dB, according to an overall plan called the Via Net Loss plan. With digital transmission and switching, which are inherently lossless, 3 dB is typically inserted at both ends of a connection, and no attempt is made to add loss to intermediate trunks. Above a 45-ms delay, the loss required for acceptable echo performance would be excessive, and echo cancelers are used. An echo canceler incorporates an internal delay line with taps that are adjusted to produce a signal duplicating the echo, which is then subtracted from the received signal, canceling the effect of the echo. The adjustment is done rapidly and continuously. One echo canceler is necessary for each voice channel, but economical integrated circuit realizations are available.

The Digital Transmission Network

Network Structure. The structure of the existing digital transmission network, based on the plesiochronous digital hierarchy, is illustrated in Fig. 17.1.3, which shows a cross-section of equipment arrangements and signal flows applicable to any of the hierarchies shown in Table 17.1.1.* Primary rate signals may be coded voice signals multiplexed together, with the encoding and multiplexing done in a unit called a *channel bank* or *Primary PCM Multiplex* as described above for the original T1 system. Digital switches typically include the coding and multiplexing functions as well, and primary rate signals can originate from other sources, such as computer data and coded video. Primary rate signals destined for a remote location may either be transmitted directly, typically over a wire pair, or further combined into higher-rate signal by the multiplexes for more economical transmission, as illustrated in Fig. 17.1.3. The *Line Terminating Equipment* of the figure include such functions as power feeding for a repeated line, error monitoring, switching from a failed line to an operating one (protection switching), and conversion of the signal to the line code. (These functions may actually be packaged with the multiplex.) In the United States, the 6.312 Mb/s line rate and crossconnect capability have not found much use, so direct multiplexing of DS-1 signals into DS-3 signals in a single piece of equipment without access to the DS-2 signal is the norm.

Figure 17.1.3 is representative of equipment found in telephone company offices. The offices are connected by transmission line systems using cable or radio, and often include regularly spaced repeaters, which serve to amplify, retiming, and regenerate the received digital signal. The line systems do not necessarily operate at a hierarchical rate. They do, however, have interfaces at hierarchical levels (in the United States at DS-1 and DS-3), and at standardized signal levels and format, and thus are readily interconnectable with other line systems,

* Interconnection between the two hierarchies is based on the common 64 kb/s rate. Conversion between A and μ -law coding and remultiplexing into appropriate format is performed at a connection point in the μ -law country, and often associated with circuit modulation equipment. Some United States–Europe links use a “hybrid hierarchy” in which the multiplexing sequence is 64 kb/s (A-law), 2.048 Mb/s, 6.312 Mb/s, 44.736 Mb/s, and 139.264 Mb/s.

FIGURE 17.1.3 Functions and equipment in the plesiochronous digital hierarchy.

signal sources, and so forth. The line systems proper are proprietary, and terminal equipment at both ends, as well as intermediate repeaters, are generally from the same manufacturer, or at least a cooperating group of manufacturers. The repeaters may be powered locally, if they are located in a telephone company office, for example, or via power fed over the cable. Paired cable systems are typically powered over the pairs that carry the signals, and conductors for the purpose may be provided in optical fiber cables.

Crossconnects. To facilitate interconnection and rearrangements, all signals of a given hierarchical rate in a telephone company office are brought together at the *crossconnects* of Fig. 17.1.3. These crossconnects may be simple wiring panels at which the various sources, multiplexes, and line terminating equipments are interconnected and accessed for testing by manually placed wiring. In the United States, such a crossconnect is referred to, for example, as a DSX-1 for a crossconnect at the primary level, and so on. A more elaborate alternative to simple wiring panels is the digital crossconnect system (DCS, or DACS for digital access and crossconnect system). These provide electronic switching of the signals and include multiplexes so that *components* of the signals may be interchanged. Thus a primary level DCS can reroute entire 1.544 Mb/s signals, and interchange 64 kb/s channels freely among such signals. (This latter function is similar to that performed by digital switches, but the DCS is too slow to be used on a call-by-call basis, and does not incorporate the signaling capability of a digital telephone switch.) This requires synchronism of the various signals, which is achieved by synchronizing all connected switches and channel banks from a master clock.

Equipment incorporating the line terminating functions, multiplex, and electronically switched crossconnect in a single unit is also available, offering space, cost, and operational savings.

Time-Division Multiplexing: Framing. If two or more synchronous digital signals are to be multiplexed, they can be adjusted in phase and pulse width and combined directly, with some method for identification of the signals for later demultiplexing. A common method of identification is to group a number of input bits into a *frame*

with an additional framing bit at the beginning of the frame. For example, in the 24-channel PCM channel bank, twenty-four 8-b words, each representing one sample, constitute 192 b of a 193-b frame, and the 193d bit is the framing bit. If no other features were desired, the framing bit could be a simple pattern such as 101010, which would allow frame to be recovered at the receiving channel bank by finding a position in the received pulse stream which alternates between 0 and 1 at intervals of 193 b. To provide additional functions while maintaining the T1 line rate, an *extended superframe format* involving a framing pattern that identifies groups of twenty-four 193-b frames is used. In this format, only six of the 24 slots allocated to framing bits have a fixed pattern used for framing, while six slots are used for cyclic redundancy check bits (e.g., an error-detecting code covering the entire superframe of 24 frames) and 12 slots are used for 4-kb/s data link for maintenance communication.

This use of a single framing bit at the beginning of a frame is common in the United States at all rates. Another method, common in Europe, is to use a multibit framing alignment word at the beginning of a much longer frame. In Synchronous Digital Hierarchy, framing bytes 8 b are included in section overhead, and distributed throughout the frame.

Synchronization, Pulse Stuffing. Multiplexing to the primary level (1.544 or 2.048 Mb/s) is synchronous, and entire 8-b bytes are multiplexed. In channel banks and switches the locally encoded voice signals are synchronous and appear 8 b at a time, so that this is a natural mode of operation. Where 64-kb/s signals from more than one source are to be intermingled, e.g., in a digital switch, they are synchronized to a central reference which is distributed via designated digital facilities. In a digital channel bank connected to a digital switch, e.g. via a digital line, the digital switch drives the line toward the channel bank at a rate synchronous with the references and the channel bank is loop-timed; i.e., it derives its transmit frequency from the signal it receives from the switch, which in turn is timed from the network reference.

Above the primary level, signals normally arrive at the multiplex a bit at a time, and it is not easy to assure that all signals that arrive at a multiplex will be synchronous. Present practice, therefore, is to stuff pulses into each input digital stream to synchronize them all to a common, higher rate. The synchronous streams are then multiplexed bit by bit. This process, called *pulse stuffing* or *positive justification*, is illustrated in Fig. 17.1.4. The location of the stuffed pulses is signaled to the receiving end (to allow for removal) on still other bits added to the frames for the purpose.

The pulse stuffing-destuffing process introduces some jitter (undesired phase modulation) in the demultiplexed pulse stream, which is usually not troublesome as it is of low amplitude and frequency.

Superframes. The pulse-stuffing scheme described above requires a low-data-rate digital channel between multiplexer and demultiplexer to signal the presence or absence of stuffed time slots. Low-data-rate channels may also be required to provide communication between terminals for maintenance functions such as switching to a spare or for parity bits for detection of transmission errors. These low-data-rate channels are provided by adding bits that are located by establishing a superframe structure encompassing many information-bit frames. The extended superframe mentioned above is an example.

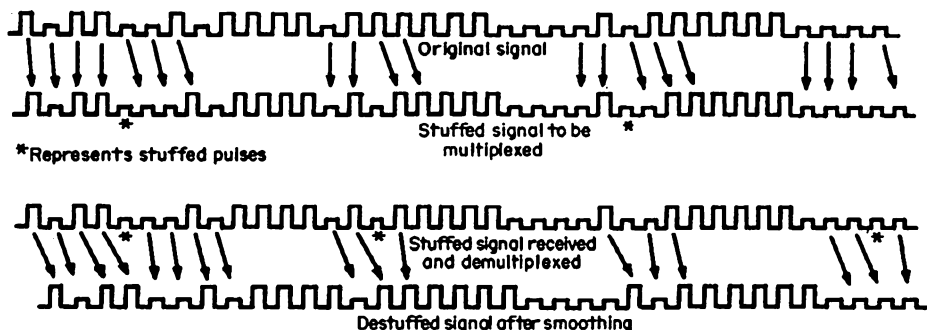

FIGURE 17.1.4 Pulse-stuffing synchronization. (Copyright 1982, Bell Telephone Laboratories, Inc. Reprinted by permission)

Regenerative Repeaters. A block diagram of a regenerative repeater is shown in Fig 17.1.5. The input signal is amplified and equalized, a timing wave is extracted in the clock-extraction circuit, and then the signal is regenerated; i.e., in each time slot a decision is made whether a 1 or 0 is present and a pulse accordingly applied (or not) to the output. The stylized waveshapes of Fig. 17.1.5 illustrate this action, and Fig. 17.1.6a shows an idealized “eye pattern” at the regenerator input, for a ternary repeater, i.e., one that can produce either a positive or negative pulse as well as a zero. An eye pattern is the superposition of waveshapes resulting from all possible pulse sequences (0 + 0, - + -, ...).

The frequency response of the equalized channel is deliberately rolled off, often with a cosine shape, to produce a pulse that may be as wide as two time slots at the base (as in Fig. 17.1.6a) rather than a close replica of the transmitted pulse. This reduces the noise and crosstalk on the equalized pulse. The adaptive equalizer acts to bring the peak of the received pulse to a standard amplitude and thus provides the proper equalization for any cable length within its range. (Several fixed equalizers may be required to span the complete range of cable lengths.) The adaptive equalizer also compensates for variations in cable temperature, and is usually analog, involving only a few singularities. Mismatching and other circuit imperfections can result in closing the eye (Fig. 17.1.6b), increasing the probability of error because of thermal or other noise.

Jitter in a repeated line results from pattern variations in the signal transmitted. As a result of imperfect equalization and other idiosyncrasies of the repeater, these pattern variations appear as phase variations applied to the timing extraction filter (see below), and any components of the phase variation at a frequency within the bandpass of this filter appear as jitter on the timing signal and hence on the repeater output. The rms jitter of a line is approximately proportional to the square root of the number of repeaters. (For T1, for example, with a repeater tank Q of 80, the rms jitter for 10 repeaters is about 3° .) Jitter in the amounts usually encountered has little effect on 64-kb/s encoded voice signals. Jitter (unlike errors) can be reduced or eliminated completely at the endpoints by writing the receiving information into a buffer memory and reading it out under control of a stable clock. Thus the major concern in practice is to assure an adequate size of buffer memory where dejitterization intentionally or inadvertently takes place. (An example of inadvertent dejitterization would be the connection of a repeated line to a terminal with an input repeater of higher Q .)

Clock extraction for a ternary repeater involves full-wave rectification of the signal, filtering the result in an LC tank or equivalent, in order to obtain a sine wave at the symbol rate, and then shaping the sine wave to obtain a sampling pulse or edge. The full-wave rectification produces a strong component at the symbol rate. The required Q of the tank circuit, or equivalent, depends on the line code selected. In any case, a higher Q in the filter reduces the jitter of the timing wave, which results from pattern variations in the digital stream. On the other hand, a higher Q increases the static offset of the sampling pulse because of temperature variations of the frequency of the tank. Arrangements used have included an LC tank with Q of 80 (T1), a monolithic crystal filter, a surface-acoustic-wave (SAW) filter, and phase-locked loop with crystal-controlled VCO (voltage-controlled oscillator).

The regenerator proper is a clocked flip-flop or similar arrangement with carefully controlled threshold. The output pulse is often clocked to about 60 percent of the time slot in ternary systems, but nonreturn to zero (NRZ) is usual in binary systems, such as fiber-optic systems.

Most regenerative repeaters have some provision for fault location, i.e., determining from an office which of the many repeaters in a failed line is at fault. This may be accomplished by feeding a small part of the output back to the originating station through a filter that passes only a particular audio frequency assigned to that manhole. To locate a faulty repeater, a digital pattern containing the particular audio frequency associated with a certain manhole is applied to the line. If the audio frequency then appears on the fault-locating pair, the repeater in that manhole and all repeaters upstream of that line are known to be operating. The procedure is then repeated with other audio frequencies until the defective repeater is located. All repeaters at a given manhole share the same audio filter, and all manholes share the same voice-frequency fault-locate pair. Recent designs for high-capacity fiber-optic and radio systems incorporate error detectors (based on parity bits or line code redundancy) in each repeater, with a method for interrogation from the terminals.

The probability that an ideal digital repeater with gaussian noise added to its input will make an error is the probability that the noise will exceed half the eye height, which for m -level transmission is

$$P_E = \frac{m-1}{m} \operatorname{erfc} \left| \frac{1}{(m-1)\sqrt{2}} \frac{\text{peak signal}}{\text{rms value of noise}} \right|$$

FIGURE 17.1.5 Representative regenerative repeater for cable system with associated external components.

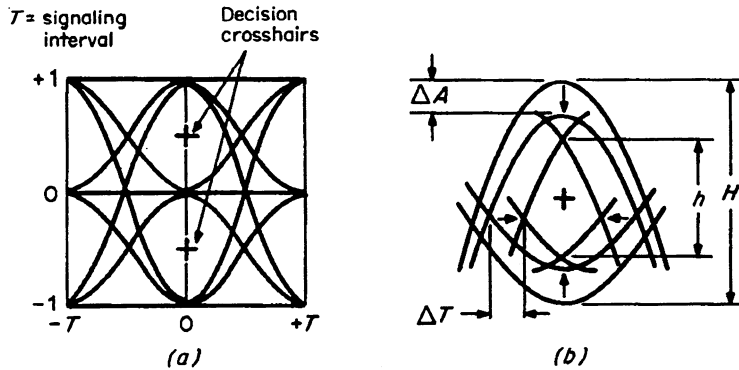

FIGURE 17.1.6 Eye diagrams for a ternary repeater: (a) ideal eye; (b) closing the eye to account for practical degradations (upper eye only). (Copyright 1982, Bell Telephone Laboratories, Inc. Reprinted by permission)

This is plotted in Fig. 17.1.7. It can be seen that in the range of usual interest, 10^{-6} or better, variation of a few decibels of signal-to-noise ratio produces a variation of many orders of magnitude in error probability. This is generally true in practice as well, even though crosstalk or some other interference, rather than gaussian thermal noise, may be the major cause of errors.

FIGURE 17.1.7 Probability of error vs. peak signal to rms gaussian noise for random m -level polar transmission. (Copyright 1982, Bell Telephone Laboratories, Inc. Reprinted by permission)

present fibers have minimum loss (but not minimum dispersion). Optical detectors are typically *pin* diodes or avalanche diodes. For both lasers and detectors, compound semiconductor alloys, such as InGaAsP are widely used. Coherent detection, in which the incoming signal is mixed or compared with a local light source of about the same wavelength, has not yet proved practical in optical systems (although it is the norm in digital radio systems) because of the lack of light sources with sufficient spectral purity and stability. Regenerative repeaters for radio use require modulators and demodulators as well as the functions described above. Figure 17.1.8 shows the block diagram of a regenerator for a 135-Mb/s (actually 3×44.736 -Mb/s) system using 64 QAM (64 quadrature amplitude modulation). The symbol rate is 22.76×10 Mb/s. This regenerator operates on a 70-MHz i.f. signal, and is used on a 30-MHz channel with radio systems in the 6-GHz band, and on a 40-MHz channel with radio systems in the 11-GHz band. In 64 QAM, the transmitted signal has 64 possible states, that is, combinations of amplitude and phase as shown in Fig. 17.1.9. Other modulation methods, such as QPSK (quaternary phase shift keying) and 8PSK, are also in use. In QPSK the transmitted amplitude is constant, but

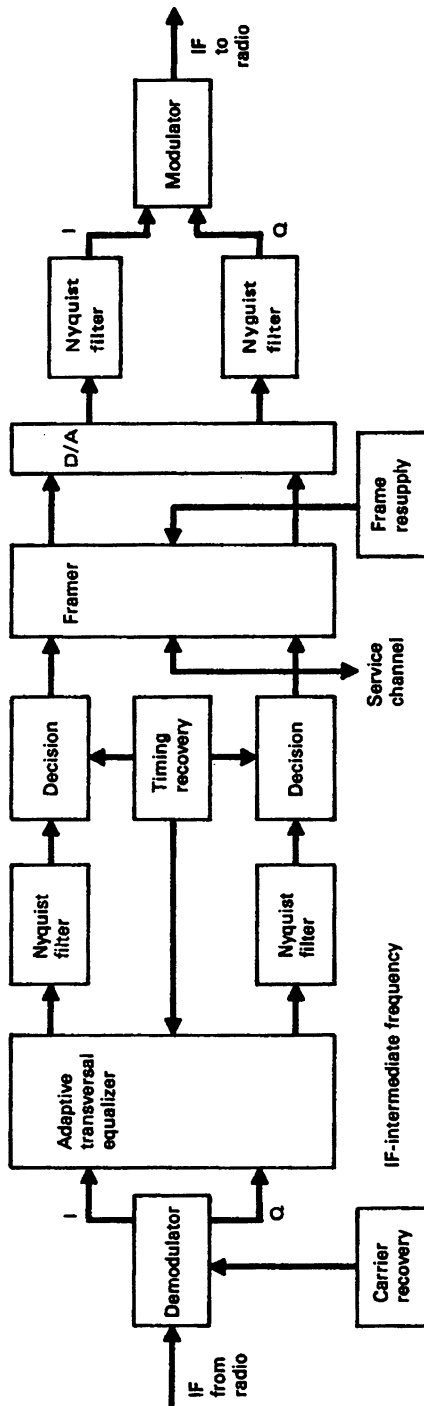

FIGURE 17.1.8 Digital regenerator for 135-Mb/s digital radio system using 64 QAM. (Copyright 1986, Bell Telephone Laboratories, Inc. Reprinted with permission)

FIGURE 17.1.9 Phase plane representation of possible signals in 64 QAM. (The signals are sinusoids with amplitude given by distance from origin and phase given by angle with I axis.) (From *AT&T Bell Laboratories RECORD*, January 1986, p. 31. Copyright 1986, Bell Telephone Laboratories, Inc. Reprinted with permission)

the phase can take on one of four values. In regenerators for radio use, the equalizer is compensating for distortion introduced by propagation effects such as multipath, and it is the development of improved equalizers that has allowed the use of high-capacity modulation such as 64 QAM.

Scramblers and Line Codes for Digital Systems. Normally it is not possible to transmit an arbitrary digital stream directly as a binary signal because of the possibility that some patterns might cause the line system to malfunction. For example, too long a string of zeros could cause loss of timing signal in the repeaters, repetitive patterns could produce strong discrete frequencies in the output of radio systems that might violate emission limits, and a variation of the average density of 1s would cause a wander of the baseline of the signal after passing through a transformer or power-separation filter. To counter these effects, the signal is usually scrambled or coded (sometimes both).

A digital signal is scrambled by adding to it, in mod 2,* a long predetermined pseudo-random pattern of 1s and 0s. It can be unscrambled at the receiving end by adding (mod 2) the same pattern, in the same phase. The pseudo-random pattern is obtained from a shift register clocked at the signal rate with some taps added and fed back to the input. Appropriately selected taps produce a maximal-length pattern $2^N - 1$ long, where N is the number of stages in the register. The phase of the sequence is normally synchronized to the framing pattern, allowing ready descrambling at the receiving end.

Scrambling may reduce the probability (but cannot *guarantee* the absence) of any unfortunate pattern such as a long string of zeros. Therefore, if scrambling is to serve this purpose, high- Q timing recovery circuits such as phase-locked loops are required, and this is typical of fiber optic and radio repeaters. Another use of scrambling is encryption of a digital signal to maintain its confidentiality. This can be accomplished by scrambling

*In mod 2 (modulo 2) addition $0 + 0 = 0$, $1 + 0 = 1$, $1 + 1 = 0$.

the signal with a very long sequence known only to the parties involved. This practice was formerly largely confined to government communications, but heightened commercial interest in privacy has led to a standard method of encrypting, the data encryption standard (DES) promulgated by the National Bureau of Standards, and reasonably priced silicon integrated circuits to implement it. Scrambling for encryption is, of course, best applied at the source and destination of the signal to be encrypted, while scrambling to control signal statistics is applied within a particular transmission system.

Coding, as opposed to scrambling, adds enough redundancy to the signal to guarantee some desired properties, regardless of the pattern to be transmitted. T1 uses a ternary (three-level) code called bipolar (or AMI, for alternate mark inversion) with all zero limitation, used on T1. In this code alternate 1s are transmitted as + and - pulses, assuring dc balance and avoiding baseline wander. Further, an average density of one pulse in eight slots with a maximum of 15 zeros between 1s is required.* This maintains timing signal sufficient for the inexpensive, low-*Q* (80) timing circuits in the repeaters.

Another scheme to guarantee timing density with a ternary code is to replace strings of zeros with a pattern with two successive pulses of the same polarity, allowing its identification and removal at the receiving end. The arrangement, called BNZS (for bipolar with *N* zero substitution) is also in considerable use. In Europe, it is called HDB or CHDB, for high-density bipolar or compatible high-density bipolar. BNZS codes all carry one information bit per ternary symbol, and codes with *N* = 3, 4, and 6 are in use (see Tables 17.1.4 and 17.1.5). Greater information capacity can be obtained using block codes such as 4B3T (each block consists of 4 b on three ternary symbols). Generally, as the information capacity is increased, the reduction in redundancy results in poorer timing and baseline-wander performance. There are many variants, but all have spectra that are zero at both zero frequency and the symbol rate, as do the bipolar and BNZS codes.

TABLE 17.1.4 B3ZS Choice of Sequences to Substitute for Three Zeros

Last pulse transmitted	Last substitute sequence used	
	00 + or + 0 +	00 - or - 0 -
+	- 0 -	00 +
-	00 -	+ 0 +

Another type of code is epitomized by the *duobinary* code, which is a 1-b-per-symbol ternary code in which adjacent pulses of opposite polarity cannot occur. Thus the redundancy is used to reduce the transmitted energy at high frequencies rather than to control baseline wander and assure timing. Scrambling, high-*Q* tanks, and circuit design to minimize baseline wander are normally required. The duobinary spectrum is maximum at zero frequency and zero at half the symbol rate. The reduction of high-frequency energy makes it attractive for sharply band-limited media such as radio channels or, on wire pairs, to minimize crosstalk. Variants with larger numbers of transmitted levels have been dubbed *partial-response codes* and can also limit the transmitted spectrum in a similar fashion.

Various ternary codes are illustrated by example in Table 17.1.5. The redundancy added in any of these codes is sufficient to allow reasonably accurate estimates of errors in transmission by detection of violations

TABLE 17.1.5 Coding Examples

Code name	Coding rule	Example
Binary		1011100110000001111
Bipolar, AMI	Invert alternate 1s	+0 - + -00 + -000000 + - + -
B3ZS, CHDB2	Invert alternate 1s, but for three 0s substituting according to Table 17.1.4	+0 - + -00 + -00 - + 0 + 0 - + - +
4B3T	Code Table	+00 + -00 + -0 - + - - -
Duobinary	From binary input sequence <i>a</i> first form sequence ^c <i>C</i> $C_n = a'_n \oplus C_{n-1}$ then output = $C_n + C_{n-1} - 1$	01111011101010100000 -0 + + + 00 + + 0000000 - - - -

^c \oplus = addition modulo 2, and a'_n is the logical inverse of a_n , that is, substitute 0 for 1 and vice versa. The first step avoids a long string of decoding errors resulting from a single transmission error.

*This is readily obtained in voice-band coding by simply not using the all-zero word, and the standard μ -law coder has this feature.

TABLE 17.1.6 CCITT Error Performance Objectives for a 27,500-km Connection at 64 kb/s

Performance classification	Objective
Errored seconds	Fewer than 8% of one-second intervals to have any errors (equivalent to 92% error-free-seconds)
Severely errored seconds	Fewer than 0.2% of one-second intervals to have a bit error ratio worse than 10^{-3}

of the constraints of the particular code. In uncoded systems parity bits may be added to accomplish this purpose. Forward-acting error correcting codes, in which redundancy is added to allow detection and correction of errors at the receiving end, have not been widely used on cable systems. They are, however, widely used on radio and satellite systems, where the capacity is limited by the transmitter power, rather than the bandwidth.

Performance Issues. Digital transmission systems consist of terminals connected by cable or radio links that include regenerative repeaters. Each repeater detects, regenerates, and retimes incoming pulses, so the only impairments introduced are errors and jitter (unwanted phase modulation). Error performance is sometimes characterized in terms of average error rate (or ratio) which is the number of errors divided by the number of bits received, with the implicit assumption that errors are more or less randomly distributed. This has not proved to be a satisfactory measure, as most systems have enough design margin against thermal noise and crosstalk (the normal causes of randomly distributed errors) that the errors on actual systems in service occur in infrequent bursts, as a result of noise impulses or other disturbances. Consequently, the CCITT states error performance objectives for 64 kb/s in terms of error free seconds and severely errored seconds as shown in Table 17.1.6.* Objectives for performance at higher rates are shown in Table 17.1.7. This table is stated in terms of blocks of bits, intended to correspond to block sizes used for error monitoring.

Jitter can be removed by reading the signal into a buffer memory, and reading it out at a constant rate. It is only necessary to organize the network so that the jitter does not exceed the capacity of the buffer memories, and the CCITT has recommended jitter limits to this end.

Maintenance Techniques in Digital Systems. Faults in the basic T1 system are detected by the inability of a channel bank to find framing pulses in its 1.544-Mb/s input signal. When such a condition persists long

TABLE 17.1.7 CCITT Error Performance Objectives for a 27,500-km Path at or Above the Primary Rate

Rate Mb/s	1.5 to 5	>5 to 15	>15 to 55	>55 to 160	>160 to 3500
Bits/block	2000 to 8000	2000 to 8000	4000 to 20,000	6000 to 20,000	15,000 to 30,000
Errored seconds	4%	5%	7.5%	16%	not specified
Severely errored seconds	0.2%	0.2%	0.2%	0.2%	0.2%
Background errored blocks	0.03%	0.02%	0.02%	0.02%	0.01%

An errored block is a block in which 1 or more bits are in error.

An errored second is a 1-s period with one or more errored blocks.

A severely errored second is a 1-s period which contains 30 percent or more errored blocks, or four contiguous blocks each of which has more than 1 percent of its bits in error, or a period of loss of signal.

A background errored block is an errored block not occurring as part of a severely errored second.

*An additional requirement based on a one-minute interval will likely be deleted as redundant in practice.

enough (perhaps 2 s), the channel bank causes the trunks it serves to be declared “busy,” lights a red alarm light, and sounds an office alarm. It also transmits a special code that causes the other channel bank to take the trunks out of service, light a yellow alarm light, and sound an alarm. Maintenance personnel then clear the trouble, perhaps by patching in a spare T1 line, and proceed with fault location and repair. Channel banks can be checked by looping, i.e., connecting digital output and input. Repeated line-fault location techniques were discussed earlier.

In higher-speed systems, automatic line and multiplex protection switching is often provided. A typical line-protection switch monitors and removes violations of the redundancy rules of the line signal on the working line at the receiving (tail) end. When violations in excess of the threshold are detected, a spare line is bridged on at the transmitting (head) end and if a violation-free signal is received on this line, the tail-end switch to spare is completed. If the spare line also has violations, there is probably an upstream failure and no switch is performed. A multiplex-protection switch is typically based on a time-shared monitor that evaluates each of several multiplexers and demultiplexers in turn by pulse-by-pulse comparison of the actual output with correct output based on current input. Multiplex monitors also usually check the incoming high- and low-speed signals using the line-code redundancy.

As the digital network has grown, there has been an increasing use of maintenance centers, to which all alarms in a geographic region are remoted, and which are responsible for dispatching and supervising maintenance personnel, directing restoration of failed facilities over other facilities or routes, and rearrangements for other purposes as well. There is also increasing provision, in network design, of alternative routes, sometimes by routing lines to form a ring, so that there are two physically separate paths between any two offices.

Synchronous Digital Hierarchy and SONET. The existing plesiochronous digital network has grown piecemeal over decades, with the parameters of new systems reflecting the technology and needs at the time of their development. In the late 1980s, a worldwide effort brought forth a new hierarchy for higher rate systems to provide capabilities not possible in the existing network. In this new hierarchy, multiplexing is by interleaving of 8-b bytes, as in the primary rate multiplexes, as opposed to the bit interleaving used elsewhere in the existing network. Further, similar formats are used for multiplexing at all levels, and it is intended that new transmission systems will be at hierarchical levels. Another important feature of the new hierarchy is an overall plan for monitoring and controlling a complex network, and the inclusion of enough *overhead* in the formats to support it. In spite of the name, the new hierarchy allows nonsynchronous signals based on the existing hierarchy to enter, and multiplexing throughout includes enough justification capability to accommodate the small frequency deviations characteristics of reference clocks.

The new hierarchy starts at 51.84 Mb/s, and all higher rates are an integral multiple of this lowest rate. Multiples up to 255 have been envisioned, and structures for several rates have been standardized within the United States. The rates of most interest are shown in Table 17.1.8.

A single frame of the STS-1 signal consists of 810 bytes, as shown in Fig. 17.1.10. The bytes appear on the transmission line read from left to right, starting with the first row. The transported signal occupies 774 bytes of the frame, with the remainder of the frame dedicated to overhead. The transported signal plus the path overhead, the *payload*, are intended to be transported across the network without alteration as the signal is multiplexed to, and recovered from, higher levels. In order to accommodate frequency and phase variations in the network, the 783 bytes of payload can start anywhere within the 783 byte locations allocated to the payload, and continue into the next frame. The starting point is signaled by a *payload pointer* included in the line overhead, so the proper alignment can be recovered at the receiving end. This pointer, as well

TABLE 17.1.8 Major Rates in the Synchronous Digital Hierarchy

Line Rate Mb/s	Designation US (SONET)	Designation CCITT	Comment
51.84	STS-1		Used to carry one 44.736 Mb/s (DS-3) signal
155.52	STS-3	STM-1	Used to carry one 139.254 Mb/s signal
622.08	STS-12	STM-4	Used for fiber optic systems
2488.32	STS-48	STM-16	Used for fiber optic systems

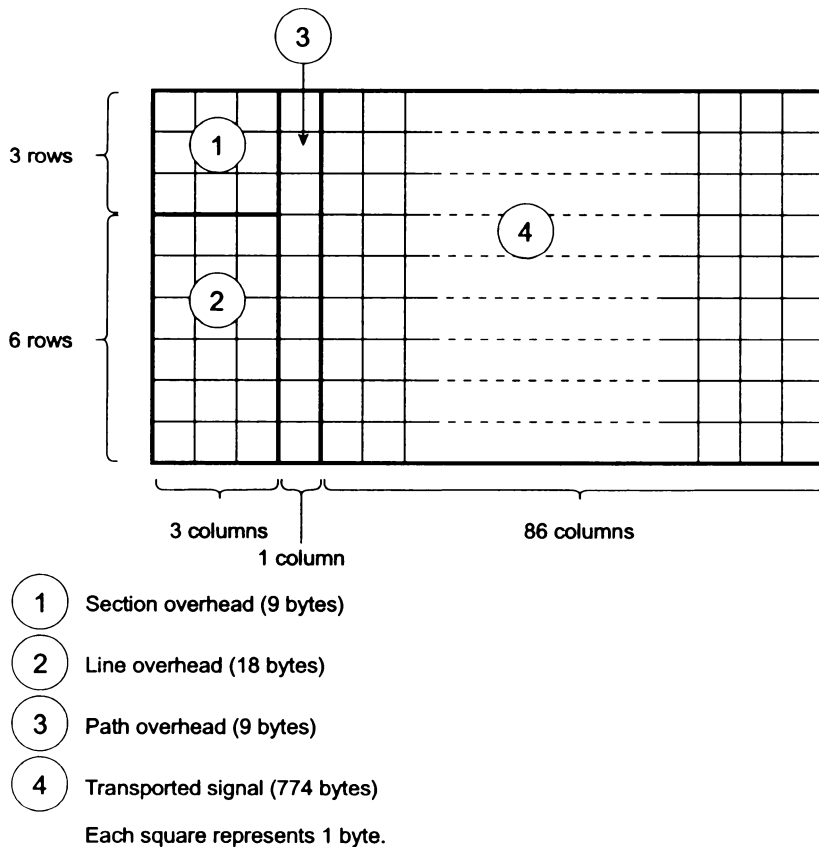

FIGURE 17.1.10 An STS-1 frame: (1) Section overhead (9 bytes); (2) line overhead (18 bytes); (3) path overhead (9 bytes); (4) transported signal (774 bytes). Each square represents 1 byte.

as the remainder of the line and section overhead bytes, are provided for the use of multiplex and line equipment, and will normally be changed several times as the frame passes through the network.

The *path* overhead is placed on the signal at the *path terminating equipment*, where the transported signal is assembled and embedded in the frame. It is not intentionally modified as the STS-1 frame passes through subsequent multiplexes and line systems, but can be read and used at intermediate points. This overhead is, from the point of view of the hierarchy, *end-to-end* information. It contains signals identifying the structure of the frame to aid in retrieving the embedded signal, status of maintenance indications, such as loss of signal for the opposite direction of transmission, a parity check on the previous frame, as well as provision for a message channel for use by the path terminating equipment.

Line overhead information may be inserted or modified when the STS-1 signal is multiplexed to a higher rate, or transferred between higher rate signals. Normally the capability to switch the higher rate signal to a standby facility in case of failure will be provided at such points, so the line overhead includes signaling for coordinating the operation of this protection switching, as well as functionality similar to the path overhead, but for use over the shorter "line."

The *section* overhead includes the framing alignment pattern by which the frame is located, and functionality similar to that of the path overhead, but for use and modification within individual sections, which end at regenerators or multiplexes.

TABLE 17.1.9 Representative North American Digital Systems for Paired Cable

Line rate, Mb/s	64-kb/s voice channel capacity	Widely used designation	Line formats	Usual medium	Typical repeater spacing, mi	Typical section loss, dB
1.544	24	T1 T10S (T1-outstate)	Bipolar with 1-in-8 1s density, 15 0s maximum	Wire pairs in single cable (but two directions in different units)	1 (on 22 gauge)	32
3.152	48	T1C, T1D, T148	Bipolar, 4B3T; duobinary; modified duobinary	As for T1, but also with shielded (screened) units	1 (on 22 gauge)	48
6.443	96	T1G	Quaternary	As for T1C		48

Frames for higher rate signals are generally similar. An STM-N frame has nine rows, and $N \times 270$ columns of which $N \times 3$ are for section overhead. The rather complex structure is based on *virtual containers*, *tributary units*, and *administrative units*, which are combinations of user signal with the overheads defined above appropriate to the administration of various types of paths.

Line Systems for Transmission

Systems on Wire Cable. Systems providing trunks on wire pair are generally designed to operate on the same cable types used for voice trunks, and to share such cables with voice trunks. Large numbers of such systems that have characteristics indicated in Table 17.1.9 are in service in North America and Japan, although the fiber systems are increasingly being used in new installations. Wire pair systems at 2.048 Mb/s are common in Europe. All the above are four-wire systems, using one pair for each direction of transmission. Two-wire systems providing 144 kb/s in both directions on a single pair have been specified and developed for use as ISDN loops, but little deployed as yet. These two-wire systems use echo cancelers, or time compression multiplexing in which the pair is used alternately in each direction (at about twice the average bit rate) with buffering at the ends.

Systems on Fiber Optic Cable. Fiber-optic systems, operating digitally, and using one fiber for each direction of transmission have developed extremely rapidly since their introduction in 1977, with steadily increasing capacity and, correspondingly, decreased per-channel cost. Systems for trunks and loops have been installed at many of the hierarchical rates (Table 17.1.1), but systems at even higher rates are most prevalent. The characteristics of such systems are summarized in Table 17.1.10, and some specific systems are shown on in Table 17.1.11. A branching unit, including 296 Mb/s regenerative repeaters, used in TAT-8 (Trans ATlantic cable 8) is shown in Fig. 17.1.11. Similar branching units in TAT-9 operate at 591 Mb/s, and include some multiplexing functions as well.

All terrestrial and submarine systems have customarily used intermediate regenerators when the system length requires gain between the terminals. Systems using optical amplifiers instead of regenerators have recently appeared, and the characteristics of one of these is also included in Table 17.1.10. In such systems, erbium doped optical amplifiers are used at intermediate points to overcome loss of the dispersion-shifted fiber with regeneration only at the ends. Figure 7.1.12 shows an amplifier designed for the system shown in the table. Typical output power of such amplifiers is +1 to +3 dBm.

Even these systems do not come close to exploiting the theoretical capacity of the fibers, and further developments are to be expected. Wavelength-division multiplexing, in which two or more transmitter-receiver pairs operate over a single fiber but at different wavelengths, is one way of tapping this capacity, and has seen limited use. The use of solitrons is being explored, and the record as of early 1993 for simulated long-distance transmission in the laboratory, 20 Gb/s over 13,000 km, used this technology.

TABLE 17.1.10 Parameters of Fiber-Optic Systems

Wavelength, nm	Fiber type	Bit rate, Mb/s	Maximum regenerator spacing, km*
850	Graded index	2–140	15–20
1300	Graded index	2–140	45–60
1300	Single mode	140–1700	25–60
1550	Single mode	1.5–2500	50–150

*Lower spacings generally correspond to higher bit rates.

TABLE 17.1.11 Some Fiber-Optic Systems

Name	Primary application	Bit rate per fiber	Wavelength, nm	Repeater spacing, km	Comment
TAT-10	Long undersea routes	591.2 Mb/s	1550	110	
FT-2000	Short and long terrestrial routes	2488.32 Mb/s	1310 or 1550	60 at 1310 nm 84 at 1550 nm	A variety of terminals is available
TAT-12	Long undersea routes	5 Gb/s	1550	33–45	Uses optical amplifiers

Terrestrial Radio. Frequencies allocated to telecommunications in the United States are shown in Table 17.1.2. Typical systems for analog signals modulate a carrier using low index FM with a signal consisting of one or more multiplexed mastergroups, and occupy a bandwidth of two or more times 4 kHz for each voice channel. Systems with very linear amplifiers have also used single-sideband AM, with a resulting bandwidth of closest to 4 kHz per voice channel.

While analog microwave radio once carried the bulk of long-haul telecommunications in the United States and many other countries, it has been mostly displaced in long-haul applications by optical fiber, particularly in the United States, and in short-haul applications by digital radio, owing to the need to interconnect with digital switches and other digital transmission systems.

A block diagram of a digital radio regenerator is shown in Fig. 17.1.8. The regenerator operates at i.f., and a complete station involves frequency conversion to and from rf, as well as receiving and transmitting antennas. An end station uses the transmitting and receiving portions of the regenerator separately to create and demodulate the transmitted and received signals.

Communications Satellite Systems. While the first experimental communications satellites were in low earth orbit, commercial satellites have almost uniformly been in a geostationary orbit, 22,300 miles above the equator. (The exceptions were in polar orbits, for better visibility from the northern polar regions.) In such an orbit, the satellite appears stationary from the earth, so a permanent communication link can be established using a single satellite, and earth stations with very directive stationary (or almost stationary) antennas. The disadvantages of this orbit are the high loss and delay resulting from the long distance the signal must travel. Table 17.1.12 lists representative applications of communication satellites, including current proposals for new low earth orbit systems.

Communications satellites receive signals from an earth station, and include *transponders*, which amplify and translate the signal in frequency and retransmit it to the receiving earth station, thus making effective use of the line-of-sight microwave bands without requiring erection of relay towers. The transponders are powered from solar cells, with batteries for periods of eclipse. *Spin-stabilized* satellites are roughly cylindrical and spin at about 60 r/min, except for a "despun" portion, including the antennas, that is pointed at the earth. *Three-axis-stabilized* satellites have internal high-speed rotating wheels for stability, and solar cells on appendages which unfold after they are in orbit. Adjustments in the position and orientation of a satellite in orbit are accomplished under control of the telemetry tracking and control (TTC) station on the earth, and the exhaustion of fuel for this purpose is the normal cause of end of life of the satellite, typically 10 to 12 years. (At end of life, the TTC moves the satellites to an unused portion of the orbit, where it remains, an archeological resource for future generations.) High reliability is necessary, and on-board spares for the electronics, switchable from the TTC, at a ratio of 50 to 100 percent, are typically provided. Table 17.1.13 gives the characteristics of two current satellites.

Most civilian communication satellites have used the common-carrier bands of 5925 to 6425 MHz in the uplinks, and the 3700 to 4200-MHz band in the downlinks. Now, direct broadcast satellites (DBS) use the 11- and 14-GHz bands for down- and uplinks, respectively. Since these bands are not so widely used in terrestrial

TABLE 17.1.12 Representative Applications of Communication Satellites

Application	Type of Service	Technical Characteristics	Status
Intercontinental telephone trunking	Point-to-point, 2-way	Earth station antennas to 30 m. FDMA, TDMA, and FM with a single channel per transponder used	The Intelsat system. Widely used where fiber optic cables are not available, also for handling peak loads on cables, and during repair of failed cables
Intercontinental TV transmission	Point-to-point, 1-way	Analog TV signals using FM with a single channel per transponder	Carried along with voice on the Intelsat satellites. Primary way of providing this service
National telephone trunks	Point-to-point, 2-way	Wide variety of antenna sizes, access methods have been used	No longer used in the United States, primarily because voice users don't like delay. Still used in countries with difficult terrain, long distances between population centers, or sparse networks
Distribution of TV signals to local broadcast stations or CATV distribution centers	Point-to-multipoint, 1-way	Smaller receiving antennas. Analog TV signals using FM with a single channel per transponder	Major provider of this service. Economics generally favorable compared to cable and microwave radio
Business and educational TV distribution, typically directly to viewing site	Point-to-multipoint, 1-way	Originally analog TV using FM, but increasingly digital, using coders, which, by removing redundancy encode the signal into 6 Mb/s or less, allowing multiple channels per transponder	Major provider of this comparatively new service
Data links, international and domestic	Point-to-point, 2-way	Low rate data channels can be multiplexed to a high rate to fill a transponder, or FDMA or TDMA can be used	Has seen considerable use, as with proper protocols, delay is not a problem in most applications. Fiber optic cables are eroding market
Maritime Mobile telephone	Fixed-point to mobile, 2-way	Operates at 1.5 GHz, with geosynchronous satellite	Via the INMARSAT system, the major modality for ship-to-shore telephony
Paging, short message	Fixed-point to mobile, 1-way	Would operate at 150 MHz with a total bandwidth of 1 MHz, using low-earth-orbit satellite	Proposal. Intent is to provide paging and limited message capability to personal receivers
Terrestrial mobile	Fixed-point to mobile, 2-way	Would operate at about 1.5 GHz, with a total bandwidth of about 20 MHz. Would use from 12 to 30 satellites in low earth orbit, using circular polarization and low directivity antennas on the mobile stations	Proposal. Intent is to provide mobile service roughly comparable to cellular, but available without the necessity for local terrestrial construction and network access

TABLE 17.1.13 Representative Communications Satellites

Satellite	Intelsat VI	Telstar 4
Type	Spin stabilized	Three-axis stabilized
Mass	4000 kg	4212 lb
Size	11.6 m high, 3.6 m diameter	Body 7.25 × 8.33 × 13.4 ft, extended length 80.4 ft
First launch	1989	1993
Launch vehicle	Ariane 4, Titan III	Atlas Centaur II AS
4/6 GHz Transponders and bandwidths	12 @ 36 MHz, 2 @ 41 MHz, 26 @ 72 MHz	24 @ 6 MHz
11/14 GHz Transponders and bandwidths	1 @ 36 MHz, 6 @ 72 MHz, 2 @ 77 MHz, 2 @ 150 MHz	8 @ 54 MHz, 16 @ 27 MHz (Can be used in pairs as 54 MHz also)
Primary power, W	2204	3744
Main applications	International telephony, TV, data	US domestic TV, data
Transponder output power, W	1.3–16 @ 4 GHz, 10 @ 11 GHz	12 @ 4 GHz, 60 @ 14 GHz (Can be doubled on some transponders)
Other features	SSTDMA (6×6 switch at microwave frequencies)	Can switch to a smaller receive spot beam to reduce and locate interference Compensates for uplink rain attenuation by increasing transponder gain

microwave relay, interference problems are less although rain attenuation is much higher. All frequencies are subject to sun-transit outage when the satellite is directly between the sun and the receiving earth station, so that the receiving antenna is pointing directly at the noisy sun. This occurs for periods of up to $\frac{1}{2}$ h/d for several days around the equinoxes. The effect can be avoided by switching to another distant satellite during the sun-transit period. The propagation delay between earth stations is about 0.25 s in each direction for geostationary

FIGURE 17.1.13 Satellite transponder.

satellites. This delay is of no consequence for one-way television transmission, but is disturbing to telephone users.

Some satellites use each frequency band twice, once in each polarization. Earth antenna directivity permits reuse of the same frequencies by different satellites as long as satellites are not too close in orbit (2° is the limit for domestic U.S. satellites in the 4- to 6-GHz band). Further frequency reuse is possible in a single satellite by using more directive satellite antennas which direct separate beams to different earth areas. Although Intelsat has made use of spot beams, most present satellite antennas have beam widths covering upward of 1000 mi on earth. A simplified transponder block diagram is given in Fig. 17.1.13.

Transponder utilization and multiple access. A transponder can be used for a single signal (single carrier operation) which may be either frequency- or time-division-multiplexed. Such signals have included a single TV signal, two or three 600-channel analog master groups multiplexed together and used to frequency modulate a carrier, thirteen 600-channel master groups using compounders and single-sideband amplitude modulation, and a digital signal with rates up to 14.0 Mb/s used to modulate a carrier using quaternary phase-shift keying (QPSK), or coded octal phase-shift keying. Single-carrier operation can be either point-to-point (as for normal telecommunication) or broadcast (as for distributing TV programs). Transponders can also be used in either of two multiple-access modes in which the same transponder carries (simultaneously) signals from several different earth stations.

In frequency-division multiplex access (FDMA) the frequency band of each transponder is subdivided and portions assigned to different earth stations. Each station can then transmit continuously in its assigned frequency band without interfering with the other signals. All earth stations receive all signals but demodulate only signals directed to that station. In the limit of subdivision, one voice channel can be placed on a single carrier (single channel per carrier or SCPC). As the high-power amplifiers (HPA) in the earth station and the satellite are highly nonlinear, power levels must be reduced considerably ("backed off") below the saturation level to reduce intermodulation distortion between the several carriers. It is also possible to use *demand assignment* in which a given frequency slot can be reassigned among several earth stations as traffic demands change.

In TDMA (time-division multiple access) each earth station uses the entire bandwidth of a transponder for a portion of the time, as illustrated in Fig. 17.1.14. This arrangement implies digital transmission (such as QPSK) with buffer memories at the earth stations to form the bursts. A synchronization arrangement that controls the time of transmission of each station is also required. As at any given time only a single carrier is involved, less backoff is required than with FDMA, allowing an improved signal-to-noise ratio. Demand assignment can be realized by reassigning burst times among the stations in the network. Satellite-switched TDMA (SSTDMA) in which a switch in the satellite routes bursts among spot beams covering different terrestrial areas is a feature of Intelsat VI.

Transmission considerations. The free-space loss between a geostationary satellite and the earth is about 200 dB. To overcome this large loss, earth stations for telecommunications trunks have traditionally used large parabolic antennas (10 to 30 m in diameter), high output power (up to several kilowatts), and low-noise receiving amplifiers (cryogenically cooled in some cases). Transponder output power is limited to the power available from the solar cells, and therefore, downlink thermal noise often accounts for most of the system noise with intermodulation in the transponder power amplifier a significant limiting factor. Consequently, the capacity of

FIGURE 17.1.14 Satellite time-division multiple access (TDMA). From Digital Communications Corporation; used by permission.

a satellite channel is often limited by the received signal-to-noise ratio (power-limited) rather than by the bandwidth of the channel.

For applications other than high-capacity trunking, the cost of large antennas at the earth stations is often prohibitive, so lower capacity is accepted, and received power may be increased by dedicating more power to the transponder or by use of spot beams, as the economics of the application dictate. Smaller antennas are less directive, possibly causing interference to adjacent satellites, unless the station is receive-only. Therefore VSATs (very small aperture terminals), which may have antennas as small as 1 m, typically operate in the higher frequency bands where directivity of smaller antennas may be adequate. Some applications, including the proposals included in Table 17.1.12, use much lower frequencies, and accept, or even exploit, the lesser directivity.

CHAPTER 17.2

SWITCHING SYSTEMS

Amos E. Joel, Jr.

A telecommunication service that includes directing a message from any input to one or more selected outputs requires a switching system. The terminals are connected to the switching system by *loops*, which together with the terminals are known as *lines*. The switching systems at nodes of a network are connected to each other by channels called *trunks*. This section deals primarily with systems that provide *circuit switching*, i.e., provision of a channel that is assigned for the duration of a call. Other forms of switching are noted later. Switching systems find application throughout a communication network. They range from small and simple manual key telephone systems or PBXs to the largest automatic local and toll switching systems.

SWITCHING FUNCTIONS

Introduction

A switching system performs certain basic functions plus others that depend on the type of services being rendered. Generally switching systems are designed to act on each message or call, although there are some switches that perform less often, e.g., to switch spare or alternate facilities. Each function is described briefly here and in greater detail in specific paragraphs devoted to each function.

A basic function of a circuit telecommunication switching system is connected by the *switching fabric*,* the transfer of communication from a source to a selected destination. Vital to this basic function are the additional functions of *signaling* and *control* (call processing) (Fig. 17.2.1). Other functions are required to *operate*, *administer*, and *maintain* the system.

Signaling

Automatic switching is remote-controlled switching. Transfer of control information from the user to the switching office and between offices requires electrical technology and a format. This is known as signaling, and it is usually a special form of data communication. Voice recognition is also used.

*The term *switching fabric* will be used in these paragraphs to identify the implementation of the connection function within a switching system. The term *communications* or *switched network* will refer to the collection of switching systems and transmission systems that constitute a communications system.

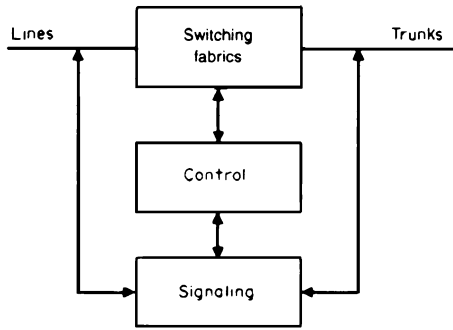

FIGURE 17.2.1 Basic switching functions in circuit switching.

Originally, signaling was developed to accommodate the type of switching technology used for local switching. Most of these systems used dc electric signals. Later, with the advent of longer distances, signaling using single- and multiple-frequency tones in the voice band was developed. Most recently, signaling between offices using digital signals has been introduced over dedicated networks, distinct from the talking channels.

As dialing between more distant countries became feasible, specific international signaling standards were set. These standards were necessarily different from national signaling standards since it was necessary to provide for differences in calling devices (dials) and call handling such as requests for language assistance or restrictions in routing.

Control

Control of switching systems and their application is called *system control*, the overall technique by which a system receives and interprets signals to take the required actions and to direct the switching fabric to carry them out.

In the past, the control of switching systems was accomplished by logic circuits. Virtually all systems now employ stored-program control (SPC). By changing and adding to a program one can modify the behavior of a switching system faster and more efficiently than with wired logic control.

Switching Fabrics

The switching fabric provides the function of connecting channels within a circuit-switching system. Store-and-forward or packet-switching systems do not need complex switching fabrics but do require connecting networks such as a bus structure.

Switching systems have generally derived their names or titles from the type of switching technology used in the switching fabric, e.g., step-by-step, panel, and crossbar. These devices constitute the principal connective elements of switching fabrics. Two-state devices that change in electrical impedance are known as *crosspoints*. Typically electromechanical crosspoints are metallic and go from almost infinite to zero impedance; electronic crosspoints change impedance by several orders of magnitude. The off-to-on impedance ratio must be great enough to keep intelligible signals from passing into other paths in the network (crosstalk). A plurality of crosspoints accessible to or from a common path or *link* is known as a *switch* or, for a rectangular array, a *switch matrix*. A crosspoint may contain more than one gate or contact. The number depends on the information switched and the technology.

Generally a number of stages of switches are used to provide a network in order to conserve the total number of crosspoints required. For connecting 100 inputs to 100 outputs, a single switch matrix requires $100 \times 100 = 10,000$ crosspoints. A two-stage fabric requires only 2000 crosspoints when formed with twenty 10×10 matrices. In a two-stage fabric, an output of each first-stage switch is connected to an input of a second-stage switch via a link. There is a connectable path for each and every input to each and every output. Since each input has access to every output, the network is characterized as having *full* access. However, two paths may not simultaneously exist between two inputs on the same first-stage switch and two outputs of a single-output-stage switch. (There is only one link between any first- and second-stage switch.) A second call cannot be placed, and this network is said to be a *blocking network*. By making the switches larger and adding links to provide parallel paths, the chance of incurring a blocking condition is reduced or eliminated. A three-stage Clos *nonblocking fabric* can be designed requiring only 5700 crosspoints. Even fewer crosspoints are needed if existing internal paths can be *rearranged* to accommodate a new connection that would otherwise encounter blocking. The design of most practical switching fabrics includes a modest degree of blocking in order to provide an economical design.

Large central-office switching networks may have more than 100,000 lines and trunks to be interconnected and provide tens of thousands of simultaneous connections. Such networks typically require six to eight stages of switches and are built to carry loads, which result in less than 2 percent of call attempts in the peak traffic period being blocked.

Network Control

While the switching system as a whole requires a control, the control required for a switching fabric may be separated in part or in its entirety from the system control function. The most general network control accepts the address of the input(s) and output(s) for which an interconnection is required and performs all the logic and decision functions associated with the process of establishing (and later releasing) connections. The control for some networks may be common to many switches or individual to each switch.

Self-routing is also used in fabrics where terminal addresses are transmitted through and acted on by the switches.

Some form of memory is involved with all networks. It may be intimately associated with the crosspoint device employed, e.g., to hold it operated, or it may be separated in a bulk memory. The memory keeps a record of the device in use and of the associated switch path. (In some electronic switching systems it may also designate a path reserved for future use.)

Operation, Administration, and Maintenance (OAM)

When switching systems are to be used by the public, a high-quality continuous service day in and day out over every 24-h period is required.

A system providing such reliable service requires additional functions and features. Examples are continuity of service in the presence of device or component failure and capability for growth while the system is in service.

Separate maintenance and administrative functions are introduced into systems to monitor, test, and record and to provide human control of the service-affecting conditions of the system. These functions together with a human input/output (I/O) interface constitute the basic maintenance functions needed to detect, locate, and repair system and component faults.

In addition to specific maintenance functions, *redundancy* in the switching system is usually necessary to provide the desired quality of service. Complete duplication of an active system with a standby system will protect against one or more failures in one system but presents severe recovery problems in the event of a simultaneous failure of both systems. Judicious subdivision of the system into parts that can be reconfigured (e.g., either of a pair of central processors may work with either of a pair of program memories) can greatly increase the ability of the system to continue operation in the presence of multiple faults.

Where there are many switching entities in a telecommunications network and as systems have become more reliable and training more expensive, the centralization of maintenance has become a more efficient technique. It ensures better and more continuous use of training and can also provide access to more extensive automated data bases that benefit from more numerous experiences.

For public operation, a basic subset of administration and operation features has become accepted as required features. These include the collecting of traffic data, service-evaluation data, and data for call billing.

SWITCHING FABRICS

Three different aspects will be considered in the design of switching fabrics: (1) the types of switching fabrics, (2) the technology of the devices, and (3) the topology of their interconnection.

Types of Switching Fabrics

The three types of switching fabrics are known by the manner in which the message passes through the network.

In *space-division* fabrics analog or digital signals representing messages pass through a succession of operated crosspoints that are assigned to the call for all or most of its duration. In *virtual circuit-switching* systems previously assigned crosspoints are reoperated and released during successive message segments.

In *time-division* fabrics analog or digital signals representing periodically sampled message segments from a plurality of time multiplexed inputs are switched to the same number of outputs. Using equal length segments assigned in time to *time slots* identifies them for address purposes in the system control.

There are two kinds of time-division switching elements, referred to as *space* switches and *time* switches (or time-slot interchanges, TSI). The space switch (also known as a time-multiplexed switch, TMS), shown in

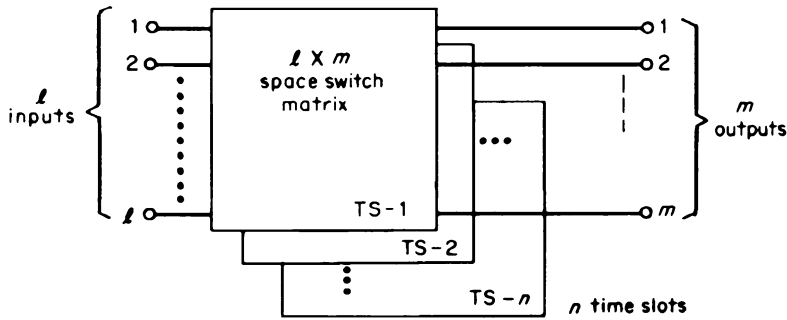

FIGURE 17.2.2 Time-multiplex switch (TMS): space switch.

Fig. 17.2.2, operates like the normal space-switch matrix but with each new time slot the electronic gates are reconfigured to provide a new set of input and output connections. The two-dimensional space switch now has an added third dimension of time.

The time-slot interchange uses a buffer memory, into which one frame of input information is stored. Under direction of the contents of the control memory, transfer logic records the sequence of information stored in the buffer, as shown in Fig. 17.2.3. To ensure the timely progression of signals through the TSI, two memories are used, one being loaded while the other is being read. The TSI necessarily creates delays in handling the information stream. Also with storage of message (voice) samples in T-stages, delay of at least one frame (e.g., 125 μ s) is introduced into transmission by each switch through which the message passes.

Channels arriving at the switch in time-multiplexed form can be further multiplexed (and demultiplexed) into frames of greater (or lesser) capacity, i.e., at a higher rate and with more time slots. This function is generally used before using TSI so that channels from different input multiplexes can be interchanged.

Time-division switch fabrics are designated by the sequence of time and space stages through which the samples pass, e.g., TSST. The most popular general form of fabric is TST. The choice of others, e.g., STS, is dependent on the size of the fabric and growth patterns.

Analog samples can be switched in both directions through bilateral gates. An efficient and accurate transfer of the pulse is effected by a technique known as *resonant transfer*. For most analog and all digital time-division networks, however, the two directions of signals to be switched are separated. Therefore two reciprocal connections or what is known as four-wire connections (the equivalent of two wires in each direction) must be established in the network. When connections transmit in only one direction, amplification and other forms of signal processing can more readily be switched into the network.

FIGURE 17.2.3 Time-slot interchange (TSI): time switch.

If multiplexing is performed in such a way that samples from an incoming circuit can be assigned arbitrarily to any of a number of time slots on an outgoing circuit, time-slot interchange and multiplexing are effectively achieved in a single operation.

With the application of digital facilities throughout telecommunications and in particular with the digitalization of speech, *digital time-division fabrics* are currently the most popular form of switching found in public networks. Digital voice communication exists throughout the public network. The *ISDN* (see Chap. 17.4) becomes a reality with digital access line interfaces in the local central offices, completing the end-to-end digital capability. As a result, switched 64,000 b/s clear digital channels are now available not only for voice but also for data.

The number of time slots provided for in a time-division fabric depends on the speed employed. Typically in a voice-band fabric there may be from 32 to 1024 time slots. The coded information in digitized samples may be sent serially (typically 8 b per sample for voice signals), in parallel, or combinations. Extra bits are sometimes added as they pass through the switch for checking parity, for other signals, or to allow for timing adjustments. For digital transmission, the crosspoints used in S stages of a switching fabric need not be linear.

Figure 17.2.4 shows the block diagram of the switching fabric for a no. 4 ESS, a large digital time-division switching system presently being deployed mainly in North America. Incoming digital T carrier streams (five T1 lines with 24 channels each) are further multiplexed to frames of 120 (DS120). The information is buffered in registers to permit synchronization of all inputs. The TSIs on the right side of the figure reverse the order of selecting and buffering; selected input sequences driven by a control memory (not shown) and sequentially gated out of the buffer attain the desired interchange in time. Note that the fabric shown is unilateral (left to right); the complete fabric includes a second unilateral fabric to carry the right-to-left portion of the conversation. This fabric has a maximum of 107,000 input channels, which can accommodate over 47,000 simultaneous conversations with essentially no blocking.

When digital time division fabrics are designed to work with digital carrier (T carrier in the United States) systems either in the loop as pair gain systems, line concentrators, or as interoffice trunks, carrier multiplexed bit streams can be synchronized and applied directly to the switch fabrics requiring no demultiplexing. This represents a cost advantage synergy between switching and transmission.

Frequency Division. Since frequency-multiplex carrier has been used successfully for transmission, its use for switching has been proposed. Connections are established by assigning the same carrier frequency to the two terminals to be connected. Generally to achieve this requires a tunable modulator and a tunable demodulator to be associated with each terminal, and therefore frequency-division switching has had little practical application. *Wave Division* switching is a version of frequency division used in optical or photonic transmission and switching. Other forms of *photonic switching* use true space division to switch optical paths en masse in *free space* (see Hinton and Miller, 1992).

Switching Fabric Technology

Broadly speaking, basically three types of technology have been used to implement switching networks. (1) From the distant past comes the *manually operated switch*, where wires, generally with plug ends, can be moved within the reach of the operator. (2) *Electromechanical* switches can be remotely controlled. They may be *electromagnetically operated* or *power-driven*. Another classification is by the contact movement distance, *gross* motion and *fine* motion. Gross-motion switches inherently have limitations in their operating speeds and tend to provide noisy transmission paths. Consequently, they have seen little recent development. (3) The *electronic* switch is prevalent in modern design.

Electronic Crosspoints. Gross- and fine-motion switches can be used only in space-division systems. Electronic crosspoints achieve much higher operating speeds. Although they can be used in space-, time-, and frequency-division systems, they have the disadvantage of not having as high an open-to-closed impedance ratio as metallic contacts. Steps must therefore be taken to ensure that excessive transmission loss or crosstalk is not introduced into connections.

The crosspoint devices are either externally triggered or are self-latching diodes of the four-layer *pnpn* type. The external trigger may be an electric or optical pulse. The devices have a negative resistance characteristic

FIGURE 17.2.4 Block diagram of no. 4 ESS digital time-division fabric.

and are operated in a linear region if they are to pass analog voice or wideband signals. For fixed-amplitude pulse transmission, as in PCM, the devices need not be operated over a linear region.

Electronic crosspoints are generally designed to pass low-level signals at high speed. Recently a new class of high-energy integrated-circuit crosspoints has been developed, which can pass signals used in telephone circuit switching such as ringing and coin control.

Switching Fabric Topology

Of all the switching functions, the topology and traffic aspects of fabrics have been most amenable to normal analytical treatment, although many less precise engineering and technology considerations are also involved.

The simplest fabric is one provided by a single-stage rectangular switch (or, equivalently, a TSI) so that any idle input can reach any idle output. If some of the contacts are omitted, *grading* has been introduced and not every input can reach every output. With the advent of electronic crosspoints and time division, grading has become less important and will not be pursued further here. When inputs to a rectangular switch exceed the outputs, *concentration* is achieved; the converse is *expansion*.

A switching fabric is usually arranged in stages. Input lines connect to a concentration stage, several stages of distribution follow, and a last expansion stage connects to trunks or other lines. Within the design of a switching system, provision is usually made for installation of switches in only the quantity required by the traffic and number of inputs and outputs of each particular application. To achieve this, the size of each stage and sometimes the number of stages is made adjustable. Consideration of control, wiring expense, transition methods (for rearranging the system during growth without stopping service), and technology leads to the configurations selected for each system.

In order to achieve acceptable blocking in networks that are smaller than their maximum designed size, more parallel paths are provided from one stage to the next. In this case, because the distribution need is also reduced, the connections between stages are rewired so that those switch inputs and outputs which are required for distribution in a large network are used for additional parallel paths instead.

It is convenient to divide the fabric into groups of stages or subfabrics according to the direction of the connection. (Calls are considered as flowing from an originating circuit, associated with the request for a connection, to a terminating circuit.) Local interoffice telephone trunks, for example, are usually designed to carry traffic in only one direction. The trunk circuit appearances at a tandem office are then either originating (incoming) or terminating (outgoing). Figure 17.2.5a illustrates such an arrangement where the whole network is *unidirectional*.

Telephone lines are usually *bidirectional*: they can originate or terminate calls. For control or other design purposes, however, they can be served by unidirectional stages, as shown in Fig. 17.2.5b. Concentration and expansion are normally used with line switching to increase the internal network occupancy above that of lines. In smaller systems a bidirectional network can serve all terminal needs: lines, trunks, service circuits, and so forth (Fig. 17.2.5c). When interconnection between trunks, as in a combined local-tandem office, is required, line stages can be kept bidirectional while trunk stages are unidirectional (Fig. 17.2.5d). When the majority of trunks are bidirectional, as may occur in a toll office, a bidirectional switching fabric is used (Fig. 17.2.5e). Many other configurations are possible.

SYSTEM CONTROLS

Stored Program Control

As discussed earlier, most modern systems use some form of general-purpose stored-program control (SPC). Full SPC implies a flexibility of features, within the capability of existing hardware, by changes in the program.

SPC system controls generally include two memory sets, one for the program and other semipermanent memory requirements and one for information that changes on a real-time basis, such as progress of telephone calls, or the busy-idle status of lines, trunks, or paths in the switching network. These latter writable memories are *call stores* or *scratch-pad memories*. The two memories may be in the same storage medium, in which case there is a need for a nonvolatile backup store such as disc or tape. Sometimes the less frequently used programs are also retrieved from this type of bulk storage when needed.

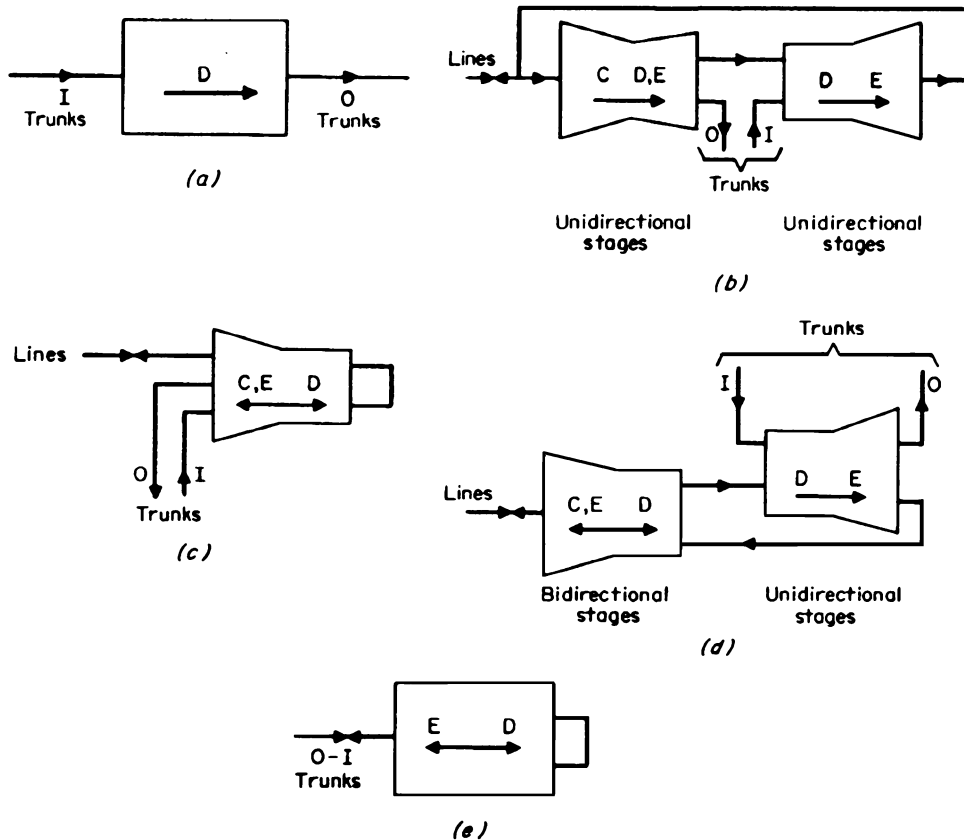

FIGURE 17.25 Switching fabrics: (a) unidirectional network (tandem); (b) unidirectional network (local); (c) bidirectional network (local); (d) combined network (local-toll); (e) bidirectional network; line stages: C = concentration, E = expansion, D = distribution; trunk stages: O = outgoing, I = incoming. Arrows indicate direction of progress of setup of call.

Nonprogram semipermanent memory is required for such data as *parameters* and *translations*. A switching system is generally designed to cover a range of applications; memory, fabric, and other equipment modules are provided in quantities needed for each particular switching office. Parameters define for the program the actual number of these modules in a particular installation. The translation data base provides relations between signal addresses and physical addresses as well as other service and feature class identification information.

Central Control

Single Active. The simplest system control in concept is the *common* or *centralized control*. Before the advent of electronics, the control of a large telephone switching system generally required up to 10 or more central controls. The application of electronics has made it possible for a system to be fully serviced by a single control. This has the advantage of greatly simplifying the access circuits between the control and the remainder of a switching system. It also presents a single point in the system for introducing additional service capabilities. It has the disadvantage that a complete control must be provided regardless of system size, and complete redundancy is often required so that the system can continue to operate in the presence of a single trouble or while changes are being made in the control.

Redundancy is usually provided by a duplicate central control that is idle and available as a standby to replace the active unit (the unit actually in control) if it has a hardware failure. The duplicate may carry out each program step in synchronism with the active unit; matching circuits observe both units and almost instantaneously detect the occurrence of a fault in either unit. Otherwise central-control faults can be detected by additional redundant self-checking logic built into each central control unit or by software checks. In these latter modes of operation the central controls may be designed to operate independently and share the workload. *Load sharing* allows the two (or more) central controls to handle more calls per unit time than would be possible with a single unit. However, in the event of a failure of one unit, the remaining unit(s) must carry on with reduced system capacity.

Load-sharing represents *independent multiprocessing* where two or more processors may have full capability of handling calls and do not depend on each other. At least part of the call store memory (containing, for example, the busy-idle indications of lines) must be accessible, either directly or through another processor, to more than one processor in order to avoid conflicting actions among processors.

A small office would require less than the maximum number of processors, so that the control cost is lower for that office; as the office grows, more processors can be added. Increasing the number of processors results in decreasing added capacity per processor. Conflicts on processor access to memory and other equipment modules, with accompanying delays, accelerate with the number of processors. Independent multiprocessing or load sharing rapidly reaches its practical limit.

Functional Multiprocessing. Another way to allocate central-control workload is to assign different functions to different processors. Each carries out its task; together they are responsible for total capability of the switching system. This functional or *dependent* multiprocessing arrangement can also evolve from a single central control. A small office can start with the entire program in one processor. When one or more functional processing units are added, the software is modified and apportioned on a functional basis. As in load sharing, the mutually dependent processors must communicate with each other directly or through common memory stores.

In handling calls, each processor may process a portion and hand the next step to a succeeding processor, as in a factory assembly line. This *sequential multiprocessing* has been used in wired-logic switching systems. Virtually all SPC-dependent multiprocessing arrangements are *hierarchical*. A master processor assigns the more routine tasks to subsidiary processors and maintains control of system.

The one or more subsidiary processors may be *centralized* or *distributed*. If the subsidiary processors are centralized, they have full access to network and other peripheral equipment. Distributed controls are dedicated to segments of the switching network and associated signaling circuits. As network and associated signaling equipment modules are added, the control capability is correspondingly enlarged. Most newer switching systems use distributed controls.

TYPES OF SWITCHING SYSTEMS

In the preceding paragraphs the various switching functions were described. A variety of switching systems can be assembled using these functions. The choice of system type depends on the environment and the quantity of the services the system is required to provide. Combining the various types of systems within one embodiment is also possible.

Circuit Switching

Circuit switching is generally used where visual, data, or voice messages must be delivered with imperceptible delay (<0.050 s) and are relatively long. For these applications connections are established through a switch that will pass the required bandwidth. The Nyquist criterion is used in time-division networks by choosing the sample rate to be at least twice the desired maximum bandwidth.

Circuit switching usually (but not always) implies message dialogue, i.e., reciprocal communication in both directions.

Circuit switching has the advantage of being able to switch a very broad spectrum of signal rates. For example, analog or digital video signals can be switched using either metallic or nonmetallic crosspoints.

Systems Other than Circuit Switching

Services that provide one-way transmission and can accept deferred delivery of data messages have been available in both public and private versions for many years; the switching involved is sometimes called *message switching*. Messages are stored in the switching system until a transmission channel is available, providing efficient use of channels, or until it is convenient to deliver the message to the recipient's station. Further, messages can be provided from the source to the communications system in bulk, or over a single high-volume *port*, which permits efficiencies in the nature and operation of such a source. Semipermanent record storage and message numbering can be provided by the switching system. Message switching lends itself particularly well to *multiple-address messages*.

The implementation of message switching service has evolved to systems that are computer-based, employing a large electronic local telephone switching system augmented with large disk stores, special input-output equipment, and special programs. The airlines industry has long been a user of computer-based electronic message switching for applications ranging from operations traffic to agent traffic.

Message switching, like circuit switching, provides for full duplex operation. A one-way service is known as *file transfer*.

Long data messages or bursts of real-time generated data are divided into packets and transmitted over networks especially arranged to take advantage of these message bursts. The packets are usually of uniform maximum length and prefixed with an address header. Switching takes place to select available network facilities over which to transmit the packets. Packets are reassembled at the receiving terminal or switching node. Retransmission of missing or defective packets are implemented at the switch.

This *packet switching* of data is used in a wide variety of private and public networks; local, campus, metropolitan, wide-area, and so forth, most with their own standard digital protocols. Analog data generally uses voice circuit switching. Packet switching may be enhanced by the use of virtual circuit switching.

Fast packet switching uses locally generated address headers that interpret incoming packet addresses so that they may pass through unique high-speed self-routing switching fabrics. As a result, packets from different inputs destined for the same output route are switched to the same fabric output(s).

By assigning packets to time slots in digital transmission systems and eliminating the checks and retransmission required by packet protocols a technique known as *frame relay* is popular. A switched version is becoming available.

To take advantage of higher speed, broadband digital transmission, such as SONET digitized visual, data, or voice services may be reduced to a fixed size (53 bytes) packet standard called a "cell." This method provides for the delivery of several or multimedia services intermixed over the same transmission facilities. Like packets, cells include headers that are interpreted by the switch in several ways depending on the type of service represented by the information contained in each cell. Networks functioning with these cells are said to employ the *Asynchronous Transfer Mode (ATM)* See McDysan and Spohn (1995).

ATM or Cell Switching enables ATM to become a ubiquitous switched services network or broadband ISDN for both private and public applications. Like fast packet switches, switch fabrics for ATM cells are designed to forward cells to the route indicated by the address. Cells are self-routed through space stage fabrics or by a time stage using a shared memory. Paths and channels through the network are identified to enable switches to act as both a combined virtual circuit and packet switch depending on the adapted service represented by particular cells. To reduce the probability of blocking in the switch, cell buffers are needed.

ATM switching is also useful in joining together backbone and other networks that use different protocols internally, such as LANs.

SIGNALING

Basic Purposes

Signaling has three basic purposes: *supervising* the call or message, *addressing* the call or message, and conveying *supplementary* information relative to the call. Supervision consists of indicating a call origination, answer or end, and station alerting. The application of these signals may be between the stations and the switch, in which case it is known as *station signaling*, or between switching offices, when it is known as

interoffice signaling. There are two basic approaches to signaling, *per channel* and *common channel*. Per channel signaling may be in or out of the bandwidth used to carry the messages. In the case of digital time-division multiplex transmission, signals may occur in each channel time slot (*in slot*) or in a separate signaling channel (*out of slot*). Common-channel signaling, on the other hand, is carried over one or more channels dedicated to signaling which usually serve many trunks. The electrical characteristics of signals are divided into three categories, *dc*, *ac*, and *digital signals*.

Standards and Compatibility

Only by following standards for the transmission and use of signaling can the various elements of a telecommunication network function together. Signaling standards for public networks operating between nations are generally established by the CCITT, now known as the "International Telecommunications Union-Telecommunications Standardization Sector (ITU-TSS)." The deliberations leading to the setting of these standards involve telecommunication administrations and recognized private operating agencies with the assistance of scientific and industrial organizations. Over the years, as new technology and requirements have appeared, new and revised signaling standards have followed.

National systems are more dependent on the type of signaling required by the local switching systems, and conditions vary widely throughout the world. In the United States the "Alliance for Telecommunications Industry Solutions (ATIS)" is responsible for devising national standards.

Station Signaling

There are few varieties of station signaling in public networks. One is the universal dc loop supervision and dial pulsing. Other signals sent over the loop are those for ringing, coin control, party identification, toll denial (signals indicating limitation of access to the DDD network of a particular station), metering, and so forth. Worldwide they vary in voltage, frequency, and how ground is used as a conductor. An important attribute is the distance or electrical range over which each signal functions satisfactorily.

A standard ac station-address signaling using two-out-of-eight frequencies (twice one-out-of-four) is known as *dual-tone multifrequency (DTMF)* (or "TOUCH TONE" as trademarked by AT&T). For digital access ISDN national standards have been issued by ATIS. *Voice recognition* is also being introduced as a means for addressing telephone calls. For purposes of interconnection to the United States network an Electronic Industries Association standard has been issued on station signaling as applied to PBXs.

Distributed Switching

The range of dc signaling has been particularly important in station signaling since it has determined the location and the number of wire centers required to serve a given area. Various signaling arrangements were developed to extend the dc loop and ringing range of central switching systems. The lower cost of electronics for small transmission and switching systems has made it economical to extend the range further and to decentralize switching.

Interoffice Signaling

Many forms of dc interoffice signaling have been developed and used. They were designed to accommodate specific electromechanical switching systems.

Signaling systems designed for use between offices, particularly over long distances and between countries, must be designed to be transmitted over carrier systems either analog or digital. For analog carrier trunks international standards have been set involving codes of two-out-of-six frequencies (multifrequency code, MFC) for address signaling and one or two frequencies for supervisory signaling. In digital carrier systems a means of carrying encoded supervisory signals in the bit stream is provided to be used with the MFC address signaling.

The per channel signaling systems have a limited number of signals that can be transmitted and usually lengthen the time of use of the transmission paths. To overcome these limitations and provide other advantages,

common channel signaling (CCS) systems have been introduced. Common-channel signaling systems consist of a full-time data link between two signaling points and the necessary terminal equipment. By appropriately encoding the data stream, a variety of signals needed for both address and supervisory as well as service enhancements can be transmitted at higher speed between SPC switches. If the CCS link carries the signals for the group of trunks between two offices only, it is said to be operating in the *associated* mode. To signal between two offices with too few trunks to justify an associated link, it is possible to signal over two or more signaling links in tandem via intermediate signaling points. These act as packet switches, routing messages between offices depending on label information contained in each packet. The links carry the signals for more than one trunk group, are not associated with any one, and are said to be operating in the *non-associated* mode.

For common-channel signaling, two international standards were adopted, one optimized for analog transmission (CCITT signaling system 6) and one optimized for use with digital data links (CCITT signaling system 7). With digital transmission becoming dominant, signaling system 7 is gradually being introduced into all networks.

Signaling Fabrics

With common channel signaling becoming the basic signaling method, its signaling links form a separate *signaling network*. The switching systems appear as users on this network.

Each office eventually will rely on this network for all its interoffice or internodal signaling needs. *Signal transfer points* (STPs) serve offices in a geographical *signal region*. An associated signaling link between two offices at any point in the signaling network, it can be added where justified by traffic and reliability considerations. To ensure service reliability, each office has access to two or more STPs in its region (see Fig. 17.2.6). Alternate signal messages from served offices are sent over A links to a different STP in the same region. Signaling networks interconnect not only signaling regions of a particular carrier but also between carriers. The

FIGURE 17.2.6 Signaling-network concept. (Adapted from R. C. Nance and B. Kaskey, *ISS Conf. Rec.*, 1976, p. 413. Copyright 1976 Inst. of Elec. and Comm. Engrs. of Japan. Used by permission)

message switches that serve as STPs employ redundancy of their own and achieve the same quality of service continuity as the switching offices.

Separate data links can also be used for signaling from customer premises, e.g., for passing the calling PBX station identification to the central office in what is known as automatic identified outward dialing (AIOD).

Tones and Announcements

Switching systems need to inform the users of progress being made in serving a particular call. Tones and verbal announcements are used for this purpose. To enable tones to be automatically detected by call originators and to prevent interference with DTMF signals, a precise (frequency) tone plan has been adopted in the United States.

The tones range from *dial tone*, which prompts the caller to start dialing, to *busy tone*, which indicates that a called line is unavailable. Similarly, where more than symbolic information is needed, verbal announcements are given to the caller.

Generally tones and announcements reach the caller through a regular switching network connection. For tones, one or more network terminals are used. If the same source supplies all terminations, low impedance is employed to prevent crosstalk between calls simultaneously reaching the same tone source.

Announcements may be composed from a recorded vocabulary; e.g., intercept systems announce number changes by concatenating a limited vocabulary of phrases and digits.

SERVICES AND OAM FEATURES

A *service* is what the user perceives as being delivered by a switching system. OAM *features* of central-office telephone switching systems are those uses of system functions which are needed to operate, administer, and maintain the switching, customer terminal, and transmission equipment to provide services.

For example, to provide telephone service (see below) a directory number or address is assigned to a line. Because directory numbers are not permanently associated with switching-network terminations, an administrative feature is required to store this association as a translation in system-control memory.

Telephone Service

The switching functions required to establish a telephone call were listed earlier. Other services also use these functions, plus such additional functions as may be needed.

Telephone service includes the ability to place calls in a telephone network. Users reach other users' telephones by dialing a sequence of digits and can similarly be reached. To respond and alert users, switching systems in a network provide the appropriate signals: dial tone, ringing, busy tone, and so on.

In many networks, operators provide additional services: assisting in placing toll calls (person-to-person), calculating charges and collecting coins in certain calls originating from public coin telephones, providing telephone numbers for users given a name and address (directory assistance), informing users whenever they have dialed a number that has been changed or is not in service (intercept), and so on. These operator services may be fully or partially automated with SPC systems connected to the network. Depending on the operating entity and the service provided, users may be billed for the use of such operator services.

Additional services are provided (again depending on the country and/or the operating entity) for additional one-time or periodic charges. These include DTMF dialing, key telephone or PBX services, or private user networks embedded within the public switched communication network, special telephone sets, and special calling services.

A user wishing to purchase or subscribe to services such as the above makes appropriate arrangements with the business office of the telephone administration or operating company. Some of the other services may be activated, used, and deactivated by dialing directly into an SPC switching system. As the connectivity of SPC systems pervades a communication network, more and more services become available to meet user needs and the trend is toward further automation of the direct control by the user in obtaining such services.

Call waiting is an example of a calling service available in the North American network where SPC switching systems are in service. When a user who has call-waiting service is engaged in a telephone conversation, a distinctive tone will be received if a new call arrives. The user can be connected to the new call by “flashing,” or briefly operating the switch hook. The system responds by placing the existing connection in a hold state and reconnects the subscribing user to the new call. By subsequent flashes of the switch hook the subscribing user can alternate connections between the two calls as needed.

New Services

With the introduction of SPC and associated bulk memory, many new services have been devised for switching offices. Usually they can be implemented with little or no additional hardware except for memory to store additional programs. Switching systems generally include a dynamic set of service capabilities.

Because of their location in networks switching systems provide for control implementation of most services. They serve party and mobile telephones, private branch exchanges, and many different rate categories (flat rate or measured service, coin, and so on.). Some central office systems include capabilities known as “CENTREX” service for serving intramural business needs directly, avoiding the need for key and PBX systems.

Just as the use of SPC in central offices has increased the number and flexibility of the services offered, the use of common channel signaling has created new opportunities to provide new services and features in public and private networks. A popular service made possible by the deployment of the common channel signaling networks is *caller identification*. Except where the caller blocks its application on specific calls or on all calls, the calling telephone number appears on a device at the called telephone after the first ring. Eventually it is expected that this service will be extended nationwide. (See Walker, 1991.) By adding centralized data bases, known as network control points (NCP) or service control points (SCP), to some of the STPs of a signaling network, it is possible to offer new network-based services. Some of those currently in service include translation of called addresses when there are special charge treatments, credit-card calling, and virtual private networks using public network facilities.

By adding *triggers* to the call processing software in each local central office, calls requiring special treatment are directed to an SCP that is able to continue call processing and addressing that is tailored to the needs of specific subscribers or organizations within an area or nationwide. This concept is known as the *Advanced Intelligent Network (AIN)*. See Majeti and Prasad, 1993. Services changes are implemented centrally through a *service management system (SMS)* using *service creation environment (SCE)* software.

Customer premises equipment has been at the forefront of offering new services. General business users need both voice and data services. Most of the PBXs designed since 1980 have included provision for switching data. With the growth of such data services have come new switching system architectures that use the same switching networks for connecting digitized voice and packetized data terminations. Many can also serve local area networks (LANs) through separate gateways or with LAN rings built into PBXs.

OAM Features

Network Management. Automatic and manual routing control is provided in large modern networks to route calls around portions of the network that are temporarily congested or where disasters or other types of problems have reduced or eliminated the ability to reach or receive traffic from portions of the network. This is known as *network management*. Network management also includes turning back calls to reduce congestion to a particular destination and the temporary augmentation of facilities to serve overloads. Further, it includes threshold measurements and alerting when offered calls do not appear to be reaching their intended specific destinations. The application of self-healing loops of digital optical facilities for trunks is improving network management and reliability.

Traffic Measurement. To observe how the switching system is operating, an administration needs indications of what loads are being carried by the system components. Typical are counts of calls, measurements of call delays, counts of call dispositions, duration of all circuits busy, and circuit use. The last measurement is best reported in terms of call hours per hour, or *erlangs*. It is often made by periodic counting of busy circuits

and reporting the average or by summing the actual hours of circuit use for all circuits in a group. Output of data may be printed out directly at a switching system or may be transmitted to a centralized support system.

Billing. Broad allocation of costs to various users of a network can be determined by traffic measurements. In public service systems, more detailed information is needed. Two basic methods are used, *bulk billing* and *detailed billing*. In bulk billing, charge units are allocated to call setup, duration of call, and distance called. In Europe, the pulse metering system is used, where the local office generates pulses on a per line basis. In North America detailed billing is used for toll calls. Call details are recorded, either centrally or locally, and charges are later computed in centralized data processing centers where bills are prepared. This process, called *automatic message accounting* (AMA), has the advantage of more flexibility and full reporting of charges to the customer at the expense of more data processing than is required of bulk billing.

For coin telephones, with pulse metering systems, the charge pulses can be used to control coin collection directly. With detailed billing systems, operators or centralized charge calculation and control capabilities are required to quote charges and handle the collection of coins.

Calls in public data networks are usually billed on the basis of duration of call or number of packets plus a network access charge. The rates may change with the time of day and priority required.

Maintenance

The place of the switching system in a communication network puts unusually severe requirements on its maintenance. Loss of service for any but very short periods is unacceptable. Detection, recovery, diagnosis, and repair of trouble must be carried out while the system continues to process calls. Central processor design therefore incorporates a considerable amount of attention to internal trouble detection and the ability to reassign faulty system elements automatically so that processing can continue without loss of calls. Tests diagnosing the nature of the trouble may also be automatic or subject to request by maintenance personnel.

Alarms and diagnosis results must be generated; most indications appear as lighted lamps or typewritten characters. A standard *user-machine language* is being adopted by the ITV-TSS.

Contents of translation and other semipermanently stored data bases change daily in a large public system. Provision is made to change this information locally or remotely. Care is needed to ensure that changes are free from error and that the data bases will not be lost. In some systems changes are made in two steps. The information is first stored in a temporary *recent change* location and later relocated to a regular data base address.

Another class of feature deals with the cutover of a new system, recovery of a failed system, and change of hardware or software in a working system.

In addition to the tests internal to the switching system, separate test sets, consoles, display boards, and test access switchboards are used to varying degrees and constitute maintenance features. The switching system is also used for connecting test circuits to remote switching and transmission systems.

In the design of systems, a critical factor is the objective in-service time. For public switching systems for two-way voice service, an objective of 2 h in 40 years downtime has been used.

Centralized Operation Support. In the past, operational features have been largely contained within the design of the switching system. There is a trend toward providing these features, as well as maintenance and administrative facilities, at a centralized point where they can service a number of switching systems. The centralized systems are known as *operations support systems* (OSS). Operations includes maintenance and administration as well as operation. The design of switching system hardware and/or software includes features needed to provide and interact with OSSs.

In some centralized support systems, programs and other information for infrequently used real-time call processing can be accessed at a centralized call processor or OSS designed with the required reliability objective.

Applications

This section gives the reader an understanding of typical switching systems. To determine whether a given switching system meets a specific application need one must first know the basic dimensions and capacity requirements.

Dimensions

Limiting the size of a system are the number of physical terminations for lines and trunks, the call-carrying capacity of the control, the traffic capability of the network(s), and the address range of the memories.

The *terminations* are those lines, trunks, service, and similar circuits, which are principal service inputs and outputs of the system. The service circuits do not extend out of the system but are used to provide a function such as ringing, or call signal receiving or transmitting.

Small data and PBX switching systems may serve tens or hundreds of terminations while large central-office voice-switching systems can have a termination capacity of over 150,000. Most switching systems are designed so that they can grow over a range of terminations, typically an order of magnitude or more. Ideally a switching system should be able to grow over a greater range, and new technology continues to expand this range.

System capacity depends on many factors, including not only the properties of the switching system but also customer traffic characteristics and customer expectation of grade of service. Grade-of-service criteria are usually defined for the average busy season busy hour (ABS) as well as for the 10 highest busy hours and for the highest busy hour. Examples of ABS criteria are 1.5 percent of calls delayed over 3 s in receiving dial tone and 2 percent of incoming calls blocked in the switching network. Capacity must be determined for each central office installation, as it depends on the amount of equipment provided.

Call Capacity. The limit to the maximum office size is frequently designed to be the capacity of the central processor(s). Processor capacity is usually stated in terms of busy hour originating plus incoming calls, although any particular office capacity calculation must consider the proportions of all types of calls. In determining engineered capacity, consideration must be given to the maximum capacity of the central processor. With the growth of services and features designed into the programs of SPCs, the more real time required to process all calls, and the lower the call capacity. Usually this corresponds to almost 100 percent use of the time available for call processing. An allowance must then be made for safety (typically 5 percent) on a high-day engineering basis, and beyond that for the ratio of high day to average business day. (A common ABS use is 70 percent of available processor time.) Then all delay criteria must be checked; if any are not met, the capacity must be lowered further.

Systems have been built with distributed microprocessors serving as many as 100,000 busy-hour call attempts (BHCA), and with a central SPC using multiprocessors and high-speed integrated-circuit technology of over 1,200,000 BHCA. Generally BHCAs are at least twice the number of successfully processed calls, owing to the large number of calls where a receiver-off-hook signal is detected without the completion or initiation of dialing.

Data-message or packet-switching capacity is measured in terms of maximum rate of *throughput*. The capacity of the control includes overhead as well as message handling. The control capacity is generally considered to be the major factor in throughput. Processing capacity can be limited by congestion delays within a system delivering or receiving calls for processing.

Switching-Fabric Capacity. The switching-fabric capacity is expressed in the number of erlangs that can be carried at an objective blocking. Fabrics for smaller offices are partially equipped; each arrangement will have its own capacity. If the average call duration is long, the erlang capacity may limit call capacity below that of the processor:

$$\text{Network calls/h} = \frac{\text{erlang capacity}}{\text{call holding time (h)}}$$

Because processors are not partially equipped and fabrics can be, designers choose to design fabrics with a smaller chance of being the limiting dimension of system capacity.

Memory Capacity. The total memory requirements depend on many components. An important factor is whether there is only one storage subsystem or separate storage subsystems are used for different storage needs. Typically, separate subsystems might be used for program and call data storage. In a message-switching system separate subsystems might be used for call processing and message storage.

One limit on memory size is the amount of memory that can be directly addressed. By having larger program words (more bits per word), more memory can be accessed, but this means that larger, more expensive program memories are required.

As in most SPC systems, software techniques can be used to extend the address range at the expense of real time. One address can refer to a table containing another range of addresses.

Physical memory modules are used to form a storage subsystem. Only as many memory modules are used as are needed to provide for the memory requirements for a particular installation.

Host/Remote Systems

The dimensional limits represent the individual maxima in each case (call attempts per hour, erlangs, and terminations). Depending on the specific environment, any one of these may limit further growth of the system, and the remaining limits would be unattainable. These limits represent approximate values, which in themselves depend on assumptions of the system environment, e.g., the ratio of intraoffice to interoffice calls in a local central office. The limits change with time as additional features and services are added to a system or when improvements in hardware or software are introduced.

Two basic switching entities are used at points distant from the host central wire center. One is the *remote line concentrator* (RLC) and the other the *remote switching unit* (RSU). Both the RLC and RSU are used to concentrate traffic at a point closer to the lines they serve. The RLC provides only for remoting this network function. Generally, in the central office an equivalent expansion function is provided, and consequently each RLC line is given a central office appearance. Some RLC systems eliminate the need for this expansion by connecting RLC trunks to links within the switching network. Generally the line range is not extended with the use of RLCs. Generally digital subscriber line carrier (SLC) systems are used to connect the host with the RLCs and RSUs. This provides a range as much as 100 mi. Recently fiber-optic links with digital transmission have also been employed by extending internal system links as in the No. 5 ESS.

Should all the trunks between the RLC and the central office be busy or the facilities carrying the trunks be severed, calls to and from the RLC lines cannot be served. Since the lines served are in a confined area, they are subject to higher traffic variation. Concentrators are generally small, serving no more than a few hundred lines.

With the advent of microprocessors, not only the network but also the control can be remoted. This means that more intelligence can be designed into the remote switching. Also, the remote switch may be able to complete intra-RSU calls without using trunks to the host office. The RSUs have been developed with SPC and limited call-processing capability so that they can provide basic service if the link to the host is lost. This is known as *stand-alone* capability.

Trends in Switching Systems

Switching systems have made the transition from those relays and other forms of electromechanical switches to all-electronic fabrics and controls. More than half of the switches in service are digital time-division systems. Whether time or space division, the major ingredient to stimulate this transition has been stored-program control. SPC has provided the flexibility and power to add to and change switching system capabilities easily. As administrations make the transition to national and international networks of SPC systems, capabilities are being extended further. The advent of common-channel signaling has provided a separate fast communication network between the processors of SPC switching systems, further increasing the capability of telecommunication networks. New services concepts that are possible within an SPC office may be extended to the entire intelligent network.

ISDN will be in full blossom by the end of this century. Other digital loop technologies will further extend the end-to-end digital capabilities of the public network. The inherent high-speed capability of optical fiber for digital transmission will be used for *Broadband ISDN* (B-ISDN). Initially ATM as part of a B-ISDN for data, file transfers and images will further extend private backbone networks to the public B-ISDN.

Switching provides access to the public network for wireless telephones and terminals. For cellular radio it also provides not only the means for access but follows mobiles as they move from one area to another.

17.52 TELECOMMUNICATIONS

As mobiles move from one system to another, Intelligent Network switches and databases will provide seamless connections. *Personal Communication System (PCS)* will provide wireless switched access for users who do not move significantly during a call.

As more telecommunications services vendors enter the switched public network many new switching solutions will be needed to deal with such things as *number portability*. The telephone number addresses used by switches in the worldwide public network are the immutable factor in extending telecommunications services. Competition generally places new requirements on public networks that are manifested and implemented in the switches.

CHAPTER 17.3

LOCAL ACCESS NETWORKS

George T. Hawley

INTRODUCTION

The invention of the telephone in 1876 began an era of communications by voice over great distances. In order for telephone communications to be effected there needed to be low cost connections between telephones that could transmit voice signals with minimum attenuation and interference. Copper wires had the best balance of cost, tensile strength, durability, and transmission performance for the purpose. For economy it was thought that one wire between each pair of telephones with ground return would be adequate. This was not the case because of high direct and induced interference in the wires so connected. The use of a balanced pair of wires improved performance although it increased the cost of a connection by over 50 percent.

It was not practical to connect every pair of telephones with dedicated wires. Central switching offices were created where dedicated lines from telephones in the vicinity of the office could be terminated and flexibly connected to lines associated with other telephones as required to place a call. By the 1890s initial installations of automatic switching equipment began in local central offices to make connections between local *loops*, the name given to the pair of wires between the telephone and the central office and between loops and *trunks*, the name given to wire pairs between central offices. Over the years intercentral office or, simply, interoffice trunks of many varieties have been developed to support toll, tandem, equal access toll, and other applications.

The first telephone loops and trunks were pairs of uninsulated wires strung along aerial pole lines between terminations. As the number of telephone lines grew in the 1880s, these *open wires* proved to be impractical in urban applications. Cables of pairs of insulated wires were invented in the 1880s to improve the physical efficiency of aerial telephone lines and to make possible the placement of underground lines. After much trial and error, paired cables, consisting of wires insulated by paper wrappings, were perfected and standardized by 1888.

By the early 1900s the modern wireline telephone networks had taken shape and have not changed much since (Fig. 17.3.1). The term local access in the context of a wireline network means the local loop facilities between the central office and the end user's premises. Until 1976, telephones and other end-user line-terminating equipment were part of the local access network and were provided by the locally franchised telephone company. In 1976 the FCC separated line terminating equipment such as telephones, private branch exchanges, data modems, and the like into an unregulated category of equipment, called customer premises equipment or CPE under Part 68 rules. Although the various types of CPE play an integral role in the transmission and signaling performance of telephone networks, they are not considered part of the local access network. Part 68 incorporates rules governing the protection of the network and so-called third parties (parties not participating in a telephone connection) from nonconforming CPE or combinations of CPE. Part 68 contains no network or end-to-end compatibility information.

The Exchange Carrier Standards Association (ECSA) codifies network interface standards between CPE and local access networks in the form of American National Standards Institute standards adopted from standards developed under the ECSA T1 Committee. Customer premises equipment standards are established by the Telecommunications Industry Association (TIA) and are generally based on pre-1976 telephone set and other CPE properties.

TELEPHONE LOCAL ACCESS-LOOP DESIGN AND TECHNOLOGIES

Design Based on Wire Pairs

Design of wireline local access facilities or loops must economically accommodate two fundamental characteristics of the society being served: (1) the tendency for the population of end users to be clustered around population centers with decreasing density as a function of increasing distance from the center and (2) the presumption that service will be provided within a day or so of a request. The first characteristic suggests the location of a central office near the center of population with decreasing numbers of lines in the local loop plant as distance from the central office increases. The second characteristic suggests a continuous inventory of unused lines available everywhere in the community to meet unscheduled demands for service.

FIGURE 17.3.1 Local telephone network, basic layout.

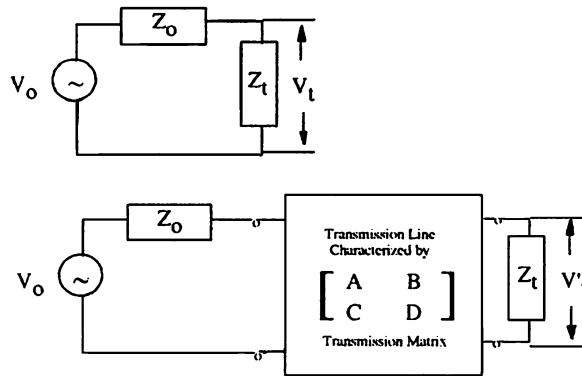

The characteristics of human hearing and voice have a further influence on the design of the local loop plant. Copper wire pairs have dc resistance and attenuate alternating current signals. The frequency range of human hearing is generally considered to be from 100 Hz to about 20,000 Hz and is sensitive to sounds over many orders of magnitude of sound pressure intensity. The human voice contains 80 percent of its energy at frequencies below 1000 Hz and over 80 percent of articulation in frequencies below

about 3000 to 4000 Hz. Faithful transmission of the human voice using energy in the frequency range between 300 and 3000 Hz provides efficient, intelligible, and recognizable communication over telephone networks.

Copper wires of larger diameter provide lower attenuation per unit length but are more expensive. In the early days of telephony, before the advent of electronic signal amplification, load coils were used to alter the transmission properties of wire pairs to reduce the attenuation of signals in the voice frequency band. The most common arrangement in the local loop is to place 88 mH coils in series with wire pairs every 6000 ft beginning 3000 ft from the central office. This technique, referred to as H88 loading, allows finer gauge wires to be used for economy at distances greater than about 18,000 ft from central offices, about 25 percent of local loops.

Similarly, there was no need to design telephone transmitters and receivers to operate effectively outside of the range of about 300 Hz to 3000 Hz. The technology employed in telephone sets for the first 100 years for the conversion of acoustic speech to electrical signals and vice versa remained essentially unchanged. The carbon microphone transmitters and electromagnetic diaphragm receivers used had limited efficiency and dictated, along with average acuity and comfortable speaking volume, the maximum voice frequency signal attenuation that could be tolerated on a connection experiencing acceptable background noise. The last major improvement in telephone set efficiency occurred in 1951 with the introduction by AT&T of the model 500 set, which properties are the basis for the current TIA standards for telephone set performance. Although new technologies exist that might further improve telephone set efficiency, 500 set equivalence is all that is required to match the characteristics of network connections and human speech and hearing comfort levels.

The design of local loops was influenced by voice frequency transmission across telephone connections as well as by early telephone properties. A typical telephone connection in a metropolitan area might involve two loops and one trunk connection. To minimize the total cost of network construction it was necessary to balance the performance of such connections against the cost of the networks needed to create the connections. Larger wire gauges improved transmission performance but increased cost. More central offices closer to customers reduced loop lengths and costs but increased the number of trunk routes required between more numerous central offices. Early designs balancing these factors resulted in loops with an average length under 2 mi and paired cables with wire gauges of 19, 22, and 24 AWG. Wire of 26 AWG was introduced in the 1920s. To achieve satisfactory voice transmission local loop designs were adopted over time that limited the maximum insertion loss at 1000 Hz to less than 8 dB with terminations simulating a telephone set at one end of the loop and a switching system line termination at the other end. Insertion loss is

$$\begin{aligned} \text{Insertion Loss} &= 20 \log (V_t/V'_t) \\ &= 20 \log ((A Z_t + B + (C Z_t + D) Z_o) / (Z_o + Z_t)) \end{aligned}$$

FIGURE 17.3.2 Definition of insertion loss of a transmission line.

defined in Fig. 17.3.2, which refers to A, B, C, D parameters to characterize transmission lines. These parameters are defined by the characteristic impedance and propagation constant of a transmission line and are discussed later in this section.

Loop design was also influenced by the operating characteristics of electromagnetic relays employed in central office switching system line circuits. The signaling protocol between telephone sets and switches is based on the flow or not of direct current from batteries in the central office through the off-hook telephone set or other CPE. Batteries with a nominal voltage of 48 V dc had a minimum value of 45 V dc in the 1950s. The relays commonly used in the early 1950s operated reliably on currents as low as 23 mA. This dictated a loop design that presented a maximum dc resistance, including the resistance of the line circuit and the telephone set to $45/0.023 = 1956 \Omega$. In the 1950s maximum telephone set resistance was less than 220Ω and line relay winding resistance was less than 440Ω with high probability, leaving about 1300Ω for the wire pair between the central office and the customer's premises. In 1954 AT&T adopted loop design rules referred to as Resistance Design rules using 1300Ω as the maximum loop resistance, assuming the use of 500-type telephone sets or equivalent.

Resistance Design rules used a combination of H88 loading, maximum loop resistance, and 500-type telephone set properties to achieve the goal of bounding the performance of the loop at satisfactory loss level while achieving economy in loop design. The Resistance Design rules are summarized as follows:

1. Maximum loop resistance less than 1300Ω at operating temperatures.
2. Maximum nonloaded loop length 18,000 ft with bridged tap < 6000 ft.
3. All loops greater than 18,000 ft use H88 loading rules.

Bridged tap is a pair of wires that branches off another pair at a junction point. At voice frequencies bridged tap acts as a capacitive load and increases attenuation.

Resistance Design rules promote voice frequency transmission performance that is consistent with residential telephone service quality requirements (less than about 8 dB insertion loss at 1000 Hz). These rules also ensure satisfactory operation of central office switch dc and voice frequency signaling circuits to the low voltage discharge level of central office battery supplies in the event of an extended power outage and the failure of emergency generators to operate.

Figure 17.3.3 illustrates application of Resistance Design principles applied to a cable route of 18,000 ft. A line is drawn parallel to the 24-gauge line so that it intersects the $1300\text{-}\Omega$ ordinate at the 18,000 ft abscissa value. The intercept with the 26-gauge line shows that a combination of 11,700 ft of 26-gauge cable and 6300 ft of 24-gauge cable will result in an 18,000-ft cable route that just meets $1300\text{-}\Omega$ loop resistance.

FIGURE 17.3.3 Example resistance design application.

The Resistance Design limit was increased to 1500 Ω in the early 1980s based on the improved dc current sensitivity of electronic switching system line circuits and the finding that the 500-type telephone set transmitter was more efficient at a loop current of 20 mA by about 2 dB than had previously been thought. Figure 17.3.4 shows the statistics of telephone loop length over the period from 1963 to 1983. It can be seen that average loop length increased slightly over the period. This resulted from the growth of suburbia with reduced housing density and the consolidation of smaller central offices into fewer, larger central offices.

Structure Based on Cables of Wire Pairs

In planning new paired cables for telephone local loops, engineers anticipate potential future demand. An economical design will provide just enough copper pairs at the right locations to satisfy demand for some time into the future so that the goal of near instant satisfaction of requests for service can be met. The new cables must be added before existing cables are full. Yet, the design must not place excessive capacity that will never be required and thereby become stranded investment. Elaborate computer aids have been developed over the years, principally by AT&T, using economic theory based on the time value of money with constraints of technology choices, tax policies, and regulatory rules to assist engineers in developing plans for building or adding to local loop cable plant. Discussion of the use of these aids and the underlying economic theory is beyond the scope of this section. However, there are two considerations that limit the choices of solutions using paired cables: the performance of twisted pair copper cable technology and the administrative structure of the areas to be served.

Copper Cable Technology

Cables consisting of copper wire pairs began to be manufactured at the end of the 1880s. The wires in each pair were twisted around one another to reduce the electromagnetic coupling, called crosstalk, with nearby pairs. Bundles of 50 or 25 pairs, called units or binder groups, are assembled into cables of up to 2700 pairs. The number of pairs possible to be bundled into a single cable is constrained by the maximum allowed cable diameter (less than 3 in. due to the diameter of underground ducts through which cables may be pulled), wire

FIGURE 17.3.4 Loop length statistics resulting from economic design principles.

gauge, wire insulation thickness, and sheath thickness. The wires are insulated from each other using a variety of materials. Paper insulation proved to be most practical in the early days of telephony. Paper produced lower attenuation than materials with a higher dielectric constant as long as the paper was kept dry. Wires were later coated with wood pulp, called pulp insulation, to allow the design of compact cable structures. Paper insulation was used in a majority of cables into the 1930s. Plastic insulation materials such as polyethylene became predominant in the 1960s. The density of pairs in polyethylene insulated cables was improved in the 1970s by introducing air bubbles into the plastic, reducing its effective dielectric constant so that the insulation coating on the wires could be of reduced diameter while maintaining the standard capacitance between the wires in the pair. This form of insulation is called “expanded” insulation.

The bundle of twisted pairs form the core of the cable, which is surrounded by a sheath. Early sheaths consisted mainly of an extruded lead jacket that kept water out of the core, provided some shielding against external electromagnetic interference and diverted lightning discharges to earth. Modern cable sheaths typically have an extruded outer polyethylene or polyvinyl chloride jacket covering a metal shield made of corrugated aluminum or steel wrapped around an inner jacket of polyethylene extruded over the core of the cable. Some typical lead sheath cable cross-sections of the past are shown in Fig. 17.3.5.

Early cable designs in the 1880s suffered from lack of standards and from increased attenuation compared to open wire pairs. By the late 1880s, standards were established that ensured predictable performance in dry cables. The two principal attributes for paired cable standardization have been wire diameter (gauge), which dictates the resistance of the wire, and capacitance per unit length. Resistance and capacitance largely control the voice frequency transmission performance of the pairs and resistance controls the dc signaling range of operation. The attenuation limitations of twisted pairs were first addressed by improvements in telephone set transmitter and receiver efficiencies. This was augmented by the use of inductive loading which trades lower voice frequency attenuation for greatly increased attenuation at frequencies above the voice range. Finally, electronic circuits came to be used to compensate for wire pair attenuation. In the local loop the use of electronics became commonplace in the 1970s.

FIGURE 17.3.5 Representative larger size twisted pair cables.

Table 17.3.1 gives example measured values of the resistance, capacitance, and variability of those quantities per 1000-ft length of typical paired copper cables.

The nominal value of capacitance used in most engineering studies is 15.7 nF/1000 ft or 83 nF/mi for local loop applications. The nominal value of inductance of twisted pairs is about 1 mH/mi or 189 μ H/1000 ft.

Twisted pairs in a local access application experience three fundamental transmission impairments: propagational attenuation and distortion, crosstalk, and induced noise (other than crosstalk). Induced noise from external sources of interference is mitigated by the cable shield and its ground connections. Crosstalk is reduced by staggered twist lengths from pair to pair and matched impedances between each wire in a pair and the cable shield (balance). Signal propagation is a function of the primary constants of a cable (resistance R ,

TABLE 17.3.1 Electrical Characteristics of Paired Copper Cables

Gauge	Insulation	No. Pairs	R (Ω /1000 ft)	Std. Dev. (R)	C (nF/1000 ft)	Std. Dev. (C)
26 AWG	pulp	300	83.6	0.65	15.38	1.57
26 AWG	PIC	100	86.0	0.69	15.12	1.23
24 AWG	PIC	600	53.4	0.56	15.38	0.66
24 AWG	DEPIC	50	51.9	0.36	15.54	0.61
22 AWG	PIC-wp	100	33.9	0.14	15.31	0.79
22 AWG	PIC	50	34.7	0.14	15.52	0.68
19 AWG	PIC-wp	50	16.7	0.14	15.63	0.70
19 AWG	DEPIC-wp	25	16.3	0.15	15.79	0.62

FIGURE 17.3.6 Representative primary constants for 22-gauge PIC copper pair.

capacitance C , inductance L , and conductance G , per unit length). Propagation of signals is characterized by the characteristic impedance Z_c and propagation constant Γ with the following relationship to the primary constants:

$$\Gamma = \sqrt{(G + i\omega C)(R + i\omega L)} \quad \text{and} \quad Z_c = \sqrt{\frac{(R + i\omega L)}{(G + i\omega C)}}$$

R , L , and G and functions of frequency. At frequencies below 0.1 MHz, G is negligible. R and L are approximately constant in the voice frequency range. At higher frequencies R increases as the square root of frequency and L decreases as the square root of frequency. Figure 17.3.6 illustrates the behavior of these parameters with increasing frequency for a typical 22 AWG copper twisted pair over a wide range of frequencies. Figure 17.3.7

FIGURE 17.3.7 Attenuation of 19, 22, 24, and 26 AWG PIC copper pairs.

FIGURE 17.3.8 Characteristic impedance of 19 and 26 AWG pairs at voice frequencies.

shows the attenuation (real part of Γ) of 19-, 22-, 24-, and 26-gauge pairs in the voice frequency range. Z_c , the characteristic impedance of a twisted pair, is illustrated for 19- and 26-gauge pairs in Fig. 17.3.8. At frequencies above the voice band Z_c approaches a resistive value of about 100 ohms.

The effect of H88 loading is illustrated in Fig. 17.3.9 for the case of an 18,000 ft long, 26 AWG loop. The figure shows the insertion loss (see Fig. 17.3.2 for a definition) of a loop with and without load coils at 3000 ft,

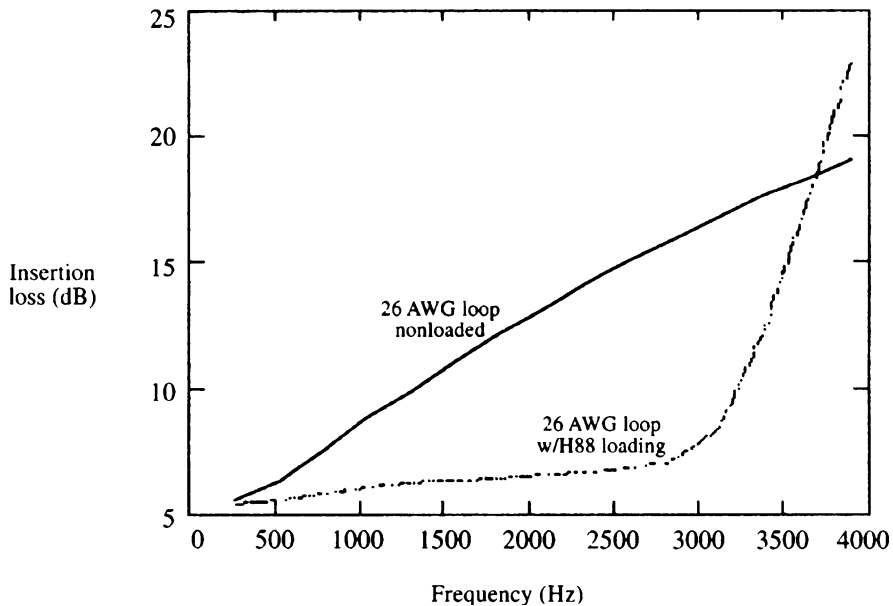

FIGURE 17.3.9 Insertion loss of 18,000 ft of 26 AWG loop, nonloaded and with H-88 loading.

9000 ft, and 15,000 ft from the central office. Terminations at each end of the loop were assumed to be 900- Ω resistors. The transmission matrix for a transmission line of length, l , is given by

$$A = D = \cosh \Gamma l, \quad B = Z_c \sinh \Gamma l, \quad \text{and} \quad C = \sinh \Gamma l / Z_c$$

The transmission matrix for a load coil is given by

$$A = D = 1, \quad C = 0, \quad \text{and} \quad B = 5.4 + i\omega.088$$

As shown in Fig. 17.3.9, the load coils cause the insertion loss to be lower and less variable to about 3000 Hz and to increase much more rapidly with frequency above 3000 Hz. In practice the terminations will not be resistive. During the course of a telephone call the impedance at the central office will be that designed into the line circuit of the switching system, typically a 900- Ω resistor in series with a 2.16 μF capacitor. At the user end of the loop the impedance will be that of an off-hook telephone, a quantity that is only loosely characterized and that typically varies with the dc current supplied by the switching system or other line circuit through the loop. Figure 17.3.10 illustrates a model for the impedance of an off-hook 500-type telephone set at two representative values of dc loop current. A resistive value of 600 Ω is often used as an approximation.

Crosstalk is the coupling of electromagnetic energy from one pair to another. The two most important forms of crosstalk are near end crosstalk (NEXT) and far end crosstalk (FEXT). NEXT is the coupled signal sensed at the same end of a circuit as the source of the unwanted signal. FEXT is the coupled signal sensed at the end of the circuit distant from the source. These types of crosstalk are illustrated in Fig. 17.3.11. NEXT is most important as an impairment in circuits that transmit signals in the same frequency range in both directions, e.g., T1 carrier lines. FEXT is more important where signals in the two directions through adjacent pairs use separate frequency bands, e.g., analog carrier systems. NEXT increases approximately as the $3/2$ power of frequency and relatively insensitive to loop length. FEXT increases approximately as the square of frequency and increases with the length of the loop.

The attenuation of crosstalk interference into a pair from another pair in a cable is called crosstalk loss. Crosstalk loss exhibits a random distribution between any pair in an n -pair cable and the other $n - 1$ pairs.

FIGURE 17.3.10 Model for 500-type Telephone Set impedance at 20- and 50-mA loop current.

FIGURE 17.3.11 Near-end and far-end crosstalk paths.

Adjacent pairs generally experience the lower crosstalk losses. Separation of directions of transmission to pairs in nonadjacent binder groups is a way to reduce crosstalk levels.

Near-end crosstalk is more important than FEXT in voice frequency circuits. If NEXT is excessive in such a circuit, the unwanted crosstalk signal may have sufficient power to be understood by a listener. This is known as *intelligible* crosstalk. This form of impairment is generally unacceptable in the local loop because the crosstalk loss between two loops is fixed by the physical proximity of the two pairs dedicated to the two loops and not a function of call connections as it is in interoffice trunks with random call-to-call crosstalk associations. The principal way to repair intelligible crosstalk in the loop is to move one of the affected parties to a different pair in a cable.

Local Access Cable Organization

It is not practical to arrange loops terminating in a central office so that 100 percent of them would pass each home and business being served. Estimates must be made of the number of lines expected to be needed in each neighborhood or serving area to satisfy the expected demand for some time into the future. It has been especially important in the United States to have sufficient excess pairs available to any neighborhood to allow new service to be initiated within a day or two.

For many years telephone company engineers used a method called *multiple plant* to provide copper pairs to neighborhoods in a way that would be both flexible and economical. The use of multiple plant provides a *feeder* cable of a given number of pairs part way from a central office to a neighborhood. At a strategic point the cable is then spliced to two or more *distribution* cables that pass the homes and businesses to be served. Some of the pairs in multiple distribution cables are connected to the same feeder pairs, creating *bridged tap*. The voice frequency impairments due to the bridged tap are bounded by limiting the sum of the lengths of all bridged taps on a loop to less than 6000 ft. These impairments are traded for the flexibility needed to supply future circuits where the location of the potential demand is uncertain.

The long-term use of multiple plant caused some problems. Foremost among these was the need to open splices to rearrange pairs to provide more feeder pair capacity than originally planned to a distribution cable. Over long periods of time, the rearrangement activity caused damage to splices and corrupted cable records through accumulated errors. In the late 1960s, the serving area concept was developed to provide a more orderly and accessible method for connecting feeder cable pairs to distribution cable pairs.

The distribution cables are designed to have a capacity of up to two pairs dedicated to each living unit anticipated to exist in a neighborhood over a period of 20 or more years into the future. The number of pairs per ultimate living unit in distribution cables varies with telephone company local practice. Feeder cables to areas served by distribution cables are designed to have sufficient capacity for 5 to 7 years of anticipated demand and, therefore, have fewer pairs than the total numbers of pairs in the distribution cables being served. The feeder cables are terminated in an aboveground housing called serving area interface or, alternatively, feeder-distribution interface. The serving area interface also terminates all of the distribution cables that pass through the serving area and provides a cross-connection field to allow any feeder pair to be connected to any distribution pair using short pairs of wires called jumpers. Typically distribution areas have 600 or fewer living units and have distribution cables less than a mile in length. Distribution cables customarily are designed with 1.2 to two pairs per ultimate living unit. It is not uncommon for a serving area interface to terminate 600 feeder pairs and 1200 distribution pairs. Historically, about half of the capital investment in the local loop has been devoted to the feeder plant and half to the distribution plant. Figure 17.3.12 illustrates the multiple plant and serving area plant concepts.

FIGURE 17.3.12 Multiple plant and serving area concept designs.

The Use of Electronics and Optics in the Local Loop

In the early 1920s electronic amplifiers began to be used in long-distance telephony. In the 1930s analog carrier systems were developed using frequency division multiplex techniques to carry multiple voice channels on a single-wire pair. These technologies were far too expensive to be used in the local loop, which continued to consist exclusively of wire pairs with those pairs longer than 18,000 using H88 loading to improve transmission.

After World War II, there was a surge of demand for telephone service that could not be met rapidly with added cables in the loop. This occasioned the examination of various electronic systems to allow a single-wire pair in the local loop to carry more than one conversation at a time. Early analog loop carrier systems, based on frequency division multiplex techniques that had been employed in telephone trunk transmission since the 1930s, were designed in the 1950s. Circuits based on the use of transistors, invented in 1947, were needed but the technology was immature. Systems cost too much and were not reliable enough to deploy widely.

By the late 1960s solid-state device technology was sufficiently economical and robust for application in the local loop. It became practical to build analog frequency division multiplex carrier systems for rural loop applications where the addition of a few circuits could obviate the construction of new cable plant. These systems typically carried six voice channels on a single pair of wires using frequency division duplex to achieve bidirectional operation with minimum NEXT. During that period it was found that investment in new cable construction for long rural loops could be reduced by employing voice frequency range extension electronics and finer gauge wires.

The principal of range extension is to aid the local switch in detecting telephone switch-hook transitions on loops of resistance higher than $1300\ \Omega$ and to amplify voice and tone signals to compensate for the added attenuation of the high-resistance loops. The amount of gain that may be inserted at the central office end of a loop is limited to 6 dB at 1 kHz to maintain the probability of encountering intelligible crosstalk at an acceptable level.

The use of a voice frequency amplifier with 6 dB of insertion gain allows loaded loops of up to $2800\ \Omega$ resistance to be used. Higher loop resistances are possible but, if transmission objectives of 8 dB insertion loss are to be maintained and crosstalk is to be acceptable, amplification is required at the customer premises end of the loop. Loop designs of up to $3600\ \Omega$ have been achieved with approximately 3 dB gain in the telephone handset. Deregulation of telephone sets by the FCC in 1976 made this option impractical, limiting the maximum copper loop resistance to $2800\ \Omega$. A $2800\text{-}\Omega$ loop resistance corresponds to about 82,000 ft of 22-gauge wire, a distance that reaches all but a small fraction of 1 percent of all loops. The $2800\text{-}\Omega$ design virtually eliminated the need for 19-gauge cable in the loop, a 50 percent savings in copper.

T1 carrier line installation began in 1962. The T1 carrier line transmits digital signals at a rate of 1.544 Mb/s, capable of carrying simultaneously 24 pulse code modulated (PCM) voice channels at 64,000 b/s

each. The T1 carrier signal contains a sequence of frames with 193 data bits each, 8 bits are assigned to each of the 24 information channels, and the remaining data bit is used to identify the start of a frame and for other, auxiliary purposes. A T1 carrier line requires two pairs of wires, one for each direction of transmission. Initial T1 line operation was devoted to interoffice trunk transmission. In 1972, the first digital loop carrier systems, employing T1 transmission, were introduced into commercial service. The first systems included a stage of switching concentration at each end of the T1 line, allowing up to 80 customer lines to share the 24-channel T1 facility with acceptable probability of blocking calls, depending on the offered traffic load.

In the mid-1970s digital loop carrier systems were introduced that used adaptive delta modulation techniques, taking advantage of knowledge of the dynamics of the human voice to reduce the data rate needed for satisfactory voice transmission to about 37,000 b/s. These systems enabled a T1 line to carry up to 40 simultaneous voice conversations with no blocking. Delta modulation was not compatible with PCM trunk transmission and gave way to the use of PCM in the next generation of loop carrier systems, the standard practice to the present time.

Digital loop carrier systems based on T1 lines are called “pair-gain” systems because they allow the simultaneous transmission of 24 voice signals, that would ordinarily require 24 pairs, on two pairs of wire thereby gaining the equivalent of 22 pairs. Early digital loop carrier systems were relatively expensive compared to wire pairs, depending on the length of the wire pair. Their use in the 1970s was largely confined to long rural loop cable routes. The value of digital loop carrier systems was the deferral of the construction of a new cable in an area of low demand for new lines. The savings due to the deferral of a major cable construction project for a few years more than offset the cost of purchasing and installing the carrier systems.

In 1979 the next generation of digital loop carrier systems was introduced using PCM at about the time of the introduction of digital local switching systems that also employed PCM transmission. These developments allowed the T1 lines from a digital loop carrier remote terminal to terminate directly on the switch without the need to convert the loop signals back to analog voice format at the switch interface. The efficiency of integrating digital loop carrier systems into the line side of digital switching systems added to the lower cost of manufacturing digital systems in the 1980s. These cost savings encouraged the routine use of digital loop carrier systems in conjunction with digital switches on much shorter than customary loop feeder cable routes in urban and suburban applications. By the mid-1980s over half of *new* loops were on digital loop carrier systems even though fewer than 10 percent of *all* loops were on digital loop carrier systems.

The density of loops increases exponentially as distance from the central office decreases. The cross-section of lines served by a digital loop carrier system remote terminal increases proportionately as they are installed on shorter loops. Typical digital loop carrier system remote terminals in the 1980s served from 96 to 544 lines each depending on the manufacturer. Typical high-density applications require more than 20 such terminals at a remote terminal location. It is not uncommon for digital loop carrier systems to be used on loops shorter than 2 mi.

Rural applications of digital loop carrier remote terminals require a cabinet of less than 30 ft³ to serve 96 lines. Urban applications required underground vaults of over 1000 ft³. The wide variety of applications of digital loop carrier remote terminals has required a large array of alternative enclosures to be deployed to meet local needs. Urban applications of digital loop carrier systems have also required a large variety of “special service” line interfaces to be supported in addition to the basic residential telephone line and coin line interface circuits.

Special services include private branch exchange analog and digital trunks, private line analog and digital data lines, foreign exchange two-wire and four-wire lines and trunks, and other specialized business services that have come to be offered over the years. These services each have specific transmission and signaling requirements to be met including the more stringent allocation of impairments to the local loop than is required for residential telephone service. Where special services are supported by copper pairs alone, signaling and transmission equipment has been installed in local central offices to compensate for the properties of wire loops in cables designed for residential service. This compensation has been designed into individual digital loop carrier plug-in “channel units” to enable telephone companies to provide special services through digital loop carrier systems.

The first trials of optical fiber in local loop transmission were conducted in the late 1970s. By the early 1980s the first commercial installations of digital loop carrier in association with optical fibers took place. The first digital loop carrier installation used multimode fibers with 50 or 62.5 μm core diameters. Multimode fiber was displaced by single-mode fiber by 1984, taking advantage of the superior cost and performance benefits of single-mode fibers. The type of single-mode fiber used typically has a core diameter of about 9 μm and is designed for minimum chromatic dispersion at an infrared wavelength of about 1300 nm.

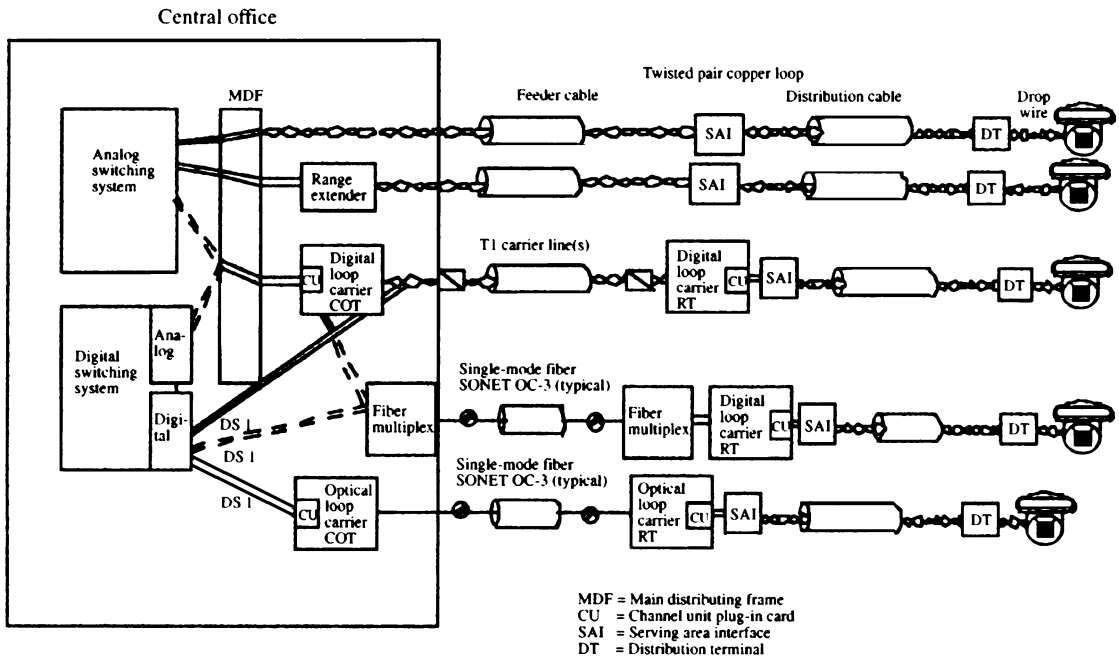

FIGURE 17.3.13 Overview of range extension, digital carrier, and optical carrier systems.

Single-mode fiber transmission was at first at 45 Mb/s and higher while typical digital loop carrier systems were based on T1 lines at 1.544 Mb/s. The use of single-mode fiber required the addition of multiplexers that combined many T1 signals from multiple digital loop carrier systems into a higher rate digital signal suitable for transmission through fibers.

In 1988 the T1 Committee of the Exchange Carrier Standards Association published the first Synchronous Optical Network (SONET) rate and format standards, creating a standard, synchronous digital signal hierarchy with standard payload mappings suitable for transmission through single-mode optical fibers. It then became practical to design a digital loop carrier system that could connect directly to single-mode fibers, eliminating the need for separate multiplexers. The current generation of digital loop carrier systems is of this type. The most popular system can serve up to 2016 voice lines over four fibers (two operating fibers and two backup fibers) using the SONET OC-3 signal format at 155.52 Mb/s.

Figure 17.3.13 summarizes the generations of loop electronic systems that have been deployed from the late 1960s to the present time.

CABLE TELEVISION LOCAL ACCESS-LOOP DESIGN AND TECHNOLOGIES

Introduction

Beginning in the late 1940s community antenna television (CATV) companies were created to address the problem of weak signal strength from distant very high frequency (VHF) television broadcast stations. The 12 television channels of the day were assigned 6 MHz bands in the frequency space between 54 MHz and 216 MHz, skipping frequencies previously allocated for FM commercial radio and other applications. The over-the-air modulation plan is amplitude modulation with vestigial sideband (AM-VSB) transmission. Early CATV systems consisted of a head end and a distribution system. The head-end usually had a tower up to

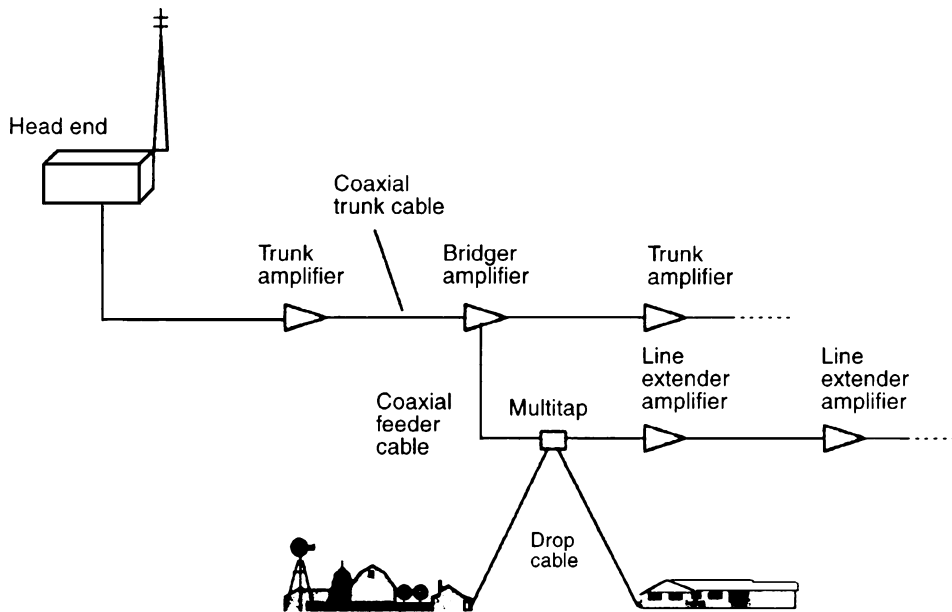

FIGURE 17.3.14 CATV Local Access Network, all coaxial cable.

several hundreds of feet high at the outskirts of a community equipped with antennas aimed at distant transmitters. The distribution system carried a composite signal through trunk coaxial cables to the neighborhoods of homes to be served. Trunk amplifiers were placed at intervals along the cable route to compensate for signal attenuation and changes in attenuation versus frequency due to temperature fluctuations. The trunk cables were connected to feeder cables through bridging amplifiers. Customers were connected to feeder coaxial cables that passed their homes via in-line multitaps. The multitaps were connected to customers homes via coaxial drop cables that terminated at a grounding block at the side of the home for connection to inside coaxial cables terminated in television sets. As the CATV transmission system carried unaltered off-air signals, television set tuners could directly access the broadcast programs. By the mid-1960s the CATV local access distribution network architecture was well established as illustrated in Fig. 17.3.14. Many CATV systems carry FM radio signals as well as television signals, since the 88- to 108-MHz FM radio band is in the middle of the VHF television band.

In the 1970s, satellite transmissions of television signals to CATV head-ends became economical. C-Band satellites were the more common type using spectrum at 5.9 to 6.4 GHz for the uplink and at 3.7 to 4.2 GHz for the downlinks with capacity for 24 analog video channels. Each channel is served by a “transponder” in the satellite. Each channel occupies 36 MHz of bandwidth using frequency modulation. The addition of satellite antennas and receivers added considerably to the capital costs of headend electronics and suggested connecting more than one local distribution network to a single master headend. The links between local headends and distant “master” headends became known as “super-trunks.” Single-mode fiber optics came into use in the super trunk and trunk plant in 1984 and 1989, respectively. CATV systems now pass more than 90 percent of the homes in the United States and serve more than 60 percent.

There are three standard channel frequency assignment plans in use in CATV systems in the United States, as specified in FCC Bulletin 21006: (1) The standard (STD) plan, (2) the interval related carriers (IRC) plan, and (3) the harmonic related carriers (HRC) plan. The IRC and HRC plans lock the carrier frequency for each channel to a precision reference oscillator to reduce some of the second- and third-order harmonic distortion noise in the multiplexed CATV signal. Most systems use the STD plan. Newly installed commercial distribution systems now carry up to 110 channels in a band of frequencies up to 750 MHz.

Table 17.3.2 gives the frequency assignments up to channel 99 for the three plans.

In 1972, the FCC required among other regulations that all CATV systems serving more than 500 subscribers be “two-way capable,” with a band of frequencies from 5 to 35 MHz being assigned to the reverse direction in a “subsplit” system. For many years this requirement was honored by installed trunk, bridging, and line amplifiers that included plug-in connectors for the attachment of duplex filters and reverse channel amplifiers to allow a system to be upgraded should the occasion arise. For the most part, this band has gone unused.

CATV System Transmission Considerations

CATV system transmission suffers from the attenuation of signals through coaxial cables, the accumulation of thermal noise through a succession of amplifiers, the accumulation of second-order and third-order harmonic noise caused by nonlinearities in active and passive components, and the ingress of external interference.

Coaxial cable propagation constant and characteristic impedance may be written in the same form as for twisted pair transmission lines:

$$\Gamma = \sqrt{(G + i\omega C)(R + i\omega L)} \quad \text{and} \quad Z_c = \sqrt{\frac{(R + i\omega L)}{(G + i\omega C)}}$$

where $C = 2\pi\epsilon/(\ln b/a)$

b = inside diameter of outer conductor

a = outside diameter of the inner conductor

$G \sim 0$. R and L vary depending on the size and material of the inner and outer conductors.

The attenuation of a coaxial cable decreases with increasing diameter and increases with the square root of frequency. Typical trunk coaxial cables are 3/4-in. or 1-in. diameter with attenuation generally in the range of 1.0 to 1.5 dB/100 ft at 550 MHz. Feeder cables are similar in design to trunk cables but smaller in diameter, typically 1/2- to 5/8-in. diameter with attenuation in the range of 1.3 to 2.0 dB/100 ft at 550 MHz.

Trunk design typically allows about 20 dB loss between amplifiers creating spacings of 1400 to 2000 ft between trunk amplifiers at the high end of the frequency band supported by the system. Trunk amplifiers often include automatic gain and gain-slope adjustment capabilities to compensate for component aging and temperature variations. The carrier-to-noise (C/N) ratio is an industry metric for signal quality. C/N should be in excess of 46 dB. This limits the maximum number of amplifiers in tandem to less than about 20, thereby limiting the length of a distribution system. However, some applications may require a greater number of amplifiers because of the distance to be covered from the headend to the most distant customers, sacrificing noise performance.

The feeder cable design must compensate for the loss of multitaps as well as the feeder cable. Line extender amplifiers are usually limited to about three in cascade and are set for 25 to 30 dB of gain. The line extender amplifiers contribute significantly to harmonic distortion in the signal because they operate at high output levels. Composite second (CS) order and composite triple beat (CTB) are metrics governing signal distortion. Each is maintained at less than -53 dBc (dB with respect to carrier power) in a well-designed system.

Subscriber drop cables are typically braided outer conductor coaxial cables with attenuation as high as 15 dB. Almost half of the total length of coaxial cable in a distribution system is composed of drop cables. The most common drop cables are RG-59 and RG-6 equivalent types.

The drop cable is connected to the feeder cable through a passive component called a multitap. Multitaps contain directional coupler circuitry with two, four, or eight drop cable connections. The attenuation toward the subscriber is fixed and is selected by the engineer/designer of the plant to match the signal level at that point along a feeder cable so that the subscriber signal level will be as close to the desired 0 dBmV level as possible. The reverse direction from the customer experiences greater attenuation to limit the interference that is transmitted back toward the headend from the subscriber's equipment.

Customer wiring may be customer-installed or CATV company-installed RG-59 coaxial cable with passive splitters to allow service to branch to different rooms in a home. In-home cables terminate either directly on television sets or VCRs or on set-top converters supplied by the CATV company. CATV services are categorized as basic, premium, and pay-per-view. Premium and pay-per-view signals are encrypted by the CATV service provider and require a set-top converter to decipher the signal. In the case of pay-per-view services, the set-top converter is addressable by the CATV provider and is instructed to decipher signals on request of individual subscribers. Basic services may be viewed without the aid of the set-top converter by television sets and through VCRs with tuner circuits designed to correctly interpret the standard, IRC, and HRC channel formats. Appliances that can do this are called cable-ready.

CATV distribution systems are powered by distributed in-line 60-V, 60-Hz supplies connected to public utility power distribution networks. CATV power supplies feed ac current over the coaxial cables in both directions from the location of the supply. As much as 10 A may be passed through the cables and associated amplifiers. Set-top converters are powered by the subscriber.

The total costs, including labor and materials of a coaxial cable distribution system, consist of about 38 percent for coaxial cable, 24 percent for electronics, 20 percent for physical hardware, and 18 percent for passive components.

The Use of Fiber Optics in CATV Distribution Systems

The use of single-mode optical fibers in CATV trunk plant has advanced very rapidly with advances in the design of laser transmitters and optical receivers capable of the linearity required to satisfactorily carry the CATV amplitude-modulated, frequency-multiplexed extremely wide bandwidth signals. The use of optical fiber trunk plant benefit the CATV operator in three ways: (1) It reduces the number of amplifiers in cascade between the headend and the subscribers, improving system performance; (2) it improves the reliability of the distribution system by eliminating many active elements; and (3) it moves the bandwidth constraint on the trunk plant to the ends of the fibers, requiring simpler engineering to upgrade the plant to greater bandwidths. Laser transmitter and optical receivers are commercially available to carry more than 100 channels in a 700-MHz bandwidth from 50 to 750 MHz on a single fiber.

Early CATV applications of optical fibers used Fabry-Perot lasers that lacked the linearity to carry amplitude modulated signals. Modern CATV trunk systems mainly use distributed feedback (DFB) lasers that exhibit superior linearity of operation. The lasers are sensitive to reflected signals from splices and connectors. Typical transmitters include an optical isolator between the laser and the trunk fiber to block reflections coming back toward the laser. DFB laser transmitters are relatively expensive but costs have been reduced to allow an optical transmitter to be dedicated to clusters of as few as 2000 homes. Optical couplers may be used to allow a laser transmitter to be shared by two to four trunk fibers. Figure 17.3.15 illustrates the use of optical fiber in a CATV distribution system trunk application. This arrangement of fiber trunks and coaxial feeder cables is commonly referred to as Hybrid Fiber-Coaxial or HFC plant.

The remote optical node or, simply, remote node that terminates the fiber at the end of the trunk plant typically contains a receiver using a *pin* photo diode detector. The remote node may contain amplifiers capable of

FIGURE 17.3.15 Cable television local access with optical fiber trunk.

serving up to four feeder cables. The attenuation of the optical signal between the laser transmitter and a remote node is commonly in the 10- to 12-dB range. If a coupler is used, over half of the allocated optical loss budget will be consumed by the coupler.

EMERGING TRENDS IN TELEPHONE AND CATV LOCAL ACCESS

New Technologies for Wire Pair Transmission

In the early 1990s, developments in integrated circuit technology have enabled digitally encoded signal formats to be defined that make more efficient use of the available frequency spectrum for wire pair transmission. As a group, these techniques are referred to as *digital subscriber line* (DSL) technologies. The first of the standard DSLs to employ full duplex transmission over a single-wire pair in the United States is the integrated services digital network (ISDN) basic rate access transmission line that enables the bidirectional transmission of 160 kb/s over nonloaded pairs over 18,000 ft in length. The ISDN basic rate access line uses a multilevel line code referred to as 2B1Q for two binary, one quaternary. The 2B1Q line code places 4 bits of information in each pulse by using four pulse amplitudes, two positive and two negative. Complex echo cancellation and signal equalization techniques are used to compensate for bridged tap and impedance discontinuity impairments.

More recently, the 2B1Q encoding has been extended to allow bidirectional signals with data rates of 784 kb/s to be transmitted over twisted pairs meeting Resistance Design criteria to a distance of 12,000 ft. This technique is referred to as high bit rate digital subscriber line or HDSL. By using HDSL, telephone companies can provide services requiring T1 data rates over two pairs that are twice as long as the spacing between regenerators on T1 carrier lines and require no conditioning, i.e., removal of bridged tap, or complex design procedures.

Another technology that has been developed recently is the asymmetric digital subscriber line (ADSL) using digital modulation and frequency division multiplexing to transport high data rate digital signals over unconditioned twisted pairs. Early modulation techniques used include discrete multitone (DMT) and carrierless amplitude and phase modulation (CAP). Transmission is asymmetric over a single twisted pair to support the possible delivery of compressed, digital video signals to residential consumers. Experimental systems offer up to 6 Mb/s transmission toward the customer with up to 640 kb/s in the reverse direction over loops up to 12,000 ft in length. There is promise that ADSL techniques may allow the transmission of signals up to 52 Mb/s data rate over much shorter, but useful distances.

Digital Video Services over Fiber and Coaxial Cables

Telephone companies have been experimenting with “fiber-to-the-curb” systems since 1988. These systems are based on the technology of digital loop carrier systems but extend optical fibers into the telephone distribution plant. There have been limited commercial deployments of systems that followed requirements in Bellcore Technical Reference (IR) TSY-000909. To date the cost of purchasing and installing FTTC systems has been too high to allow economical mass deployment for switched and private line telephone services in this way.

TR-909 compliant FTTC systems consist of a host digital terminal (HDT), a fiber distribution system, and optical network units (ONU). The HDT provides the connections to the local telephone switch, private lines that do not terminate on the switch, and network management systems. The HDT may be located in the central office or at a remote terminal site distant from the central office. ONUs provide the service interface circuits for connection to the end users and test and maintenance circuits to allow remote testing to be done on the drop wire connection to the home from a centralized maintenance system.

The distribution connection from the ONU may be a simple point-to-point time division multiplex arrangement or, alternatively, a point-to-multipoint arrangement having more than one ONU sharing the optical interface at the HDT. Point-to-multipoint connections may use a variety of multiple access protocols. Most common to date are time division multiple access (TDMA) systems that broadcast the same time division multiplex signal to all ONUs but receive signals from each ONU in turn, allowing multiple ONUs to share the single HDT optical receiver and transmitter. Figure 17.3.16 illustrates one form of FTTC connections with tandem HDTs that are located in the outside plant as well as in the central office. The HDT may also serve the function of an optical loop carrier terminal in this example, remote or central office, since all

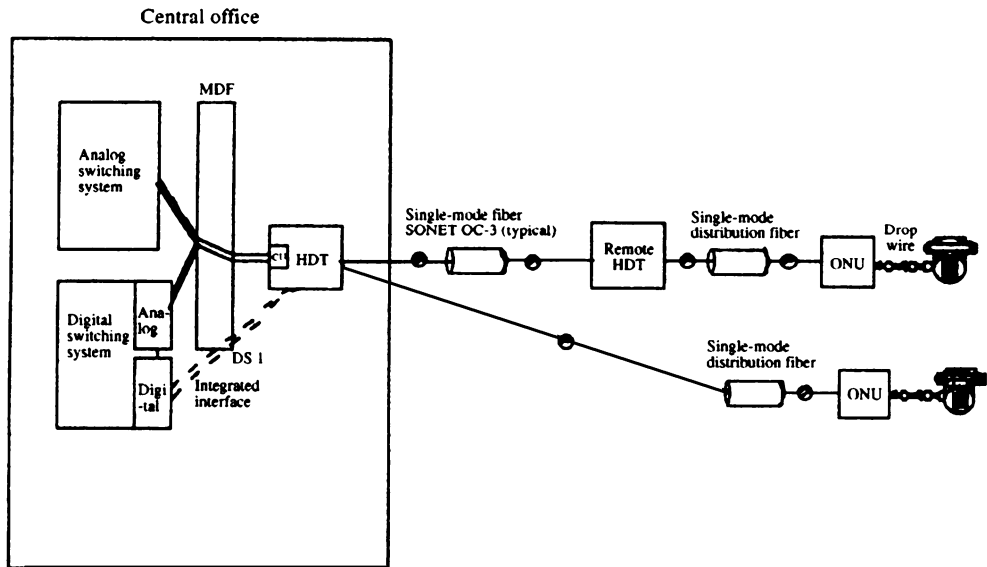

FIGURE 17.3.16 Telephone fiber-to-the-curb example.

of the service, switch, maintenance, and network management interfaces are the same. This may be accomplished if the optical loop carrier system has an architecture that enables the provision of optical distribution interfaces to ONUs as well as twisted pair distribution interfaces to end users. Otherwise, the remote HDT must be connected to a digital switch via a pair of back-to-back fiber multiplexers and to an analog switch via a pair of multiplexers and a digital loop carrier COT.

The telephone local access challenges have increased since the FCC Video Dial Tone order, issued in June 1992. After lengthy deliberations, the FCC reaffirmed the order in November 1994 and has since begun approving telephone company Section 214 construction applications. Video digital tone is regarded as a common carrier video services delivery service that telephone companies may provide. Heretofore, telephone companies have been restrained from providing cable television services and have not been allowed to own cable television companies in their franchise territories.

After considerable study, telephone companies have arrived at different conclusions regarding the best combination of technologies to use for video dial tone services. If these services are to include multicast analog video channels such as the local broadcast stations, then hybrid fiber-coaxial plant is considered to be the most economical approach. Some companies have decided to replace their telephone loop plant with HFC plant for video dial tone applications and have decided to include telephony services to be transported over the same plant.

This has stimulated a number of equipment suppliers to begin the development of systems that drive telephone services over HFC plant, illustrated in Fig. 17.3.17. Although not absolutely required, most systems in development use a second fiber from the HDT in the central office for the return or upstream direction of transmission. The application of telephony to HFC plant significantly increases the reliability requirements of the plant. In particular power supplies must be equipped with 8 h of battery reserve operation in the event of power failures in a neighborhood in order to provide telephone service of comparable reliability to existing wireline services.

Adding telephony services requires that coaxial termination units that derive the telephony service interfaces, much like those in optical network units and digital loop carrier systems, must be installed at or near subscriber homes. The coaxial termination units communicate toward the HDT using frequencies under the downstream 50 MHz lower bound for splitt systems. Emerging systems are carrying the upstream telephony signals in the range of approximately 15 to 40 MHz using various modulation and multiplexing designs to maximize the efficiency of use of the limited spectrum. Some systems incorporate frequency shifting circuitry to avoid, as needed, the significant levels of ingress noise found in the lower frequencies of the upstream band. Some systems also assign digital channels on demand for added efficiency rather than dedicating upstream

FIGURE 17.3.17 Hybrid fiber-coaxial plant with video and telephony capabilities.

channels full time to customer lines. CATV system operators, interested in providing alternate local telephone access, are also likely to employ such systems to derive telephony services over HFC plant.

Great strides have been made in the development of algorithms for reducing the amount of data required to carry television signals in digital form. Standards for these techniques have been drafted by the International Standards Organization Motion Picture Experts Group (MPEG). The emerging standards are referred to as MPEG1 and MPEG2. These algorithms take advantage of the frame-to-frame redundancy in motion pictures and television signals to remove more than 90 percent of the data contained in digitally encoded versions of the material. The MPEG1 standard was developed primarily for CD-ROM applications that allow fixed data transfer rates of up to about 1.5 Mb/s but has been extended to provide higher quality signals at higher data rates for satellite and potential CATV distribution. MPEG2 incorporates a packet transport protocol that allows the multiplexing of multiple images in a single data stream and supports variable data rate encodings. The MPEG standards are asymmetric, favoring simple decoding and complex encoding processes in support of unidirectional transmission.

MPEG encoding of video, coupled with efficient digital signal modulation techniques such as quadrature amplitude modulation (QAM) allows several video signals to be carried in the 6 MHz channel space of a single analog video signal. The number of compressed, digital signals that can be carried in a channel can be 10 or more and is a function of the compression ratio achieved for a given level of quality and the modulation method chosen. With MPEG and digital modulation a modern CATV distribution system can carry many hundreds of programs simultaneously.

Advances have also been achieved in the area of Asynchronous Transfer Mode (ATM) standards that allow the flexible multiplexing of voice, video, and data signals together despite great disparities in the data rates of the individual signals. ATM standards support the mapping of signals into fixed length packets, 53 bytes in length, called cells, that can be transported and switched readily through high-speed optical transmission lines. The SONET standards include a payload mapping to support the transport of ATM signals through the SONET digital signal hierarchy. It is believed by many that video dial tone networks will rely on ATM-based switches to allow end users to call up digitally compressed video program material on demand from archives of material.

Both hybrid fiber-coaxial and fiber-to-the-curb access networks can support the transmission of digitally compressed video signals, multicast and switched on demand. The latter part of the 1990s will witness a great

17.74 TELECOMMUNICATIONS

upheaval in local access networks as CATV companies and telephone companies race to modernize their local access plant to support compressed, digital video service offerings. In the process they will discover the technological approaches that are most suitable and economical for the purpose. The Telecommunications Act of 1996 has caused the FCC to order telephone companies to unbundle their local access networks to support facility-based local access competition. This will add regulatory and competitive uncertainties, perhaps retarding the introduction of new technology.

CHAPTER 17.4

BROADBAND SYSTEMS

David H. Su, David E. Cypher, John J. Knab, William W. Wu

Broadband systems refer in general to Broadband Integrated Services Digital Network (B-ISDN), which provides user access at a speed over the T1 rate (1.5 Mb/s). Integrated Services Digital Networks are defined to be networks that provide end-to-end digital connectivity to support a wide range of services, including voice and nonvoice services. Nonvoice services include image and video, as well as high-speed data transmission. B-ISDN allows the traditional interactive computer applications to run at higher speeds and enables the development of innovative distributed applications using computing and storage resources distributed over the network. It also enables new applications that were not possible because of bandwidth limitations, such as distribution or broadcasting of digital video information.

The concept of ISDN began to emerge in the 1970s, and the set of international standards were issued in the early 1980s by the ITU-T (formerly CCITT). The initial ISDN consists of multiples of fixed 64 kb/s channels, up to a total of 1.5/2.0 Mb/s. Subsequently, the idea of integrated services was extended to broadband networks, such as Synchronous Optical Network (SONET) at a speed of 155 Mb/s or higher, and was named Broadband ISDN (B-ISDN) to contrast it with the original lower bandwidth ISDN. In this section the term ISDN (without the B prefix) refers to the narrowband ISDN.

In addition to the speed difference, ISDN uses synchronous time division multiplexing for 64 kb/s channels, while B-ISDN uses an asynchronous fast packet switching technique called Asynchronous Transfer Mode (ATM) in which data channels are identified by a virtual path/virtual channel identifier in each packet. The size of the packets is fixed and small; the packets are called ATM cells.

This section first introduces the basic concepts of narrowband ISDN, then covers the physical interfaces and services of broadband ISDN.

THE NARROWBAND ISDN

From a telephone user's perspective, there have been very few changes in the way a telephone set works ever since it was invented. The few major evolutions include powering from the central offices, automatic switching, and tone dialing. The underlying telecommunications network, however, has gone through major changes such as digitalization of transmission facilities and development of intelligent network architecture. ISDN provides a revolutionary change of the capability and functionality of telephone sets. The definition given above shows several unique characteristics of ISDN: (1) It allows end-to-end digital connections by providing digital access on the local subscribers loop from the customer's premises to the central office; (2) it provides an integrated service by carrying voice and nonvoice data, including text, image, and motion video, over a single physical interface. In addition, it also provides a signaling channel separate from the user's data channels, permitting access to advanced features of an intelligent network.

Digital Access to Customer Premises

Over the years, the public telephone network has evolved from an analog transmission network into a digital network. Most of the central offices use digital switching, and trunk lines employ digital transmission facilities. The link from the central office to the customers' premises, called the Local Subscribers Loop, however, remains analog. ISDN standards define two types of digital interfaces: the *Basic Rate Interface* (BRI) and the *Primary Rate Interface* (PRI). Each of them provides a signaling channel called the D channel, and a number of user data channels called B channels. The BRI D-channel can also carry limited user data.

The basic rate interface consists of two 64 kb/s B-channels and a 16-kb/s D-channel (2B+D). The B-channel uses 64 kb/s rate since that is the basic rate at which all analog voice signals are digitalized. The physical interface operates at a 192 kb/s rate, using time division multiplexing for the B and D channels and other overhead bits. The primary rate interface has two formats. One is based on the T1 (U.S.) digital hierarchy and the other is based on the E1 (European) digital hierarchy. The T1-based PRI consists of 23 B-channels and one D-channel (23B+D) while the E1 rate consists of 30B+D. The bandwidth of each B- or D-channel is 64 kb/s. The B-channels could be combined into multirate circuit mode ($N \times 64$) channels at increments of 64 kb/s. Some special rates are defined as H channels, for example, the H_0 channel at 384 kb/s, and the H_{10} channel at 1472 kb/s.

Out-of-Band Signaling

In the Plain Old Telephone System (POTS), the signaling between a user and the network for control of a connection is by means of on-off hook current levels and dialing pulses/tones in line with user data. In ISDN, a data link connection (based on Q.921) is established between a terminal and the central office switch on the D channel. Call control signals (based on Q.931) could be exchanged at any time, independent of the use of the data stream on the B channels. Call control information includes the called and calling numbers, bandwidth requirements and B-channel assignment, service request (voice or data, circuit or packet), end-to-end protocol selection, and so forth. Additional services could be invoked or provided, such as call redirect from the terminal, call waiting notification, conference call, or additional end-to-end-user data for call setup.

ISDN Services

Very often multiple phone lines are needed in an office, one for voice and one or more for data (using modems). ISDN enables multiple connections and services over a single physical interface. Not only can it provide high-speed connections at 64 kb/s, which are not possible with modems, it also allows multiple connections to be synchronized or coordinated. Instead of dedicating a phone line for a specific service, ISDN allows a greater freedom in the sharing of phone facilities. The bearer services, or the basic services to which users can subscribe to run their applications include circuit mode and packet mode services, as described below.

Circuit-Mode Data Service. This service provides an unrestricted channel so that the bit stream is passed unchanged end to end. The actual application is controlled by user equipment at each end and could thus, in principle, transport voice or data with necessary protocols such as X.25 or Frame Relay.

Circuit-Mode Speech and Voiceband Services. The Speech and Voiceband services carry voice signals as currently provided by POTS. The bit stream is assumed to be digitalized analog signals using appropriate encoding standards. Conversion may take place when passing through networks employing different encoding standards. The Voiceband service is for 3.1 kHz audio, which is used for modems.

Packet-Mode Data Service. This service allows access to the X.25 packet network service offered by the network to which the terminal is directly connected. From the users' perspective, the packet switching network is fully integrated with the circuit switching network. The service is available only on the BRI B and D channels.

BROADBAND ISDN AND ASYNCHRONOUS TRANSFER MODE NETWORKS

The concept of broadband ISDN was a logical extension of narrowband ISDN in the evolution of telecommunications networks. The standards development started in the late 1980s, and ITU-T reached its first agreement on general aspects of B-ISDN in 1988. While B-ISDN was originally developed as a telecommunications technology, it has been adapted for data communications as well. In particular, it has been used as a new Local Area Network (LAN) technology. The ATM Forum, an industry consortium, has speeded up the development and made major contributions in this area.

Since the major feature of B-ISDN is the use of ATM, the terms B-ISDN and ATM are used synonymously.

Asynchronous Transfer Mode Cell Switching

The use of ATM technology is a major paradigm shift from synchronous networks where user data are carried in fixed time slots in the transmission facilities. ATM uses an asynchronous time division multiplexing technique to carry information in fixed size ATM cells. An ATM cell consists of two fields: a payload field for user data and a header field for identification of the user channel. Cells are assigned to user channels on demand, therefore the bandwidth occupied by a given user may vary from zero to the capacity of the physical link.

The size of an ATM cell is 53 octets, the first five for the header and remaining 48 for the payload. The header, among other things, contains an 8-bit virtual path identifier (VPI), a 16-bit Virtual Channel Identifier (VCI), and an 8-bit Header Error Check (HEC). The switch simply relays the cells based on the VPI/VCI number. The HEC is needed to prevent misrouting. There is no error control for the cell payload. Error recovery must be performed by the end systems. All that is required of the network is the delivery of cells in their original sequence.

There are two types of connections: *Virtual Path Connection* (VPC) and *Virtual Channel Connection* (VCC). VPC is analogous to a big pipe which allows end points to do their own distribution and assignment of individual virtual channels. The network will route cells based on the VPI. The VCI is for individual connections in which the network will route cells based on the combined value of VPI/VCI.

Physical Layer

Since B-ISDN was developed for public telecommunications network, it is expected that the standard-based SONET and synchronous digital hierarchy interfaces will be the most important physical media for B-ISDN/ATM networks. For the OC-3 interface the SONET STS-3c synchronous payload envelope is continually filled with ATM cells, byte aligned. This gives an effective rate of about 150 Mb/s over the 155.52 Mb/s interface. The mapping for the OC-12 interface has also been defined.

Currently not all network transmission facilities are SONET based; the existing digital hierarchy, the DS3, DS1 (for the United States) and E3, E1 (for Europe) are also to be used for ATM interfaces. There are two ways to map ATM cells into the DS3 payload: the DS3 Physical Layer Convergence Protocol (PLCP) format and the direct mapping format. The PLCP frame consists of 12 rows of ATM cells, each preceded by 4 octets of overhead. At the end the frame is stuffed with a variable number of nibbles (4 bits) to fill up the 125 μ s frame. The direct mapping format continuously fills the DS3 payload with ATM cells with nibble alignment.

For use in the LAN environment, other less expensive media have also been accepted. These include 155.52 Mb/s over Category 5 Unshielded or Shielded Twisted Pair (UTP and STP), 51.84 Mb/s over Category 3 UTP, and 25.6 and 25.2 Mb/s over various twisted pairs. Additional fiber formats could also be used; this includes 100 Mb/s over multimode fiber using the FDDI 4 bit/5 bit (4B/5B) code, and 155 Mb/s over multimode fiber using 8B/10B code.

Another important transmission medium for B-ISDN is the use of communications satellites. The subject is covered later.

B-ISDN Services

B-ISDN provides integrated services for voice, text, image, and video just like the narrowband ISDN, but at a wider range of bandwidth. Since B-ISDN uses packet mode for information transfer, it needs to simulate the

services provided in the traditional circuit mode transfer. Therefore, cell transfer delay and delay variation become important service parameters. It is a major challenge for the service provider to take full advantage of statistical multiplexing while maintaining the desired level of quality of services.

Constant Bit Rate Service (CBR). This service is for applications that generate a stream of bits at a constant rate and have a real-time requirement, such as voice and video applications. These applications require tightly constrained cell transfer delay and delay variations.

Variable Bit Rate Service (VBR). This service supports applications that generate bursty traffic. Some applications may have real-time requirements, such as compressed voice and video applications. Other applications may be non-real-time but still require a bound on cell transfer delay.

Unspecified and Available Bit Rate Service (UBR and ABR). This service supports the traditional data communication applications, such as e-mail, file transfer, and interactive traffic. The source is expected to be bursty. The network provides the best effort delivery service, and may discard cells when congestion occurs. The ABR service requires a flow control mechanism that provides feedback to the source from the destination as well as from network nodes.

ATM Adaptation, Signaling, and Interworking Functions

ATM Adaptation. Because of the diversity of services that must be supported in a B-ISDN/ATM network, some type of interface must be provided between the ATM layer protocol and the applications on the end systems. The ATM adaptation layer (AAL) protocol was developed for this purpose as well as for the end-to-end error control, which is not provided by the ATM layer cell switching protocol. The major functions of AAL at the sender side include: (1) packing of user messages into AAL message(s) with insertion (when necessary) of sequence numbers, error protection (parity, CRC or FEC), clocking signal, and padding; (2) segmentation of messages into ATM cells and delivery for transmission of cells at the specified rate. The receiver side performs the reverse functions, including error checking of cells received, recovery of source clock and handling of cell transfer delay (for CBR traffic), reassembly and delivery of messages to the application, and notification of transmission errors. There are several types of AALs defined, each designed to meet the requirement of a particular service, for example, type 1 for CBR service and type 5 for ABR/UBR and some VBR services.

ATM Signaling. Since ATM is a connection-oriented protocol, a B-ISDN/ATM network must provide connection setup. The procedure uses the signaling protocol Q.2931, which is an extension of the one used for narrowband ISDN. During the call setup, the calling and called parties and the network must check or negotiate the relevant service parameters such as cell rate (peak, sustainable, minimum), cell transfer delay (mean, maximum, variation), and cell loss ratio, depending on the service requested.

Interworking with other Networks. The higher bandwidth of B-ISDN/ATM networks enable better use of applications involving multimedia and digital video. In addition to addressing new applications, we must still make these networks interwork seamlessly with existing POTS, ISDN, Frame Relay, LANs, and the Internet. One important issue is support of connectionless IP Internet in a connection-oriented ATM network. The LAN emulation service developed at the ATM forum and the adaptation of Internet router functions to the ATM network are examples of solutions for interworking.

Satellite Links for B-ISDN/ATM Networks

As was mentioned earlier, the standard-based SONET and Synchronous Digital Hierarchy will be widely used for ATM. However, for regions not served with fiber, satellite communications can be used to provide the physical layer for B-ISDN/ATM networks. It is shown here that data rates of 155.52 Mb/s are possible using satellites and modems available today. It is shown that higher data rates could be supported but only in restricted cases.

TABLE 17.4.1 Modulation and Coding Performance for Various Modulation Types Used in Satellite Communications.*

Modulation (Coding Rate)	Eb/No dB	Rb dB* Mb/s	Rb Mb/s	BW MHz
QPSK(1/2)	9.0	84.6	288	374
QPSK(1/2,RS)	5.2	88.4	692	990
QPSK(3/4)	11.0	82.6	182	158
QPSK(3/4, RS)	6.5	87.1	512	488
8PSK(5/6)	12.0	81.6	146	76
8PSK(2/3, RS)	7.5	86.1	407	291
16 QAM(7/8, RS)	10.9	82.7	186	76

*For C band zone, Example: 8PSK(2/3,RS) is 8 phase shift keying with rate 2/3 inner code with Reed-Solomon outer code.

Link Budget. Link budgets, which are fundamental to satellite communications, were performed for both C and Ku band with INTELSAT satellite systems to determine the maximum practical data rate that could be supported with the Standard A antenna (15 m) for C band and the Standard C antenna (11 m) for Ku band. These link budgets yielded a system carrier to noise density C/N_0 of about 93.6 dB*Hz for the C band zone beam with a saturated effective isotropic radiated power (e.i.r.p.) of 34 dBW and a system C/N_0 of about 2 dB greater for the Ku spot beam with a saturated e.i.r.p. of 46 dBW. These links are operated several dB backoff to accommodate phase and amplitude modulation.

Supportable Data Rates. With these values of C/N_0 , the maximum data rate supportable can be calculated. Table 17.4.1 gives typical values for a bit error rate (BER) = 10^{*-11} when using the C band zone beam. The bit energy to noise density E_b/N_0 values were taken from the EFDATA Corporation Modem manufacturer's literature and are based on measured values, but at lower data rates than are considered below. (It is reasoned that the modem performance is independent of data rate if all other parameters are equal.) Table 17.4.1 also gives the approximate required bandwidth to support the modulation and coding used. These modems use either a convolutional code with the Viterbi decoder or the concatenated code scheme with an outer code of the Reed-Solomon (of rate approximately 9/10) and an inner code of the convolutional type just mentioned. The bandwidth (BW) required is given by the formula:

$$BW = Rb^*(1/R)^*(1/f)^*1.3 \text{ Hz}$$

where Rb = data rate

R = inner code rate

f = modulation factor and is 2 for quadrature phase shifting keying (QPSK), 3 for 8 phase shift keying (8PSK), and 4 for 16 quadrature amplitude modulation (16 QAM)

if the Reed-Solomon (RS) outer code is used when BW is increased by 10 percent.

There are three commonly used data rates considered here: 44.736 Mb/s (DS-3), 155 Mb/s (OC-3), and 622 Mb/s (OC-12). These data rates are used in the ATM architecture. Using the modulations given in Table 17.4.1 above, Table 17.4.2 yields the required bandwidth for the three data rates mentioned.

From Table 17.4.2, it seems that the DS-3 can be supported on 36 MHz transponders only for 8PSK and 16 QAM modulation. A transponder with a bandwidth of about 43 MHz can support DS-3 using all combinations except QPSK(1/2) and QPSK(1/2,RS). Consulting Table 17.4.1 shows that a DS-3 link can be supported by any entry in the table, as far as the required E_b/N_0 is concerned. If a 72 MHz bandwidth transponder is considered, then Table 17.4.2 shows that a DS-3 link can be supported by all modulation/coding combinations.

The OC-3 (155.5 Mb/s) rate can be supported on about an 81-MHz transponder using the 8PSK(5/6) as shown in Table 17.4.2. Table 17.4.1 shows that the maximum data rate supportable from the E_b/N_0 viewpoint is about 146 Mb/s. If one has a C band zone 72-MHz transponder, available on INTELSAT, this combination of modulation, coding, and transponder bandwidth will give performance close to the goal of the target BER and is recommended for OC-3 transmission. Results using the Ku band zone with the Standard C terminal will yield improved performance because of the 2-dB link improvement.

TABLE 17.4.2 Bandwidth Required for Certain Data Rates and Modulation

Modulation (coding rate)	44.736 Mb/s DS-3 (BW, MHz)	155.5 Mb/s OC-3 (BW, MHz)	622 Mb/s OC-12 (BW, MHz)
QPSK(1/2)	58	202	809
QPSK(1.2, RS)	64	222	890
SPSK(3/4)	39	135	539
QPSK(3/4, RS)	43	149	593
8PSK(5/6)	23	81	324
8PSK(2/3, RS)	32	111	445
16QAM(7/8, RS)	18	64	150

Tables 17.4.1 and 17.4.2 show that there is no combination of modulation/coding and available transponders that will support the OC-12 data rate. However, Table 17.4.1 shows that the QPSK(1/2,RS) will support OC-12 from the required E_b/N_0 viewpoint but requires a bandwidth of 890 MHz. This clearly presents a problem since the fixed satellite service bands are only 500 MHz wide. The only other parameter in this discussion is the size of the earth station required to support OC-12 in a transponder of wider bandwidth. For example, a transponder of 500 MHz would support 8PSK(2/3,RS) but requires an E_b/N_0 of about 7.5 dB (see Table 17.4.1). This would require a C/N_0 of about 98.8 dB⁰/Hz, equivalent to an antenna at C band of about 26 m in diameter. This is clearly a very large antenna by today's standards.

The other main parameter on the satellite besides the transponder bandwidth is the downlink e.i.r.p. This parameter could be increased allowing for one of the higher order modulations to be used. A several dB increase in the downlink e.i.r.p. would allow for 16QAM(7/8,RS) to be used to support the OC-12 data rate but the bandwidth would still be larger than 150 MHz.

It has been shown that the maximum data rate that can be supported is about 155 Mb/s using what is available now and in the near future. The present designs of satellites do not permit the support of OC-12 (622-Mb/s) rate. If this rate is to be supported by commercial satellite links, then the satellites of the future must increase both their transponder power and bandwidth.

CHAPTER 17.5

WIRELESS NETWORKS

Matthew. N. O. Sadiku

The recent past has seen fast-moving developments in the field of telecommunications. Wireless communications in particular continue to experience growth at an unprecedented rate. This is partly caused by our growing dependence on computer, cellular phone, pagers, fax machines, e-mail, and the Internet. The demand for real-time information exchange is being made on an increasingly mobile workforce. Many jobs require workers to be mobile, e.g., inventory clerks, healthcare workers, policemen, and emergency care specialists. It is estimated that roughly 48 million U.S. workers cannot do without one form of tetherless communication. Their work tools must be mobile.

Wireless refers to any communication that uses electromagnetic or acoustic waves as a medium, rather than a wire connection. It could be the technology that allows seamless and instant access to information across any number of devices and platforms. Wireless technologies are targeted to meeting certain needs, which include:

- Bypass physical barriers (roads, railroads, buildings, rivers, and so forth)
- Remote data entry
- Mobile objects (car, airplanes, ships, and so forth)
- Connectivity to hard-to-wire places
- Worldwide connectivity for voice, video, and data communications
- Satellite communications
- Inexpensive setup

Wireless communication works on the same set of fundamental principles, whether it is computer nodes on a local area network (LAN) or the common cordless telephone. In this chapter, those common fundamentals are presented first. We will then discuss cordless phones, paging, cellular networks, personal communications systems (PCSs), and wireless data networks such as cellular digital packet data (CDPD), wireless LAN, and wireless asynchronous transfer mode (ATM).

PROPAGATION CHARACTERISTICS

The major factors that affect the design and performance of wireless networks are the characteristics of radio or electromagnetic wave propagation over the geographical area. The concept of propagation refers to the various ways by which an electromagnetic (EM) wave travels from the transmitting antenna to the receiving antenna. Propagation of EM wave may be regarded as a means of transferring energy or information from one point (a transmitter) to another (a receiver). Here we describe the free space propagation model and the empirical path loss formula.

FIGURE 17.5.1 Basic wireless systems.

Free Space Propagation Model

Wireless links typically experience free space propagation. The free space propagation model is used in predicting received signal strength when the transmitter and receiver have a clear line-of-sight path between them. If receiving antenna is separated from the transmitting antenna in free space by distance r , as shown in Fig. 17.5.1, the power received P_r by the receiving antenna is given by Friis equation

$$P_r = G_r G_t \left(\frac{\lambda}{4\pi r} \right)^2 P_t \quad (1)$$

where P_t = transmitted power
 G_r = receiving antenna gain
 G_t = transmitting antenna gain
 λ = wavelength ($=c/f$) of the transmitted signal

Friis equation relates the power received by one antenna to the power transmitted by the other, provided that the two antennas are separated by $r > 2d^2/\lambda$, where d is the largest dimension of either antenna. Thus, Friis equation applies only when the two antennas are in the far-field of each other. It also shows that the received power falls off as the square of the separation distance r . The power decay as $1/r^2$ in wireless systems as exhibited in Eq. (1) is better than the exponential decay in power in a wired link. In actual practice, the value of the received power given in Eq. (1) should be taken as the maximum possible because some factors can serve to reduce the received power in a real wireless system.

From Eq. (1), we notice that the received power depends on the product $P_t G_t$. The product is defined as the *effective isotropic radiated power* (EIRP), i.e.

$$\text{EIRP} = P_t G_t \quad (2)$$

The EIRP represents the maximum radiated power available from a transmitter in the direction of maximum antenna gain relative to an isotropic antenna.

Empirical Path Loss Formula

In addition to the theoretical model presented in the preceding section, there are empirical models for finding path loss. Of the several models in the literature, Okumura et al.'s model is the most popular choice for analyzing mobile-radio propagation because of its simplicity and accuracy. The model is based on extensive measurements in and around Tokyo between 200 MHz and 2 GHz, compiled into charts, which can be applied to VHF and UHF mobile-radio propagation. The medium path loss is given by

$$L_p = \begin{cases} A + B \log_{10}(r), & \text{for urban area} \\ A + B \log_{10}(r) - C, & \text{for suburban area} \\ A + B \log_{10}(r) - D, & \text{for open area} \end{cases} \quad (3)$$

FIGURE 17.5.2 Radio propagation over a flat surface.

where r (in kilometers) is the distance between the base and mobile stations, as illustrated in Fig. 17.5.2. The values of A , B , C , and D are given in terms of the carrier frequency f , the base station antenna height h_b (in meters), and the mobile station antenna height h_m (in meters) as

$$A = 69.55 + 26.16 \log_{10}(f) - 13.82 \log_{10}(h_b) - a(h_m) \quad (4a)$$

$$B = 44.9 - 6.55 \log_{10}(h_b) \quad (4b)$$

$$C = 5.4 + 2 \left[\log_{10} \left(\frac{f}{28} \right) \right]^2 \quad (4c)$$

$$D = 40.94 - 19.33 \log_{10}(f) + 4.78 [\log_{10}(f)]^2 \quad (4d)$$

where

$$a(h_m) = \begin{cases} 0.8 - 1.56 \log_{10}(f) + [1.1 \log_{10}(f) - 0.7] h_m, & \text{for medium/small city} \\ 8.28 [\log_{10}(1.54 h_m)]^2 - 1.1, & \text{for } f \geq 200 \text{ MHz} \\ 3.2 [\log_{10}(11.75 h_m)]^2 - 4.97, & \text{for } f < 400 \text{ MHz} \\ & \text{for large city} \end{cases} \quad (5)$$

The following conditions must be satisfied before Eq. (3) is used: $150 < f < 1500$ MHz; $1 < r < 80$ km, $30 < h_b < 400$ m; $1 < h_m < 10$ m. Okumura's model has been found to be fairly good in urban and suburban areas, but not as good in rural areas.

CORDLESS TELEPHONY

Cordless telephones first became widespread in the mid-1980s as products became available at an affordable price. The earliest cordless telephone used narrow band technology and used separate channels for frequency channel for transmission to/from the base station. They had limited range, poor sound quality, and poor security—people could easily intercept signals from another cordless phone because of the limited number of channels. The Federal Communications Commission (FCC) granted the frequency range of 47 to 49 MHz for cordless phones in 1986 and the frequency range of 900 MHz in 1990. This improved their interference problem, reduced the power needed to run them, and allowed cordless phones to be clearer, broadcast a longer distance, and choose from more channels. However, cordless phones were still quite expensive.

The use of digital technology transformed the cordless phone. Digital technology represents the voice as a series of 0s and 1s, just as a CD stores music. Digital cordless phones in the 900-MHz frequency range were introduced in 1994. Digital signals allowed the phones to be more secure and decreased eavesdropping. With the introduction of digital spread spectrum (DSS) in 1995, eavesdropping on the cordless conversations was practically made impossible. The opening up of the 2.4-GHz range by the FCC in 1988 increased the distance over which a cordless phone can operate and further increased security. With the cordless phone components getting smaller, more and more features and functions can be placed in phones without making them any bigger. Such functions may include voice mail, call screening, and placing outside calls. With many appealing features, there continues to be a strong market interest in cordless telephones for residential and private office use.

As shown in Fig. 17.5.3, the cordless telephone has gone through an evolution. This started with the 46/49 MHz telephones. Although earlier cordless telephones existed, the 46/49 MHz cordless telephones were the first to be produced in substantial quantities. The second generation used 900-MHz frequency range resulting in longer range. The third generation introduced the spread spectrum telephones in the 900 MHz band. The fourth generation changed from 900-MHz to 2.4-GHz band, which is accepted worldwide. The fifth generation of cordless telephones is emerging now and employs time division multiple access (TDMA).

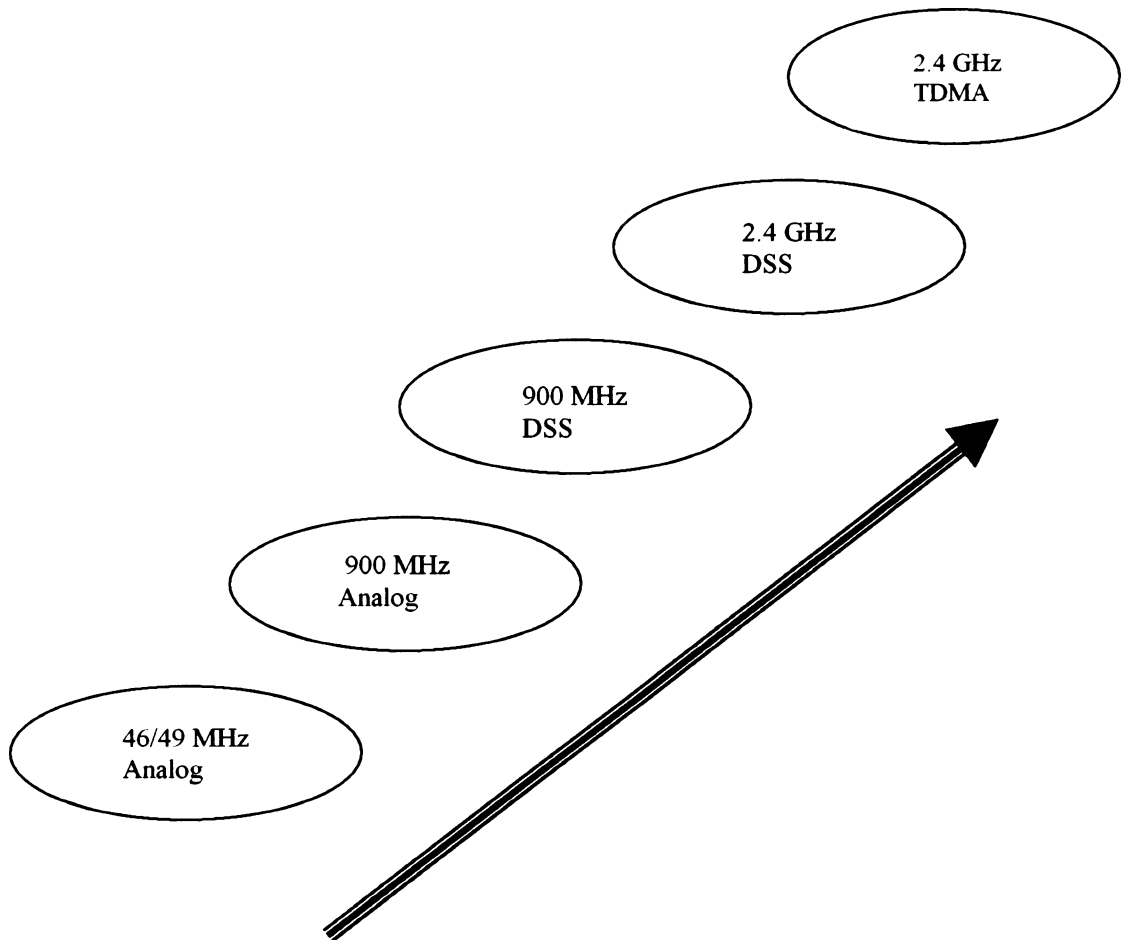

FIGURE 17.5.3 Evolution of cordless phone.

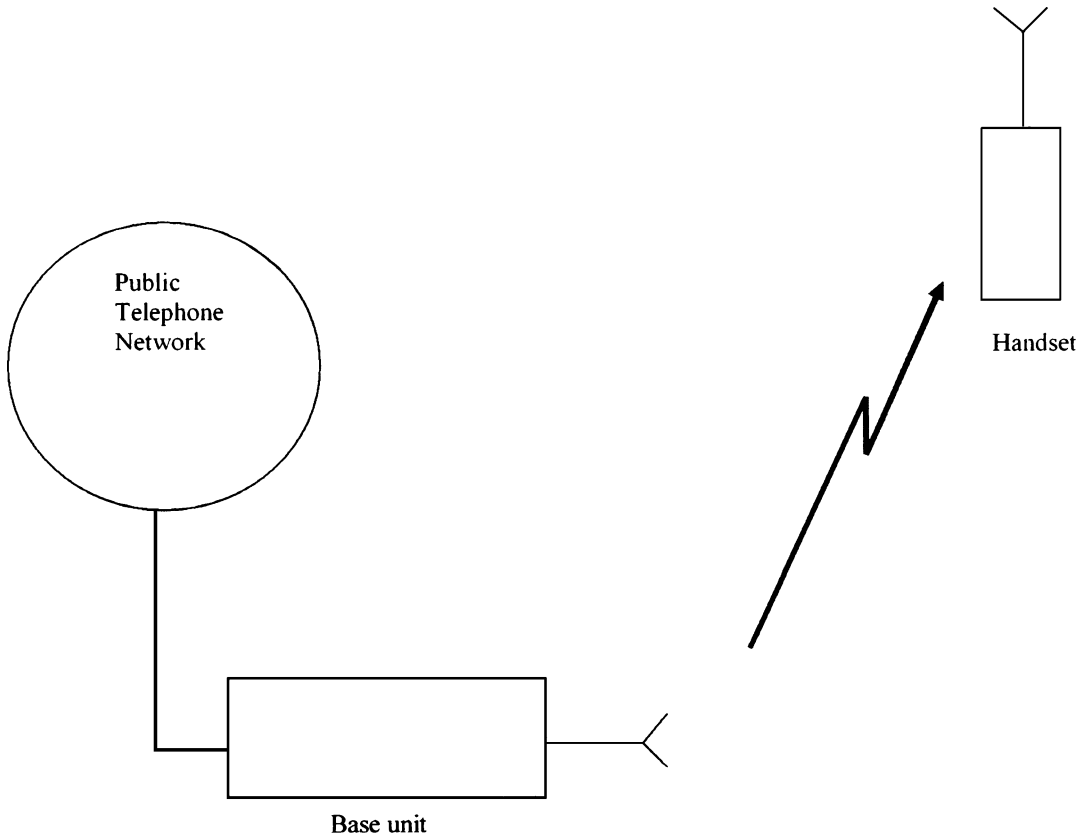

FIGURE 17.5.4 Cordless telephone system configuration.

Basic Features

A cordless phone basically combines the features of telephone and radio transmitter/receiver. As shown in Fig. 17.5.4, it consists of two major units: base and handset. The base unit interfaces with the public telephone network through the phone jack. It receives the incoming call through the phone line, converts it to an FM radio signal, and then broadcasts that signal. The handset receives the radio signal from the base, converts it to an electrical signal, and sends that signal to the speaker, where it is converted into the sound wave. When someone talks, the handset broadcasts the voice through a second FM radio signal back to the base. The base receives the voice signal, converts it to an electrical signal, and sends that signal through the phone line to the other party. The base and handset operate on a frequency pair (duplex frequency) that allows one to talk and listen simultaneously.

Types of Cordless Telephone

Over the years, several types of cordless have been developed. These include:

- *CT1*: This first generation cordless telephone was introduced in 1983. It provides a maximum range of about 200 m between handset and base station. It is an analog phone that is primarily designed for domestic use. It employs analog radio and uses eight RF channel and frequency division multiple access (FDMA) scheme.

TABLE 17.5.1 CT1 Cordless Telephone Duplex Frequencies

Channel number	Base unit transmission frequency (kHz)	Handset transmission frequency (MHz)
1	1642.00	47.45625
2	1662.00	47.46875
3	1682.00	47.48125
4	1702.00	47.49375
5	1722.00	47.50625
6	1742.00	47.51875
7	1762.00	47.53125 or 47.44375
8	1782.00	47.54375

Operation has to be on not more than one of the pair of frequencies shown in Table 17.5.1 at any one time. As the number of users grew, so did the co-channel interference levels, while the quality of the service (customer satisfaction) deteriorated.

- **CT2:** This second generation cordless telephone uses digitized speech and digital transmission, thereby offering a clearer voice signal than analog CT1. Another advantage is that CT2 does not suffer from the inherent interference problems associated with CT1.
- **DECT:** DECT stands for digital enhanced cordless telecommunications. The DECT specification was developed by European Telecommunications Standards Institute (ETSI) and operates throughout Europe in the frequency band 1880 to 1900 MHz. DECT provides cordless telephones with the greater range, up to several hundred meters, allows encryption, provides for greater number of handsets, and even allows data communication. It uses high-frequency signals (1.88 to 1.9 GHz) and also employs time division multiple access (TDMA), which allows several conversations to share the same frequency. Although CT1, CT2, and DECT are European standards, the US PCS standards have followed these models too. DECT is being adopted increasingly worldwide.
- **PHS:** The personal hand-phone system (PHS) was introduced in Japan in 1995 for private use as well as for PCS. Unlike conventional cellular telephone systems, the PHS system employs ISDN technology. With PHS, a subscriber can have two separate telephone numbers: one for the home and the other for outside the home. The PHS system uses TDMA format because of the flexibility for call control and economy—characteristics common to the cellular system. To allow for two-way communication, forward and reverse channels are located on the same frequency by employing time-division duplex (TDD). It employs carrier spaced 300 kHz apart over a 23-MHz band from 1895 to 1918 MHz. Each carrier supports four channels—one control channel broadcast on a carrier, while three speech channels broadcast on other carrier waves. PHS is attracting attention around the world, particularly in Asian nations.
- **ISM:** The 900-MHz digital spread spectrum (DSS) cordless telephone operates in the 902 to 928 MHz industrial-scientific-medical (ISM) band. The spread spectrum systems have the additional advantage of enhanced security. The channel spacing is 1.2 MHz and there are 21 nonoverlapping channels in the band. The system is operated using TDD at a frame rate of 250 Hz. It provides clear sound, superb range, and security. It has a greater output power than other cordless phones. This increased power dramatically boosts range. The 2.4-GHz DSS cordless telephone is an upgrade of this.

Cordless telephones are categorized by the radio frequency used and whether transmission between the handset and base unit is in the form of analog or digital signals. Generally speaking, the clarity of a cordless telephone improves with the use of higher frequencies and digital technology. Regulatory authorities in each country also specify and allocate the frequencies that may be used by cordless telephones in their respective countries and all telephones intended for use in their countries must receive their approvals. All cordless telephones are approved in the respective markets in which they are sold. Table 17.5.2 shows the common cordless telephone standards and their respective frequency range. In common with all areas of communications, the trend is away from analog systems to digital systems.

TABLE 17.5.2 Comparison of Cordless Telephone Standards

Standard	Analog cordless telephone			Digital cordless telephone		
	CT1	JCT	900 MHz	DECT	PHS	ISM
Region	Europe	Japan	worldwide	Europe	Japan	USA
Frequency (MHz)	914/960	254/380	900	1880–1990	1895–1918	2400–2485
Range (km)	Up to 7	0.3	0.25	0.4	0.2	0.5

JCT—Japanese cordless telephone; PHS—Personal Hand-phone System.

PAGING

Paging started as early as 1921 when the concept of one-way information broadcasting was introduced. The 1930s saw the widespread use of radio paging by government agencies, police departments, and the armed forces in the United States. Paging systems have undergone dramatic development. Radio transmission technology has advanced and so are the computer hardware and firmware (computer program) used in radio-paging systems.

One-Way Pagers

A paging system is a one-way wireless messaging system that allows continuous accessibility to someone away from the wired communications network. In its most basic form, the person on-the-move carries a palm-sized device (the pager) that has an identification number. The calling party inputs this number, usually through the public telephone network, to the paging system which then signals the pager to alert the called party. Early paging systems were nonselective and operator assisted. Not only did it waste airtime, the system was inconvenient, labor-intensive, and offered no privacy. With automatic paging, a telephone number is assigned to each pager and the paging terminal can automatically signal for voice input from the calling party.

The basic paging system consists of the following components:

- *Input Source:* A caller enters a page from a phone or through an operator. Once it is entered, the page is sent through the public switched telephone network (PSTN) to the paging terminal for encoding and transmission through the paging system.
- *Encoder:* The encoder typically accepts the incoming page, checks the validity of the pager number, looks up the database for the subscriber's pager address, and converts it into the appropriate paging signaling protocol. The encoded paging signal is then sent to the transmitters (base stations).
- *Base Station:* This transmits page codes on an assigned radio frequency. Most base stations are designed specifically for paging but some of those designed for two-way voice can also be used.
- *Page Receivers:* These are the pagers, which are basically FM receivers turned to the same RF frequency as the paging base station in the system. A decoder in each pager recognizes the unique code assigned to the pager and rejects all other codes for selective alerting. The most basic function of the pager is alerting. On receiving its own paging code, the receiver sets off an alert that can be audible (tone), visual (flashing indicator), or silent (vibrating). Messaging functions can also include voice and/or display (numeric/alphanumeric) messaging.

Today's paging systems offer much more than the basic system described above. A paging system subscriber can be alerted anytime and at almost any place as coverage can be easily extended, even across national borders. Paging systems are increasingly migrating from tone and numeric paging, to alphanumeric paging. Alphanumeric pagers display alphabetic or numeric messages entered by the calling party. The introduction of alphanumeric pagers also enables important information/data (e.g., business, financial news) to be constantly updated and monitored. Pagers that can display different ideographic languages, e.g., Chinese and Japanese, are now available in the market. The specific language supported is determined by the computer program installed in the pager.

Two-Way Pagers

The conventional paging systems are designed for one-way communication—from network toward pagers. Such systems provide the users one or more of the following services: beep, voice messaging, numeric messaging, and alphanumeric messages. With the recent development in paging systems, it is possible to supply a reverse link and thus allow two-way paging services. Two-way paging offers some significant capabilities with distinct advantages.

Two-way paging is essentially alphanumeric paging that lets the pager send messages, either to respond to received messages or to originate its own messages. The pagers come in various shapes and sizes. Some look almost like today's alphanumeric pagers, while some add small keyboards and larger displays. Two-way paging networks employ the 900-MHz band, a small fraction of the spectrum originally meant for PCS.

Networks are built around protocols. Two-way messaging network is based on Reflex, which is basically an extension of Motorola's Flex protocol for one-way paging. Reflex is a new generation of paging protocols. But reflex is a proprietary protocol. In view of the fact that two-way paging is the dominant application for wide area wireless networks and that a set of open, nonproprietary protocols is required to enable the convergence of the two-way paging and the Internet, efficient mail submission and delivery (EMSD) has been designed. EMSD is an open, efficient, Internet messaging protocol that is highly optimized for short messages. Devices that provide two-way paging capabilities should use this protocol (e.g., dedicated pagers, cell phones, palm PCs, handheld PCs, laptops, and desktops).

The majority of pagers are used for the purpose of contacting someone on the move. The most popular type of pager used for this application is the alphanumeric pager that displays the telephone number to call back after alerting the paging subscriber. Although they are not common or cheap, the trend toward alphanumeric paging is inevitable with improved speed and better pagers. There will be more varied applications of paging such as the sending of e-mail, voice mail, faxes, or other useful information to a pager, which will also take on more attractive and innovative forms. Future pagers may compete more aggressively with other two-way technologies, such as cellular and PCS. Although paging does not provide real-time interactive communications between the caller and the called party, it has some advantages over other forms of PCS, such as cellular telephone. These include less bandwidth requirement, larger coverage area, lower cost, and lighter weight. Owing to these advantages, paging service is bound to be in a strong competitive PCS services in years to come.

With more than 51 million paging subscribers worldwide, major paging markets in the world, especially in Asia, continue to expand rapidly. With the use of pagers getting more and more integrated into our daily lives, we will be seeing a host of new and exciting applications. There will emerge satellite pagers, which will send and receive messages through satellite systems such as Iridium, ICO, and Globalstar. With the help of such pagers, it is possible to supply paging services in global scale.

CELLULAR NETWORKS

The conventional approach to mobile radio involved setting up a high-power transmitter on top of the highest point in the coverage area. The mobile telephone must have a line-of-sight to the base station for proper coverage. Line-of-sight transmission is limited to as much as 40 to 50 miles on the horizon. Also, if a mobile travels too far from its base station, the quality of the communications link becomes unacceptable. These and other limitations of conventional mobile telephone systems are overcome by cellular technology.

Areas of coverage are divided into small hexagonal radio coverage units known as *cells*. A cell is the basic geographic unit of a cellular system. A cellular communications system employs a large number of low-power wireless transmitters to create the cells. These cells overlap at the outer boundaries, as shown in Fig. 17.5.5. Cells are base stations transmitting over small geographic areas that are represented as hexagons. Each cell size varies depending on the landscape and tele-density. Those stick towers one sees on hilltops with triangular structures at the top are cellular telephone sites. Each site typically covers an area of 15 miles across, depending on the local terrain. The cell sites are spaced over the area to provide a slightly overlapping blanket of coverage. Like the early mobile systems, the base station communicates with mobiles via a channel. The channel is made of two frequencies—one frequency (the forward link) for transmitting information to the base station and the other frequency (the reverse link) to receive from the base station.

FIGURE 17.5.5 A typical wireless seven-cell pattern; cells overlap to provide greater coverage.

Fundamental Features

Besides the idea of cells, the essential principles of cellular systems include cell splitting, frequency reuse, handover, capacity, spectral efficiency, mobility, and roaming.

- *Cell Splitting:* As a service area becomes full of users, the single area is split into smaller ones. This way, urban regions with heavy traffic can be split into as many areas as necessary to provide acceptable service, while large cell can be used to cover remote rural regions. Cell splitting increases the capacity of the system.
- *Frequency Reuse:* This is the core concept that defines the cellular system. The cellular-telephone industry is faced with a dilemma: services are growing rapidly and users are demanding more sophisticated call-handling features, but the amount of the EM spectrum allocation for cellular service is fixed. This dilemma is overcome by the ability to reuse the same frequency (channel) many times. Several frequency-reuse patterns are in use in the cellular industry, each with its advantages and disadvantages. A typical example is shown in Fig. 17.5.6, where all the available channels are divided into 21 frequency groups numbered 1 to 21. Each cell is assigned three frequency groups. For example, the same frequencies are reused in cell designated 1 and adjacent locations do not reuse the same frequencies. A cluster is a group of cells; frequency reuse does not apply to clusters.
- *Handoff:* This is another fundamental feature of the cellular technology. When a call is in progress and the switch from one cell to another becomes necessary, a handoff takes place. Handoff is important because as a mobile user travels from one cell to another during a call, as adjacent cells do not use the same radio channels, a call must be either dropped or transferred from one channel to another. Dropping the call is not acceptable. Handoff was created to solve the problem. A number of algorithms are used to generate and process a handoff request and eventual handoff order. Handing off from cell to cell is the process of transferring the mobile unit that has a call on a voice channel to another voice channel, all done without interfering with the call. The need for handoff is determined by the quality of the signal, whether it is weak or strong. A handoff threshold is predefined. When the received signal level is weak and reaches the threshold, the system provides

FIGURE 17.5.6 Frequency reuse in a seven-cell pattern cellular system.

a stronger channel from an adjacent cell. This handoff process continues as the mobile moves from one cell to another as long as the mobile is in the coverage area.

- *Mobility and Roaming:* Mobility implies that a mobile user while in motion will be able to maintain the same call without service interruption. This is made possible by the built-in-handoff mechanism that assigns a new frequency when the mobile moves to another cell. Because of several cellular operators within the same region using different equipment and a subscriber is only registered with one operator, some form of agreement is necessary to provide services to subscribers. Roaming is the process whereby a mobile moves out of its own territory and establishes a call from another territory. If we consider a cell (an area) with a perimeter L where ρ mobile units per unit area are located, the average number of users M crossing the cell boundaries per unit time is

$$M = \frac{\rho VL}{\pi} \tag{6}$$

where V is the average velocity of the mobile units.

- *Capacity*: This is the number of subscribers that can use the cellular system. For an FDMA system, the capacity is determined by the loading (no. of calls and the average time per call) and system layout (size of cells and amount of frequency reuse utilized). Capacity expansion is required because cellular systems must serve more subscribers. It takes place through frequency reuse, cell splitting, planning, and redesigning of the system.
- *Spectral Efficiency*: This a performance measure of the efficient use of the frequency spectrum. It is the most desirable feature of a mobile communication system. It produces a measure of how efficiently space, frequency, and time are used. Expressed in channels/MHz/km², channel efficiency is given by

$$\eta = \frac{\text{total no. of channels available in the system}}{\text{bandwidth} \times \text{total coverage area}}$$

$$\eta = \frac{\frac{B_w}{B_c} \times \frac{N_c}{N}}{B_w \times N_c \times A_c} = \frac{1}{B_c \times N \times A_c} \quad (7)$$

where B_w = bandwidth of the system in MHz
 B_c = channel spacing in MHz
 N_c = number of cells in a cluster
 N = frequency reuse factor of the system
 A_c = area covered by a cell in km²

Cellular System

A typical cellular network is shown in Fig. 17.5.7. It consists of the following three major hardware components [3]:

- *Cell Site (Base Stations)*: The cell site acts as the user-to-MTSSO interface, as shown in Fig. 17.5.7. It consists of a transmitter and two receivers per channel, an antenna, a controller, and data links to the cellular office. Up to 12 channels can operate within a cell depending on the coverage area.
- *Mobile Telephone Switching Office (MTSSO)*: This is the physical provider of connections between the base stations and the local exchange carrier. MTSSO is also known as mobile switching center (MSC) or digital multiplex switch-mobile telephone exchange (DMS-MTX) depending on the manufacturer. It manages and controls cell site equipment and connections. It supports multiple-access technologies such as AMPS, TDMA, CDMA, and CDPD. As a mobile moves from one cell to another, it must continually send messages to the MTSSO to verify its location.
- *Cellular (Mobile) Handset*: This provides the interface between the user and the cellular system. It is essentially a transceiver with an antenna and is capable of tuning to all channels (666 frequencies) within a service area. It also has a handset and a number assignment module (NAM), which is a unique address given to each cellular phone.

Cellular Standards

Because of the rapid development of cellular technology, different standards have resulted. These include:

- *Advanced Mobile Phone System (AMPS)*: This is the standard introduced in 1979. Although it was developed and used in North America, it has also been used in over 72 countries. It operates in the 800-MHz frequency band. It is based on FDMA. The mobile transmit channels are in the 825- to 845-MHz range, while the mobile receive channels are in the 870- to 890-MHz range. There is also the digital AMPS, which is also known as TDMA (or IS-54). FDMA systems allow for a single mobile telephone to call on a radio channel;

FIGURE 17.5.7 A typical cellular network.

each voice channel can communicate with only one mobile telephone at a time. TDMA systems allow several mobile telephones to communicate all the same time on a single radio carrier frequency. This is achieved by dividing their signal into time slots.

- *IS-54 and IS-95*: The IS-54 is a North American standard developed by the Electronic Industries Association (EIA) and the Telecommunications Industry Association (TIA) to meet the growing demand for cellular capacity in high-density areas. It is based on TDMA and it retains the 30-kHz channel spacing of AMPS to facilitate evolution from analog to digital systems. The IS-95 standard was also adopted by EIA/TIA. It is based on CDMA, a spread-spectrum technique that allows many users to access the same band by assigning a unique orthogonal code to each user.
- *Global System for Mobile Communications (GSM)*: This is a digital cellular standard developed in Europe and designed to operate in the 900-MHz band. It is a globally accepted standard for digital cellular communication. It uses a 200-kHz channel divided into eight time slots with frequency division multiplexing (FDM). The technology allows international roaming and provides integrated cellular systems across different national borders. GSM is the most successful digital cellular system in the world. It is estimated that many countries outside Europe will join the GSM partnership.
- *Personal Digital Cellular (PDC)*: This is a digital cellular standard developed in Japan. It was designed to operate in 800-MHz and 1.5-GHz bands.

- *Future Public Land Mobile Telecommunication Systems (FPLMTS)*: This is a new standard being developed in ITU to form the basis for third-generation wireless systems. It will consolidate today's increasingly diverse and incompatible mobile environments into a seamless infrastructure that will offer a diverse portfolio of telecommunication services to an exponentially growing number of mobile users on a global scale. It is a digital system based on 1.8- to 2.2-GHz band. It is being tested to gain valuable user and operator experience. In many European countries, the use of GSM has allowed cross-country roaming. However, global roaming has not been realized because there are too many of these incompatible standards.

PERSONAL COMMUNICATION SYSTEMS

The GSM digital network has pervaded Europe and Asia. A comparable technology known as PCS is beginning to make inroads in the United States. According to FCC, "PCS is the system by which every user can exchange information with anyone, at anytime, in any place, through any type of device, using a single personal telecommunication number (PTN)." PCS is an advanced phone service that combines the freedom and convenience of wireless communications with the reliability of the legacy telephone service. Both GSM and PCS promise clear transmissions, digital capabilities, and sophisticated encryption algorithms to prevent eavesdropping.

PCS is a new concept that will expand the horizon of wireless communications beyond the limitations of current cellular systems to provide users with the means to communicate with anyone, anywhere, anytime. It is called PCS by the FCC or personal communications networks (PCN) by the rest of the world. Its goal is to provide integrated communications (such as voice, data, and video) between nomadic subscribers irrespective of time, location, and mobility patterns. It promises near-universal access to mobile telephony, messaging, paging, and data transfer.

PCS/PCN networks and the existing cellular networks should be regarded as complimentary rather than competitive. One may view PCS as an extension of the cellular to the 1900-MHz band, using identical standards. Major factors that separate cellular networks from PCS networks are speech quality, complexity, flexibility of radio-link architecture, economics of serving high-user-density or low-user-density areas, and power consumption of the handsets. Table 17.5.3 summarizes the differences between the two technologies and services.

PCS offers a number of advantages over traditional cellular communications:

- A truly personal service, combining lightweight phones with advanced features such as paging and voice mail that can be tailored to each individual customer.
- Less background noise and fewer dropped calls
- An affordable fully integrated voice and text messaging that works just about anywhere, anytime
- A more secure all-digital network that minimizes chances of eavesdropping or number cloning
- An advanced radio network that uses smaller cell sites
- A state-of-the-art billing and operational support system

TABLE 17.5.3 Comparison of Cellular and PCS Technologies

Cellular	PCS
Fewer sites required to provide coverage	More sites required to provide coverage (e.g., a 20:1 ratio)
More expensive equipment	Less expensive cells
Higher costs for airtime	Airtime costs dropping rapidly
High antenna and more space needed for site	Smaller space for the microcell
Higher power output	Lower power output

FIGURE 17.5.8 Various cell sizes.

Basic Features

PCS refers to digital wireless communications and services operating at broadband (1900 MHz) or narrow-band (900 MHz) frequencies. Thus there are three categories of PCS: broadband, narrowband, and unlicensed. Broadband PCS addresses both cellular and cordless handset services, while narrowband PCS focuses on enhanced paging functions. Unlicensed service is allocated from 1890 to 1930 MHz and is designed to allow unlicensed short-distance operation.

The salient features that enable PCS to provide communications with anyone, anywhere, anytime include:

- *Roaming Capability:* The roaming service should be greatly expanded to provide universal accessibility. PCS will have the capability to support global roaming.
- *Diverse Environment:* Users must be able to use the PCS in all types of environments, e.g., urban, rural, commercial, residential, mountains, and recreational area.
- *Various Cell Size:* With PCS, there will be a mix of broad types of cell sizes: the picocell for low power indoor applications, the microcell for lower power outdoor pedestrian application, macrocell for high power vehicular applications, and supermacrocell with satellites, as shown in Fig. 17.5.8. For example, a picocell of a PCS will be in the 10 to 30 m range; a microcell may have a radius of 50 to 150 m; and a macrocell may have a radius of 1 km.
- *Portable Handset:* PCS provides a low-power radio, switched access connection to the PSTN. The user should be able to carry a single, small, universal handset outside without having to recharge its batter.
- *Single PTN:* The user can be reached through a single PTN regardless of the location and the type of service used.

The FCC frequency allocation for PCS usage is significant. FCC allocated 120 MHz for licensed operation and another 20 MHz for unlicensed operation, amounting to a total of 140 MHz for PCS, which is three times the spectrum currently allocated for cellular network. The FCC's frequency allocation for PCS is shown in Tables 17.5.4 and 17.5.5 for licensed and unlicensed operators. To use the PCS licensed frequency band, a company must obtain a license from FCC. To use the unlicensed (or unregulated) PCS spectrum, a company must use equipment that will conform with the FCC unlicensed requirements that include low power transmission to prevent interference with other users in the same frequency band.

PCS Architecture

A PCS network is a wireless network that provides communication services to PCS subscribers. The service area of the PCS network is populated with base stations, which are connected to a fixed wireline network

TABLE 17.5.4 The PCS Frequency Bands for Licensed Operation

Block	Spectrum low side (MHz)	Spectrum high side (MHz)	Bandwidth (MHz)
A	1850–1865	1930–1945	30
D	1865–1870	1945–1950	10
B	1870–1885	1950–1965	30
E	1885–1890	1965–1970	10
F	1890–1895	1970–1975	10
C	1895–1910	1975–1990	30
Total			120

through mobile switch centers (MSCs). Like a cellular network, the radio coverage of a base station is called a cell. The base station locates a subscriber or mobile unit and delivers calls to and from the mobile unit by means of paging within the cell it serves.

PCS architecture resembles that of a cellular network with some differences. The structure of the local portion of a PCS network is shown in Fig. 17.5.9. It basically consists of five major components:

- Terminals installed in the mobile unit or carried by pedestrians
- Cellular base stations to relay signals
- Wireless switching offices that handle switching and routing calls
- Connections to PSTN central office
- Database of customers and other network-related information

Since the goal of PCS is to provide anytime-anywhere communication, the end device must be portable and both real-time interactive communication (e.g., voice) and data services must be available. PCS should be able to integrator or accommodate the current PSTN, ISDN, the paging system, the cordless system, the wireless PBX, the terrestrial mobile system, and the satellite system. The range of applications associated with PCS is depicted in Fig. 17.5.10.

PCS Standards

The Joint Technical Committee (JTC) has been responsible for developing standards for PCS in the United States. The JTC committee worked cooperatively with the TIA committee working on the TR-46 reference model and ATIS committee working on the T1P1 reference model. Unlike GSM, PCS is unfortunately not a single standard but a mosaic consisting of several incompatible versions coexisting rather uneasily with one another. One major obstacle to PCS adoption in the United States has been the industry's failure to sufficiently convince customers on the advantages of PCS over AMPS, which already offers a single standard. This places the onus on manufacturers to inundate phones with features that attract market attention without compromising the benefits inherent in cellular phones. However, digital cellular technology enjoys distinct advantages. Perhaps the most significant advantage involves security because one cannot adequately encrypt AMPS signals.

TABLE 17.5.5 The PCS Frequency Bands for Unlicensed Operation

Block	Spectrum (MHz)	Bandwidth (MHz)
Isochronous	1910–1920	10
Asynchronous	1920–1930	10
Total		20

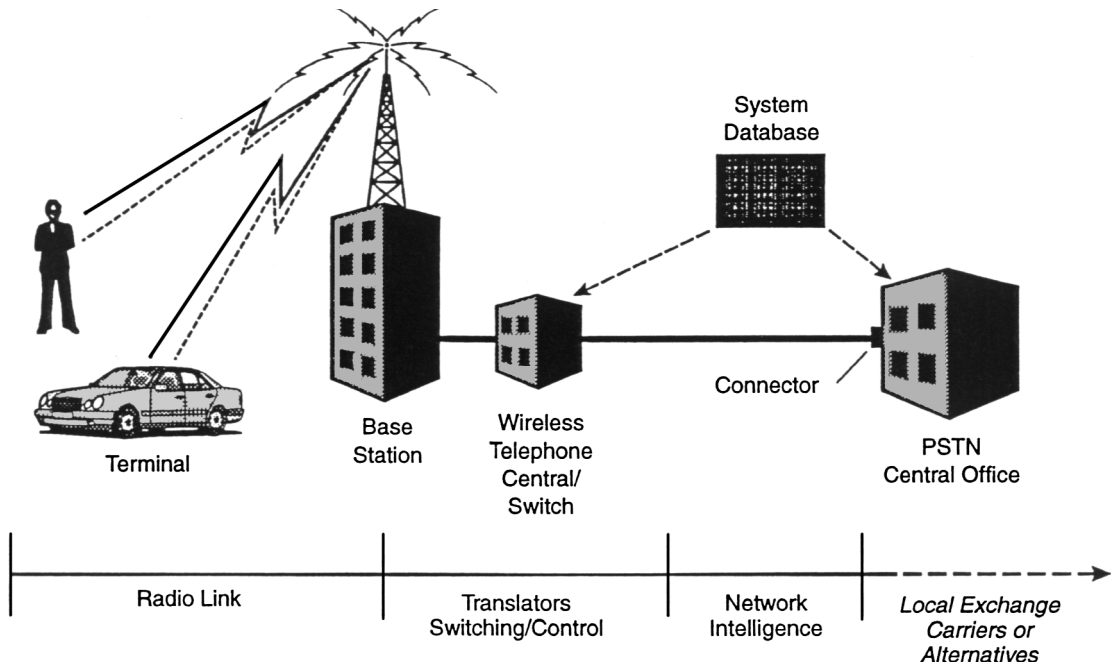

FIGURE 17.5.9 Structure of PCS network.

Satellites are instrumental in achieving global coverage and providing PCS services. Mobile satellite communications for commercial users is evolving rapidly toward PCS systems to provide basic telephone, fax, and data services virtually anywhere on the globe. Satellite orbits are being moved closer to the earth, improving communication speed and enabling PCS services. Global satellite systems are being built for personal communications. In the United States, the FCC licensed five such systems: Iridium, Globalstar,

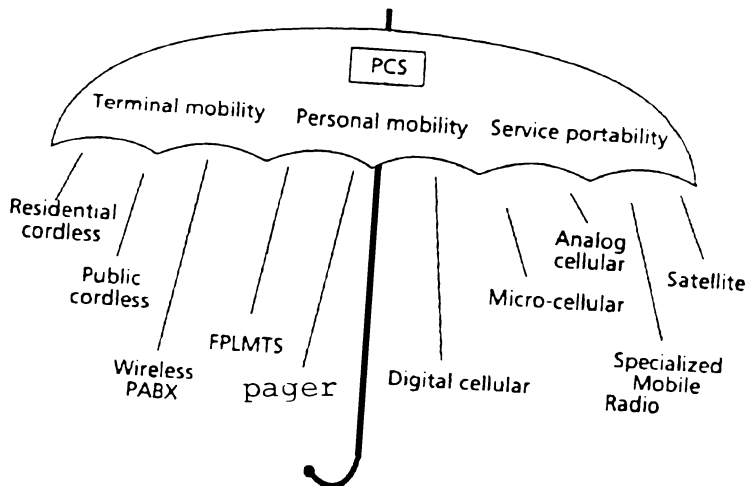

FIGURE 17.5.10 Range of applications associated with PCS.

Odyssey, Ellipso, and Aries. In Europe, ICO-Global is building ICO. Japan, Australia, Mexico, and India are making similar effort.

Future growth and success of PCS services cannot be taken for granted. Like any new technology, the success of PCS system will depend on a number of factors. These include initial system overall cost, quality, and convenience of the service provided, and cost to subscribers.

WIRELESS DATA NETWORKS

Wireless data networks are designed for low speed data communications. The proliferation of portable computers coupled with the increasing usage of the Internet and the mobile user's need for communication is the major driving force behind these networks. Examples of such networks include CDPD, wireless LAN, and wireless ATM.

Cellular Digital Packet Data

Cellular digital packet data is the latest in wireless data communication. CDPD systems offer one of the most advanced means of wireless data transmission technology. CDPD is a cellular standard aimed at providing Internet protocol (IP) data service over the existing cellular voice networks and circuit switched telephone networks. The technology solves the problem of business individuals on the move who must communicate data between their work base and remote locations.

The idea of CDPD was formed in 1992 by a development consortium with key industry leaders including IBM, six of the seven regional Bell operating companies, and McCaw Cellular. The goal was to create a uniform standard for sending data over existing cellular telephone channel. The Wireless Data Forum (www.wirelessdata.org), formerly known as CDPD Forum, has emerged as a trade association for wireless data service providers and currently has over 90 members. CDPD has been defined by the CDPD Forum CDPD Specification R1.1 and operates over AMPS.

By building CDPD as an overlay to the existing cellular infrastructure and using the same frequencies as cellular voice, carriers are able to minimize the capital expenditures. It costs approximately \$1 million to implement a new cellular cell site and only about \$50,000 to build the CDPD overlay to an existing site.

CDPD is designed to exploit the capabilities of the advanced cellular mobile services (AMPS) infrastructure throughout North America. One weakness of cellular telephone channels is that there are moments when the channels are idle (roughly 30 percent of the air time is unused). CDPD exploits this by detecting and using the otherwise wasted moments by sending packets during the idle time. As a result, data are transmitted without affecting voice system capability. CDPD transmits digital packet data at 19.2 kbps using idle times between cellular voice calls on the cellular telephone network.

CDPD has the following features:

- It is an advanced form of radio communication operating in the 800- and 900-MHz bands.
- It shares the use of the AMPS radio equipment on the cell site.
- It supports multiple, connectionless sessions.
- It uses the Internet protocol (IP) and the open systems interconnection (OSI) connectionless network protocol (CLNP).
- It is fairly painless for users to adopt. To gain access to CDPD infrastructure, one only requires a special CDPD modem.
- It supports both the TCP/IP protocols as well as the international set of equivalent standards.
- It was designed with security in mind unlike other wireless services. It provides for encryption of the user's data as well as conceals the user's identity over the air link.

CDPD provides the following services:

- Data rate of 19.2 kbps.

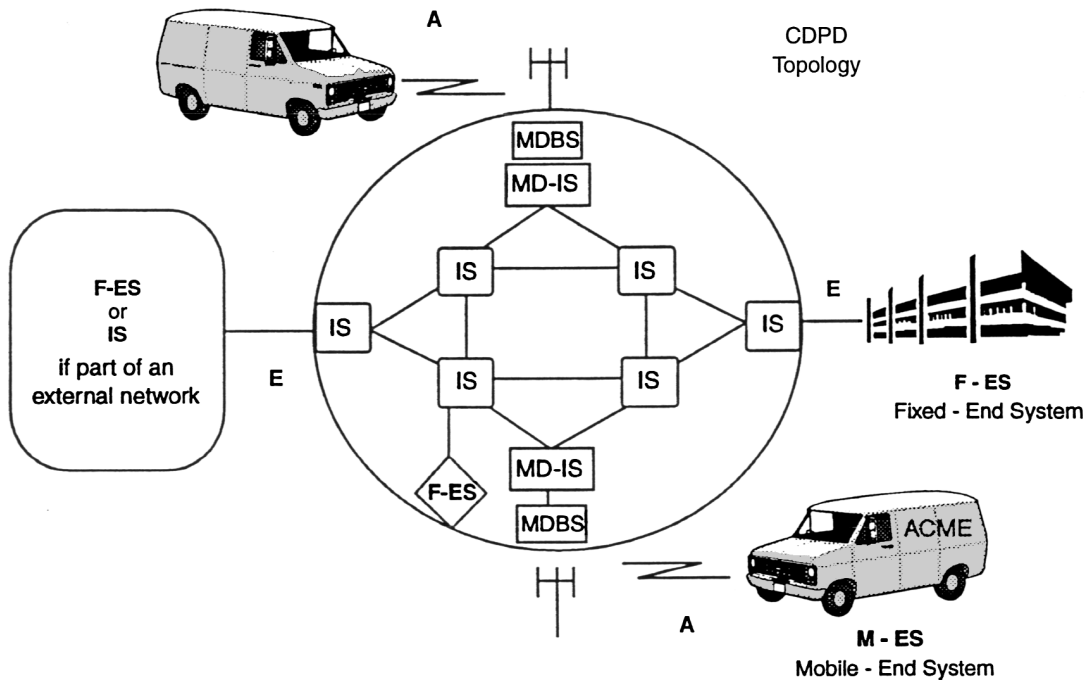

FIGURE 17.5.11 Major components of a CDPD network.

- Connectionless as the basic service; a user may build a connection-oriented service on top of that if desired.
- All three modes of point-to-point, multicast, and broadcast are available.
- Security that involves authentication of users and data encryption.

CDPD is a packet switched data transfer technology that employs radio frequency (RF) and spectrum in existing analog mobile phone system such as AMPS. The CDPD overlay network is made of some major components that operate together to provision the overall service. The key components that define CDPD infrastructure are illustrated in Fig. 17.5.11. They are as follows:

- *Mobile End System (MES)*: This is the subscriber's device for gaining access to the wireless communication services offered by a CDPD service. It is any mobile computing device, which is an equipment with a CDPD modem. Examples of an MES are laptop computers, palmtop computers, and personal digital assistants (PDAs), or any portable computing devices.
- *Fixed End System (FES)*: This is a stationary computing device (e.g., a host computer, a UNIX workstation, and so forth) connected to landline networks. The FES is the final destination of the message sent from an MES.
- *Intermediate System (IS)*: This is made up of routers that are CDPD compatible. It is responsible for routing data packets into and out of the CDPD service provider network. It may also perform gateway and protocol conversion functions to aid network interconnection.
- *Mobile Data Base Station (MDBS)*: CDPD uses a packet switched system that splits data into small packets and sends them across the voice channel. This involves detecting idle time on the voice channel and sending the packets on the appropriate unoccupied voice frequencies. This detection of unoccupied frequencies and sending of packets is done by the MDIS. Thus, the MDIS is responsible for relaying data between the mobile units and the telephone network. In other words, it relays data packets from the MES to the mobile data intermediate system (MDIS) and vice versa.

- *Mobile Data Intermediate System:* MDBSs that service a particular cell can be grouped together and connected to the backbone router, also known as the MDIS. The MDIS units form the backbone of the CDPD network. All mobility management functions are taken care of by MDIS. In other words, the MDIS is responsible for keeping track of the MES's location and routing data packets to and from the CDPD network and the MES appropriately.

Very little new equipment is needed for CDPD service since existing cellular networks are used. Only the MDBSs are to be added to each cell. One can purchase CDPD cellular communication systems for Windows or MS-DOS computers. The hardware can be a handheld AMPS telephone or a small modem which can be attached to a notebook computer. One would need to put up the antenna on the modem.

In order to effectively integrate voice and data traffic on the same cellular network without degrading the service provided for the voice customer, the CDPD network employs a technique known as *channel hopping*. When a mobile unit wants to transmit, it checks for an available cellular channel. Once a channel is found, the data link is established and the mobile unit can use the assigned channel to transmit as long as the channel is not needed for voice communication. Because voice is king, data packets are sent after giving priority to voice traffic. Therefore, if a cellular voice customer needs the channel, it will take priority over the data transmission. In that case, the mobile unit is advised by the MDBS to "hop" to another available channel. If there are no other available channels, then extra frequencies purposely set aside for CDPD can be used. This is a rare situation because each cell typically has 57 channels and each channel has an average idle time of 25 to 30 percent. The process of establishing and releasing channel links is called channel hopping and it is completely transparent to the mobile data unit. It ensures that the data transmission does not interfere with the voice transmission. It usually occurs within the call setup phase of the voice call. The major disadvantage of channel hopping is the potential interference to the cellular system.

CDPD has been referred to as an "open" technology because it is based on the OSI reference model, as shown in Fig. 17.5.12. The CDPD network comprises many layers: layer 1 is the physical layer; layer 2 is the data link layer; and layer 3 is the network layer; and so forth. For example, the physical layer corresponds to a functional entity that accepts a sequence of bits from the medium access control (MAC) layer and transforms them into a modulated waveform for transmission onto a physical 30 kHz RF channel. The network can use either the ISO

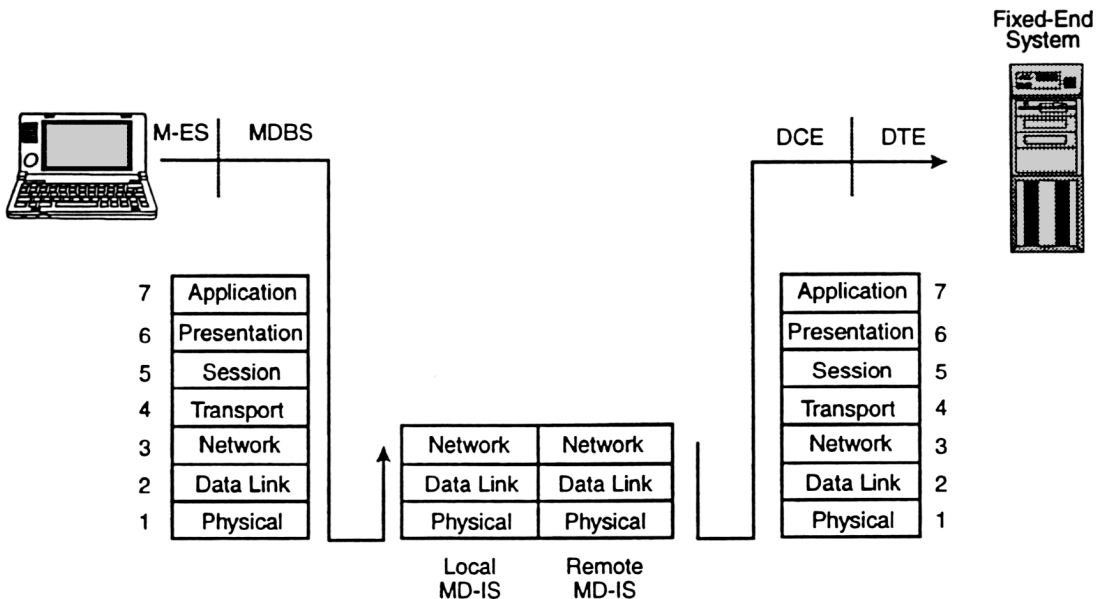

FIGURE 17.5.12 OSI reference model.

connectionless network protocol (CLNP) or the transmission control protocol/Internet protocol (TCP/IP). For now, CDPD can coexist with PCS and CDMA-based infrastructure.

Wireless LAN

Wireless local area network (WLAN) is a new form of communication system. It is basically a local area network, confined to a geographically small area such as a single building, office, store, or campus, that provides high data connectivity to mobile stations. Using electromagnetic airwaves (radio frequency or infrared), WLANs transmit and receive data over the air. A WLAN suggests less expensive, fast, and simple network installation and reconfiguration.

WLAN does not compete with wired LAN. Rather, WLANs are used to extend wired LANs for convenience and mobility. Wireless links essentially fill in for wired links using electromagnetic radiation at radio or light frequencies between transceivers. A typical WLAN consists of an access point and the WLAN adapter installed on the portable notebook. The access point is a transmitter/receiver (transceiver) device; it is essentially the wireless equivalent of a regular LAN hub. An access point is typically connected with the wired backbone network at a fixed location through a standard Ethernet cable and communicates with wireless devices by means of an antenna. WLANs operate within the prescribed 900-MHz, 2.4-GHz, and 5.8-GHz frequency bands. Most LANs use 2.4-GHz frequency bands because it is most widely accepted.

A wireless link can provide services in several ways. One way is to act as a stand-alone WLAN for a group of wireless nodes. This can be achieved using topologies similar to wired LAN, namely, a star topology can be formed with central hub controlling the wireless nodes, a ring topology with each wireless node receiving or passing information sent to it or a bus topology with each wireless capable of hearing everything said by all the other nodes. A typical WLAN configuration is shown in Fig. 17.5.13.

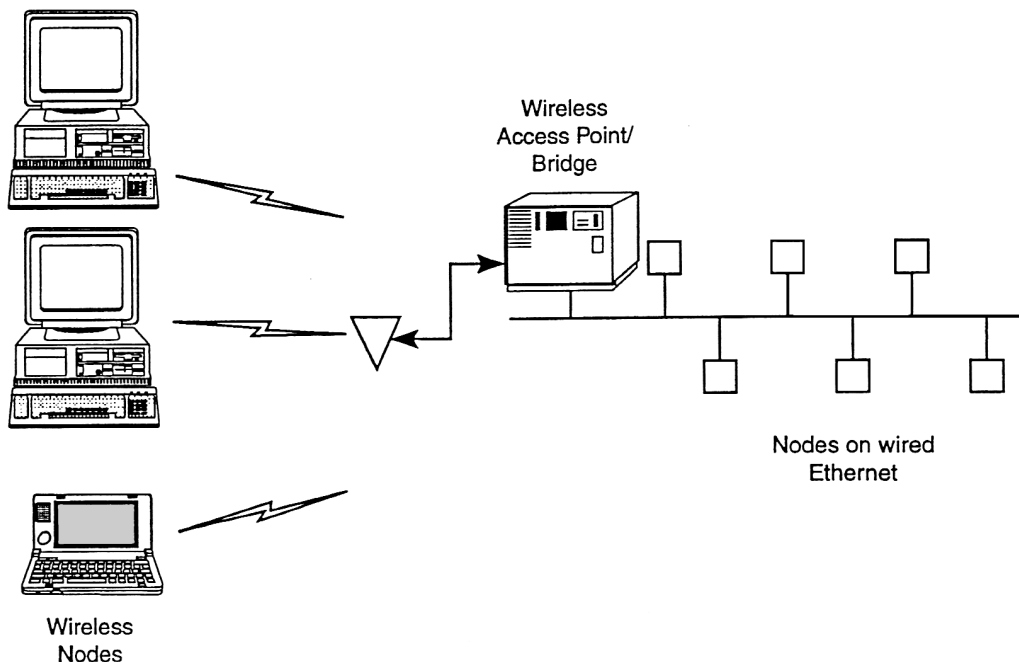

FIGURE 17.5.13 Connection of a wired LAN to wireless nodes.

When designing WLANs, manufacturers have to choose from two main technologies that are used for wireless communications today: radio frequency (RF) and infra red (IR). Each technology has its own merits and demerits. RF is used for applications where communications are over long distances and are not line-of-sight. In order to operate in the license free portion of the frequency spectrum known as the ISM band (industrial, scientific, and medical), the RF system must use a modulation technique called *spread spectrum* (SS). The second technology used in WLAN is infra red, where the communication is carried by light in the invisible part of the spectrum. It is primarily used for very short distance communications (less than 1 m), where there is a line-of-sight connection. Since IR light does not penetrate solid materials (it is even attenuated greatly by window glass), it is not really useful in comparison to RF in WLAN system. However, IR is used in applications where the power is extremely limited such as a pager.

Wireless ATM

Asynchronous transfer mode technology is the result of efforts to devise a transmission and networking technology to provide high-speed broadband integrated services: a single infrastructure for data, voice, and video. Until recently, the integration of wireless access and mobility with ATM has received little attention.

The concept of wireless ATM (WATM) was first proposed in 1992. It is now regarded as the potential framework for next generation wireless broadband communications that will support integrated quality-of-service (QoS) multimedia services. WATM technology is currently migrating from research stage to standardization and early commercialization.

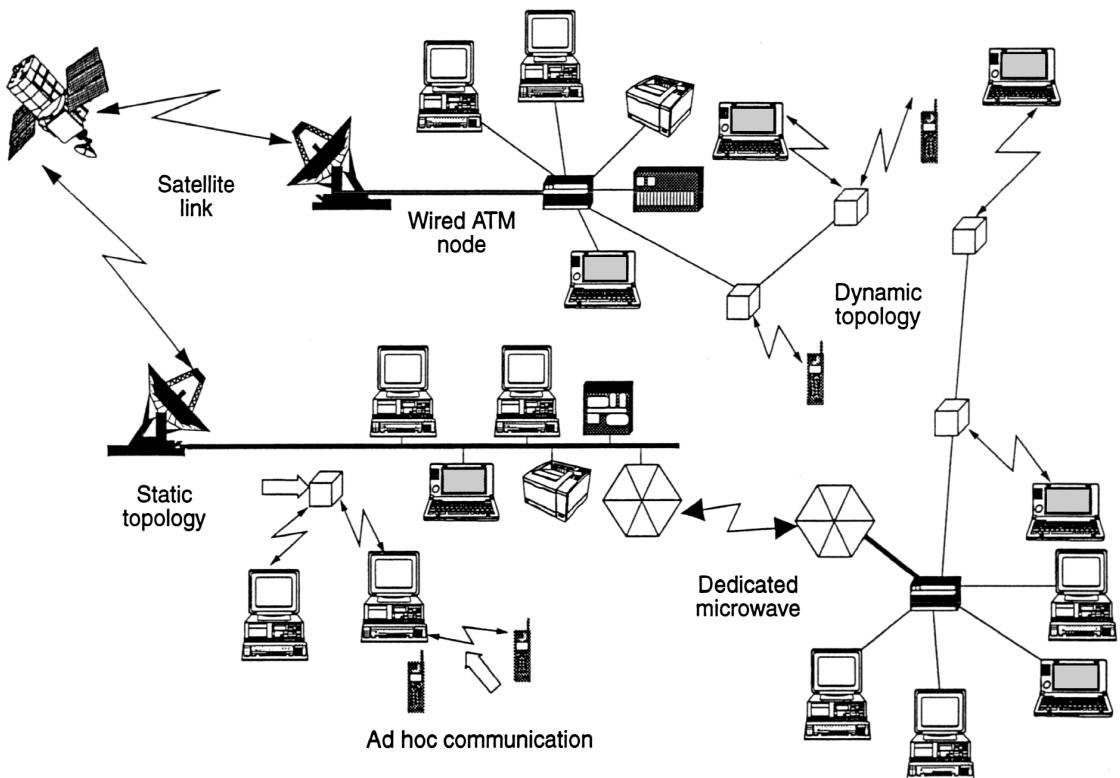

FIGURE 17.5.14 A typical wireless ATM network.

Wireless ATM network is basically the wireless extension of fixed ATM network. The 53-byte ATM cell is too big for wireless ATM network. Therefore, WATM networks may use 16 or 24 bytes payload. Thus, in a wireless ATM network, information is transmitted in the form of a large number of small transmission cells called *picocells*. Each picocell is served by a base station, while all the base stations in the network are connected via the wired ATM network. The ATM header is compressed or expanded to standard ATM cell at the base station. Base stations are simple cell relays that translate the header formats from the wireless ATM network to the wired ATM network. ATM cells are transmitted via radio frames between a central station (B-CS) and user radio modules (B-RM) as shown in Fig. 17.5.14. All base stations operate on the same frequency so that there is no hard boundary between picocells.

Reducing the size of the picocells helps in mitigating some of the major problems related to wireless LANs. The main difficulties encountered are the delay spread because of multipath effects and the lack of a line-of-sight path that results in high attenuation. Also, small cells have some drawbacks compared to large cells.

From Fig. 17.5.14, we notice that a wireless ATM typically consists of three major components: (1) ATM switches with standard UNI/NNI capabilities, (2) ATM base stations, and (3) wireless ATM terminal with a radio network interface card (NIC). There are two new hardware components: ATM base station and WATM NIC. The new software components are the mobile ATM protocol extension and WATM UNI driver.

In conventional mobile networks, transmission cells are “colored” using frequency-division multiplexing or code-division multiplexing to prevent interference between cells. Coloring is considered a waste of bandwidth because in order for it to be successful there must be areas between reuse of the color in which it is idle. These inactive areas are wasted rather than be used for transmission.

Wireless ATM architecture is based on integration of radio access and mobility features. The idea is to fully integrate new wireless physical layer (PHY), medium access control (MAC), and data link control (DLC), wireless control and mobility signaling functions into the ATM protocol stack.

Wireless ATM is not as matured as wireless LAN. No standards have been defined by either ITU-T or ATM Forum. However, the ATM Forum’s WATM Working Group (started in June 1996) is developing specifications that will facilitate deployment of WATM.

CHAPTER 17.6

DATA NETWORKS AND INTERNET

Matthew N. O. Sadiku

The coming of the information age has brought about unprecedented growth in telecommunications-based services, driven primarily by the Internet, the information superhighway. Within a short period of time, the volume of data traffic transported across communications networks has grown rapidly and now exceeds the volume of voice traffic. While voice networks, such as the ubiquitous telephone network, have been in use for over a century, computer data networks are a recent phenomenon.

A computer communications network is an interconnection of different devices to enable them to communicate among themselves. Computer networks are generally classified into three groups on the basis of their geographical scope: local area networks (LANs), metropolitan area networks (MANs), and wide area networks (WANs). These networks differ in geographic scope, type of organization using them, types of services provided, and transmission techniques. LANs and WANs are well-established communication networks. MANs are relatively new. On the one hand, LAN is used in connecting equipments owned by the same organization over relatively short distances. Its performance degrades as the area of coverage becomes large. Thus LANs have limitations of geography, speed, traffic capacity, and the number of stations they are able to connect. On the other hand, WAN provides long-haul communication services to various points within a large geographical area, e.g., a nation or continent. With some of the characteristics of LANs and some reflecting WANs, the MAN embraces the best features of both.

We begin this chapter by looking at the open systems interconnection (OSI) reference model, which is commonly used to describe the functions involved in data communication networks. We then examine different LANs, MANs, and WANs including the Internet.

OSI REFERENCE MODEL

There are at least two reasons for needing a standard protocol architecture such as the OSI reference model. First, the uphill task of understanding, designing, and constructing a computer network is made more manageable by dividing it into structured smaller subtasks. Second, the proliferation of computer systems has created heterogeneous networks—different vendors, different models from the same vendor, different data formats, different network management protocols, different operating systems, and so on. A way to resolve this heterogeneity is for vendors to abide by the same set of rules. Attempts to formulate these rules have preoccupied standards bodies such as International Standards Organization (ISO), Consultative Committee for International Telephone and Telegraph (CCITT) [now known as International Telecommunication Union (ITU)], Institute of Electrical and Electronics Engineers (IEEE), American National Standards Institute (ANSI), British Standards Institution (BSI), and European Computer Manufacturers Association (ECMA). Here we consider the more universal standard protocol architecture developed by ISO.

The ISO divides the task of networking computers into seven layers so that manufacturers can develop their own applications and implementations within the guidelines of each layer. In 1978, the ISO set up a committee

FIGURE 17.6.1 OSI reference model.

to develop a seven-layer model of network architecture (initially for WANs), known as the OSI. The model serves as a means of comparing different layers of communication networks. Also, the open model is standard-based rather than proprietary-based; one system can communicate with another system using interfaces and protocols that both systems understand. Network users and vendors have “open systems” in which any standard computer device would be able to interoperate with others.

The seven layers of the OSI model are shown in Fig. 17.6.1 and briefly explained as follows. We begin with the application layer (layer 7) and work our way down.

- *Application Layer:* This layer (layer 7) allows transferring information between application processes. It is implemented with host software. It is composed of specific application programs and its content varies with individual users. By application, we mean a set of information-processing desired by the user. Typical applications (or user programs) include login, password check, wordprocessing, spreadsheet,

graphics program, document transfer, electronic mailing system, virtual terminal emulation, remote database access, network management, bank balance, stock prices, credit check, inventory check, and airline reservation. Examples of application layer protocols are Telnet (remote terminal protocol), file transfer protocol (FTP), simple mail transfer protocol (SMTP), remote login service (rlogin), and remote copy protocol (rcp).

- *Presentation Layer:* This layer (layer 6) presents information in a way that is meaningful to the network user. It performs functions such as translation of character sets, interpretation of graphic commands, data compression/decompression, data reformatting, and data encryption/decryption. Popular character sets include American Standard Code for Information Interchange (ASCII), Extended Binary Coded Decimal Interchange Code (EBCDIC), and Alphabet 5.
- *Session Layer:* A session is a connection between users. The session layer (layer 5) establishes the appropriate connection between users and manages dialog between them i.e., controlling starting, stopping, and synchronization of the dialog. It decides the type of communication such as two-way simultaneous (full duplex), two-way alternate (half-duplex), one-way, or broadcast. It is also responsible for checking for user authenticity and providing billing. For example, login and logout are the responsibilities of this layer. IBM's network basic input/output system (NetBIOS), sequenced packet exchange (NetWare's SPX), manufacturing automation protocol (MAP), and technical and office protocol (TOP) operate at this layer.
- *Transport Layer:* This layer (layer 4) uses the lower layers to establish reliable end-to-end transport connections for the higher layers. Its other function is to provide the necessary functions and protocols to satisfy a quality of service (QoS) (expressed in terms of time delay, throughput, priority, cost, and security) required by the session layer. It creates several logical connections over the same network by multiplexing end-to-end user addresses onto the network. It fragments messages from the session layer into smaller units (packets or frames) and reassembles the packets into messages at the receiving end. It also controls the end-to-end flow of packets, performs error control and sequence checking, acknowledges successful transmission of packets, and requests retransmission of corrupted packets. For example, the transmission control protocol (TCP) of TCP/IP and Internet transport protocol (ITP) of Xerox operate at this level.
- *Network Layer:* This layer (layer 3) handles routing procedure and flow control. It establishes routes (virtual circuits) for packets to travel and routes the packets from their source to destination and controls congestion. (Routing is of greater importance on MANs and WANs than on LANs.) It carries addressing information that identifies the source and ultimate destination. It also counts transmitted bits for billing information. It ensures that packets arrive at their destination in a reasonable amount of time. Examples of protocols designed for layer 3 are X.25 packet switching protocol and X.75 gateway protocol, both by CCITT. Also, the Internet protocol (IP) of TCP/IP and NetWare's Internetwork Packet Exchange (IPX) operate at this layer.
- *Data Link Layer:* This layer (layer 2) specifies how a device gains access to the medium specified in the physical layer. It converts the bit pipe provided by the physical layer into a packet link, which is a facility for transmitting packets. It deals with procedures and services related to the node-to-node data transfer. A major difference between the data link layer and the transport layer is that the domain for the data link layer is between adjacent nodes, whereas that of the transport layer is end-to-end. In addition, the data link layer ensures error-free delivery of data; hence it is concerned with error-detection, error correction, and retransmission. The error control is usually implemented by performing checksums on all bits of a packet after a cyclic redundancy check (CRC) process. This way, any transmission errors can be detected. The layer is implemented in hardware and is highly dependent of the physical medium. Typical examples of data link protocols are binary synchronous communications (BSC), synchronous data link control (SDLC), and high-level data link control (HDLC). For LANs and MANs, the data link layer is decomposed into the media-access control (MAC) and the logical link control (LLC) sublayers.
- *Physical Layer:* This layer (layer 1) consists of a set of rules that specifies the electrical and physical connection between devices. It is implemented in hardware. It is responsible for converting raw bits into electrical signal and physically transmitting them over a physical medium such as coaxial cable or an optical fiber between adjacent nodes. It provides standards for electrical, mechanical, and procedural characteristics required to transmit the bit stream properly. It handles frequency specifications, encoding the data, defining voltage or current levels, defining cable requirements, defining the connector size, shapes, and pin number, and so on. RS-232, RS-449, X.21, X.25, V.24, IEEE 802.3, IEEE 802.4, and IEEE 802.5 are examples of physical-layer standards.

TABLE 17.6.1 Summary of the Functions of OSI Layers

Layer	Name	Function
7	Application layer	Transfers information between application processes
6	Presentation layer	Syntax conversion, data compression, and encryption
5	Session layer	Establishes connection and manages a dialog
4	Transport layer	Provides end-to-end transfer of data
3	Network layer	End-to-end routing and flow control
2	Data link layer	Medium access, framing, and error control
1	Physical layer	Electrical/mechanical interface

A summary of the functions of the seven layers is presented in Table 17.6.1. The seven layers are often subdivided into two. The first consists of the lower three layers (physical, data link, and network layers) and is known as the communications subnetwork. The upper three layers (session, presentation, and application layers) are termed the host process. The upper layers are usually implemented by networking software on the node. The transport layer is the middle layer, separating the data-communication functions of the lower three layers and the data-processing functions of the upper layers. It is sometimes grouped with the upper layers as part of the host process or grouped with the lower layers as part of data transport.

LOCAL AREA NETWORKS

A LAN is a computer network that spans a geographically small area. It consists of two or more computers that are connected together to share expensive resources such as printers, exchange files, or allow electronic communications. Most LANs are confined to a single building or campus. They connect workstations, personal computers, printers, and other computer peripherals. Users connected to the LAN can use it to communicate with each other. LANs are capable of transmitting data at very fast rates, much faster than data can be transmitted over a telephone line; but the distances are limited. Also, since all the devices are located within a single establishment, LANs are usually owned and maintained by an organization. A key motivation for using LANs is to increase the productivity and efficiency of workers.

LANs differ from MANs and WANs by geographic coverage, data transmission and error rates, topology and data routing techniques, ownership, and sometimes by the type of traffic. Unique characteristics that differentiate LANs include:

- LANs generally operate within a few kilometers, spanning only a small geographical area.
- LANs usually have very high bit rates, ranging from 1 Mbps to 10 Gbps.
- LANs have a very low error rate, say $1:10^8$.
- A LAN is often owned and maintained by a single private company, institution, or organization using the facility.

There are different kinds of LANs. The following features differentiate one LAN from another:

- *Topology*: The geometric arrangement of devices on the LAN. As shown in Fig. 17.6.2, this can be bus, ring, star, or tree.
- *Protocols*: These are procedures or rules that govern the transfer of information between devices connected to a LAN. Protocols are to computer networks what languages are to humans.

(a) Bus

(b) Ring

(c) Star

FIGURE 17.6.2 Typical LAN topologies.

FIGURE 17.6.2 (Continued)

- *Media*: The transmission medium connecting the devices can be twisted-pair wire, coaxial cables, or fiber optic cables. Wireless LAN use radio waves as media. Of all these media, optic fiber is the fastest but the most expensive. Common LANs include Ethernet, token ring, token bus, and star LAN. For bus or tree LANs, the most common transmission medium is coaxial cable. The two common transmission methods used on coaxial cable are baseband and broadband. A baseband LAN is characterized by the use of digital technology; binary data are inserted into the cable as a sequence of pulses using Manchester or Differential encoding scheme. A broadband LAN employs analog signaling and a modem. The frequency spectrum of the cable can be divided into channels using frequency division multiplexing (FDM). One of the most well-known applications of broadband transmission is the community antenna television (CATV). However, baseband LANs are more prevalent.

The Institute of Electrical and Electronics Engineers (IEEE) has established the following eight committees to provide standards for LANs:

- IEEE 802.1—standard for LAN/MAN bridging and management
- IEEE 802.2—standard for logical link control protocol
- IEEE 802.3—standard for CSMA/CD protocol
- IEEE 802.4—standard for token bus MAC protocol
- IEEE 802.5—standard for token ring MAC protocol
- IEEE 802.7—standard for broadband LAN
- IEEE 802.10—standard for LAN/MAN security
- IEEE 802.11—standard for wireless LAN

Token ring is a network architecture that uses token passing technology and ring-type network structure. Although token ring is standardized in IEEE 802.5 standard, its use has quite much faded to few organizations. Ethernet (IEEE 802.3) is the most popular and the least expensive high-speed LAN.

Ethernet is a LAN architecture developed by Xerox Corp. in cooperation with DEC and Intel in 1976. The IEEE 802.3 standard refined the Ethernet and made it globally accepted. Ethernet has since become the most popular and most widely deployed LAN in the world.

Conventional Ethernet uses a bus or star topology and supports data transfer rates of 10 Mbps. It uses a protocol known carrier sense multiple access with collision detection (CSMA/CD) as an access method to handle simultaneous demands. Each station or node attached to the Ethernet must sense the medium before transmitting data to see if any other station is already sending something. If the medium appears to be idle,

then the station can begin to send data. If two stations sense the medium idle and transmit at the same time, collision may take place. When such a collision occurs, the two stations stop transmitting, wait, and try again later after a randomly chosen delay period. The delay period is determined using Binary Exponential Backoff.

Ethernet is one of the most widely implemented LAN standards. A newer version of Ethernet, called *Fast Ethernet* (or 100Base-T) supports data transfer rates of 100 Mbps. Gigabit Ethernet (or 1000Base-T) delivers at 1 Gbps speed. Upcoming 10 Gbps version of Ethernet is expected to be ready by 2002.

Security is an important issue with LANs since they are designed to provide access to many users. Network security is a measure designed to protect LAN users against attacks that originate from the network and other networks such as Internet connected to it. When individuals send private communications through a LAN, they desire secure communications. Currently, there are no systems in wide use that will keep data secure as they transit a public network. Several methods are being used to prevent attacks. One approach is to encrypt data as they leave one machine and decrypt it at the destination. Encryption is the fundamental tool for ensuring security in data networks. Another approach is to regulate which packets can go between two sites. For example, firewalls are placed between an organization's LAN and the Internet. A firewall is simply a group of components that collectively form a barrier between two networks.

METROPOLITAN AREA NETWORKS

Metropolitan area networks are basically an outgrowth of LANs. A variety of users and applications drive the requirements for MANs. The requirements include cost, scalability, security, reliability, compatibility with existing and future networks, and management issues. To meet these requirements, several proposals have been made for MAN protocols and architectures. Of these proposed MANs, fiber distributed data interface (FDDI) and distributed queue dual bus (DQDB) have emerged as standards that compete for use as backbones.

FDDI

In the mid 1970s, it was recognized that the existing copper technology would be unsuitable for future communication networks. Optical fibers offer some benefits over copper in that they are essentially immune to electromagnetic interference (EMI), have low weight, do not radiate, and reduce electrical safety concerns.

FDDI was proposed by the American National Standard Institute (ANSI) as a dual token ring that supports data rates of 100 Mbps and uses optical fiber media. An optical fiber is a thin, flexible glass or plastic structure (or waveguide) through which light is transmitted.

The FDDI specification recommends an optical fiber with a core diameter of 62.5 μm and a cladding diameter of 125 μm . There are two types of optical-fiber mode: single mode and multimode. A mode is a discrete optical wave or signal that propagates down the fiber. In a single mode fiber, only the fundamental mode can propagate. In multimode fiber, a large number of modes are coupled into the cable, making it suitable for the less costly light-emitting diode (LED) light source. The advantages of fiber optics over electrical media and the inherent advantages of a ring design contribute to the widespread acceptance of FDDI as a standard.

FDDI is a collection of standards formed by ANSI X3T9.5 task group over a period of 10 years. The standards produced by the task group cover physical hardware, physical and data link protocol layers, and a conformance testing standard. The original standard, known as *FDDI-I*, provides the basic data-only operation. An extended standard, *FDDI-II*, supports hybrid data and real-time applications.

FDDI is a follow-on to IEEE 802.5 (token ring) in that FDDI is based on token ring mechanics. Although the FDDI MAC protocol is similar (but not identical) to token ring, there are some differences. Unlike in token ring, FDDI performs all networking monitoring and control algorithms in a distributed way among active stations and does not need an active monitor. (Hence the term "distributed" in FDDI.) Whenever any device is down, other devices reorganize and continue to function, including token initialization, fault recovery, clock synchronization, and topology control.

The key highlights of FDDI are summarized as follows:

- ANSI standard through the X3T9.5 committee
- Dual counter-rotating ring topology for fault tolerance
- Data rate of 100 Mbps
- Total ring loop of size 100 km
- Maximum of 500 directly attached stations or devices
- 2 km maximum distance between stations
- Variable packet size (4500 bytes, maximum)
- 4B/5B data encoding scheme to ensure data integrity
- Shared medium using a timed-token protocol
- Variety of physical media, including fiber and twisted pair
- 62.5/125 μm multimode fiber-optic-based network
- Low bit error rate of 10^{-9} (one in one billion)
- Compatibility with IEEE 802 LANs by use of IEEE 802.2 LLC
- Distributed clocking to support large number of stations
- Support for both synchronous and asynchronous services

FDDI has two types of nodes: stations and concentrators. The stations transmit information to other stations on the ring and receive from them. Concentrators are nodes that provide additional ports for attachments of stations to the network. A concentrator receives data from the ring and forwards it to each of the connected ports sequentially at 100 Mbps. While a station may have one or more MAC, a concentrator may or may not have a MAC. As shown in Fig. 17.6.3, each FDDI station is connected to two rings, primary and secondary simultaneously. Stations have active taps on the ring and operate as repeaters. This allows the FDDI network to be so large without signal degradation. The network uses its primary ring for data transmission, while the secondary ring can be used either to ensure fault tolerance or for data. When a station or link fails, the primary and secondary rings form a single one-way ring, isolating the fault while maintaining a logical path among users, as shown in Fig. 17.6.4. Thus, FDDI's dual-ring topology and connection management functions establish a fault-tolerance mechanism.

FDDI was developed to conform with the OSI reference model. FDDI divides the physical layer of the OSI reference model into two sublayers: physical layer dependent (PMD) and physical layer (PHY), while the data link layer is split into two sublayers: media access control (MAC) and IEEE 802.2 LLC. A comparison of the FDDI architectural model to the lower two layers of the OSI model along with the summary of the functions of the FDDI standards is illustrated in Fig. 17.6.5. The FDDI MAC uses a timed-token rotation (TTR) protocol for controlling access to the medium. With the protocol, the MAC in each station measures the time that has elapsed since the station last received a token. Each station on the FDDI ring uses three timers to regulate its operation. The station management (SMT) controls the other three layers (PMD, PHY, and MAC) and ensures proper operation of the station. It handles such functions as initial FDDI ring initialization, station insertion and removal, ring's stability, activation, connection management, address administration, scheduling policies, collection of statistics, bandwidth allocation, performance and reliability monitoring, bit error monitoring, fault detection and isolation, and ring reconfiguration.

Though the original FDDI, described above, provides a bounded delay for synchronous services, the delay can vary. FDDI was initially envisioned as a data-only LAN. The full integration of isochronous and bursty data traffic is obtained with the enhanced version of the protocol, known as FDDI-II. FDDI-II is described by the hybrid ring control (HRC) standard that specifies an upward-compatible extension of FDDI. FDDI-II adds one document, HRC, to the existing four documents that specify FDDI standard. FDDI-II builds on original FDDI capabilities and supports integrated voice, video, and data capabilities but maintains the same transmission rate of 100 Mbps. FDDI-II therefore expands the range of applications of FDDI. FDDI-II supports both packet switched (synchronous and asynchronous) and circuit switched (isochronous) traffic. It can connect high-performance workstations, processors, and mass storage systems with bridges, routers, and gateways to other LANs, MANs, and WANs.

FIGURE 17.6.3 FDDI rings.

DQDB and SMDS

The IEEE 802 committee perceived the need for high-speed services over wide areas and formed the IEEE 802.6 MAN committee in 1982. The committee reached a consensus to use the DQDB as the standard MAC protocol. A by-product of DQDB is the switched multimegabit data service (SMDS).

The DQDB standard is both a protocol and a subnetwork. It is a subnetwork in that it is a component in a collection of networks to provide a service. The term “distributed-queue dual-bus” refers to the use of a dual-bus topology and a MAC technique based on the maintenance of distributed queues. In other words, each station connected to the subnetwork maintains queues of outstanding requests that determine access to the MAN medium. The DQDB subnetwork provides all stations on the dual bus with the knowledge of the frames queued at all other stations, thereby eliminating the possibility of collision and improving data throughput.

The DQDB subnetwork has many features, some of which make it attractive for high-speed data services. Such features include:

- *Shared media*: It extends the capabilities of shared media systems over large geographical areas.
- *Dual bus*: Its use of two separate buses carrying data simultaneously and independently makes it distinct from IEEE 802 LANs.
- *High speed*: It operates at a variety of data rates, ranging from 34 Mbps to 155 Mbps.

FIGURE 17.6.4 FDDI isolates fault without impairing the network.

- *Compatibility with legacy LANs:* It is compatible with IEEE 802.X LAN standards. A DQDB station should recognize the 16-bit and 48-bit addresses used by IEEE 802.X LAN standards. DQDB is designed to support data traffic under connectionless IEEE 802.2 LLC.
- *Fault tolerance:* It is tolerant to transmission faults when the system is configured in a loop.
- *Congestion control:* It is based on a distributed queuing algorithm as a way of resolving congestion.
- *Segmentation:* Its use of ATM technique allows long variable length packets to be segmented into short fixed-length segments. This provides efficient and effective support for small and large packets and for isochronous data.
- *Flexibility:* It uses a variety of media including coaxial cable and fiber optics. It can simultaneously support both circuit switched and packet switched services.
- *Compatibility:* It is compatible with current IEEE 802 LANs and future networks such as BISDN.

The DQDB network span of about 50 km, transmission rate of about 150 Mbps, and slot size of 53 bytes allow many slots to be in transit between the nodes. DQDB supports different types of traffic, which may be classified into two categories, isochronous and nonisochronous (asynchronous).

The DQDB dual-bus topology is shown in Fig. 17.6.6. As both buses are operational at all times, the capacity of the subnetwork is twice the capacity of each bus. In this network, nodes are connected to two unidirectional buses, which operate independently and propagate in opposite directions as shown in Fig. 17.6.6. Every node is able to send information on one bus and receive on the other bus. The head station (frame generator) generates a frame every 125 μ s to suit digitized voice requirement. The frames are continuously generated on

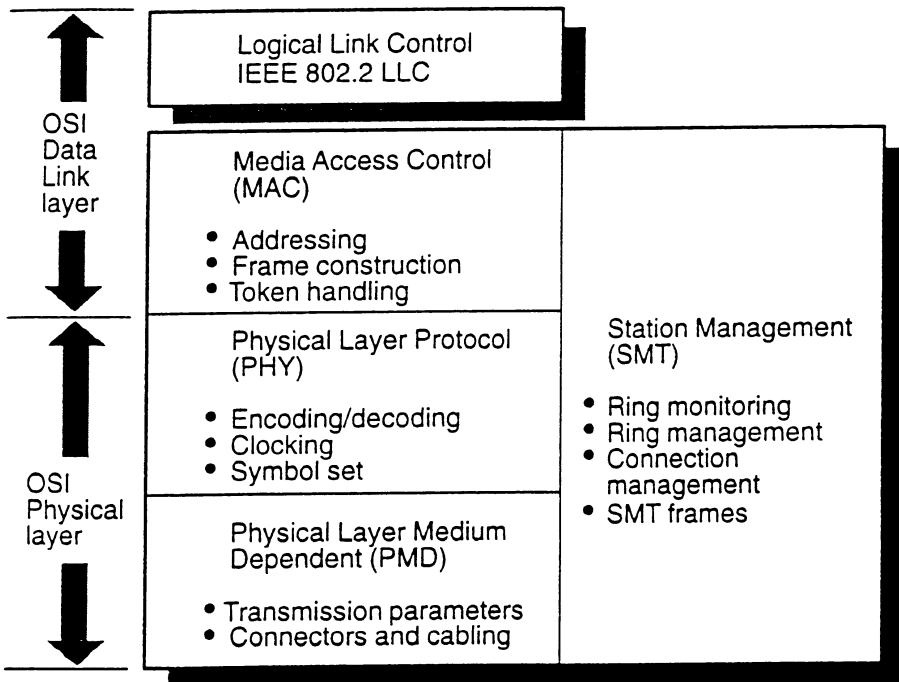

FIGURE 17.6.5 Summary of the functions of the FDDI standards.

each bus so that there is never any period of silence on the bus. The frame is subdivided into equal-sized slots. The empty slots generated can be written into by other nodes. The end station (slave frame generator) terminates the forward bus, removes all incoming slots, and generates the same slot pattern at the same transmission rate on the opposite bus. The slots are 53 octets long, the same as ATM cells, to make DQDB MANs compatible to BISDN.

SMDS represents the first broadband service to make use of DQDB MAN standard and technologies. The need for a high-speed, connectionless data service that provides both high transmission speed, low delay, and

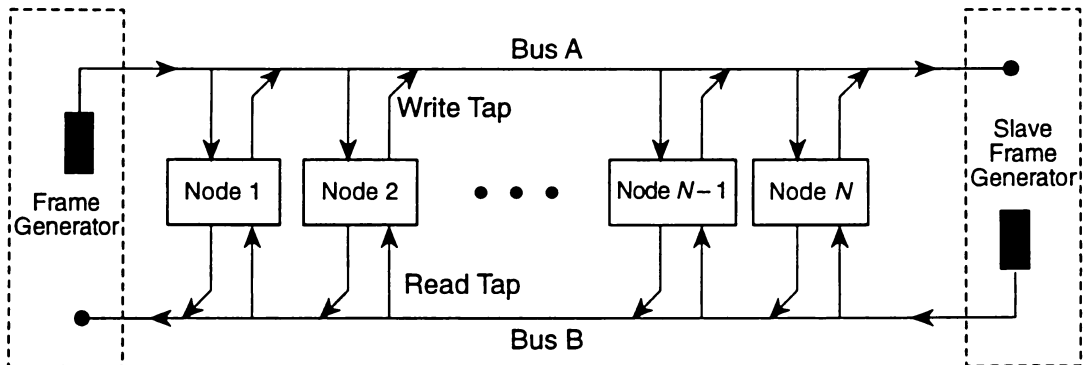

FIGURE 17.6.6 Open bus topology of DQDB network.

a simple, efficient protocol adaptation for LAN interconnection led to a connectionless data service known as *switched multisegment data service* in the United States or *connectionless broadband data service* (CBDS) in Europe. SMDS is the first service offering of DQDB. It is a cell-based, connectionless, packet-switched network that focuses on transmitting data and data only.

SMDS was developed by Bell Communications Research (Bellcore), the research arm of the seven Bell regional holding companies and popularized by the SMDS Interest Group (SIG).

SMDS is not a technology but a service. Although a DQDB can be configured as either a loop bus or an open bus, SMDS uses the open bus topology. SMDS is a connectionless, public, cell-switched data service. The service is connectionless because there is no need for setting up a physical or virtual path between two sites. SMDS offers services characteristically equivalent to LAN MAC. It operates much the same way as a LAN, but over a greater geographical area with a larger number of users.

Compared with other competing high-speed technologies such as FDDI, SMDS has no theoretical distance limitation as FDDI. FDDI's use of tokens limits the perimeter of the FDDI ring to about 60 mi. The data rate of FDDI (100 Mbps) does not match any of the standardized public transmission rate, whereas SMDS is based on standard public network speeds. FDDI will probably be used for high-speed LANs and complement SMDS rather than compete with it.

WIDE AREA NETWORKS

A WAN is an interconnected network of LANs and MANs. A WAN connects remote LANs and ties remote computers together over long distances. Computers connected to a WAN are often connected through public networks, such as the telephone system. They can also be connected through leased lines or satellites. WANs are, by default, heterogeneous networks that consist of a variety of computers, operating systems, topologies, and protocols. The largest WANs in existence is the Internet.

Because of the long distance involved, WANs are usually developed and maintained by a nation's public telecommunication companies (such as AT&T in the United States), which offer various communication services to the people. Today's WANs are designed in the most cost-effective way using optical fiber. Fiber-based WANs are capable of transporting voice, video, and data with no known restriction to bandwidth. Such WANs will remain cutting edge for years to come. There is also the possibility of connecting networks using wireless technologies.

Circuit and Packet Switching

For a WAN, communication is achieved by transmitting data from the source node to the destination node through a network of intermediate switching nodes. Thus, unlike a LAN, a WAN is a switched network. There are many types of switched networks, but the most common methods of communication are circuit switching and packet switching. Circuit switching is a much older technology than packet switching. Circuit switching systems are ideal for communications that require data to be transmitted in real time. Packet-switching networks are more efficient if some amount of delay is acceptable.

Circuit switching is a communication method in which a dedicated path (channel or circuit) is established for the duration of a transmission. This is a type of point-to-point network connection. A switched circuit is maintained while the sender and recipient are communicating, as opposed to a dedicated circuit, which is held open regardless of whether data are being sent or not. The most common circuit-switching network is the telephone system.

Packet switching is a technique whereby the network routes individual packets of data between different destinations based on addressing within each packet. A packet is a segment of information sent over a network. Any message exceeding a network-defined maximum length (a set size) is broken up into shorter units, known as packets. Packet-switching is the process by which a carrier breaks up messages (or data) into these segments, bundles, or packets by the source data terminal equipment (DTE) before they are sent. Each packet is switched and transmitted individually through the network and can even follow different routes to its destination and may arrive out of order.

Most modern WAN protocols, such as TCP/IP, X.25, and frame relay, are based on packet-switching technologies. Besides data networks such as the Internet, wireless services such as cellular digital packet data (CDPD) employ packet switching.

FIGURE 17.6.7 DTEs, DCEs, and PSEs make up an X.25 network.

X.25

For roughly 20 years, X.25 was the dominant player in the WAN packet-switching technology until frame relay, SMDS, and ATM appeared. X.25 has been around since the mid-1970s and so is pretty well debugged and stable. It was originally approved in 1976 and subsequently revised in 1977, 1980, 1984, 1988, 1992, and 1996. It is currently one of the most widely used interfaces for data communication networks. There are literally no data errors on modern X.25 networks.

X.25 is a communications packet-switching protocol designed for the exchange of data over a WAN. It is regarded as a standard, a network, or an interface protocol. It is a popular standard for packet-switching networks approved in 1976 by the International Telecommunication Union—Telecommunication Standardization Sector (ITU-T) for WAN communications. It defines how connections between user devices and network devices are established and maintained. X.25 uses a connection-oriented service that ensures that packets are transmitted in order. Through statistical multiplexing, X.25 enables multiple users to share bandwidth, as it becomes available, therefore ensuring flexible use of network resources among all users. X.25 is also an interface protocol in that it spells the required interface protocols that enable a DTE to communicate with data circuit-terminating equipment (DCE), which provides access to the network. The DTE-DCE link provides full-duplex multiplexing allowing a virtual circuit to transmit in either direction.

X.25 network devices fall into three general categories: DTE, DCE, and packet-switching exchange (PSE). DTE devices are user end systems that communicate across the X.25 network. They are usually terminals, personal computers, or network hosts, and are located on the premises of individual subscribers. DCE devices are carrier's equipment, such as modems and packet switches, that provide the interface between DTE devices and a PSE and are generally located in the carrier's facilities. PSEs are switches that compose the bulk of the carrier's network. They transfer data from one DTE device to another. Figure 17.6.7 illustrates the relationships between the three types of X.25 network devices.

The packet assembler/disassembler (PAD) is a device commonly found in X.25 networks. PADs are used when a DTE device is too simple to implement the full X.25 functionality. The PAD is located between a DTE device and a DCE device, and it performs three primary functions: buffering, packet assembly, and packet disassembly. The PAD buffers data sent to or from the DTE device. It also assembles outgoing data into packets and forwards them to the DCE device; this includes adding an X.25 header. Finally, the PAD disassembles incoming packets before forwarding the data to the DTE; this includes removing the X.25 header.

A virtual circuit is a logical connection created to ensure reliable communication between two network devices. Two types of X.25 virtual circuits exist:

- *Switched Virtual Circuits (SVCs)*: SVCs are very much like telephone lines; a connection is established, data are transferred, and then the connection is released. They are temporary connections used for sporadic data transfers.
- *Permanent Virtual Circuits (PVCs)*: A PVC is similar to a leased line in that the connection is always present. PVCs are permanently established connections used for frequent and consistent data transfers. Therefore, data may always be sent, without any call setup.

Maximum packet sizes vary from 64 to 4096 bytes, with 128 bytes being a default on most networks.

X.25 users are typically large organizations with widely dispersed and communications-intensive operations in sectors such as finance, insurance, transportation, utilities, and retail. For example, X.25 is often chosen for zero-error tolerance applications by banks involved in large-scale transfers of funds, or by government uses that manage electrical power networks.

Frame Relay

Frame relay is a simplified form of packet switching (similar in principle to X.25) in which synchronous frames of data are routed to different destinations depending on header information. It is basically an interface used for WAN. It is used to reduce the cost of connecting remote sites in any application that would typically use expensive leased circuits.

Frame relay is an *interface*, a method of multiplexing traffic to be submitted to a WAN. Carriers build frame relay networks using switches. The physical layout of a sample frame relay network is depicted in Fig. 17.6.8. The CSU/DSU is the channel service unit/data service unit. This unit provides a “translation” between the telephone company’s equipment and the router. The router actually delivers information to the CSU/DSU over a serial connection, much like the computer uses a modem, only at a much higher speed.

All major carrier networks implement PVCs. These circuits are established via contract with the carrier and typically are built on a flat-rate basis. Although SVCs have standards support and are provided by the major frame relay backbone switch vendors, they have not been widely implemented in customer equipment or carrier networks.

Two major frame relay devices are frame relay access devices (FRADs) and routers. Stand-alone FRADs typically connect small remote sites to a limited number of locations. FRAD is also known as *frame relay assembler/disassembler*. Frame relay routers offer more sophisticated protocol handling than most FRADs. They may be packaged specifically for frame relay use, or they may be general-purpose routers with frame relay software.

FIGURE 17.6.8 Physical layout of a typical frame relay network.

Frame relay is the fastest growing WAN technology in the United States. In North America it is fast taking on the role that X.25 has had in Europe. It is used by large corporations, government agencies, small businesses, and even Internet service providers (ISPs). The demand for frame relay services is exploding, and for two very good reasons—speed and economics. Frame relay is consistently less expensive than equivalent-leased services and provides the bandwidth needed for other services such as LAN routing, voice, and fax.

INTERNET

The Internet is a global network of computer networks (or WAN) that exchange information via telephone, cable television, wireless networks, and satellite communication technologies. It is being used by an increasing number of people worldwide. As a result, the Internet has been growing exponentially with the number of machines connected to the network and the amount of network traffic roughly doubling each year. The Internet today is fundamentally changing our social, political, and economic structures, and in many ways obviating geographic boundaries.

Internet Protocol Suite

The Internet is a combination of networks, including the Arpanet, NSFnet, regional networks such as NY ser-net, local networks at a number of universities and research institutions, and a number of military networks. Each network on the Internet contains anywhere from two to thousands of addressable devices or nodes (computers) connected by communication channels. All computers do not speak the same language, but if they are going to be networked they must share a common set of rules known as *protocols*. That is where the two most critical protocols, transmission control protocol/Internet-working protocol (TCP/IP), come in. Perhaps the most accurate name for the set of protocols is the *Internet protocol suite*. (TCP and IP are two of the protocols in this suite.) TCP/IP is an agreed-upon standard for computer communication over Internet. The protocols are implemented in software that runs on each node.

The TCP/IP is a layered set of protocols developed to allow computers to share resources across a network. Figure 17.6.9 shows the Internet protocol architecture. The figure is by no means exhaustive, but shows the major protocols and application components common to most commercial TCP/IP software packages and their relationship.

As a layered set of protocols, Internet applications generally use four layers:

- *Application Layer*: This is where application programs that use the Internet reside. It is the layer with which end users normally interact. Some application-level protocols in most TCP/IP implementations include FTP, TELNET, and SMTP. For example, FTP (file transfer protocol) allows a user to transfer files to and from computers that are connected to the Internet.
- *Transport Layer*: It controls the movement of data between nodes. TCP is a connection-based service that provides services need by many applications. User datagram protocol (UDP) provides connectionless services.
- *Internet Layer*: It handles addressing and routing of the data. It is also responsible for breaking up large messages and reassembling them at the destination. IP provides the basic service of getting datagrams to their destination. Address resolution protocol (ARP) figures out the unique address of devices on the network from their IP addresses.
- *Network Layer*: It supervises addressing, routing, and congestion control. Protocols at this layer are needed to manage a specific physical medium, such as Ethernet or a point-to-point line.

TCP/IP is built on connectionless technology. IP provides a *connectionless, unreliable, best-effort* packet delivery service. Information is transferred as a sequence of datagrams. Those datagrams are treated by the network as completely separate.

TCP sends datagrams to IP with the Internet address of the computer at the other end. The job of IP is simply to find a route for the datagram and get it to the other end. In order to allow gateways or other intermediate

systems to forward the datagram, it adds its own header, as shown in Fig. 17.6.10. The main things in this header are the source and destination Internet address (32-bit addresses, such as 128.6.4.194), the protocol number, and another checksum. The source Internet address is simply the address of your machine. The destination Internet address is the address of the other machine. The protocol number tells IP at the other end to send the datagram to TCP. Although most IP traffic uses TCP, there are other protocols that can use IP, so one has to tell IP which protocol to send the datagram to. Finally, the checksum allows IP at the other end to verify that

the header was not damaged in transit. IP needs to be able to verify that the header did not get damaged in transit, or it could send a message to the wrong place. After IP has tacked on its header, the message looks like what is in Fig. 17.6.10.

Addresses and Addressing Scheme

For IP to work, every computer must have its own number to identify itself. This number is called the IP address. You can think of an IP address as similar to your telephone number of postal address. All IP addresses on a particular LAN must start with the same numbers. In addition, every host and router on the Internet has an address that uniquely identifies it and also denotes the network on which it resides. No two machines can have the same IP address. To avoid addressing conflicts, the network numbers have been assigned by the InterNIC (formerly known simply as NIC).

Blocks of IP addresses are assigned to individuals or organizations according to one of three categories—Class A, Class B, or Class C. The *network* part of the address is common for all machines on a local network. It is similar to a postal zip code that is used by a post office to route letters to a general area. The rest of the address on the letter (i.e., the street and house number) are relevant only within that area. It is only used by the local post office to deliver the letter to its final destination. The *host* part of the IP address performs this same function. There are five types of IP addresses:

- *Class A format*: 126 networks with 16 million hosts each; an IP address in this class starts with a number between 0 and 127
- *Class B format*: 16,382 networks with up to 64K hosts each; an IP address in this class starts with a number between 128 and 191
- *Class C format*: 2 million networks with 254 hosts each; an IP address in this class starts with a number between 192 and 223
- *Class D format*: Used for multicasting, in which a datagram is directed to multiple hosts
- *Class E format*: Reserved for future use

The IP address formats for the three classes are shown in Fig. 17.6.11.

IPv6

Most of today's Internet uses Internet Protocol Version 4 (IPv4), which is now nearly 25 years old. Because of the phenomenal growth of the Internet, the rapid increase in palmtop computers, and the profusion of smart cellular phones and PDAs, the demand for IP addresses has outnumbered the limited supply provided by IPv4. In response to this shortcoming of IPv4, the Internet Engineering Task Force (IETF) approved IPv6 in 1997.

Class A	0	Network (7)	Host (24)
Class B	10	Network (14)	Host (16)
Class C	110	Network (21)	Host (8)

FIGURE 17.6.11 IP Address formats.

FIGURE 17.6.12 IPv6 header format.

IPv4 will be replaced by Internet Protocol Version 6 (IPv6), which is sometimes called the Next Generation Internet Protocol (or IPng). IPv6 adds many improvements and fixes a number of problems in IPv4, such as the limited number of available IPv4 addresses.

With only a 32-bit address field, IPv4 can assign only 2^{32} different addresses, i.e., 4.29 billion IP addresses, which are inadequate in view of rapid proliferation of networks and the two-level structure of the IP addresses (network number and host number). To solve the problem of severe IP address shortage, IPv6 uses 128-bit addresses instead of the 32-bit addresses of IPv4. That means IPv6 can have as many as 2^{128} IP addresses, which is roughly 3.4×10^{38} or about 340 billion billion billion unique addresses.

The IPv6 packet consists of the IPv6 header, routing header, fragment header, the authentication header, TCP header, and application data. The IPv6 packet header is of fixed length, whereas the IPv4 header is of variable length. The IPv6 header consists of 40 bytes as shown in Fig. 17.6.12. It consists of the following fields:

- *Version (4 bits)*: This is the IP version number, which is 6.
- *Priority (4 bits)*: This field enables a source to identify the priority of each packet relative to other packets from the same source.
- *Flow Label (24 bits)*: The source assigns the flow label to all packets that are part of the same flow. A flow may be a single TCP connection or a multiple of TCP connections.
- *Payload Length (16 bits)*: This field specifies the length of the remaining part of the packet following the header.
- *Next Header (8 bits)*: This identifies the type of header immediately following the header.
- *Hop Limit (8 bits)*: This is to set some desired maximum value at the source and the field denotes the remaining number of hops allowed for the packet. It is decremented by 1 at each node the packet passes and the packet is discarded when the hop limit becomes zero.
- *Source Address (128)*: The address of the source of the packet.
- *Destination Address (128 bits)*: The address of the recipient of the packet.

There are three types of IPv6 addresses:

1. Unicast is used to identify a single interface.
2. Anycast identifies a set of interfaces. A source may use an anycast address to contact any node from a group of nodes.
3. Multicast identifies a set of interfaces. A packet with a multicast address is delivered to all members of the group.

IPv6 is expected to gradually replace IPv4, with the two coexisting for a number of years during a transition period. IPv6 may be most widely deployed in mobile phones, PDAs, and other wireless terminals in the future.

BISDN AND ATM

ISDN is a high-speed communication network, which allows voice, data, text, graphics, music, video, and other source material to be transmitted simultaneously across the world using end-to-end digital connectivity. ISDN stands for Integrated Services Digital Network. “Digital network” means that the user is given access to a telecom network ensuring high-quality transmission via digital circuits, while “integrated services” refers to the simultaneous transmission of voice and data services over the same wires. This way, computers can connect directly to the telephone network without first converting their signals to an analog form using modems. This integration brings with it a host of new capabilities combining voice, data, fax, and sophisticated switching. And because ISDN uses the existing local telephone wiring, it is equally available to home and business customers. ISDN was intended to eventually replace the traditional plain old telephone service (POTS) phone lines with a digital network that would carry voice, data, and video.

ISDN service is available today in most major metropolitan areas and probably will be completely deployed throughout the United States very soon. Many ISPs now sell ISDN access. However, the idea of using existing copper wiring to provide this network decreased ISDN capabilities in reality. When the digital video systems started to develop in the 1980s, it was soon noticed that the maximum bandwidth (2.048 Mbps) of the ISDN is not enough. That is why broadband ISDN (BISDN) was born.

BISDN is a digital network operating at data rates in excess of 2.048 Mbps—the maximum rate of standard ISDN. BISDN is a second generation of ISDN. BISDN is not only an improved ISDN but also a complete redesign of the “old” ISDN, now called narrowband ISDN. It consists of ITU-T communication standards designed to handle high-bandwidth applications such as video. The key characteristic of broadband ISDN is that it provides transmission channels capable of supporting rates greater than the primary ISDN rate. Broadband services are aimed at both business applications and residential subscribers.

BISDN’s foundation is cell switching, and the international standard supporting it is *Asynchronous Transfer Mode* (ATM). Because BISDN is a blueprint for ubiquitous worldwide connectivity, standards are of the utmost importance. Major strides have been made in this area by the International Telecommunications Union-Telecommunications (ITU-T) during the past decade. More recently, the ATM Forum has advanced that agenda.

ATM is a fast packet-oriented transfer mode based on asynchronous time-division multiplexing. The words *transfer mode* say that this technology is a specific way of transmitting and switching through the network. The term *asynchronous* refers to the fact that the packets are transmitted using asynchronous techniques (e.g., on demand), and the two end points need not have synchronized clocks. ATM will support both circuit switched and packet switched services. ATM can handle any kind of information, i.e., voice, data, image, text, and video in an integrated manner.

An ATM network is made up of an ATM switch and ATM end points. An ATM switch is responsible for cell transit through an ATM network. An ATM end point (or end system) contains an ATM network interface adapter. Examples of ATM end points are workstations, routers, digital service units (DSUs), LAN switches, and video coder-decoders (CODECs). An ATM network consists of a set of ATM switches interconnected by point-to-point ATM links or interfaces. ATM switches support two primary types of interfaces: user-network interface (UNI) and network-network interface (NNI). The UNI connects ATM end systems (such as hosts and routers) to an ATM switch. The NNI connects two ATM switches.

In ATM the information to be transmitted is divide into short 53 byte packets or cells. There are reasons for such a short cell length. First, ATM must deliver real-time service at low bit rates. Thus the size allows ATM to carry multiple forms of traffic. Both time-sensitive traffic (voice) and time-insensitive traffic (data) can be carried with the best possible balance between efficiency and minimal packetization delay. Second, using short, fixed-length cells allows for time-efficient and cost-effective hardware such as switches and multiplexers.

Each ATM cell consists of 48 bytes for information field and 5 bytes for header. The header is used to identify cells belonging to the same virtual channel and thus used in appropriate routing. The ATM cell structure is shown in Fig. 17.6.13. The cell header comes in two forms: the UNI header and the NNI header. The UNI is described as the point where the user enters the network. The NNI is the interface between networks. The typical header therefore looks like that shown in Fig. 17.6.14 for the UNI. The header is slightly different for NNI, as shown in Fig. 17.6.15.

ATM is connection-oriented and connections are identified by the virtual channel identifier (VCI). A virtual channel (VC) represents a given path between the user and the destination. A virtual path (VP) is created by multiple virtual channels heading to the same destination. The relationship between virtual channels and

FIGURE 17.6.16 Relationship between virtual channel, virtual path, and transmission path.

virtual paths is illustrated in Fig. 17.6.16. A virtual channel is established at connection time and torn down at termination time. The establishment of the connections includes the allocation of a virtual channel identifier and/or virtual path identifier (VPI) and also includes the allocation of the required resources on the user access and inside the network. These resources, expressed in terms of throughput and quality of service (QoS), can be negotiated between user and network either before the call set up or during the call. Having both virtual paths and channels make it easy for the switch to handle many connections with the same origin and destination.

ATM can be used in existing twisted pair, fiber-optic, coaxial, and hybrid fiber/coax (HFC), SONET/SDH, T1, E1, T3, E3, E4, and so on, for LAN and WAN communications. ATM is also compatible with wireless and satellite communications.

Figure 17.6.17 depicts the architecture for the BISDN protocol. It is evident that the BISDN protocol uses a three-plane approach. The user plane (U-plane) is responsible for user information transfer including flow control and error control. The U-plane contains all of the ATM layers. The control plane (C-plane) manages the call-control and connection-control functions. The C-plane shares the physical and ATM layers with the U-plane, and contains ATM adaptation layer (AAL) functions dealing with signaling. The management plane (M-plane) includes plane management and layer management. This plane provides the management functions and the capability to transfer information between the C- and U-planes. The layer management performs layer-specific management functions, while the plane management deals with the complete system.

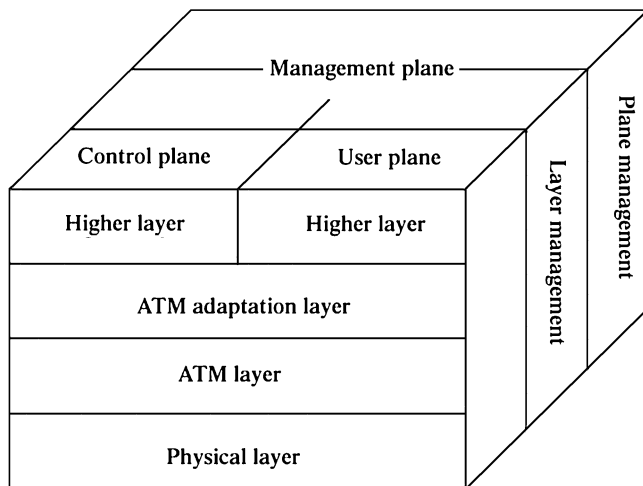

FIGURE 17.6.17 BISDN protocol reference model.

17.124 TELECOMMUNICATIONS

Figure 17.6.17 also shows how ATM fits into BISDN. The ATM system is divided into three functional layers, namely, the physical layer, the ATM layer, and the ATM adaptation layer.

BISDN access can be based on a single optical fiber per customer site. A variety of interactive and distribution broadband services is contemplated for BISDN: high-speed data transmission, broadband video telephony, corporate videoconferencing, video surveillance, high-speed file transfer, TV distribution (with existing TV and/or high-definition television), video on demand, LAN interconnection, hi-fi audio distribution, and so forth.

D. R. Means, P. J. Yankura

Telephone equipment ranges from the familiar desk or wall telephone set to the versatile communications system terminal of the information age. Telecommunications has merged with compute technologies in telephones to make available the entire spectrum of voice, data, video, and graphics. Terminal equipment now allows the exchange of this information over the telephone network.

The Telephone Set

The basic functions of the telephone set include signaling, alerting, central office supervision, and transmission of voice communications. In a typical call sequence, when the caller (the near-end party) picks up the handset, the telephone draws loop current (the telephone line is known as a *loop*) from the central office battery, which signals the central office (CO) that it wants service. The loop current also provides power for telephone functions. The caller then dials, sending address signals to the central office by either pulse or tone dialing. The CO collects the address signal in registers and sets up a transmission path with the CO for the number being called. The called CO sends an alerting signal to the called telephone, causing it to ring. When the called or far-end party picks up their handset, loop current is drawn signaling the CO to trip (interrupt) ringing and complete the talking circuit.

The functional elements of traditional telephones (Fig. 17.7.1) include a carbon transmitter to convert acoustic energy to an electrical voice signal, an electromagnetic receiver to convert the electrical voice signal back into acoustic energy, a switch hook to turn the telephone on and off, rotary dial contacts, which make and break loop current, a loop-equalizer circuit to compensate for loop resistance, a balance circuit, a hybrid transformer for coupling the transmitter and receiver to the telephone line, and an electromechanical ringer. The two-wire telephone line connections are known as Tip and Ring. The loop equalizer, balance circuit, and hybrid transformer are collectively known as the speech network. Such traditional speech networks are called *passive* networks. Electronic speech networks using solid-state components are called *active* networks.

The ringer is shown bridged across the telephone line. The capacitor C_1 blocks the flow of loop current through the ringer. Resistor R_1 and varistor V_1 constitute the loop-equalizer circuit. On long loops with low loop current, varistor V_1 maintains a high resistance and takes little current away from the rest of the speech network. On short loops, higher levels of loop current result in a lower resistance of V_1 , thereby reducing the transmit and receive levels.

FIGURE 17.7.1 Traditional passive network telephone set.

The combination of a three-winding hybrid transformer and impedance balancing circuitry provides the means of coupling the transmitter and receiver to the loop independently. This is called an *antisidetone* network. Sidetone is that portion of the transmitted signal that is heard in the receiver while talking. Sidetone is subjectively desirable because it provides the live quality of face-to-face conversation. The antisidetone network is designed to provide a sidetone signal at about the same level as received speech. If the sidetone level is too high, the talker tends to speak softly to keep the sidetone level pleasant, which results in signal strength too low for good transmission. If the sidetone level is too low, the talker perceives the telephone as dead or inoperative.

Incoming voice signals from the telephone loop are transformer coupled to the receiver. The induction voltages are such that most of the incoming signal power is delivered to the receiver with little power to the balance network. Outgoing voice signals generated by the transmitter induce voltages in two of the transformer windings that cancel each other, so that most of the signal power is divided between the balance circuit resistor R_2 and loop impedances with little to the receiver. The choice of impedance and turns ratios provides a compromise in sidetone balance and impedance matching to the telephone line. Capacitor C_2 prevents dc power from being dissipated in R_2 . Varistor V_2 helps match the balance circuit impedance to the loop impedance.

The main advantage of an active over a passive network is its smaller physical volume, lower cost, and greater versatility. An active network also provides power gain, thus allowing the use of microphones such as electrets. In the active network the gain of the transmit and receiver amplifiers can be automatically adjusted, depending on the loop current, to provide loop equalization.

FIGURE 17.7.2 Typical active-network circuit.

A basic active network is shown in Fig. 17.7.2. The base of Q_1 is returned to common (at voice frequencies) by capacitor C_1 . The emitter of Q_1 is virtual ground, since its low base impedance is divided by the transistor's beta. A received signal appearing on the telephone line is routed to the receiver through the voltage divider consisting of R_2 and R_3 ; R_2 is connected to a virtual ground. The other end of the receiver is returned to common through the low output impedance of the transmit amplifier.

The transmit signal is first amplified by the amplifier and further amplified by transistor Q_1 . The voltage gain of this common-base stage is determined by the input impedance of the telephone line and the impedance of R_1 in parallel with C_2 . The antisidetone balance is achieved by adjusting the voltage divider (R_2 and R_3) to compensate for the gain of the common-base stage, leaving about the same potential at both

FIGURE 17.7.3 Loop simulator.

ends of the receiver. Capacitor C_2 is added to minimize any phase shift through this stage caused by the capacitance of the telephone line.

Transmission

Terminal equipment is part of a transmission and signaling circuit set up by a network provider for voice frequency transmission in the range of 300 to 3300 Hz. Four important characteristics a telephone must have in order to work properly in this circuit are dc resistance (for dc powering and loop supervision), ac impedance at 1000 Hz, signal power level at both the receiver and transmitter, and audio frequency response.

A simple loop simulator is shown in Fig. 17.7.3. A ring generator (86 V, 20 Hz, 400 Ω), present only during ringing, is not shown. DC power is provided by a nominal 48-V battery. Loop current is limited by the resistance of relay coils or current limiting circuits in the central office, and by the resistance of the loop itself. Maximum loop resistance is 1300 Ω, which is 15,000 ft of 26 AWG cable. With a 300-Ω telephone, loop current is about 20 to 80 mA. At 1000 Hz the transmission cable has a characteristic impedance of 600 Ω, which the telephone should match for maximum energy transfer and minimum echo.

Typical signal levels are shown in Fig. 17.7.4. Desirable sound power at the receiver was determined by subjective testing of people. The transmitter, while converting acoustic power into electrical energy, must also amplify the energy by about 20 dB to compensate for the 20-dB loss in converting the electrical energy back into acoustic power. The loop resistance provides an attenuation of 2.8 dB/m for 26 AWG cable. Today, virtually all central offices' trunks are digital, so there is no transmission loss between them.

Telephone receivers and transmitters are designed to achieve desired frequency characteristics. For example, telephone handset microphones have a rising response characteristic near 3 kHz to compensate for capacitive shunting loss in the loop and simulate the effects of acoustic diffraction about the human head that is present in face-to-face conversation.

FIGURE 17.7.4 Transmission circuit signal levels.

Multifunction Electronic Telephones

Most new telephones are electronic. Conventional components, such as the bell ringer, the hybrid transformer, and the mechanical dial (rotary or push button) are replaced by active electronic devices that are incorporated into large-scale integrated (LSI) circuits. A typical dial-pulse electronic telephone set contains a tone ringer, an active network, an electronic dial keypad, a dial-pulsing transistor, and a low-power microphone. Several advantages result. The overall reliability of the telephone increases, automated manufacturing assembly is possible, telephone-set weight and size are reduced, and finally, overall transmission performance of the telephone is improved.

A diagram of a typical microcomputer-controlled multifunction electronic telephone is given in Fig. 17.7.5. Telephone features include last-number redial, repertory dialing, dial-tone detectors, speakerphone, integrated answer/record, hold, conference (for two-line telephones), and display of the dialed digits. Repertory dialing permits the user to store several telephone numbers in an auxiliary memory for automatic dialing. The dial circuit can produce pulse dialing or dual-tone multifrequency (DTMF) tones. The architecture often includes both general-purpose and custom LSI circuits, such as DTMF generator chips, clock (timer) chips, and display-driver chips, or it may contain one very large-scale integrated (VLSI) circuit. The microcomputer controls the operation of the various LSI circuits. The microcomputer receives information from the ringing detector, the dial keypad, function buttons, the electronic line switch, and the active network, and controls such items as the tone generator (ringer), the integrated answer/record system, the dial circuits, the display, and the speakerphone.

Electronic logic performs a variety of common switching functions, such as switching out the transmitter and lowering the gain to the receiver during dialing, functions performed by mechanical switches in traditional telephone sets. The line switch may also be electronic. The switch hook, rather than closing line circuit contacts when the handset is lifted, turns on a solid-state line switch. The user can also turn the telephone on and off electronically without having to lift the handset. Speakerphone, answer/record, and hold operations are common uses for an electronic line switch.

The media for message storage is either tape or solid-state electronic memory. Audio storage on tape uses standard tape deck recording and playback techniques. Storage in solid-state memory requires conversion to a digital format with the use of a CODEC. This digital data is stored and retrieved under control of a microprocessor. To further conserve relatively expensive memory, a DSP can be used to massage the data. Dead time is removed, and various compression algorithms are used to conserve memory. Here a trade-off is made between the amount of memory needed and the quality of the speech desired.

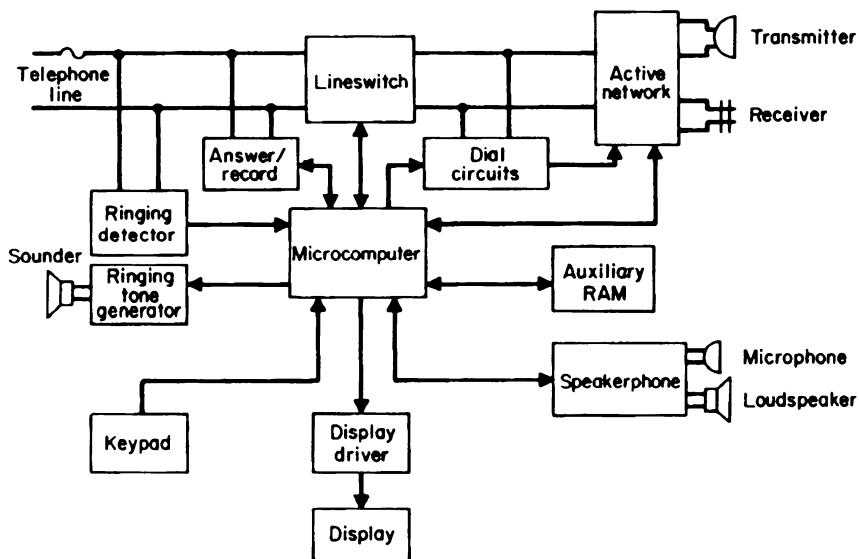

FIGURE 17.7.5 Multifunction electronic telephone.

Speakerphones must pick up much lower speech signals than a handset transmitter and must generate more acoustic energy than a handset receiver can, so it often requires more power than can be drawn over the telephone line. To prevent feedback from the loudspeaker to the microphone, the loudspeaker is muted when speech (or noise) is detected. Because the microphone must be very sensitive to pick up ordinary conversation it also picks up room reverberation, which causes speech to sound as if the speaker is in a tin can. New highly directional microphones can minimize unwanted echo and produce more natural speech.

Cordless Telephones

In a cordless telephone, the usual telephone functions are performed over a radio link, thereby eliminating the handset cord and providing the user with added mobility. A cordless telephone block diagram (Fig. 17.7.6) shows a portable handset unit, used for talking, listening, dialing, and ringing, and a fixed base unit, used for interfacing between the telephone line and radio link. More sophisticated applications include units with duplex intercoms and base units with integrated speakerphones or telephone answer/record devices.

FIGURE 17.7.6 Cordless telephone: (a) base unit and (b) handset unit.

The normal listening and talking signals as well as ringing and DTMF signaling are transmitted over a radio-frequency link as a frequency-modulated carrier. This carrier is centered in one of ten 20-kHz-wide channels with the base-to-handset channels in the 46.6- to 47-MHz band and the handset-to-base channels in the 49.6- to 50-MHz band. Before 1983 the base-to-handset link used the 1.6- to 1.7-MHz band and there were only five FCC allocated channels. As cordless telephones became more popular, interference between people using the same channel became common. To minimize the probability of hearing conversations from nearby cordless telephones on the same channel, the FCC limits the maximum radiated field strength to 10,000 (V/m at 3 m, which allows satisfactory cordless telephone performance up to 1000 ft from the base station under ideal conditions. To minimize interference, some telephones scan the available channels and choose any vacant channel found.

Typical cordless telephones employ full duplex signaling between handset and base using *frequency shift keying (FSK)* modulation of the carrier. By embedding a digital code in all exchanges of information between handset and base, it is possible to virtually eliminate false operations and ringing. A security code is also embedded to prevent access of the base unit by a neighbor's handset.

Increasing user traffic in the 46/49 MHz frequency bands has caused renewed congestion. Therefore, the FCC has allowed use of one of the commercial bands with frequencies ranging from 902 to 928 MHz, using either analog or digital modulation schemes. Units using digital communication provide a higher degree of security because they do not allow simple FM demodulation by scanners or FM receivers, thereby preventing eavesdropping. This band also has less congestion and allows better RF propagation throughout the usable area, decreasing noise and interference.

Video Telephones

New video telephones provide motion video in color over the public switched telephone network. Advancements made in audio and video compression algorithms have made this possible. See Early et al. (1993). Previous video systems required a special transmission line, making them suitable only for business users. The video telephone first establishes a talking connection with another video telephone, then video mode is entered by pressing a "video" button on each telephone. In "video" mode compressed audio and video signals are transmitted between the two telephones.

The full-duplex DSP-based modem uses a four-dimensional, 16-state trellis code and supports data rates of 19.2 and 16.8 kb/s. The 19.2 kb/s mode transmits 6 bits per baud at 3200 baud, and the 16.8 kb/s mode transmits 6 bits per baud at 2800 baud. The modem will automatically drop back to the slower speed if the error rate indicates that the connection will not support the higher speed. The speech compression is achieved using a code-excited linear prediction (CELP) algorithm that has been enhanced by incorporating fractional-pitch prediction and constrained stochastic excitation. The speech encoder operates at 6.8 kb/s.

The video signal is preprocessed to produce three separate video frames. One frame contains the luminance information with a resolution of 128 pixels by 112 lines. The other two frames contain chrominance information with resolutions of 32 pixels by 28 lines. The frames are each segmented into 16 by 16 blocks for processing. A motion estimator compares the block being processed with blocks from the previous frame, and generates an error signal based on the best match. This signal is converted to the frequency domain using the discrete cosine transform. The transformed signal is quantized, encoded, and sent to the output buffer for transmission. The transmitted frame rate is 10 frames per second using an overlay scan instead of a TV raster scan. If there is a large amount of motion, the frame rate is reduced so that the output buffer does not overflow. A button on the telephone can be used to adjust the frame rate transmitted from the distance set. However, a higher frame rate decreases the resolution of the received image. A self-view mode is also provided to allow the near-end party to view the image that is being transmitted to the far-end party.

Bell and Tone Ringers

In traditional telephones an electromechanical bell ringer is used to alert the customer to an incoming call. The typical ringer has two bells of different pitch that produce a distinctive sound when struck by a clapper driven by a moving-armature motor. The ringer coil inductance in series with a capacitor resonates at 20 Hz to provide a low-impedance path for a 20-Hz ringing signal. The high inductance of the ringer coil prevents loading of the speech network or DTMF generator when the handset is off-hook.

Other ringer connections are used when customers are on party lines and must be rung selectively. Selective ringing schemes include the connection of the ringer between the tip or ring conductors and ground, or ringers tuned to different ringing frequencies (16 to 68 Hz).

Electronic tone ringers are used in most new telephones. A resistor-capacitor circuit is bridged to the telephone line to provide the proper input impedance (defined by FCC rules) for a ring-detect chip. Tone ringers can have equivalent effectiveness and acceptability to the customer when compared to bell ringers if acoustic spectral content and loudness are adequate. Typically, the tone ringer consists of a detector circuit, which distinguishes between valid ringing signals and transients on the telephone line, and a tone generator and amplifier circuit that drives an efficient electroacoustic transducer. The transducer may be a small ordinary loudspeaker, a modified telephone receiver, or a special piezoelectric-driven sounder (see Fig. 17.7.10).

Tone and Pulse Dialers

Dial-pulse signaling interrupts the telephone line current with a series of breaks. The number of breaks in a string represents the number being dialed; one break is a 1 and 10 breaks is a 0. These breaks occur at a nominal rate of 10 pulses per second, with 600 ms between pulse trains. The ratio of the time the line current is broken to the total cycle time (percent break) is nominally 61 percent. Dial pulse signaling can be used with all central offices.

The mechanical rotary dial in the traditional telephone uses a single cam to open and close the dial contacts. The dial is driven by a spring motor that is wound up by the user as each digit is dialed. The return motion is controlled by a speed governor mechanism to maintain the proper dial-pulsing rate.

DTMF signaling consists of sending simultaneously two audio frequencies of at least 50-ms duration representing a single number, separated by at least 45-ms intervals between numbers. On the standard 4-by-3 dial format, each

column and each row is associated with a different frequency, as shown in Fig. 17.7.7. This method of signaling permits faster dialing for the user and more efficient use of the switching systems. Since the frequencies are in the audio band, they can be transmitted throughout the telephone network.

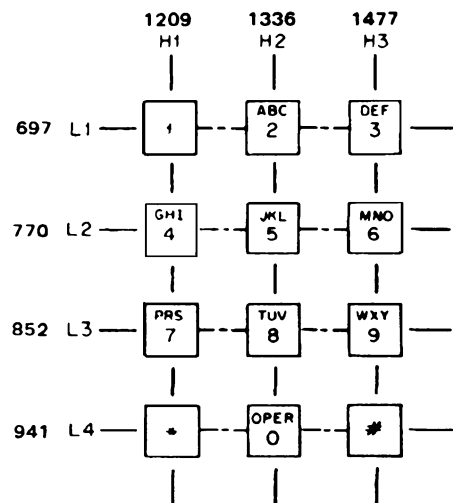

FIGURE 17.7.7 Basic arrangement of pushbuttons for dual-frequency dialing.

Pushbutton dials originally used for DTMF signaling were laid out in a rectangular format to accommodate the cranks and levers necessary to operate the mechanical switches. With modern electronic push-button dials any layout can be used, but the 4-by-3 format is still popular for its dialing speed. Pushbutton dials can perform the dial-pulse function electronically. These electronic “rotary dials” interrupt the line current with transistors or relays. Since the user can enter a number into the dial faster than the number can be pulsed out, a first-in, first-out memory is used to store the number as it is dialed. The dial-pulse timing is generated using an internal clock.

Several methods have been used to generate DTMF signals. Early methods used an inductor-capacitor oscillator with two independently tuned transformers. Different values of inductances are switched into the circuit to obtain different frequencies. Another method is a resistor-capacitor oscillator. Here a twin-tee notch filter in the feedback loop of a high-

gain amplifier gives the desired frequency. Two amplifier-filter units are used, one for each frequency group. A modern method to generate DTMF signals uses CMOS integrated circuits to use digit synthesis techniques (Fig. 17.7.8). The keypad information is combined with a master clock to generate the desired frequency. This information is fed to a D/A converter, whose output is a stair-step waveform. The waveform is filtered and fed to a driver circuit, which provides the desired sine-wave frequency signals to the telephone line.

The latest method used to generate DTMF signals is in software. If a digital speech processor is available in the product, a subroutine can be written to generate the appropriate DTMF waveform. The output is a digital word that is periodically fed to a CODEC for conversion to an analog signal. This is fed to a buffer amplifier that drives the telephone line.

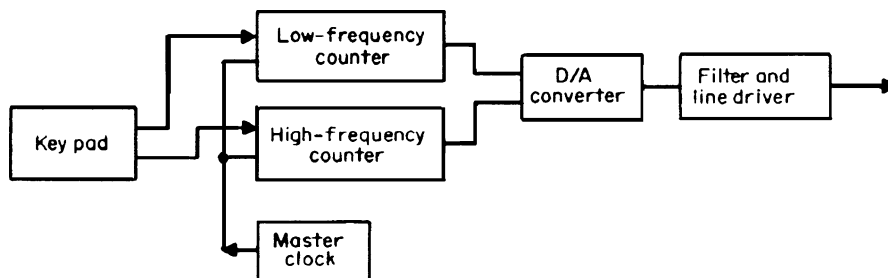

FIGURE 17.7.8 Digital-synthesis circuit.

To combine the versatility of both pulse and DTMF signaling, many telephones have the ability to switch between the two systems. This permits the user to use pulse dialing for making the telephone call and then switch to DTMF for end-to-end signaling for services such as bank-by-phone.

Microphones

The granular carbon microphone, often called a transmitter in telephony, dates back over 100 years to the birth of telephony. Sound striking the diaphragm imparts a pressure fluctuation on the carbon aggregate (Fig. 17.7.9a). Since granule contact force and dc resistance R_0 are inversely related, a modulation of the telephone loop current I_0 results. Carbon transmitters offer 20 to 25 dB of inherent signal-power gain and have a nonlinear input/output relationship that advantageously favors speech over low level background noise, but their low resistance consumes loop power. Electronic telephones require a microphone that consumes much less power.

The electret microphone is a small capacitive microphone that is widely used today. It has low sensitivity to mechanical vibrations, a low power requirement, and high reliability. An electret has no inherent gain, so requires a preamplifier. An effective bias voltage V_0 depends on a polymer diaphragm's trapped electret charge (Fig. 17.7.9b). The piezoelectric ceramic unimorph element (Fig. 17.7.10) is used as a microphone in cordless and cellular handsets. Its piezoelectric activity owes to an electrically polarized, synthetic (as opposed to natural crystal) ferroelectric ceramic. The flexural neutral axis of the structural composite is not at the ceramic's midplane; thus, vibration results in variation of the ceramic's diameter that induces a voltage across its thickness as defined through the piezoelectric constant d_{31} .

Receivers

The receiver converts the electrical voice signal back into acoustic sound pressure. Either one of the following designs is often used. The electromagnetic (moving-iron) receiver uses voice coil currents to modulate the dc flux,

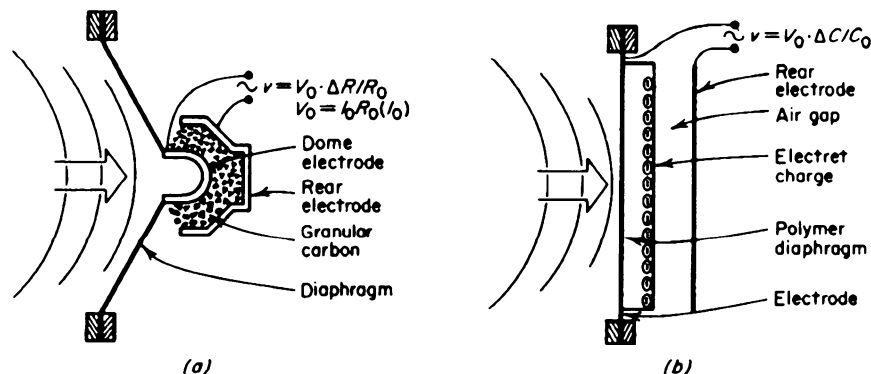

FIGURE 17.7.9 Microphones: (a) Carbon and (b) electret.

FIGURE 17.7.10 Piezoelectric ceramic unimorph.

which produces variable force on the iron armature (Fig. 17.7.11a). The electrodynamic (moving-coil) receiver uses coil current perpendicular to the dc magnetic field to generate an axial force on the movable coil (Fig. 17.7.11b). The constant (dc) reluctance of the coil air gap results in less distortion than in the electromagnetic receiver. The moving-coil unit has a lower, more nearly real impedance compared with the moving-iron design. Both of these permanent magnet devices can be used as a microphone, since their input/output is reversible.

Certain hearing aids can inductively couple to the leakage flux from receivers that generate an external magnetic field. Some receiver types (e.g., piezoelectric) must have an induction coil added to the design to provide an adequate magnetic field. Most telephones are required to provide a magnetic field (see Public Law 100-394, 1988) in order to provide the hearing impaired with access to the telephone network.

Handsets

The handset holds the microphone and receiver. It may also contain a line switch, dial keypad, and other circuits to make it a complete one-piece telephone. The handset positions the transmitter in proper location with respect to the mouth when the receiver is held on the ear. Standard dimensions for the relative mouth and ear locations have been defined (Fig. 17.7.12) for a head that is statistically modal for the population.

The handset should provide an acoustic seal to the ear, provide proper acoustic coupling for its transmitter and receiver, and be heavy enough to operate the telephone switch hook when placed on it. Handsets for hearing impaired users may also contain an amplifier and a volume control.

Protection

The user must be protected against contact with ringing voltages, lightning surges, and test signals applied to the telephone line. Telephone service personnel are trained to work on live telephone lines, but users are not. Lightning surges that are induced onto the telephone might be 1000 V peak but are of limited energy (Fig. 17.7.13). (See Carroll and Miller, 1980). Test signals applied from the central office can be up to 202 V dc.

Telephone cables, often strung on the same poles as power cables, are subject to power crosses if the power cable breaks (as in a storm) and falls on the telephone cables. The telephone company installs

FIGURE 17.7.11 Receivers: (a) central armature magnetic (moving armature) and (b) dynamic (moving coil).

FIGURE 17.7.12 Handset modal dimensions.

primary protectors at building entrances to shunt voltages from power crosses and direct lightning strikes to ground.

Extraneous signals can cause very high acoustic output from the receiver. Either a varistor, V_3 in Fig. 17.7.1, placed directly across the receiver terminals, or the telephone's circuit design is used to limit maximum acoustic output to 125 dBA.

Finally, the telephone network itself needs protection from excessive signal power, fault voltages, and other disturbances caused by the terminal equipment. Requirements for telephone network protection are contained in FCC Rules and Regulations, Part 68.

TELEPHONES WITH ADDED FUNCTIONS

Herbert M. Zydney, R. M. Sachs

Key Telephone Sets

Key telephones are designed for users who need access to more than one central-office (CO) line or PBX extension. In almost all cases, this is accomplished by the addition or illuminated keys (hence the term "key"

FIGURE 17.7.13 Induced lightning energy distribution.

telephone) to a telephone instrument. These are arranged to correspond to the line or extension and are generally illuminated to identify their status, either directly or by adjacent LEDs or LCDs. The keys can be operated independently to select the desired line. To permit switching between two calls, a hold key is provided so that the active call can be maintained in a “hold” state before operating the key associated with a different call. To allow the user to be alerted, a common audible ringer is provided, which sounds when a new call occurs on any line. Where the telephone is used as a part of a self-contained system, a key is also included so that internal, or “intercom,” calls can be made between individual key telephone sets. As technology has evolved, more features have been included in key telephones that improve the efficiency of telephone system operation. Because these newer systems are software controlled, a number of the features are not fully resident in the telephone itself, but depend on a distributed architecture to fully implement them.

Examples include:

- (a) *Memory Dialing*: Prestored telephone numbers can be dialed at either the touch of one button or by an abbreviated code from the dial pad.
- (b) *Speaker/Microphone Services*: A loudspeaker powered at the station can support hands-free dialing or, when connected to the telephone channel, permit hands-free intercom services or speaker phone operations.
- (c) *Display-Based Features*: The most advanced key telephone sets offer a display of either numeric or alphanumeric characters, sometimes augmented by graphic symbols. In conjunction with system software support, these permit users to identify who is calling them, determine the status of other telephones in the same system, and retrieve messages such as the intercom extensions of unanswered calls.

The technology used to implement key telephones presently in use is quite varied. Four categories are worth singling out:

Electromechanical Key Telephone Sets. These early-style telephones generally use electromechanical keys with a relatively large number of electrical contacts for most functions. Individual CO lines and control leads are brought to each telephone, and the actual switching of lines occurs within the telephone set. Additional wires provide control of illumination and ringing. They rely on external line-holding relay circuits and power for their operation, although standard telephone operation is possible on a stand-alone basis. A common hold button activates the external relay holding bridge for all telephones and is released when any other telephone activates its line key. Many key stations are arranged to offer visual and audible signals for status identification using varying rates of interruption for different states. For ease of installation, dedicated wires are usually grouped into 25-pair (50-conductor) cables with a standard connector. Some of the larger telephones, with dozens of line keys, can have four or more such connectors.

Key Telephone Sets with Internal Control. By adding electronic circuitry within the key telephone, many of the functions accomplished by the external relay circuitry can occur internally. Every CO line is brought to each telephone. Internally, ringing signals can be sensed and holding bridges can be applied. Complementary electronics in other telephones can sense the holding bridges and provide the necessary visual signals for multiple line states and access. Because of limitations associated with the power and sensitivity of CO lines, these key sets generally are limited to two, or at the most, four lines. External power, often rectified in the set, is required for the larger systems; smaller systems can operate from the power provided over CO loops.

Electronic Key Telephone Sets. Electronic sets (see Silverio et al., 1985) are different from the first two classes because the CO lines terminate in a centralized switch (often called a key service unit or control unit) rather than in the telephone itself. One, or sometimes two, voice paths are terminated in the telephone itself. A separate digital data link between the telephone and the control unit is used to exchange information, including what keys have been pressed and what visual and audible status information is to be presented to the user. There is little standardization in the functional definition of the conductor pairs. The voice pair generally operates at 600 Ω or 900 Ω , although the actual transmission levels may differ from standard loop levels. The digital data link may be provided on either one or two pairs and can operate from less than 1 to over 200 kb/s. Power is derived in a number of ways: the simplest is to dedicate one pair to power; alternatively, the power may be impressed on a center tap of paired transformers carrying either voice or data and removed and filtered in the telephones; lastly, the digital signals can be shaped so that they have no dc component, and the power may then be sent along with the data. Voltage of +24, +36, and -48 V are commonly used. The basis of operations within the telephone

is to scan input stimuli such as keys in real time, format messages, and then send them serially to the key service unit. Messages from the key service unit are demultiplexed and are used either to drive audible ringers or to flash lights. Advanced systems embed a cyclic redundancy check with each message to minimize false operations. Somewhat more complex message structures are involved where displays are to be updated. This approach minimizes the requirement for changes within the telephone to customize it to the user's needs. For example, software in the key service unit is responsible for determining the meaning of most keys on the telephone sets. If it is changed, only the set labels are varied. The circuitry for operating the set is implemented in a number of ways. Small 4- and 8-bit microprocessors are common, although the smallest sets use custom VLSI for their operation. Wiring is reduced to as few as two pairs, although up to four pairs are also used where a second voice path is required. Depending on the speed of transmission, twisted wire pairs without bridge taps are usually required, which makes these sets of limited use in residential locations unless the locations are rewired.

Digital Key Telephones. The most technologically advanced key telephones send and receive voice signals in digitally encoded format. See Murato et al. (1986). The standard network encoding of 64 kb/s in mu-law format is most common. The telephone contains a compatible codec that converts from analog to digital formats. As with the electronic key telephones, many designs have nonstandard interfaces. The most basic digital key telephones combine the digital data stream and the encoded voice stream on two pairs. More advanced telephones add an additional channel for binary data at speeds from 9.2 to 64 kb/s. As an option, or at times built-in, this channel appears at a standard EIA RS 232 interface, which can directly interface with compatible terminals or desktop computers. The key service unit can switch this data channel independently of the voice channel. The conductor formats vary. Some systems use two pairs, each carrying the combined voice and other signals in different directions at speeds up to about 200 kb/s. Other systems use just a single pair at speeds approximating 500 kb/s. These operate by sending information to the telephone preceded by a flag bit; the telephone synchronizes to this data stream and, at its conclusion, replies with a return message. This format is defined as time-compression multiplex in transmission terminology; informally, it is referred to as "ping-pong" because the signals go back and forth constantly. In recent years, international standards bodies have defined a new network standard, ISDN (integrated services digital network). The protocols formulated for this service network are broad enough to embrace the needs of digital key telephones. The implementation costs and flexibility of this new standard have become low enough that these protocols are now appearing in digital key telephone sets.

PC-Emulation of Key Telephone Sets

With the increasing number of desktops that have both telephones and PCs, the two are being integrated in a number of forms. In the simplest arrangement, logical connections are made between the PC and the telephone. Graphics software recreates the telephone on the face of the screen, allowing keyboard commands or mouse-and-click operations to replace buttons. Graphic displays replace the illumination of traditional telephones. A more advanced configuration builds circuitry into the PC, eliminating the requirement for a physical instrument entirely, if the PC has audio capability. User benefits include simpler operation for complex features, built-in help screens, and better integration with data bases. For example, if the PC is able to receive the incoming telephone number of the calling party, the PC screen can automatically display information about the incoming caller.

Speakerphone

A speakerphone is basically the transmission portion of a telephone set in which the handset has been replaced by a microphone and loudspeaker, typically located within a few feet of the user. This arrangement provides the user freedom to move about with hands free during a telephone conversation, as well as some reduction in fatigue on long calls. It also facilitates small-group participation on a telephone call and can be of benefit in special cases involving hearing loss and physical handicaps.

The lengthened transmitting and receiving acoustical paths in the speakerphone arrangement, compared with those of a conventional telephone, introduce loss, which can be on the order of 20 dB or more in each path. This requires that gain be added to both the transmit and receive channels over that provided in a conventional telephone. The amount of gain that can be added in each channel to compensate for the loss in the acoustical paths is limited by two problems. A "singing" problem may occur if an acoustic signal picked up by the microphone is

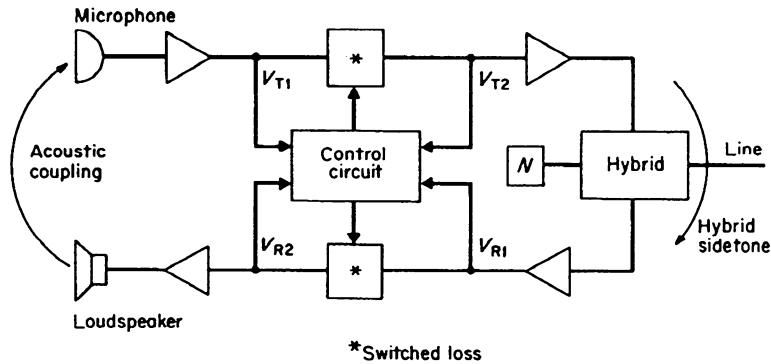

FIGURE 17.7.14 Block diagram of a voice-switched speakerphone. (Copyright American Telephone and Telegraph Co. Used by permission)

fed back to the loudspeaker via the sidetone path and returns to the microphone through acoustic coupling in the room. Singing can occur when too much gain is added in this loop. Even before reaching this condition, however, the return of room echoes to the distant talker can become highly objectionable. Echoes occur when coupling from loudspeaker to microphone causes the incoming speech to be returned to the distant party with delay.

A solution to these problems can be found in *voice switching*, in which only one direction of transmission is fully active at a time. With voice switching, a switched-loss or switched-gain element is provided in both the transmit and receive channels, which operate in a complementary fashion. In this manner, full gain is realized in the chosen direction of transmission, while margin is provided against singing and distant talker echo. Voice switching, however, results in one-way-at-a-time communication. Also, there can be a problem of clipping of a portion of the speech, since control of the voice-switching operation is derived from the speech energy itself. A functional diagram of the essential elements for a voice-switched speakerphone is shown in Fig. 17.7.14, in which a measure of the speech energy is provided to the control circuit from four distinct locations in the transmission paths. Signals V_{T1} and V_{R1} that are a measure of the speech energy in the transmit and receive paths, respectively, are compared to determine the direction of transmission to be enabled. Signal V_{T2} is used by the control circuit to guard against switching falsely into receive because of transmit energy arriving in the receive path through the hybrid sidetone circuit. Similarly, the control circuit uses V_{R2} to guard against switching falsely into transmit because of receive energy arriving in the transmit path from acoustic coupling. Many speakerphone designs do not use all four control signals directly, but equivalent functions are generally provided by other means.

Another solution to echo control and reduction that enables full duplex performance of speaker-phones is acoustic echo cancellation (AEC). With this technique, the signal driving the speakerphone's loudspeaker is compared to the signal generated by the microphone. The speakerphone builds an acoustic model to remove the acoustic echo from the microphone signal before it is transmitted over the telephone network. The use of AEC in speakerphones has been enabled by the availability of lower cost, high function digital signal processors (DSPs), and advances in adaptive signal processing needed to handle dynamic changes of the acoustic environment as people move about and room conditions change. Once the AEC is adapted, the need for switched loss is diminished and the speakerphone can attain a full-open, or full duplex, condition. This allows for very natural and fluid voice communications.

An AEC is typically placed between the control circuits of a speakerphone and the signals to and from its transducers. This effectively eliminates echoes before they pass the control circuit. Typically there is a signaling connection between the AEC and the control circuit to communicate the status of the AEC. This allows the control circuit to switch less loss when the AEC has adapted, and to prevent the AEC from adapting during periods of double-talking. Hybrid echo cancellers (see Sondhi and Presti, 1966) is typically placed between the hybrid and the control circuit of the speakerphone.

While voice switching and acoustic echo cancellation is effective in eliminating the problems of singing and distant-talker echo, it does not relieve the higher transmitted levels of room ambient noise and reverberant (barrel effect) speech caused by increased gain in the transmit channel. Both of these problems can be reduced by one or more of the following methods: (1) install the speakerphone in a quiet, nonreverberant room; (2) reduce the transmit gain and the actual talker-to-microphone distance; (3) reduce the transmit gain and the

effective talker-to-microphone distance with the use of a directional microphone; and (4) roll off the low-frequency end of the transmit response slightly to reduce the pickup of low-frequency noise and reverberant room modes, at the expense of a slight reduction in voice naturalness.

DATA TERMINALS

W. J. Lawless

Data Terminal Equipment (DTE)

Data terminals are used in a variety of data communication systems. Terminals can be classified into two categories: general-purpose terminals and special-purpose terminals. General-purpose terminals contain many elements found in a modern day personal computer (PC) and thus it is very common to use a PC to emulate a data terminal. In some applications, where cost is particularly important, a teletypewriter data terminal containing only the basic terminal elements is used as a general-purpose data terminal.

Special-purpose data terminals have been designed for a number of applications. In some cases the functionality is limited as in the case of a send-only or a receive-only terminal. Likewise, special purpose terminals are used in applications requiring special functionality such as in handheld applications and point-of-sale applications.

In either case the data terminal is used to communicate messages. Some common applications include inquiry-response, data collection, record update, remote batch, and message switching.

Data terminals are typically made up of combinations of the following modules: keyboard, CRT display, printer, storage device, and controller. These modules can be organized into the categories of operator *input-output*, terminal *control*, and *storage*.

Keyboards are available in a number of formats. In some cases, two formats are provided on the same keyboard, side by side or integrated, e.g., typewriter with a numeric pad. Future designs call for multifunction keyboards whose designations or functions can be easily changed by the user, because in many cases differently trained operators will be using the same terminal to enter different types of data for different applications. There is also a trend toward special-application keyboards, such as the cash register keyboard used by a fast food chain in which the name of each item on the menu appears on a proximity-switch plastic overlay.

CRT displays allow the operator to enter, view, and edit information; editing information with a CRT display is typically much faster than if a mechanical printer were used. The most popular CRT displays exhibit 24 lines of up to 80 characters each. Other size variations include 12 lines of up to 80 characters and a full page display (approximately 66 lines of up to 80 characters). Other features found on CRT displays include blinking, half-intensity, upper- and lowercase character sets, foreign-character sets, variable character sizes, graphic (line-drawing) character sets, and multicolor displays.

Printers for data terminals generally are classified into three types—dot-matrix, inkjet, and laser printers. Dot-matrix printers are lowest in cost but are also lowest in print speed and print quality. Laser printers are highest in cost but provide the highest print speed and quality. Inkjet devices are intermediate in cost, speed, and quality.

Storage devices for data terminals include electronic (RAM, ROM), magnetic (floppy disk, hard disk), and optical (CD-ROM). Optical storage is emerging as the most popular medium for storage and retrieval of large amounts of information, particularly in applications such as online encyclopedias, image retrieval, and large databases.

Controllers interconnect the channel interface and the various terminal components and make them interact to perform the terminals' specific functions. They also perform other functions, such as recognizing and acting on protocol commands, e.g., polling and selecting sequences in selective calling systems; code translation; and error detection and correction. Controller designs typically use microprocessors to increase their functions, including programmability, which greatly increases terminal versatility.

Standardized codes, protocols, and interfaces provide a uniform framework for the transmission and reception of data by data terminals. Codes and some character-oriented protocols and interfaces are discussed in Chap. 1.

IBM's binary synchronous communication (bisynch) protocol has been implemented widely. It accommodates half-duplex transmission and is character-oriented. Bit-oriented protocols that provide both half- and full-duplex transmission are also in widespread use. The American National Standards Institute's (ANSI) Advanced Data Communications Control Procedures (ADCCP), the International Organization for Standardization's High Level Data Link Control (HDLC), and Synchronous Data Link Control (SDLC) are the current standards for bit-oriented protocols. Although there are differences, they are generally compatible, and the trend is for other bit-oriented protocols to establish compatibility with them.

Display Terminals (Text and Graphics)

Terminals for the entry and electronic display of textual and or graphic information generally are used for communicating between people and computers and, increasingly, between people. Typical application areas include

FIGURE 17.7.15 Display-terminal organization.

computer program preparation, data entry, inquiry-response, inventory control, word processing, financial transactions, computer-aided design, and electronic mail. A terminal is divided functionally into control, display, user input, and communication-line-interface portions (see Fig. 17.7.15). The first three portions are detailed in the following sections. Interface to a communication line is typically through either an analog or digital modem.

Terminals have differing amounts of control or decision-making logic built into them. A popular classification scheme is based on terminal control capabilities. A nonintelligent ("dumb") terminal is a basic I/O and control device. Although it may have some information buffering, it must rely on the computer to which it is connected for most processing of any external information and editing of output displays. A "smart" terminal has

both information entry and editing capabilities, and although it too is generally connected to a computer, it can perform information processing locally. The terminal usually contains a microcomputer that is programmed by the terminal manufacturer to meet the general and special needs of a user. An "intelligent" terminal has a microcomputer that can be programmed by a user to meet user-specific needs (as mentioned earlier, it is very common to use a PC as a smart or intelligent terminal). Terminals can be connected to a supporting computer either directly or through a cluster controller that supervises and services the data-communication needs of a number of terminals.

The most common terminal display device is a cathode-ray tube (CRT) similar to that used in a home TV receiver. In a home TV receiver, the refreshing is done by the broadcast station, which sends 30 complete images per second. In a terminal, the refreshing must be provided by the control logic from information stored electronically in the terminal. This storage may be in a separate electronic memory or memory that is part of the microcomputer. In either case the microcomputer can address, enter, or change the information.

Flat panel displays are an alternative to the CRT. Since these devices require much less space and power, they are ideal for laptop and notebook terminals and computers. The most common technology is liquid-crystal displays (LCD). For LCD, liquid-crystal molecules in most displays align themselves parallel to an electric field and lie flat when no field is present. In another type of display, the crystals tilt in different directions in response to a field. Depending on the device construction and the type of liquid crystals used, some of those orientations allow light to pass; others block it out. The result is either a dark image on a light background or the reverse.

Most display terminals have a typewriterlike keyboard and a few extra buttons as input devices for the entry of textual and control information. Text is entered at a position on the display indicated by a special symbol called a *cursor*. The control moves this cursor along much as a typewriter head moves along as text is entered via the keyboard. Different manufacturers use different cursors (underlines, blinking squares, video-inverted characters).

To allow editing of existing images or flexible entry of additions, auxiliary control devices are provided to change the cursor position. The simplest is a set of five buttons, four of which move the cursor up, down, right, or left one character position from the current position. The fifth indicates that the cursor is to be "homed" to the upper left-hand corner of the image, where textual entry usually starts. Another popular position-controlling device is a joystick, a lever mounted on gimbals. Movement of the top of the lever is measured by potentiometers attached to the gimbals. The control senses the potentiometer outputs and moves the cursor correspondingly.

Another form of control for the cursor is the mouse. Movement of the mouse on the desktop provides a direct relationship with the movement of the cursor on the screen. A precision mouse will typically use either a magnetic or optical tablet that maps the position of the mouse on the tablet to a particular spot on the screen. A less-accurate form of the mouse uses friction between the desk surface and a ball contact on the bottom of the mouse to indicate the *relative* motion of the cursor. This form of mouse typically uses two optically sensed shafts mounted perpendicular to each other to detect movement of the ball contact. A mouse can have one to three buttons on top.

Additional input methods include track balls, pressure-sensitive pads, and even eye-position trackers. These find utility in specific areas such as artwork generation, computer image processing, industrial applications, training, and games.

Terminals intended for display of complex graphic information, e.g., for computer-aided design, generally have either tablet-stylus devices, light pens, or mice for input of new information or indication of existing information. One popular tablet-stylus has a surface area under which magneto-strictive waves are alternately propagated horizontally and vertically. A stylus with a coil pickup in the tip senses the passing of a wave under the stylus position. Electronic circuitry measures the time between launching of a wave and its sensing by the stylus and computes the position of the stylus from that time and the known velocity of the wave.

A light pen senses when light is within its field of view. In a raster-scan display, the time from the start of a displayed image until the light-pen signal is received indicates where the pen is in the raster-scan pattern and, with suitable scaling factors, gives the position of the pen over the image. In a directed-beam display, pen-position locating is more complicated. The centering of a special tracking pattern under the pen is sensed, and through a feedback arrangement controlled by the terminal computer the pattern is moved to keep it centered. The position of the pattern is then the same as the pen position.

Multimedia terminals are now becoming more commonplace. These terminals combine text, image, and voice capabilities. In the office environment, tighter coupling between data, e-mail, fax, and voice will take place. Similarly, with more of the workforce working at home, either full-time or part-time, multimedia services in the home will be required.

Data Transmission on Analog Circuits

The devices used for DTE generate digital signals. These signals are not compatible with the voice circuits of the public telephone network, partly because of frequency range but more importantly because these circuits are likely to produce a small frequency offset in the transmitted signal. The offset causes drastic changes in the received waveform. This effect, while quite tolerable in voice communications, destroys the integrity of individual pulses of a baseband signal. Compatible transmission is obtained by modulating a carrier frequency within the channel passband by the baseband signal in a modem (modulator-demodulator).

For a band-limited system, Nyquist showed that the maximum rate for sending noninterfering pulses is two pulses (usually called symbols) per second per hertz of bandwidth. The bit rate depends on how these pulses are encoded. For example, a two-level system transmits 1 b with each pulse. A four-level system transmits 2 b per pulse, an eight-level system transmits 3 b, and so forth. Unfortunately, we cannot go to an arbitrarily large number of levels because, assuming that the total power is limited, the levels will become so closely spaced that the random disturbances in the transmission medium will make one level indistinguishable from the next. Shannon's fundamental result states that there is a maximum rate, called the *channel capacity*, up to which one can send information reliably over a given channel. This capacity is determined by the random disturbances on the channel. If these random disturbances can be characterized as white Gaussian noise, the channel capacity C is given by

$$C = W \log_2 (1 + S/N)$$

where W is the bandwidth of the channel and S and N are the average signal and noise powers, respectively.

FIGURE 17.7.16 Binary (a) amplitude-, (b) frequency-, and (c) phase-modulated carrier waves.

rate, it gives much better performance in the presence of impulse noise and gain change. It is used extensively in low- and medium-speed (voice-band) telegraph and data systems.

A binary phase-modulated (PM) carrier wave is shown in Fig. 17.7.16c, where a phase change of 180° is depicted. However, this modulation method is usually employed in either four-phase or eight-phase systems. In a four-phase-change system, the binary bits are formed in pairs, called *dibits*. The dibits determine the phase change from one signal element to the next. The four phases are spaced 90° apart. In effect, this method employs a four-state signal, and such a system is inherently capable of greater transmission speeds for the same bandwidth, as is obvious from the Nyquist-Shannon criteria stated above. With improvement of voice channels, the four-phase (quaternary-phase-modulated) scheme is being employed increasingly for medium-speed (voice-band) data transmission systems to give higher transmission speeds than FM for the same bandwidth. The system is useful only in synchronous transmission.

In present-day modems FSK is the preferred modulation technique for bit rates below 1800 b/s. At 2400 b/s, the commonly used modulation technique is PSK using four phases, and at 4800 b/s it is PSK using eight phases. The latter requires the use of an adaptive equalizer, an automatically adjustable filter that minimizes the distortion of the transmitted pulses resulting from the imperfect amplitude and phase characteristics of the channel. At 9600 b/s, the preferred modulation technique is quadrature amplitude modulation, a combination of amplitude and phase modulation.

Above 9600 b/s (e.g., 19,200 and 28,800 b/s) the preferred modulation technique is quadrature amplitude modulation combined with a coding technique called trellis-coded modulation (TCM). TCM provides much improved performance at the expense of more complex implementation. CCITT Recommendation V.34 specifies this type of modulation for 19.2 kb/s.

Data Transmission on Digital Circuits

The techniques outlined in the previous section apply for transmission over the analog telephone network, sometimes referred to as public switched telephone network (PSTN). While local access to PSTN is over analog facilities (typically, twisted copper wires), the interexchange and long-distance telephone network consists principally of digital facilities. Analog signals are converted via pulse-code-modulation into digital signals for transmission over these digital facilities. If digital access to the long-distance digital facilities is provided, then end-to-end digital transmission is possible. Data signals then need not go through the digital to analog conversion outlined in the previous section, but can remain digital end-to-end (from source to destination).

An early example of an end-to-end digital system was AT&T's Digital Data System, which was deployed during the mid-1970s. Here, digital access lines together with Central Office digital multiplexers enabled transmission at rates of 2.4, 4.8, 9.6, and 56 kb/s.

With today's more elaborate commercial modulation and coding techniques it is possible to transmit data at approximately 70 percent of the capacity of the channel. With the most complex modulation and coding techniques, it is possible to get very close to the capacity of the channel, but this is achieved at the expense of considerable processing complexity and delay.

Data transmission employs all three modulation methods (amplitude, frequency, and phase) plus combinations of them. A description of these methods is given in Sec. 12.

An on-off amplitude-modulated (AM) signal is shown in Fig. 17.7.16a. This modulation scheme is little used for voice-band modems because of its inferior performance compared to other modulation schemes.

An example of a binary frequency-modulated (FM) carrier wave, sometimes called frequency-shift keying (FSK), is shown in Fig. 17.7.16b). While FM or FSK requires somewhat greater bandwidth than AM for the same symbol

Switched network digital systems are provided today via ISDN, which provide circuits at 64 and 128 kb/s. Higher bandwidth circuits and services are now being offered by various entities. Modern systems use packet-switching techniques rather than circuit-switching to enable very efficient use of the digital transmission facilities. These packet-switched systems typically use frame relay and asynchronous transfer mode (ATM) protocols.

In addition to the advances in the long-distance marketplace, changes are also taking place in the local access area. Regional Bell operating companies as well as alternate access providers are beginning to deploy local distribution systems using optical fiber and coax cable combinations. While the initial thrust for these systems is to provide multichannel video to the home, the broadband facilities also provide an excellent vehicle for broadband multimedia data services to the home.

Local Area Networks

As with wide area networks, a local network is a communication network that interconnects a variety of devices and provides a means for information exchange among those devices. See Stallings and Van Slyke (1994). There are several key distinctions between local networks and wide area networks:

1. The scope of the local network is small, typically a single building or a cluster of buildings. This difference in geographic scope leads to different technical solutions.
2. It is usually the case that the local network is owned by the same organization that owns the attached devices.
3. The internal data rates of local networks are much greater than those of wide area networks.

The key elements of a local area network are the following:

- Topology: bus or ring
- Transmission medium: twisted pair, coaxial cable, or optical fiber

TABLE 17.7.1 LAN Technology Elements

Element	Options	Restrictions	Comments
Topology	Bus	Not with optical fiber	No active elements
	Ring	Not CSMA/CS or broadband	Supports fiber, high availability with star wiring
Transmission medium	Unshielded twisted pair	—	Inexpensive; prewired; noise vulnerability
	Shielded twisted pair	—	Relatively inexpensive
	Baseband coaxial cable	—	—
	Broadband coaxial cable	Not with ring	High capacity; multiple channels; rugged
	Optical fiber	Not with bus	Very high capacity; security
Layout	Linear	—	Minimal cable
	Star	Best limited to twisted pair	Ease of wiring; availability
Medium access control	CSMA/CD	Bus, not good for broadband or optical fiber	Simple
	Token passing	Bus or ring, best for broadband	High throughput, deterministic

Source: Stallings, W. and Van Slyke, R. "Business Data Communications," Macmillan College Publishing Company, 1994.

- Layout: linear or star
- Medium access control: CSMA/CD or token passing

Together, these elements determine not only the cost and capability of the LAN but also the type of data that may be transmitted, the speed and efficiency of communications, and even the kinds of applications that can be supported. Table 17.7.1 provides an overview of these elements.

Data Communication Equipment (DCE) Trends

Most modern businesses of significant size depend heavily on their data-communications networks. Large businesses usually have a staff of specialists whose job it is to manage the network. To assist in this network-management function, DCE manufacturers have provided various testing capabilities in their products. Sophisticated DCEs now are capable of automatically monitoring their own “health” and reporting it to the centralized location where the network management staff resides. These new capabilities are frequently implemented through the use of microprocessors. Some DCEs can also establish whether a trouble is in the modem itself or the interconnecting channel. If it is the channel that is in trouble, equipment is available that automatically sets up dialed connections to be used as backup for the original channel. Another capability is to send in a trouble report automatically when a malfunction is detected.

CHAPTER 17.8

MEMS FOR COMMUNICATION SYSTEMS

D. J. Young

MEMS FOR WIRELESS COMMUNICATIONS

Introduction

The increasing demand for wireless communication applications, such as cellular telephony, cordless phone, and wireless data networks, motivates a growing interest in building miniaturized wireless transceivers with multistandard capabilities. Such transceivers will greatly enhance the convenience and accessibility of various wireless services independent of geographic location. Miniaturizing current single-standard transceivers, through a high-level of integration, is a critical step toward building transceivers that are compatible with multiple standards. Highly integrated transceivers will also result in reduced package complexity, power consumption, and cost. At present, most radio transceivers rely on a large number of discrete frequency-selection components, such as radio-frequency (RF) and intermediate-frequency (IF) band-pass filters, RF voltage-controlled oscillators (VCOs), quartz crystal oscillators, and solid-state switches, to perform the necessary analog signal processing. These off-chip devices severely hinder transceiver miniaturization. MEMS technology, however, offers a potential solution to integrate these discrete components onto silicon substrates with microelectronics, achieving a size reduction of a few orders of magnitude. It is therefore expected to become an enabling technology to ultimately miniaturize radio transceivers for future wireless communications.

MEMS Variable Capacitors

Integrated high-performance variable capacitors are critical for low noise VCOs, antenna tuning, tunable matching networks, and so on. Capacitors with high quality factor (Q), large tuning range, and linear characteristics are crucial for achieving system performance requirements. On-chip silicon pn junction and MOS-based variable capacitors suffer from low quality factors, limited tuning range, and poor linearity, and are thus inadequate for building high-performance transceivers. MEMS technology has demonstrated monolithic variable capacitors achieving stringent performance requirements. These devices typically rely on an electrostatic actuation method to vary the air gap between a set of parallel plates or vary the capacitance area between a set of conductors or mechanically displace a dielectric layer in an air-gap capacitor. Improved tuning ranges have been achieved with various device configurations. Capacitors fabricated through using metal and metalized silicon materials have demonstrated superior quality factors compared to solid-state semiconductor counterparts. Besides the above advantages, micromachined variable

FIGURE 17.18.1 Micromachined RF switch: (a) switch up; (b) switch down.

capacitors suffer from a reduced speed, potentially a large tuning voltage, and mechanical thermal vibration commonly referred to as Brownian motion, which deserves great attention when used to implement low phase noise VCOs.

MEMS Switches

The microelectromechanical switch is another potentially attractive miniaturized component offered by micro-machining technologies. These switches offer superior electrical performance in terms of insertion loss, isolation, linearity, and so on and are intended to replace off-chip solid-state counterparts switching between the receiver and transmitter signal paths. They are also critical for building phase shifters, tunable antennas, and filters. The MEMS switches can be characterized into two categories: capacitive and metal-to-metal contact types. Figure 17.8.1 presents the cross-sectional schematic of an RF MEMS switch. The device consists of a conductive membrane, typically made of aluminum or gold alloy suspended above a coplanar electrode by a few micrometers air gap. For RF or microwave applications, actual metal-to-metal contact is not necessary; rather, a step change in the plate-to-plate capacitance realizes the switching function. A thin silicon nitride layer with a thickness on the order of 1000 Å is typically deposited above the bottom electrode. When the switch is in on-state, the membrane is high, resulting in a small plate-to-plate capacitance; hence, a minimum high-frequency signal coupling (high isolation) between the two electrodes. The switch in the off-state with a large enough applied dc voltage, however, provides a large capacitance owing to the thin dielectric layer, thus causing a strong signal coupling (low insertion loss). The capacitive switch consumes near-zero power dissipation, attractive for low power portable applications. Superior linearity performance has also been demonstrated because of the electromechanical behavior of the device. Metal-to-metal contact switches are important for interfacing large bandwidth signals including dc. This type of device typically consists of a cantilever beam or clamped-clamped bridge with a metallic contact pad positioned at the beam tip or underneath bridge center. Through an electrostatic actuation, a contact can be formed between the suspended contact pad and an electrode on the substrate underneath. High performance on a par with the capacitive counterparts has been demonstrated. Microelectromechanical switches, either capacitive or metal contact versions, exhibit certain drawbacks including low switching speed, high actuation voltage, sticking phenomena due to dielectric charging, metal-to-metal contact welding, and so on, thus limiting device life time and power handling capability. Device packaging with inert atmosphere (nitrogen, argon, and so on) and low humidity is also required.

MEMS Resonators

Microelectromechanical resonators based on polycrystalline silicon comb-drive fingers, suspended beams, and center-pivoted dick configurations have been proposed for performing analog signal processing. These micro-resonators can be excited into mechanical resonance through an electrostatic drive. The mechanical motion will cause a device capacitance change resulting in an output electrical current when a proper dc bias voltage is applied. This output current exhibits the same frequency as the mechanical resonance, thus achieving an electrical filtering function through the electromechanical coupling. The resonators can obtain high-quality factors close to 10,000 in vacuum with operating frequencies above 150 MHz reported in literatures and size reduction by a few orders of magnitude compared to discrete counterparts. These devices with demonstrated performance are attractive for potentially implementing low-loss IF band-pass filters for wireless transceivers design. Future research effort is needed to increase the device operating frequency up to gigahertz (GHz) range. As with other MEMS devices, the micromachined resonators also have certain drawbacks. For example, vacuum packaging is required to achieve a high-quality factor for building low loss filters. The devices may also suffer from a limited dynamic range and power-handling capability. The mechanical resonant frequency is strongly dependent on the structure dimensions and material characteristics. Thus, a reliable tuning method is needed to overcome the process variation effect and inherent temperature sensitivity.

Micromachined Inductors

Integrated inductors with high-quality factors are the key components for implementing low noise oscillators, low loss matching networks, and so forth. Conventional on-chip spiral inductors suffer from limited quality factors around 5 at 1 GHz, an order of magnitude lower than the required values from discrete counterparts. The poor performance is mainly caused by substrate loss and metal resistive loss at high frequencies. Micromachining technology provides an attractive solution to minimize these loss contributions; hence enhancing the device quality factors. Q factors around 30 have been achieved at 1 GHz matching the discrete component performance. Three-dimensional coil inductors have been fabricated on silicon substrates by micromachining techniques. Levitated spiral inductors have also been demonstrated. All these devices exhibit three common characteristics: (1) minimizing device capacitive coupling to the substrate, (2) reducing winding resistive loss through employing highly conductive materials, and (3) nonmovable structures upon fabrication completion.

MEMS FOR OPTICAL COMMUNICATIONS

Introduction

High-speed communication infrastructures are desirable for transferring and processing real-time information such as voice and video. Optical fiber communication technology has been identified as the critical backbone to support such systems. High-performance optical data switching network, which routes various optical signals from their sources to destinations, is one of the key building blocks for system implementation. At present, optical signal switching is performed by using hybrid optical-electronic-optical (O-E-O) switches. These devices convert incoming lights from input fibers to electrical signals first and then route them to the proper output ports after signal analyses. At the output ports, the electrical signals are converted back to streams of photons or optical signals for further transmission over the fibers to their next destinations. The O-E-O switches are expensive to build, integrate, and maintain. Furthermore, they consume a substantial amount of power and introduce additional latency. It is therefore highly desirable to develop all-optical switching network in which optical signals can be routed without intermediate conversion into electrical form, thus minimizing power dissipation and system delay. While a number of approaches are being considered for building all-optical switches, MEMS technology is attractive for providing arrays of tiny movable mirrors, which can redirect incoming beams from input fibers to corresponding output fibers. These micromirrors can be batch fabricated using silicon micromachining technologies, achieving a low-cost integrated solution. A significant reduction in power dissipation is also expected.

MEMS Mirrors

Various micromachined mirrors have been developed over the years. They can be typically divided into two categories: (1) out-of-plane mirrors and (2) in-plane mirrors. The out-of-plane mirrors are usually fabricated by polycrystalline silicon surface micromachining techniques. After sacrificial release, the mirror structures can be folded out of the substrate and position secured by silicon hinges. The mirror surface can be moved by an electrostatic vibromotor, comb-drive fingers, and other electrostatic means. These mirrors can achieve one degree of freedom and thus are attractive for routing optical signals in a two-dimensional switching matrix and also for raster-scanning display applications. The in-plane mirrors are typically fabricated using a thick single crystal silicon layer on the order of a few tens micrometers from a SOI wafer by deep RIE and micromachining techniques. The thick structural layer minimizes mirror warping, critical for high-performance optical communication applications. Self-assembly technique relying on deposited film stress has also been employed to realize lifted-up micromirror structures. The mirror position can be modulated by a vertical actuation of comb-drive fingers and electrostatic pads or a lateral push-pull force. Micromirrors with two degrees of freedom have also been demonstrated by similar techniques. These mirrors with an analog actuation and control scheme are capable of directing optical beams to any desired position, and are thus useful for implementing large three-dimensional optical switching arrays to establish connections between any set of fibers in the network.

No other invention in the twentieth century has impacted virtually every aspect of our life like the digital computer. The hardware along with software have forever changed how we work with everything from the automobile to our checking accounts. It goes to the deepest parts of our oceans and planet to well beyond our solar system. In spite of how pervasive and sophisticated they are, they remain fairly simple and straight forward devices (although anyone who works with them regularly could easily argue with us on this point). An understanding of the material in this section should allow us to work with many hardware and software challenges.

Computers are organized into basic activities. This is referred to as the architecture of the computer as well as the software. The first part to look at is data processing. Data are merely the representation of something in the real world such as money by their binary equivalent. After we look at the rest of the architecture of the computer we will look at how these can be varied in the design process to produce different types of computer activities.

Next we look at how software can control the interactions of the hardware to produce the desired results. Keep in mind that even though there are a number of different software packages that we use, they all do essentially the same things and all that is different is really just the syntax of the specific application.

Future trends in this field will essentially focus on two areas. The first will be in the area of how we interact with computer and input and output data. We already have the ability to use handwritten interaction and voice interaction. It is in the area of verbal interaction with the computer where we will most likely see the end of the keyboard as we know it. Current voice interactive software can achieve accuracies of 97 percent with training. This compares favorably with keyboard input and is decidedly faster for everyone but the most skilled typist.

The other area will be in the basic architecture of both the hardware and software. Increasingly we are developing portions of the computer into parallel processors that will enable a major shift in the way software will be developed. Eventually we will have computers that come from a manufacturer with a defined hardware and software architecture. Once the computer is turned on it will begin reconfiguring its hardware and software to adapt to the needs of the user. C.A.

CHAPTER 18.1

COMPUTER ORGANIZATION

PRINCIPLES OF DATA PROCESSING

Memory, Processing, and Control Units

The basic subsystems in a computer are the input and output sections, the store, arithmetic logic unit (processing unit), and the control section. Each unit is described in detail in this chapter. Generally, a computer operates as follows: An external device such as a disc file delivers a program and data to specific locations in the computer store. Control is then transferred to the stored program, which manipulates the data and the program itself to generate the output. These output data are delivered to a device, such as a CD-ROM/RW, DVD, printer, or display, where the information is used in accordance with the purpose of the digital manipulation.

Historical Background

There has been a line of development of mechanical calculator components, beginning with Babbage in the early 1800s and leading to a variety of mechanical desk and larger mechanical calculators. Another line of development has used relays as computing circuit elements. Today's computers have benefited from these lines of development, but especially they are based on electronic components, the vacuum tube, and the transistor. The transistor, first described by Shockley, Bardeen, and Brattain in 1947, began a line of development that is today characterized by the miniaturization and low-power operation of very large-scale integration (VLSI).

VLSI permits the interconnection of large numbers of computing elements by means of microscopic layered structures on a semiconductor substrate (usually silicon) or *chip* sometimes as small as $1/4$ in. square. Since the entire arithmetic and logic circuit of a computer can be built on a single chip (microprocessor), computers incorporating VLSI are often called *minicomputers* or *microcomputers*.

Binary Numbers

Most transistors display random variations of their operating parameters over relatively wide limits. Similarly, passive circuit elements experience a considerable degree of variation, and noise and power-supply variations, and so forth, limit the accuracy with which quantities can be represented. As a result, the preferred method is to use each circuit in the manner of an on-off switch, and representation of quantities in a computer is thus almost always on a *binary* basis. Figure 18.1.1 shows the binary numbers equivalent to the decimal numbers between 1 and 10. Figure 18.1.2 shows the addition of binary 6 to binary 3 to obtain binary 9.

The process of addition can be dissected into digital, logical, or boolean operations upon the binary digits, or bits (b). For example, a first step in the procedure for addition is to form the so-called EXCLUSIVE-OR addition between bits in each column. This function of two binary numbers is expressed in Fig. 18.1.3a in tabular form. This table is called a *truth table*. In Fig. 18.1.3b is the table used to generate the *carries* of a binary

FIGURE 18.1.3 Addition tables for decimal and binary numbers. The binary addition table (a) is called the EXCLUSIVE-OR or module-2 truth table; the carry table (b) performs the AND or intersection operation.

bit from one column to another. This latter function of two binary numbers is variously called the AND function, *intersection*, or *product*. The entries at each intersection in each table are the result of the combination of two binary numbers in the respective row and column. Figure 18.1.3 also shows the decimal addition tables. They illustrate the relative simplicity of the binary number system.

The names truth table and logical function arise from the fact that such manipulations were first developed in the *sentential calculus*, a subsection of the calculus of logic, dealing with the truth or falsity of combinations of true or false sentences.

Binary Encoding. Information in a digital processing machine is not restricted to numerical information since a different specific numeric code can be assigned to each letter of the alphabet. For example, A in the *EBCDIC code* (see next paragraph) is given by the binary sequence 11000010. When alphanumeric information is specified, such a code sequence represents the symbol A, but in the numeric context the same entry is the binary number equal to decimal 194.

Computer Codes

Alphanumeric information is stored in a computer via coded binary bits. Some of the more useful codes are:

ASCII (American Standard Code for Information Interchange), a seven-level alphanumeric code comprising 32 control characters, an uppercase and lowercase alphabet, numerals, and 34 special characters (Fig. 18.1.4). This code is used in personal computers and non-IBM machines. "A" in ASCII is given by the 7-bit binary codes 1000001.

BCDIC (binary-coded decimal interchange code), a six-level alphanumeric code that provides alphabetic (caps), numeric, and 28 special characters.

Binary code, a representation of numbers in which the only two digits used are 0 and 1, and each position's value is twice that of its right-hand neighbor (with the rightmost place having a value of 1).

Binary-coded decimal (BCD) code, in which the first ten 4-bit (hexadecimal) codes are used for the decimal digits, and each nibble represents one decimal place. Codes A through F are never used.

EBCDIC (expanded BCD interchange code), an eight-level alphanumeric code comprising control codes, an uppercase and lowercase alphabet, numerals, and special characters (Fig. 18.1.5). This code is used in IBM mainframe computers.

Gray code, a binary code that does not follow the positional notation of true binary code. Only one bit changes from any Gray number to the next.

Hexadecimal byte code, a two-digit hexadecimal number for each byte, with values ranging from 00 to FF.

Hexadecimal code, a base-16 number code that uses the letters A, B, C, D, E, and F as one-digit numbers for 10 through 15.

Hollerith code, a 12-level binary code used on punchcards to represent alphanumeric characters. Holes on the punchcard are ones, unpunched positions are zeros.

FIGURE 18.1.4 American Standard Code for Information Interchange (ASCII).

Most computers are designed to work internally in binary fashion but at each juncture of input or output to translate the codes, either by programming or by hardware, so as to accept and offer decimal numeric information. Such systems are complicated, and failures in the coding and decoding system can prevent interaction with the program.

Communication needs lead to a compromise between the human requirement for a decimal system and the machine requirement for binary. An example is the use of the base-16 (hexadecimal) system, which is relatively amendable to human recognition and manipulation. The binary code is broken into 4-bit groups. Each 4-bit group is represented by a decimal numeral or letter, as indicated in Fig. 18.1.6. In this case, 0011 is three, and 1010 is ten or A.

Error-Correction Codes

Though the circuits in modern digital systems have reached degrees of reliability undreamed of in the relatively recent past, errors can still arise. Hence it is desirable to detect and, if possible, correct such errors. It is

possible by appropriate selection of binary codes to detect errors. For example, if a 6-b code is used, a seventh bit can be added to maintain the number of 1 bits in the group of 7 as an odd number. When any group of 7 with an even number of 1s is found by appropriate circuits in the machine, an error is detected. Such a procedure is known as *parity checking*. Although these error-control coding schemes were originally developed for noisy transmission channels, they are also applicable to storage devices in data-processing systems.

Boolean Functions

Figure 18.1.7 illustrates truth tables for functions of one, two, and three binary variables. Each x entry in each table can be either 0 or 1. Hence for one variable x four functions $f(x)$ can be formed; for two variables x_1 and x_2 , 16 functions $f(x_1, x_2)$ exist; for three variables, 256 functions, and so on. In general, if $f(x_1, \dots, x_n)$ is a function of n binary variables, 2^{2^n} such functions exist.

For functions of one variable, the most important is the *inverse function*, defined in Fig. 18.1.8. This is called NOT A or \bar{A} , where A is the binary variable. Also illustrated in Fig 18.1.8 are the two most important functions of two binary variables, the AND (*product* or *intersection*) and the OR (*sum* or *union*). If A and B are the two variables, the AND function is usually represented as AB and the OR as $A + B$.

Figure 18.1.9 shows how the products AB , $\bar{A}B$, $A\bar{B}$ and $\bar{A}\bar{B}$ are summed to yield any function of two binary variables. Each of these products has only one 1 in the four positions in their respective truth tables, so that appropriate sums can generate any function of two binary variables. This concept can be expanded to functions of more than two variables, i.e., any function of n binary variables can be expanded into a sum of products of the variables and their negatives. This is the general theorem of boolean algebra. Such a sum is called the *standard sum* or the *disjunctive normal form*.

The fact that any binary function can be so realized implies that mechanical or electrical simulations of the AND, OR, and NOT functions of binary variables can be used to represent any binary function whatever.

FIGURE 18.1.7 Binary functions of (a) one, (b) two, and (c) three binary variables.

FIGURE 18.1.8 Significant functions of one and two binary variables: (a) the negation (NOT) function of one binary variable; (b) the OR function of two binary variables; (c) the AND function of two binary variables.

FIGURE 18.1.9 The four products of two binary variables (top). The realization of the EXCLUSIVE-OR function is shown below.

Electronic Realization of Logical Functions

Logical functions can be realized using electronic circuits. Figure 18.1.10 illustrates the realization of the OR function and Fig. 18.1.11 illustrates the realization of the AND circuit using diodes. Each input lead is associated with a boolean variable, and the upper level of voltage represents the logical 1 for that variable; in the OR circuit, any input gives rise to an output. Thus for a three-variable input, the output is $A + B + C$. With the AND function no output is realized unless all inputs are positive; the output function generated is ABC .

The inverse function (NOT) of a boolean variable cannot be readily realized with diodes. The circuit shown in Fig 18.1.12 uses the inverting property of a grounded-emitter transistor amplifier to perform the inverse function. Also shown in Fig. 18.1.12 is an example of how the OR function and the NOT function are combined to form the NOT-OR (NOR) function. In this case, since the transistor circuit provides both voltage and current gain, the signal-amplitude loss associated with transmission through the diode can be compensated, so that successive levels of logic circuits can be interconnected to form complex switching nets.

Figure 18.1.13 illustrates the realization of the EXCLUSIVE-OR function. Note that the variables are represented by the wiring of interconnected circuit blocks, while the function is realized by the circuit blocks themselves.

Levels of Operation in Data Processing

A detailed sequence of operations is generally required in a data-processing system to realize even simple operations. For example, in carrying out addition, a machine typically performs the following sequence of operations:

FIGURE 18.1.10 Diode realization of an OR circuit. A positive input on any line produces an output.

FIGURE 18.1.11 Diode realization of an AND circuit. All inputs must be positive to produce an output.

FIGURE 18.1.12 Use of a transistor circuit for inverting a function. The circuit shown forms the NOT-OR (NOR) of the inputs.

1. Fetch a number from a specific location in storage.
 - a. Decode the address of the program instruction to activate suitable memory lines. Such decoding is accomplished by activating appropriate AND and OR gates to apply voltage to the lines in storage specified by the instruction address.
 - b. Sequence storage to withdraw the information and place it in a storage output register.
 - c. Transmit information from the storage output register into the appropriate ALU.

2. Withdraw a number from storage and add it to the number in the ALU. These operations break down into:
 - a. Decode the instruction address, activate storage lines, and transmit the information to the ALU input for addition.
 - b. Form the EXCLUSIVE-OR of the second number with the number in the ALU to form the sum less the carry. Form the AND of the two numbers to develop the first-level carry.
 - c. Form the second-level EXCLUSIVE-OR sum.
 - d. AND the first-level carry with the first-level EXCLUSIVE-OR sum to form the second-level carry.
 - e. Generate the third-level EXCLUSIVE-OR by forming the EXCLUSIVE-OR of the second-level carry with the second-level EXCLUSIVE-OR sum, AND the second-level carries with the second-level EXCLUSIVE-OR for the third-level carry and so forth until no more carries are generated.

3. Store the result of the addition into a specified location in storage.

This sequence illustrates two basic types of operation in a data-processing machine. Operations denoted above by numbers are of specific interest to the programmer, since they are concerned with the data stored and the operations performed thereupon. The second level, denoted above by letters, are operations at the logical-circuit level within the machine. These operations depend on the particular configurations of circuits and other hardware in the machine at hand.

FIGURE 18.1.13 Circuit realization of the EXCLUSIVE-OR function.

If only the higher-level (numbered) instructions are used, some flexibility in machine operation is lost. For example, only an add operation is possible at the higher level. At the lower-level (lettered) operations the AND or EXCLUSIVE-OR of the data words can be formed and placed in storage.

The organization of current digital computers follows the lines of these two divisions (numbered and lettered, above). The *macroinstruction set* associated with each machine can be manipulated by the programmer. These instructions are usually implemented in a numerical code. For example, the instruction “load ALU” might be 01 in binary. “Add ALU” might be given by 10 and “store ALU” by 11. Similarly, each instruction has an associated storage address to provide source data. The microinstruction set comprises a series of suboperation that is combined in various sequences to realize a given macroinstruction.

Two methods of realizing the sequence of suboperations specified by the operations portion of the instruction have been used in machine design. In one such method a direct decoding of the information from the instruction occurs when it is placed in an instruction address register. Specific clock sequences turn on the successively required lines that have been wired in place to realize the action sought.

An alternative for actuating a subprogram is to store a number of information bits, called *microinstructions*, that are successively directed to the appropriate control circuits to activate selectively and sequentially individual wires to gate sequential actions for the realization of the requisite instruction.

The first method of computer design is called *hard-wired*, and the second is the *microprogrammed*. The microprogram essentially specifies a sequence of operations at the individual circuit level to specify the operations performed by macroinstructions. Microprogramming is preferred in modern computer designs.

Types of Computer Systems

There is a wide variety of computer-system arrangements, depending on the type of application. One type of installation is that associated with *batch processing*. A computer in a central job location receives programs from many different sources and runs the programs sequentially at high speed. An overall supervisory program, called an *operating system*, controls the sequence of programs, rejecting any that are improperly coded and completing those which are correct.

Another type of system, the *time-shared system*, provides access to the computer from a number of remote input-output stations. The computer scans each remote station at high speed and accepts or delivers information to that location as required by the operator or by its internal program. Thus a small terminal can gain access to a large high-speed system.

Still another type of installation, the *microcomputer*, involves an individual small computer that, though limited in power, is dedicated to the service of a single operator. Such applications vary from those associated with a small business, with limited computational requirements, to an individual engaged in scientific operations.

Other computers are used for dedicated control of complex industrial processes. These are individual, once-programmed units that perform a *real-time* operation in *systems control*, with sensing elements that provide the inputs. Highly complex interrelated systems have been developed in which individual computers communicate with and control each other in an overall major *systems network*. Among the first of such systems was the SAGE network, developed in the 1950s for defense against missile or aircraft attack.

Computers that are interconnected to share workload or problems are said to form a *multiprocessing system*. A computer system arranged so that more than program can be executed simultaneously is said to be *multiprogrammed*.

Interactive systems allow users to communicate directly with the computer and have the computer respond. The development of these systems parallels that of the keyboard and of the video display. The systems are used commercially (e. g., airline reservations) and scientifically (users input data at their terminals or telephones and get a response to their input). The *terminal*, a widely used input/output device, has a keyboard and a visual display. A terminal may be *dumb*, which means that it has no computing power, or *smart*, which indicates computing capabilities, such as those provided by a personal computer. *Client-server* systems are interactive systems where the data are at a remote computer called a server.

Internal Organization of Digital Computers

The internal organization of a data-processing system is called the *system architecture*. Such matters as the minimum addressable field in memory, the interrelations between data and instruction word size, the instruction format and length or lengths, parallel or serial (by bit or set of bits) ALU organization, decimal or binary internal organization, and so forth, are typical questions for the system architect. The answers depend heavily on the application for which the computer is intended.

Two broad classes of computer systems are *general-purpose* and *special-purpose* types. Most systems are in the general-purpose class. They are used for business and scientific purposes. General-purpose computers of varying computer power and memory size can be grouped, sharing a common architecture. These are said to constitute a *computer family*.

A computer scientifically designed for, and dedicated to the control of, say, a complex refinery process is an example of a special-purpose system.

A number of design methods have been adopted to increase the speed and functional range for a small increase in cost. For example, in the instruction sequence, the next cell in storage is likely to be the location of the next instruction. Since an instruction can usually be executed in a time that is short compared with storage access, the store is divided into subsections. Instructions are called from each subsection independently at high speed and put into a queue for execution. This type of operation is called *look-ahead*. If the instructions are not sequential, the queue is destroyed and a new queue put in its place.

Since instructions and data tend to be clustered together in storage, it is advantageous to provide a small, high-speed store (local store) to work with a larger, slower-speed, lower-cost unit. If the programs in the local store need information from the larger store, a least-used piece of the local store reverts to the larger store and a batch of data surrounding the information sought is automatically brought into the high-speed unit. This arrangement is called a *hierarchical memory* and the high-speed store is often called a *cache*.

NUMBER SYSTEMS, ARITHMETIC, AND CODES

Representation of Numbers

A set of codes and names for numbers that meets the requirements of expendability and convenience of operation can be obtained using the following power series:

$$N = A_n X^n + A_{n-1} X^{n-1} + \cdots + A_1 X + A_0 + A_{-1} X^{-1} + \cdots + A_{-m} X^{-m} \quad (1)$$

Here the number is represented by the sum of the powers of an integer X , each having a coefficient A_i . A_i may be an integer equal to or greater than zero and less than X . In the decimal system, X equals 10 and the coefficients A_i range from 0 to 9.

Note that Eq. (1) can be used to represent X^{m+n+1} numbers ranging between 0 and $X^{n+1} - X^m$ with an accuracy limited by X^m . Thus m and n must be of reasonable size to be useful in most applications. A useful property of the power series is the fact that its multiplication by X^k can be viewed as a shift of the coefficients of any given term by the number of positions specified by the value of k . These results are independent of the choice of X in the series representation.

There is little reason to write the value of the number in the form shown in Eq. (1) since complete information on the value can be readily deduced from the coefficient A_i . Thus, a number can be represented merely by a sequence of the values of the coefficients. To determine the value of the implied exponents on X , it is customary to mark the position of the X_0 term by a period immediately to the right of its coefficient. The power series for a number represented in the decimal system ($X = 10$) and its normal decimal notation are

$$3 \times 10^3 + 0 \times 10^2 + 2 \times 10^1 + 4 \times 10^0 + 6 \times 10^{-1} + 2 \times 10^{-2} = 3,024.62 \quad (2)$$

The value of X is called the *radix* or *base* of the number system. Where ambiguity might arise, a subscript to indicate the radix is attached to the low-order digit, as in $1000_2 = 8_{10} = 10_8$ (1000 binary equals 8 decimal equals 10 octal). The power series for a number in base 2 and its representation in binary notation is

$$1 \times 2^4 + 1 \times 2^3 + 0 \times 2^2 + 1 \times 2^1 + 1 \times 2^0 + 0 \times 2^{-1} + 1 \times 2^{-2} + 1 \times 2^{-3} = 11011.011 \quad (3)$$

Number-System Conversions

Since computer systems, in general, use number systems other than base 10, conversion from one system to another must be carried out frequently. Equation (4) shows the integer N represented by a power series in base 10 and base 2

$$\sum_{i=0}^n A_i 10^i = \sum_{j=0}^m B_j 2^j \quad (4)$$

The problem is to find the correlation between the coefficients A_i and B_j . In the binary series, if N is divisible by 2, then B_0 must be 0. Similarly, if N is divisible by 4, B_1 must be 0, and so forth. Thus if the decimal coefficients A_i are given, successive divisions of the decimal number by 2 will yield the binary number, the binary digits depending on the value of the remainder of each successive division. This process is shown in Fig. 18.1.14.

The conversion of a binary integer to a decimal integer is

$$\begin{aligned} 100011011 &= 1 \times 2^8 + 0 \times 2^7 + 0 \times 2^6 + 0 \times 2^5 \\ &\quad + 1 \times 2^4 + 1 \times 2^3 + 0 \times 2^2 + 1 \times 2 + 1 \times 2^0 \\ &= 283 \end{aligned}$$

In the case of conversion of an integer in binary to an integer in decimal, the powers of 2 are written in decimal notation and a decimal sum is formed from the contribution of each term of the binary representation. For conversion from a binary fraction to a decimal fraction, a similar procedure is used since the value of terms as multiplied by the A_i can be added together in decimal form to form the decimal equivalent.

The conversion of a decimal fraction to a binary fraction is defined by

$$0.5764_{10} = A_{-1}2^{-1} + A_{-2}2^{-2} + \dots + A_{-n}2^{-n} \quad (5)$$

To determine the values of the A_i , first multiply both sides of Eq. (27.5) by 2 to give

$$1.1528_{10} = A_{-1} + A_{-2}2^{-1} + \dots + A_{-n}2^{n-1} \quad (6)$$

Since the position of the decimal point (more accurately called the *radix point*) is invariant, and since in a binary series each successive term is at most half of the maximum value of the preceding term, the leading 1 in the decimal number in Eq. (6) indicates that A_{-1} must have been 1. A second multiplication by 2 can similarly determine the coefficient A_{-2} . This process of conversion of a base-10 fraction to a base-2 fraction is illustrated in Fig. 18.1.15.

Conversion from binary integers to octal (base 8) and the reverse can be handled simply since the octal base is a power of 2. Binary to octal conversion consists of grouping the terms of a binary number in threes and replacing the value of each group with its octal representation. The process works on either side of a decimal point. The octal-to-binary conversion is handled by converting each octal digit, in order, to binary and retaining the ordering of the resulting groups of three bits.

Since there are not enough symbols in decimal notation to represent the 16 symbols required for the hexadecimal system, it is customary in the data processing field to use the first six letters of the alphabet to complete the set.

Conversions from decimal to octal or hexadecimal can proceed indirectly by first converting decimal to binary and then binary to octal or hexadecimal. Similarly, a reverse path from octal or hexadecimal to binary to decimal can be used. Direct conversions, however, between hexadecimal and octal and decimal exist and are widely used. In going from hexadecimal or octal to decimal, each term in the implied power series is expressed directly in decimal, and the result is summed. In converting from a decimal integer to either hexadecimal or octal, the decimal is divided by either 16 or 8, respectively, and the remainder becomes the next higher-order digit in the converted number. Examples of four common number representations are shown in Table 18.1.1.

Binary-Arithmetic Operations

Figure 18.1.16 shows an example of the addition of two binary numbers, 1001 and 1011 (9 and 11 in decimal). The rules for manipulation are similar to those in decimal arithmetic except that only the two symbols 1 and 0 are used and the addition and carry tables are greatly simplified.

Figure 18.1.17 shows an example of binary multiplication with a multiplication table. This process is also simple compared with that used in the decimal system. The rule for multiplication in binary is as follows: if a particular digit in the multiplier is 1, place the multiplicand in the product register; if 0, do nothing; in either case shift the product register to the right by one position; repeat the operations for the next digit of the multiplier.

Figure 18.1.18 shows an example of binary subtraction and the subtraction and borrow tables. The subtraction table is the same as the addition table, a feature unique to the binary system. The borrow operation is handled in

FIGURE 18.14 Conversion from a decimal to binary by repeated division of the decimal integer. At each division the remainder becomes the next higher-order binary digit.

FIGURE 18.15 Conversion of a decimal fraction into a binary fraction. At each stage the number to the right of the decimal is multiplied by 2. The resulting number to the left of the decimal point is entered as the next available lower-order position of the binary fraction to the right of the binary radix point.

TABLE 18.1.1 Comparison of Decimal, Binary, Octal, and Hexadecimal Numbers

Decimal	Binary	Octal	Hexadecimal	Decimal	Binary	Octal	Hexadecimal
0	0	0	0	8	1000	10	8
1	1	1	1	9	1001	11	9
2	10	2	2	10	1010	12	A
3	11	3	3	11	1011	13	B
4	100	4	4	12	1100	14	C
5	101	5	5	13	1101	15	D
6	110	6	6	14	1110	16	E
7	111	7	7	15	1111	17	F

Binary	=	Decimal
1011	=	11
+ 1001	=	9
10100	=	20

FIGURE 18.1.16 Binary addition and corresponding decimal addition.

0	0
1	0

FIGURE 18.1.17 Binary multiplication. The binary multiplication table is the AND function of two binary variables. The process of multiplication consists of merely replicating and adding the multiplicand, as shown, if a 1 is found in the multiplier. If 0 is found, a single 0 is entered and the next position to the left in the multiplier is taken up.

a fashion analogous to that in decimal. If a 1 is found in the preceding column of the subtrahend, it is borrowed, leaving a 0. If a 0 is found, an attempt is made to borrow from the next higher-order position, and so forth.

An example of binary division is

101	√	111110	6	√	30
		101			
		101			
		101			
		101			
		0			

The procedure is as follows:

1. Compare the divisor with the leftmost bits of the dividend.
2. If the divisor is greater, enter a 0 in the quotient and shift the dividend and quotient to the left.
3. Try subtraction again.
4. When the subtraction yields a positive result, i.e., the divisor is less than the bits in the dividend, enter a 1 in the quotient and shift the dividend and the quotient left one position.
5. Return to step 1 and repeat.

Binary division, like binary multiplication, is considerably simpler than the decimal operation.

Subtraction by Complement Addition

If subtraction were performed by the usual method of borrowing from the next higher order, a separate subtraction circuit would be required. Subtraction can be performed, however, by the method of *adding complements*

Binary	Decimal	<i>A - B, less borrow</i>	<i>A - B, borrow</i>
100110	38	01	01
- 1001	9	0 01	0 00
11101	29	1 10	1 10

FIGURE 18.1.18 Binary subtraction and corresponding decimal subtraction. The subtraction table is the same as the addition table. The borrow operation is handled analogously to decimal subtraction.

(or adding 1's complements, as the method is also called). By this method, the *subtrahend*, i.e., the number that is to be subtracted, is *inverted*, changing the 0s to 1s and the 1s to 0s. Then the inverted subtrahend is added to the *minuend*, i.e., the number that is to be subtracted from, and an additional 1 is added to find the difference. As an example, consider the subtraction $1101 - 1001$. The subtrahend (1001) is first inverted to form the complement (0110). The difference is formed by adding the minuend and the complement of the subtrahend (plus 0001) as follows: $1101 - 1001 = 1101 + 0110$ (complement) $+ 0001 = (1)0011 + 0001 = 0100$. Note that in subtraction by complement addition, a leading 1 (in parentheses) in the result (difference) must be suppressed, and that 1 must be added to obtain the result. The result of this operation can be verified by observing that the decimal equivalent of this operation is $13 - 9 = 3 + 1 = 4$.

Floating-Point Numbers

In a computer having a fixed number of bits that define a word, the bits represent the maximum size of a numerical value. For example, if 40-bit positions are provided for a word, the maximum decimal number that can be represented is in the order of 1.009×10^{12} . Though this number is large, it does not suffice for many applications, especially in science, where a greater range of magnitudes may be routinely encountered. To extend the range of values that can be handled, numbers are represented in floating-point notation. In floating point the most significant digits of the number are written with an assumed radix point immediately to the left of the highest-order digit. This number is called the *fraction*. The intended position of the radix point is identified by a second number, called the *characteristic*, which is appended to the fraction: The characteristic denotes the number of positions that the assumed radix point must be shifted to achieve the intended number. For example, the number 146.754 in floating point might be 146754.03 where 146754 would be equivalent to 0.146754 and the 0.03 would denote a shift of the decimal point three places to the right. In binary notation the number 11011.011 (27.375 in decimal) might be represented in floating point as 11011011.101 with the fraction again to the left of the decimal and the characteristic to the right.

With floating-point addition and subtraction, a shift register is required to align the radix points of the numbers. To perform multiplication or division, the fraction fields are appropriately multiplied or divided and the exponents summed or subtracted, respectively. As with fixed-point addition or subtraction, provision is usually made to detect an overflow condition in the characteristic fields. In some systems provision is made to note when an addition or subtraction occurs with such widely differing characteristics that justification destroys one of the two numbers (by shifting it out the end of a shift register).

Numeric and Alphanumeric Codes

The numeric codes used to represent numerical values previously discussed include the hexadecimal, octal, binary, and decimal codes. In many applications the need arises for the coding of nonnumeric as well as numeric information, and such coding must use the binary scheme. A code embracing numbers, alphabetic characters, and special symbols is known as an *alphanumeric code*.

A widely used code with its roots in the past is the telegraph code (the Baudot code). Other alphanumeric codes have been devised for special purposes. One of the most significant of these, because of its present use and its contribution to the design of other codes, is the Hollerith code, developed in the 1890s. Hollerith's equipment contributed to the development of electromechanical accounting machines that provided the foundation for electronic computers.

Another code of importance in the United States is the American Standard Code for Information Interchange (ASCII) (see Fig. 18.1.19). This code, developed by a committee of the American National Standards Institute (ANSI), has the advantage over most other codes of being *contiguous*, in the sense that the binary combination used to represent alphanumeric information is sequential. Hence alphabetic sorting can be easily accomplished by arithmetic manipulation of the code values.

Codes used for data transmission generally have both data characters and *control characters*. The latter perform control functions on the machine receiving information. In more sophisticated codes, such as

	000	001	010	011	100	101	110	111

ASCII, these control functions are greatly extended and hence are applicable to machines of different design.

Other Numeric Codes. Not all numeric information is represented by binary numbers. Other codes are also used for numeric information in special applications. Figure 18.1.20 shows a widely used code called the *reflected* or *Gray* code. It has the property that only 1 b is changed between any two successive values, irrespective of number size. This code is used in digital-to-analog systems since there is no need for propagation of carry integers in sequential counting as in a binary code.

FIGURE 18.1.21 Two-dimensional parity checking, in which a single error can be corrected and a triple error detected.

Error Detection and Correction Codes

The integrity of data in a computer system is of paramount importance because the serial nature of computation tends to propagate errors. Internal data transmission between computer-system units takes place repeatedly and at high speed. Data may also be sent over wires to remote terminals, printers, and other such equipment. Because imperfections of transmission channels inevitably produce some erroneous data, means must be provided to detect and correct errors whenever they occur.

A basic procedure for error detection and correction is to design a code in which each word contains more bits than are needed to represent all the symbols used in a data set. If a bit sequence is found that is not among those assigned to the data symbols, an error is known to have occurred.

One such commonly used error-detection code is called the *parity check*. Suppose that 8 bits are used to represent data and that an additional bit is reserved as a check bit. A simple electronic circuit can determine whether an even or odd number of 1 bits is included in the eight bit positions. If an even number exists, a 1 can be inserted in the check position. If an odd number of 1s exist, the check position contains a 0. As a result all code words must contain an odd number of 1 bits. If a 9-b sequence is found to contain an even number of 1s, an error can be presumed.

Decimal digit	Position						
	1	2	3	4	5	6	7
0	0	0	0	0	0	0	0

7	0	0	0	1	1	1	1
8	1	1	1	0	0	0	0
9	0	0	1	1	0	0	1

Parity checks 8, 4, 2, 1 code

FIGURE 18.1.22 A Hamming code. The parity bit in column 1 checks parity in columns 1, 3, 5, and 7; the bit in column 2 checks 2, 3, 6, and 7; and the bit in column 4 checks 4, 5, 6, and 7. The overlapping structure of the code permits the correction of a single error or the detection of single or double errors in any code word.

There are limitations in the use of the simple parity check as a mechanism for error detection, since in many transmission channels and storage systems there is a tendency for a failure to produce simultaneous errors in two adjacent positions. Such an error would not be detected since the parity of the code word would remain unchanged.

To increase the power of the parity check, a list of code words in a two-dimensional array can be used, as shown in Fig. 18.1.21. The code words in the horizontal dimension have a parity bit added, and the list in the vertical dimension also has an added parity bit, in each column. If one bit is in error, errors appear in both the row and the column. If simultaneous errors occur in two adjacent positions of a code word, no parity error will show up in that row, but the column checks will detect two errors. This code can detect any 3-b errors.

It is possible to design codes that can detect directly whether errors have occurred in two bit positions in a single code word. Figure 18.1.22 shows such a code, an example of a *Hamming* code. The code positions in columns 1, 2, and 4 are used to check the parity of the respective bit combinations. Two code words of a Hamming code must differ at three or more bit positions, and therefore any 2-b error patterns can be detected. The pattern formed by the particular parity bits that show errors indicates which bit is in error in the case of a single bit failure.

In general, if two code words must differ at D or more bit positions, the code can detect up to $D - 1$ bit errors. For $D = 2t + 1$, the code can detect $2t$ bit errors or correct t bit errors.

COMPUTER ORGANIZATION AND ARCHITECTURE

Introduction

Over the past 40 years great progress has been made as component technology has moved from vacuum tubes to solid-state devices to large-scale integration (LSI). This has been achieved as a result of increased understanding of semiconductor materials along with improvements in the fabrication processes. The result has been significant enhancement in the performance of the logic and memory components used in computer construction along with significant reductions in cost and size. Figure 18.1.23, for example, indicates the reduction in volume of main memory that has occurred in the last 40 years. The volume required to store 1 million characters has been reduced by a factor of 3 million in that period. Similarly, during that same period, the system cost to execute a specific mix of instructions has also decreased by a factor of 5000. Integrated circuit manufacturers are able to incorporate millions of transistors in the area of a square inch. Large-scale integration (LSI) and VLSI have led to small-size, lower cost, large-memory, ultrafast computers ranging from the familiar PC to the high-performance, high-priced supercomputers. There is no reason to expect that this progress will not continue into the future as new technology improvements continue to occur.

These advances in component technology have also had a major impact on computer organization and its realization. Functions and features that were too expensive to be included in earlier designs are now feasible, and the trade-offs between software and hardware need to be reevaluated as hardware costs continue to decrease. New approaches to computer organization must also be considered as technology continues to improve. The advances in component technology also have had a major impact on such aspects of computer realization as packaging, coding, and power.

Basic Computer Organization

The basic organization of a digital computer is shown in the block diagram of Fig. 18.1.24. This structure was proposed in 1946 by von Neumann. It is a tribute to his genius that this design, which was intended for use in

FIGURE 18.1.23 The reduction by a factor of 6400 in memory size from the first- to the fourth-generation families of IBM computers.

solving differential equations, has also been applicable in solving other types of problems in such diverse areas as business data processing and real-time control. Von Neumann recognized the value of maintaining both data and computer instructions in storage and in being able to modify instructions as well as data. He recognized the importance of branch or jump instructions to alter the sequence of control of computer execution. His contributions were so significant that the vast majority of computers in use today are based on his design and are called von Neumann computers.

The four basic elements of the digital computer are its *main storage*, *control unit*, *arithmetic-logic unit* (ALU), and *input/output* (I/O). These elements are interconnected as shown in Fig. 18.1.24. The ALU, or *processor*, when combined with the control unit, is referred to as the *central processing unit* (CPU).

Main storage provides the computer with directly addressable fast-access storage of data. The storage unit stores programs as well as input, output, and intermediate data. Both data and programs must be loaded into main storage from input devices before they can be processed.

The control unit is the controlling center of the computer. It supervises the flow of information between the various units. It contains the sequencing and processing controls for instruction decoding and execution and for handling interrupts. It controls the timing of the computer and provides other system-related functions.

The ALU carries out the processing tasks specified by the instruction set. It performs various arithmetic operations as well as logical operations and other data processing tasks.

Input/output devices, which permit the computer to interact with users and the external world, include such equipment as card readers and punches, magnetic-tape units, disc storage units, display devices, keyboard terminals, printers, teleprocessing devices, and sensor-based devices.

FIGURE 18.1.24 Block diagram of a digital computer illustrating the main elements of the von Neumann architecture.

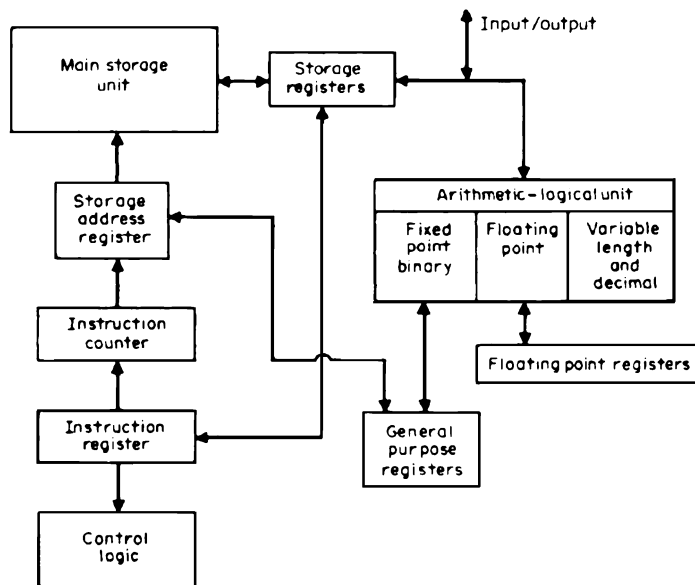

FIGURE 18.1.25 Basic structure of a digital computer showing a typical register organization and interconnections.

Detailed Computer Organization

The block diagram of Fig. 18.1.25 provides an overview of the basic structure of the digital computer. Computer systems are complex, and block diagrams cannot describe the computer in sufficient detail for most purposes. One is therefore forced to go to lower levels of description. There are at least five levels^{66a} that can describe the implementation of a computer system:

1. Processor-memory-switch (block-diagram) level
2. Programming level (including the operating system)
3. Register-transfer level
4. Switching-circuits level
5. Circuit or realization level

Each of these levels is an abstraction of the levels beneath it. A number of computer-hardware description languages have been developed to represent the components used in each level along with their modes of combination and their behavior.

A *register* is a device capable of receiving information, holding it, and transferring it as directed by control circuits. The actual realization of registers can take a number of forms depending on the technology used. Registers store data temporarily during a program's execution. Some registers are accessible to the user through instructions.

Registers are found in every element of the computer system. They are an integral part of main storage, being used as storage registers to contain the information being transferred from memory (read) or into memory (write) as well as storage address registers (SAR) to hold the address of the location in storage involved in the information transfer. In the control unit, the instruction (or program) counter contains the storage address of the instruction to be executed while the instruction register holds the instruction being decoded and executed.

In the ALU internal registers are used to hold the operands and partial results while arithmetic and logical operations are being performed. Other ALU registers, called *general-purpose registers*, are used to accumulate

the results of arithmetic operations but can be used for other purposes such as indexing, addressing, counting looping operations, or subroutine linkage. In addition, floating-point registers may be provided to hold the operands and accumulate the results of arithmetic operations on floating-point numbers. Of all the registers mentioned, only the general-purpose and floating-point registers are accessible to program control and to the programmer. Figure 18.1.25 shows the primary registers and their interconnections in the basic digital computer.

At the register transfer level of abstraction one can describe a digital computer as a collection of registers between which data can be transferred. Logical operations can be applied to the data during the transfers. The sequencing and timing of the transfers are scheduled and controlled by logic circuits in the control unit.

The data transferred between registers within the computer consist of groups of binary digits. The number of bits in the group is determined by the computer architecture and in particular by the organization of its main storage. Main storage is structured into segments, called bytes, and each storage word is uniquely identified by a number, called its *address*, assigned to it. A byte consists of 8 binary bits and is the standard for describing memory elements. Many computers read groups of bytes (2, 4, 6, 8) from memory in one access. A group of bytes is referred to as a word, which can vary in length from one computer to another. A memory access is a sequence to read data from memory or store it into memory. The 1s and 0s can be interpreted in various ways. These bit patterns can be interpreted as: (1) a pure binary word, (2) a signed binary number, (3) a floating-point number, (4) a binary-coded decimal number, (5) data characters, or (6) an instruction word.

In a signed binary number the high-order (leftmost) bit indicates the sign of the number. If the bit is 0, the number is positive; a 1 indicates it is negative. Thus

0b7 bits represents a positive 7-bit number

1b7 bits represents a negative 7-bit number

A negative number is carried in 2's-complement (inverted) form. For example,

$$11111110_2 = 2^{10}$$

A binary-coded decimal code uses 4 b to represent a decimal digit. It uses the binary digit combinations for 0 to 9; combinations greater than 9 are not allowed. Thus

$$0101_2 = 5_{10} \quad 1010_2 = \text{illegal}$$

The sign of the decimal number can be indicated in several ways. One technique uses the low-order bits to indicate the sign; for example,

bbbbb100 represents a positive 3-digit number

bbbbb1011 represents a negative 3-digit number

Thus, $0001010100111011_2 = -153_{10}$.

For external communication, as well as text processing and other nonnumeric functions, the digital computer must be able to handle character sets. The byte has been accepted as the data unit for representing character codes. The two most common codes, described earlier, are the American Standard Code for Information Interchange (ASCII) and the Extended Binary-Coded Decimal Interchange Code (EBCDIC). The 16-b word 11000111110010110 coded in EBCDIC represents the two-letter word "go." (See Figs. 18.1.4, 18.1.5, and 18.1.9).

The *instruction word* is composed of two major parts, an *operation part* and an *operand part*. The length of the instruction word is determined by the computer architecture. Some computers have a single format for their instruction words and thus a single length, whereas other computers have several formats and several different lengths. The operation part consists of the operation code that describes the particular operation to be performed by the computer as a result of executing that instruction. The operand part usually contains the addresses of the two operands involved in the operation. For example, the RR (register-to-register) instruction format in the System/370 is

Op Code	Reg 1	Reg 2
bbbbbbbb	bbbb	bbbb
0 7	8 11	12 15

The instruction 1AB4 (in hexadecimal), for example, instructs the computer to add the contents of register 11 to the contents of register 4 and to put the resulting sum in register 11, replacing its original contents. Most computers use the two-address instruction with three sections: The first section consists of the op-code and the second and third sections each contain an address of an operand. Different computers use these addresses differently. In some cases, the operand section is used as a modifier or to extend the instruction length. A single-operation computer has two sections—an op code and an operand, usually a memory address, with the accumulator the implied source or destination.

Two facts should be noted. First, the discussion thus far may have implied that digital computers can deal only with fixed-length words. That is true for some computers, but other families of computers can also deal with variable-length words. For these, the operand part of the instruction contains the address of the first digit or character of each variable-length word plus a measure of its length, i.e., the number of characters it contains. The second fact is that it is impossible to distinguish between the various data representations when they are stored. For example, there is nothing to indicate whether a word of memory contains a binary number or a binary-coded decimal (BCD) number. Programmers must make the distinction in the programs they develop and not attempt meaningless operations such as adding a binary number to a decimal number. The only way the computer distinguishes an instruction word from other data words is by the time when, as discussed in the next section, it is read from storage into the control unit.

Instruction Execution

The digital computer operates in a cyclic fashion. Each cycle is called a *machine cycle* and consists of two main subcycles, the *instruction (I) cycle* (sometimes called the *fetch cycle*) and the *execution (E) cycle*. During the machine cycle, the following basic steps occur in sequence (see Fig. 18.1.25):

1. The cycle begins with the I cycle:
 - a. The contents of the instruction counter are transferred to the storage address register (SAR). (The instruction counter holds the address of the next instruction to be executed.)
 - b. The specified word is transferred from storage to the instruction register. (The control unit assumes that this storage word is an instruction.)
 - c. The contents of the instruction register are decoded by logical circuits in the control unit. This identifies the type of operation to be performed and the locations of the operands to be used in the operation.
2. At this point, the E cycle begins:
 - a. The specified computer operation is performed using the designated operands, and the result is transferred to the location indicated by the instruction.
 - b. The instruction counter is advanced to the address of the next instruction in the sequence. (If a branch, or change in execution control sequence, is to occur, the contents of the instruction counter are replaced by an address as directed by the instruction currently being executed.)
3. At this point, the I cycle is repeated.

To indicate in more specific terms what happens in the CPU during instruction execution it is necessary to go to the switching level of description. The following paragraphs describe of the operations of the ALU and the control section in more detail.

Arithmetic Logic Unit

The ALU performs arithmetic and logical operations between two operands, such as OR, AND, EXCLUSIVE-OR, ADD, MULTIPLY, SUBTRACT, or DIVIDE. The unit may also perform operations such as INVERT on only one operand, and it tests for minus or zero and forms a complement.

Adders and multipliers are at the heart of the ALU. In Fig. 18.1.26 one bit position of an ALU is shown as part of a wider data path. One latch (part of a register *A*) feeds an AND circuit that is conditioned by a CONTROL *A*. The output feeds INPUT *A* of the adder circuits. One latch of register *B* is also ANDed with CONTROL *B* and feeds the other input into the adder. A true-complement circuit is shown on the *B* line. This latter circuit has to do with subtraction and can be assumed to be a direct connection when adding. Each adder stage is a combinatorial circuit that accepts a carry from the stage representing the next lower digit in the binary number (assumed to be on the right). The collection of outputs from all adder stages is the sum. This sum is ANDed into register *D* by CONTROL *D*.

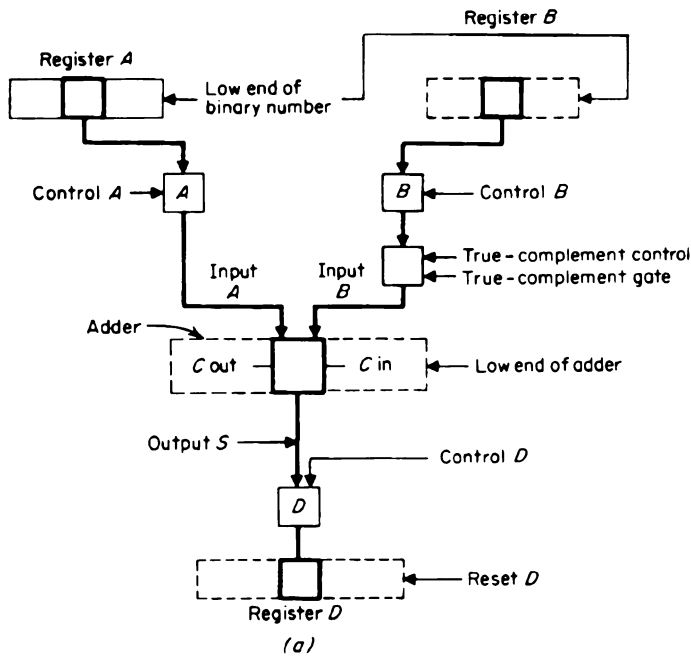

FIGURE 18.1.26 Basic addition logic. The heart of the ALU is the adder circuit shown in functional form in (a). The control section applies the appropriate time sequence of pulses (b) on the control to perform addition. Heavy lines indicate a repeat of circuitry in each bit position to form a machine adder.

All bit positions of each of the registers are gated by a single control line. If the gate is closed (control equal to 0), all outputs are 0s. If the gate is open (control equal to 1), the bit pattern appearing in the register is transmitted through the series of AND circuits to the input of the adders. Thus, a gate is a two-way AND circuit for each bit position. The diagram of Fig. 18.1.26 illustrates all positions of an n -position adder since all positions are identical. In such a case heavy lines, as shown, indicate that this one line represents a line in each bit position.

Binary Addition

At the outset of an addition, it is assumed that registers A and B (Fig. 18.1.26a) contain the addends. An addition is performed by pulsing the control lines with signals originating in the control section of the CPU. Time is assumed to be metered into fixed intervals by an oscillator (clock) in the control section. These time slots are numbered for easier identification (Fig. 18.1.26b). At time 1 the inputs are gated to the adder, and the adders begin to compute the sum. At the same time, register D is *reset* (all latches set to 0). At time 2 the outputs of the adders have reached steady state, and control line D is raised, permitting those bit positions for which the sum was 1 to set the corresponding latches in register D . Between times 2 and 3, the result is latched up in register D , and at time 3, control D is lowered. Only after the result is locked into D and cannot change, may control A and B be lowered. If they were lowered earlier, the change might propagate through the adder to produce an incorrect answer.

The length of the pulses depends on the circuits used. The times from 2 to 3 and 3 to 4 are usually equal to a few logic delays (time to propagate through an AND, OR, or INVERTER). The time from 1 to 2 depends on the length of the adder and is proportional to the number of positions in a parallel adder because of potential carry-propagation times. This delay can be reduced by *carry look-ahead* (some-times called *carry bypass*, or *carry anticipation*).

Binary Subtraction

Subtraction can be accomplished using the operation of addition, by forming the complement of a number. Negative numbers are represented throughout the system in complement form. To subtract two numbers such as B from A , a set of logic elements may be put into the line shown in Fig. 18.1.26a an input B . Using 2's complement, the sign of a number is changed by complementing each bit and adding 1 to the result. The inversion of the bit is performed by the logic element interposed on the input B line in Fig. 18.1.26a known as a *true-complement (T/C) gate*. This unit gates the unmodified bit if the control is 0 and inverts each bit if the control is 1. The boolean equation for the output of the T/C gate is

$$\text{Output} = \overline{\text{T/C}} \cdot B + \text{T/C} \cdot \overline{B}$$

The T/C gate is a series of EXCLUSIVE-ORS with one leg, common to all bit positions, connected to the T/C control line. The other leg of each EXCLUSIVE-OR is connected to one bit of the circuit containing the number to be complemented.

The T/C gate produces the 1's complement; a 1 must be added in the low-bit position to produce the true complement. The low stage of an adder may be designed to have an input for a carry-in, designed to accommodate the 1 bit automatically produced from the high-order position of the T/C gate. Such a logical interconnection accomplishes the required 1 input for a true-complement system when a positive number B is subtracted from a positive number and is called an *end-around carry*. Consistency of operation is obtained by entering the appropriate high-order T/C gate into the low-order carry position.

Decimal Addition

In some systems the internal organization of a computer is such that decimal representations are used in arithmetic operations. In BCD, a conventional binary adder can be used to add decimal digits with a small amount of additional hardware. Adding two 4-b binary numbers produces a 4- or 5-b binary result. When two BCD

FIGURE 18.1.27 Binary adder with decimal-add feature. If the input of the binary add is 1010 or greater, the addition of a binary 6 produces the correct result by modulo-10 addition.

numbers are added, the result is correct if it lies in the range 0 to 9. If the result is greater than 9, that is the resulting bit pattern is 1010 to 10010, the answer must be adjusted by adding 6 to that group of 4 b, this number being the difference between the desired base (10) and the actual base ($2^4 = 16$). The binary carry from a block of 4 b must also be adjusted to generate the appropriate decimal carry.

The circuits to accomplish decimal addition are shown in Fig. 18.1.27. A test circuit generates an output if the binary sum is 1010 or greater. This output causes a 6 to be added into the sum and also is ORed with the original binary carry to produce a decimal carry. The added circuits needed to perform decimal additions with a binary adder represent one-half to two-thirds of the circuits of the original binary adder.

Decimal Subtraction

In most computers that provide for decimal operation, decimal numbers are stored with a sign and magnitude. To perform subtraction the true complement is formed by subtracting each decimal digit in the number from 9 and adding back 1. Once the complement is formed, addition produces the desired difference.

In a machine that provides for decimal arithmetic a *decimal true-complement* switch may be incorporated in each group of four BCD bits to form the complement. As with binary, provision must be made for the addition of an appropriate low-order digit and for the occurrence of overflows.

Shifting

All computers have shift instructions in their instruction repertoire. Shifting is required, for example, for multiply and divide operations.

FIGURE 18.1.28 Shift gates. In many systems shifting is accomplished in conjunction with the output of the adder, i.e., position shifts can be accomplished with only one circuit delay.

The minimum is a shift of one position left or right, but most computers have circuits permitting a shift of one or more bits at a time, that is, 1, 4, or 8.

In shifting, a problem arises with the bit(s) shifted out at the end of the register and the new (open) bit position(s). Those shifted out at one end can be inserted in the other end (referred to as *end-around shift* or *circulate*), or they can be discarded or placed in a special register. The newly created vacancies can be filled with all 0s, all 1s, or from another special register.

In a typical computer, shifting is not performed in a shift register but with a set of gates that follow the adders. The outputs of the shift gates are connected to the output register, with an offset by providing a separate gate for each distance and direction of shift. One bit position of the output register can therefore be fed from several adder outputs, but only one gate is opened at a time, as in Fig. 18.1.28. The pattern shown is repeated for every bit position.

Multiplication

Figure 18.1.29 shows a possible data-flow system for multiplication, i.e., the data flow of the adder shown in Fig. 18.1.26 with the addition of register C to hold the multiplier and the shift registers as shown in Fig. 18.1.28. An extra register E holds any extra bits that might be generated in the process of multiplication. Register E in the particular system shown also receives the contents of C after transmission through C 's shift register.

Computers also have an extension of the shift instruction called *rotate*. A shift usually occurs as a result, but the leading bit of the shift right or left is rotated to the opposite end of the register. This feature can be used for bit detection without losing data.

The process of binary multiplication involves decoding successive bits in the multiplier, starting with its lowest-order position. If the bit is a 1, the multiplier is added into an accumulating sum; if 0, no addition takes place. In either case the sum is moved one position to the right and the next higher-order bit in the multiplier considered.

In Fig. 18.1.29 the multiplier is stored in register C , the multiplicand in A , and all others are reset to zero. If the low-order position of C is a 1, the contents of B and C are added and shifted one position to the right into register D . After the addition, register C is shifted one position to the right and stored in register E . If the low-order bit in C had been a zero, only register B would have been gated into the adders; i.e., the addition of the contents of A would have been suppressed, but subsequent operations would have remained the same.

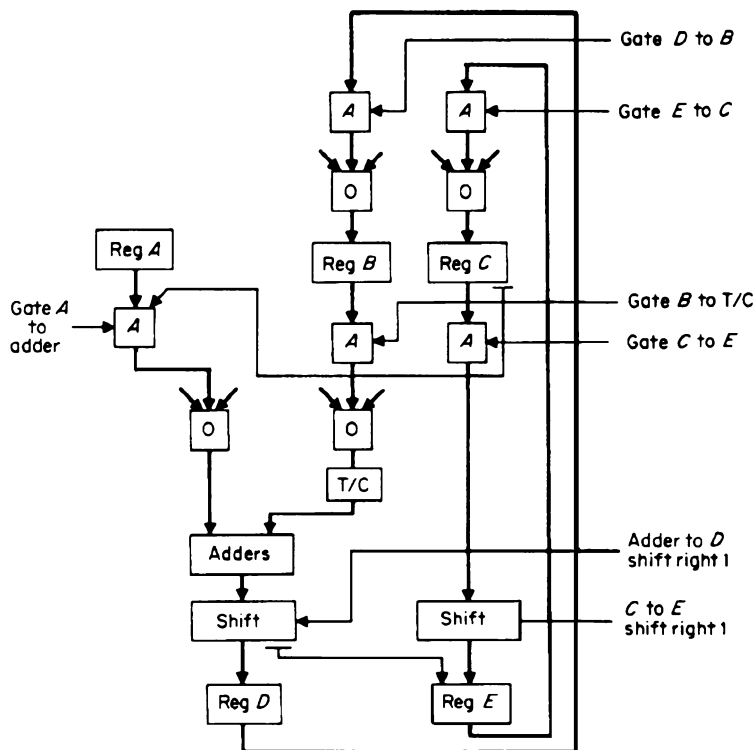

FIGURE 18.129 Data flow for multiplication.

Each add and shift operation subsequent to an add may generate low-order bits that may be shifted into register *E*, since the contents of *C* are shifted to the right, unused positions become successively available. After the add and shift cycles, registers *D* and *E* are transferred into *B* and *C*, respectively, and the process is repeated until all positions of the multiplier are used. The content of *D* and *E* is the product.

Division

To provide for the division of two numbers the functions of the registers in Fig. 18.129 must be rearranged as shown in Fig. 18.130. A gating loop is provided from the shift register to register *A*. Initially the divisor is placed in register *B* and the dividend in *A*. The T/C gate is used to subtract *B* from *A*, and if the result is zero or positive, a 1 is placed in the low-order position of register *E*. If the result is negative, a 0 is placed in *E* and the input from *B* ungated to reset to the contents of *A*. The shift register then shifts the output of the adder one position to the right and gates it back to *A*. *E* is gated through *C* and shifted on to the right. The whole process is repeated until the dividend is exhausted. *E* contains the quotient and *A* the remainder.

Floating-Point Operations

In some applications, it is convenient to represent numerical values in floating-point form. Such numbers consist of a *fraction* that represents the number's most significant digits, in a portion of the field of a word in the machine, and a *characteristic* in the remaining portion. The characteristic denotes the decimal-point position

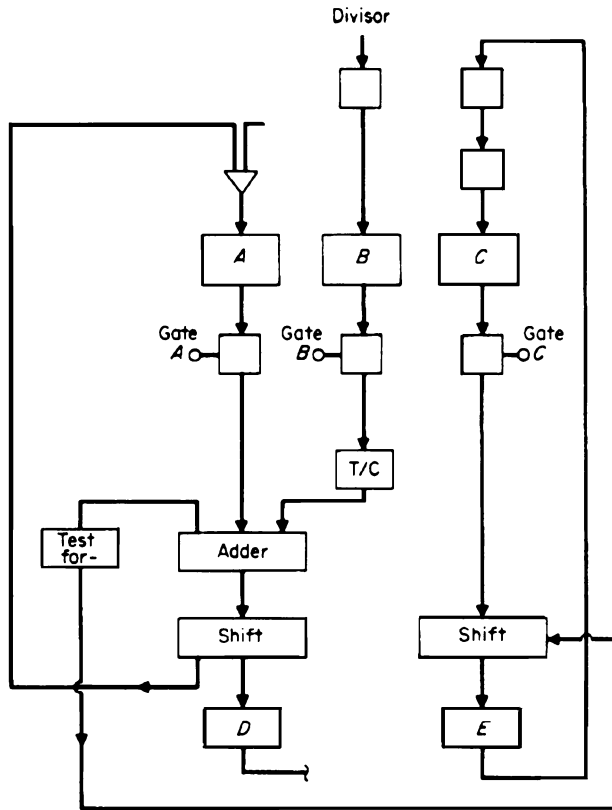

FIGURE 18.1.30 Data flow for division. B holds the divisor and A the dividend. A trial subtraction is made of the high-order bits of B from A , and if the results are 0 or positive, a 1 is entered into the lower-order bit of E and the result of the subtraction shifted left and reentered into A (with gate A closed). If the result had been negative the B gate would have closed to negate the subtraction, and a 0 would have been entered into E . The output of the adder would then have been shifted left one position and reentered in A .

relative to the assumed decimal point in the characteristic field. In floating-point addition and subtraction, justification of the fractions according to the contents of the characteristic field must take place before the operation is performed; i.e., the decimal points must be lined up.

In an ALU such as in Fig. 18.1.29, the operation proceeds in the following way. Two numbers A and B are placed in registers A and B , respectively. The control selection then gates only the characteristic fields into the adder, in a subtract mode of operation. The absolute difference is stored in an appropriate position of the control section. Controlled by the sign of the subtraction operation, the fraction of the least number is placed through the adder into the shift register. The control section then shifts the fraction the required number of positions, i.e., according to the stored difference of characteristic fields, and places the result back in the appropriate register. Addition or subtraction can then proceed according to the generating machine instruction.

This procedure is costly of machine time. Instead of using the ALU adder for the characteristic-field difference, provision can be made for subtraction of the characteristics in the control section. In such a case, only the characteristics A and B need be entered into registers A and B and the lesser number can be placed in B so that shifting can be accomplished by the circuits normally used in multiplication.

Control Section

The control section is the part of a CPU that initiates, executes, and monitors the system's operations. It contains clocking circuits and timing rings for opening and closing gates in the ALU. It fetches instructions from main storage, controls execution of these instructions, and maintains the address for the next instruction to be executed. The ALU also initiates I/O operations.

Basic Timing Circuits

Basic to any control unit is a continuously running oscillator. The speed of this oscillator depends on the type of computer (parallel or serial), the speed of the logic circuits, the type of gating used (the type of registers), and the number of logic levels between registers. The oscillator pulses are usually grouped to form the basic operating cycle of the computer, referred to as *machine cycles*. In this example four pulses are combined into such a group.

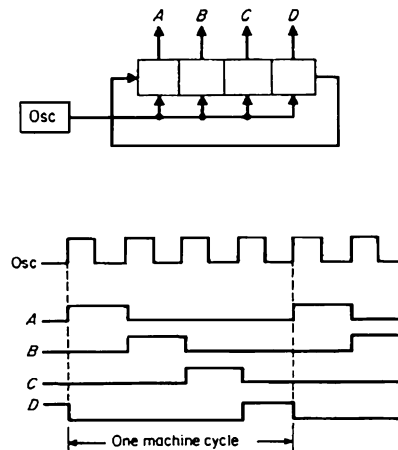

FIGURE 18.1.31 Oscillator and ring circuit. Many control functions can be performed by using an oscillator in conjunction with a timing ring that sequentially sends signals on separate lines, in synchronism with the oscillator.

In Fig. 18.1.31 an oscillator is shown that drives a four-stage ring. At any one time, only one stage is on. Suppose an addition is to be performed between registers *A* and *B* and the result is to be placed back in *B*. The addition circuitry described in Fig. 18.1.29 uses three registers, two for the addends (registers *A* and *B*), and one for temporary storage (register *D*). The operation to be performed is to add the content of register *A* to the content of register *B* and store the result in register *B*. Register *D* is required for temporary storage since if *B* were connected back on itself, an unstable situation would exist; i.e., its output (modified by *A*) would feed its input.

The operation of the four-stage clock ring in controlling the addition and transfer is shown in Fig. 18.1.32. Action is initiated by the coincidence of an ADD signal and clock pulse *A*, which starts the *add ring*. This latter ring has two stages and advances to the next stage upon occurrence of the next *A* clock pulse. The timing chart in Fig. 18.1.32 describes one sequence of actions required and the gates needed for the addition. The circuit diagram shows a realization of these gates. Each register is reset before it is reused, and all pulses are derived from the four basic clock pulses shown in Fig. 18.1.31. The add ring initiates the add

by opening the gates between registers *A* and *B* and the adder. The add latch is then reset, *D* is reset, the ring stage transferred, and so forth. An ADD-FINISHED signal is furnished, and may be used elsewhere in the system.

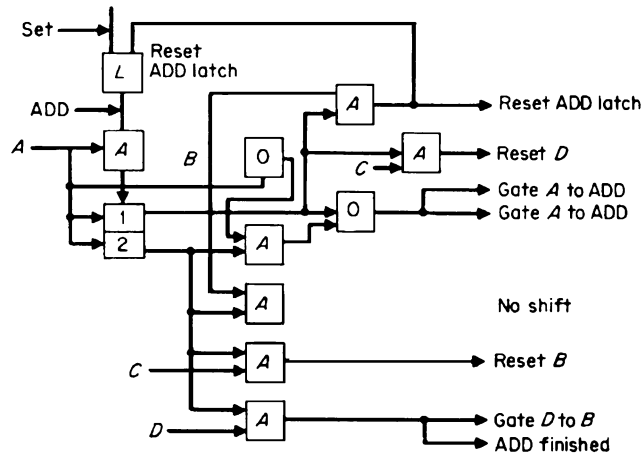

In the timing diagram, it is assumed that the time required for transmission through the adder is about one machine cycle and that one clock cycle is sufficient for the signal to propagate through the necessary gating and set the information in the target register. These times must include the delay in the circuits and any signal-propagation delay.

Control of Instruction Execution

The following approach for the design of a control section is straightforward but extravagant of hardware. For each instruction in the computer a timing diagram is developed similar to the one shown for the add operation in the previous section. These timings are implemented in rings that vary in length, according to the complexity of the instruction. The concept is simple and has been widely used, but it is costly. To reduce cost, rings are used repeatedly within one instruction and/or by several instructions. Subtraction, for example, might use the ADD ring, except for an extra latch that might be set at ring time 1, clock time *A* (denoted 1.A) and reset at 2.C. This new latch feeds the T/C gates. Another latch that might be added to denote decimal arithmetic would also be set at 1.A time and reset at 2.C time. The addition of two latches and a few additional ANDS and ORS permits the elimination

(a)

(b)

FIGURE 18.1.32 Control circuit (b) and timing chart (a) for addition. The timing ring shown in Fig. 18.1.31 to control the adder circuit shown in Fig. 18.1.29 with the help of additional switching circuits.

of three two-stage rings and associated logic. Further reductions in the number of required circuits can be achieved by considering the iterative nature of some instructions, such as multiplication, division, or multiple shifting.

Controls Using Counters (Multiplication)

To exemplify this approach multiplication is considered. Multiplication can be implemented as many add-shift cycles, one per digit in the multiplier (say N). The control for such an instruction can be implemented using one $2N + 1$ position ring, the first position initializing and the next $2N$ positions for N add-shift cycles (two positions are needed per add cycle). Such an approach requires not only an unnecessarily long ring but is relatively inflexible for other than N -bit multipliers.

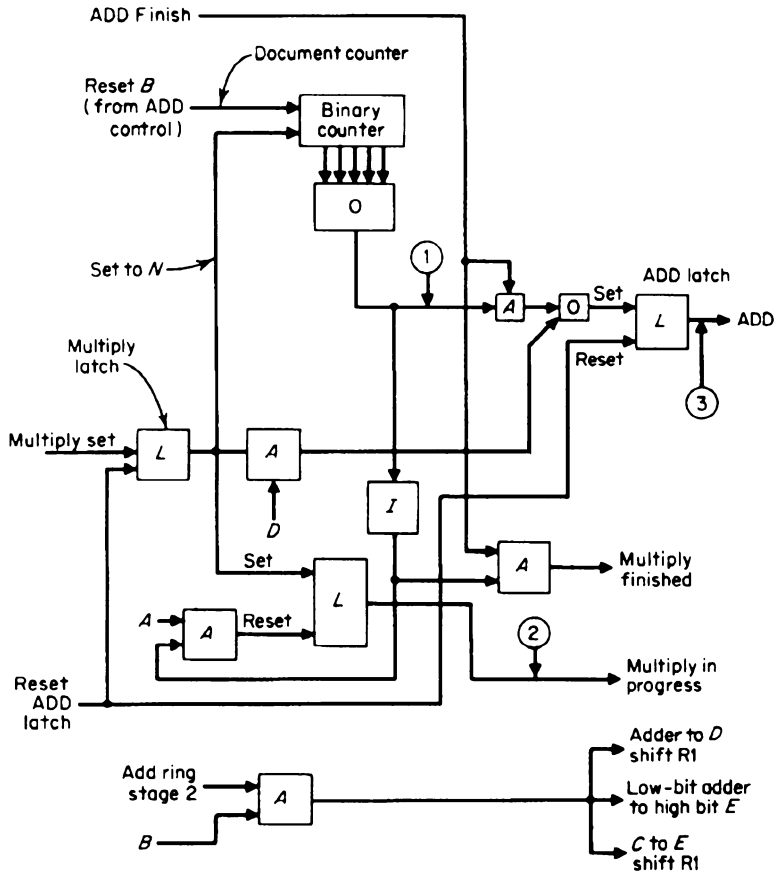

FIGURE 18.1.33 Control circuit for multiplication. Repetitive operations such as add and shift are combined in cyclical fashion. The timing diagram of Fig. 18.1.32a is assumed.

The alternate approach, requiring considerably less hardware, uses the basic operation in multiplication, an add and a shift. Therefore a multiply can be implemented by using the controls for the add-shift instruction, plus a binary counter, plus some assorted logic gates to control the gates unique to the multiply, as in Fig. 18.1.33. In the figure some of the less important controls needed for multiply have not been included to simplify the presentation. For example, the NO SHIFT signal for add must be conditioned with a signal that multiply is not in progress, and during multiplication an ADD-FINISHED signal should be ignored (nor start an I cycle), the reset B also resets C , the reset D also resets E , gate D to B also gates E to C , gating of A to the adder is conditioned on the last bit of C , and so forth.

In Fig. 18.1.33 the action is started by raising the MPY line that sets a *multiply* latch. This in turn sets the binary counter to the desired cycle count. Also set is the ADD-LATCH, and the addition cycles start. When the counter goes to 0, the ADD-LATCH is no longer set and the MULTIPLY-FINISHED signal is raised.

Microprogramming

The control of the E cycle, in the preceding descriptions, is performed by a set of sequential circuits designed into the machine. Once an execution is initiated, the clocking circuits complete the operation, through wired

paths in a specific manner. An alternative method of design for a control unit is *microprogramming*. The concept is not sharply defined but has as its objective implementation of the control section at low cost and with high flexibility.

In many cases it is desirable to design compatible computers, i.e., units with the same instruction set, with widely varying performance and cost. To provide a slower version at a lower cost, the width of the data path is reduced to lower circuit counts in the ALU. On the other hand, to operate with the same instruction set, the reduced data-path width usually implies more iterative operations in the control section, at added cost.

Considerable investment is required for programming development, and normally such systems run only on computers with identical instruction sets. If appropriate flexibility is provided, one computer can mimic the instruction set of another. Microprogramming provides for such operations. The process by which one system mimics another is called emulation.

Control lines are activated not by logic gates in conjunction with counters but by words in a storage system that are translated directly into electric signals. The words selected are under the control of the instruction decoder, but the sequence of words may be controlled by the words themselves by provisions of a field that does not directly control gates but specifies the location of the next word. The name given to these control words is *microinstruction* as opposed to machine instruction or instruction.

When two computers are designed for the same instruction set but with different data-path widths, the microinstruction sets of the two computers are radically different. For the small computer, the program for a given machine instruction is considerably longer than that for the large computer. The same instructions can be used in both computers. The difference in control-system cost between the two is not large. Although the microprogram is longer with the smaller computer, the difference is in the number of storage places provided, not in the control-section hardware.

The design of the sequence of microprogramming words is conceptually little different from other programming. The microprogram implementation, however, requires a thorough knowledge of a machine at the gate level. A *microinstruction counter* is used to remember the location of the next microinstruction, or a field can be provided to allow branching or specification of a next instruction.

A microprogram generally does not reside in main store but in a special unit called a *control store*. This may not be addressable by the user, or it may be a separate storage unit. In many cases, the microprogram is stored in a read-only store (ROS); i.e., it is written at the factory. ROS units are faster and may be cheaper per bit of storage and do not require reloading when power is applied to the computer. Alternatively the microprogram may be stored in medium that can be written into, called a *writable control store* (WCS). By reloading the WCS, entirely different macroinstruction can be implemented, using the same microinstruction set in a different microprogram. By such means emulation is achieved at minimal expense.

CPU Microprogramming

Figure 18.1.34 shows an ALU and Fig. 18.1.35 a control section with microprogram organization. The microinstructions embodied in these two units are shown in Table 18.1.2.

To simplify the program several provisions have been made:

1. Each microinstruction contains the control-store address of the next microinstruction. If omitted, the address in one microinstruction is the current address of the one written just below it. It may *not* be next in numeric sequence.
2. An asterisk at the beginning of a line in a program indicates a comment. This means that the entire line contains information about the program and does not translate into a microinstruction.
3. To simplify the drawing, a gate in a path is indicated by placing an X in the line and omitting from the drawing any control lines controlling these gates. It is also assumed that where two lines join, OR circuits are implied.
4. Rather than listing a numeric value for each field, a shorthand description for the desired action is invented. All actions not so described are assumed to be zero. For example, A to ADD implies that register A is gated to the adder, or T/C means raise T/C gate. These charges do not in any way modify the concept of microprogramming but make the result more readable.

FIGURE 18.1.34 Microprogrammed ALU.

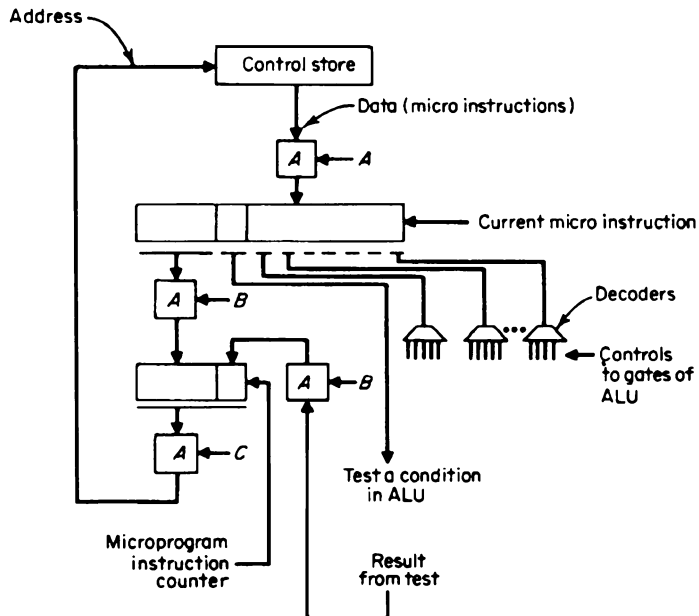

FIGURE 18.1.35 Microprogrammed control unit.

TABLE 18.1.2 Microinstructions Embodied in an ALU and a Control Section

Current address	Microinstruction	Comment
51	•ADD	
8	B to ADD, C to ADD, NO-SHIFT	Add two operands
9	E to B	
	A(2) to MS-ADR-REG, B to MS, GO TO 1	Store result branch to 1, next microinstruction executed to be taken from control-store location 1
52	•SUBTRACT	
	B to ADD, C to ADD, NO-SHIFT T/C, GO TO 8	Go to 9, where result is stored
53	•BRANCH (unconditional)	
	A(3) to 1C, GO TO 1	This is the macroinstruction branch
54	•MULTIPLY	
17	Set an N into counter, C to ADD, NO-SHIFT	Initialize
18	E to D, set C to 0s	
	If last bit D = 1, then (B to ADD), C to ADD shift-R 1, 0 to input of high end of shifter, output of low end of shifter to F	Perform one add shift if last bit D = 1, only shift if last D = 0
19	E to C, F to G, COUNT down by 1	Increment counter
20	D to ADD, SHIFT-R1, G to input of high end of shifter	Shift D
21	E to D, if counter is not 0 then GO TO 17	Close loop
22	C to ADD	Store result in two MS locations
23	E to B, force 1 into C	
24	A(2) to ADD, C to ADD NO-SHIFT; A(2) to MS-ADR-REG B to MS	Store first half of result, increment result address
25	E to A(2)	
26	D to ADD, NO-SHIFT	
27	E to B	
28	A(2) to MS-ADR-REG, B to MS GOT TO 1	Store second half of result Branch to 1-fetch
55	•SHIFT LEFT	
	A(2) to COUNTER, C to ADD, NO-SHIFT	Operand 1 is number of bits operand 2 is to be shifted
10	If COUNTER = 0 then GO TO 9 E to B	Test if shift count was 0
11	B to ADD, SHIFT L1, COUNT down by 1	Shift loop
12	IF COUNT not 0, then GO TO 11 E to B	
13	GO TO 9	Completed shift

NOTE 1: (Location 7) This special test places the op-code bit pattern into the low part of the address for the next instruction, causing a branch to the appropriate microroutine for each op code. Branches are as follows:

Op code	Instruction	Address
1	ADD	51
2	SUBTRACT	52
3	BRANCH	53
4	MULTIPLY	54
5	SHIFT LEFT	55

NOTE 2: (Location 1) It is assumed that START button sets microinstruction counter to 1.

Instruction FETCH

In the preceding paragraphs the execution of instructions (E cycles) is discussed. In these cases, operations are initiated by setting an appropriate latch for the function to be performed. The signals that set the latch are in turn generated by circuits that interpret the information of the operation-code part of an instruction cycle (I cycle).

Whenever an instruction has completed execution (or when the computer operator presses the start button on the console), a *start-cycle* signal is generated at the next A time of the master-clock timing ring. This signal starts the I-cycle ring. The first action of this ring is to fetch the instruction to be executed from the main store by gating the instruction counter (IC) (sometimes called *program counter*) to the address lines of main storage and initiating a main-store cycle by pulsing a line called *start MS*.

These operations are illustrated in Fig. 18.1.36. At ring time 2, the instruction arrives back and is placed in the instruction register (IR). The instruction typically contains three main fields: the *operation code* (op code),

FIGURE 18.1.36 Implementation of equipment for an I cycle in a two-address machine. The instruction is first brought from main store and deposited in the instruction register. The operation proceeds by successively gating the information associated with two address fields into register A. The first is moved out of A, while the second is being sought from main store.

that determines what instructions is to be executed (ADD, SUBTRACT, MULTIPLY, DIVIDE, BRANCH), and the two addresses of the two operands participating in the operation. For certain classes of instruction, the operands must be delivered to appropriate locations before the E cycle begins.

During ring time 3 and 4, the first operand is fetched from main store and stored in *A*. During ring time 5, this operand must be transferred from *A* to an alternate location, depending on the nature of the instruction being executed. During ring time 5 and 6, the second operand is fetched and stored in *A*. Ring time 6 is also used to gate the op code to the *instruction decoder*, which is a combinatorial logic circuit accepting the *operation code*, or *instruction code*, from the *P b* in the op code. The decoder has 2^P input wires, one for each unique input combination. Thus for each bit combination entering the decoder, one output line is activated. These signals represent the start of an E cycle with each wire initiating the execution of one instruction by setting some latch, e.g., an add or multiply latch, or by initiating an appropriate microprogram.

Some op-code bit combinations may not be valid instruction codes. The outputs of the decoder are ORED together and fed into a circuit that ultimately interrupts the normal processing of the computer and indicates the invalid condition. At the beginning of the I cycle, the content of the instruction counter (IC) points to the instruction to be executed next. An *increment-counter* signal is generated during the I cycle in order to increment the counter, so that the address stored in IC points to the next sequential instruction in the program.

Instruction- and Execution-Cycle Control

In normal program operation, I and E cycles alternate. The I cycle brings forth an instruction from storage, sets up the ALU for execution, resets the instruction counter for the next I cycle, and initiates an E cycle. A number of conditions serve to interrupt this orderly flow, as follows:

1. When no more work is to be done, the end of a program is reached and the computer goes to a WAIT state. Such a state is reached, for example, by a specific instruction that terminates operations at the end of the I cycle in question, by a signal from the instruction counter when a predetermined limit is reached.
2. A STOP button may prevent the next setting of the *Start I cycle* latch. A START button resets this latch.
3. When starting up after a shutdown, e.g., in the morning, activity is usually initiated by depressing an INITIAL PROGRAM LOAD button on the operator's console (the name varies from system to system, e.g., IPL, LOAD, START). The button usually performs three functions: a reset of all rings, latches, and registers to some predefined initial condition; a read-in operation from an I/O device into main store (usually the first few locations) of a short program; and an initiation of an I cycle. Program execution generally starts at a fixed location so that the IC initially is set to this value. In most computers, including PCs, this value is called IMPL (initial microprogrammed program load), which initializes the machine and performs self-testing on memory, I/O ports, and internal status conditions.
4. In multiprogramming, i.e., concurrent operations on more than one program, only one program at a time is in operation in the CPU, but transfers occur from one to another as required by I/O accesses, and so forth. The program to be transferred is handled by an *interrupt*. Under interrupt, an address is forced into the instruction counter so that on completion of the E cycle of the current program, a new instruction is referenced that starts the interruption. This instruction initiates program steps that store the data of the old program, e.g., in special registers or in special main-store locations. The contents of the IC, part of the IR, the contents of any registers, and the reason for the interruption are stored. The collection of these fields together is called a *program status word* (PSW). In most computers, this information, plus general registers must be saved when switching machine states. It can be referenced to reinstate action at later time on the program interrupted.

Branch and Jump Instructions

Two kinds of instruction permit change in program sequence: *conditional* and *unconditional*. The purpose of such instructions is to permit the system to make some decision, so as to alter the flow of program, and to continue execution at some point not in the original sequence. In nonconditional branches the original program instruction provides for a branch or jump whenever the particular instruction occurs.

Conditional branches take the extra step of determining if some condition to be tested has been satisfied. Either the op code or the operand 1 field normally defines the test and/or the condition to be tested for. If the specified test has been satisfied, the branch is executed as described above. Otherwise no action is taken, and the next normally sequenced instruction is executed.

Advanced Architectural Features

The basic structure of the digital computer and its operation have been described in the previous paragraphs. This structure has proved to be flexible and adaptable to the solution of many different applications. There is, however, a continuing need to increase the performance of the computer and to make it easier to program so that even more applications can be handled. This has been achieved through a number of different approaches. One has been to develop sophisticated operating systems and to couple them closely to the hardware design of the computer. The net effect is that a programmer viewing the computer does not distinguish between the hardware and the operating system but perceives them as an integrated whole.

A second solution has been the development of architectural features that permits overlapped processing operations within the computer. This is in contrast to earlier computers that were strictly sequential and resulted in reduced performance and low throughput because vulnerable computer resources could remain idle for relatively long periods of time. The newer architectural features include such concepts as data channels, storage-organization enhancements, and pipelining described briefly in the following paragraphs. Another totally different approach to improved computer performance has been the development of computers with non-von Neumann architecture, described in the next section.

An increase in computer performance can be achieved by overlapping input/output (I/O) operations and processor operations. *Channels* have been introduced in large systems to permit concurrent reading, writing, and computing. The channel is in effect a special processor that acts as a data and control buffer between the computer and its peripheral devices. Figure 18.1.37 shows the organization of the computer when channels are introduced. Each channel can accommodate one or more I/O device control units. The channel is designed with a standard interface that is designed to permit a standard set of control status signals and data signals and sequences to be used to control I/O devices. This permits a number of different I/O devices to be attached to each channel by using I/O device control units that also meet the standard interface requirements. Each device control unit is usually designed to function with only one I/O device type, but one control unit may control several devices.

The channel functions independently of the CPU. It has its own program that controls its operations. The CPU controls channel activity by executing I/O instructions. These cause it to send control information to the channel and to initiate its operation. The channel then functions independently by being given a channel program to execute. This program contains the commands to be executed by the channel as well as the addresses of storage locations to be used in the transfer of data between main storage and the I/O devices. The channel in turn issues orders to the device control unit, which in turn controls the selected I/O device. When the I/O operation is completed, the channel interrupts the CPU by sending it a signal indicating that the channel is

FIGURE 18.1.37 Computer organization with channels, separate logical processors that permit simultaneous input, output, and processing.

again free to perform further I/O operations. Several channels can be attached to the CPU and can operate concurrently. In PCs, I/O operation is controlled by adapter cards that fit into the motherboard.

Cache Storage

Cache storage was introduced to achieve a significant increase in the performance of the CPU at only a modest increase in cost. It is, in effect, a very high-speed storage unit that is added to the computer but is designed to operate in a unique way with the main storage unit. It is transparent to the program at the instruction level and can thus be added to a computer design without changing the instruction set or requiring modification to existing programs. Cache storage was first introduced commercially on the IBM System/360 model 85 in 1968.

Virtual Storage

Properly using and managing the memory resources available in the computer has been a continuing problem. The programmer never seems to have enough high-speed main storage and has been forced to use fairly elaborate procedures such as overlays to make programs fit into main storage and run efficiently. *Virtual-storage* systems were introduced to permit the programmer to think of memory as one uniform *single-level storage* unit but to provide a *dynamic address-translation unit* that automatically moves program blocks on pages between auxiliary storage and high-speed storage on demand.

Pipelining

A further improvement in computer performance was achieved through the use of *pipelining*. This technique consists of decomposing repetitive processes within the computer into subprocesses that can be executed concurrently and in an overlapped fashion.

Instruction execution in the control unit of the CPU lends itself to pipelining. As discussed earlier, instruction execution consists of several steps that can be executed relatively independently of each other. There is instruction fetch, decoding fetching the operands, and then execution of the instruction. Separate units can be designed to perform each one of these steps. As each unit finishes its activity on an instruction, it passes it on to the next succeeding unit and begins to work on the next instruction in succession. Even though each instruction takes as long to execute overall as it does in a conventional design, the net effect of pipelining is to increase the overall performance of the computer. For example, under optimal conditions, once the pipeline is full, when one instruction finishes, the next instruction is only one unit behind it in the pipeline. In this four-unit example, the net effect would be to increase the speed of instruction execution by a factor of 4.

This approach can be carried to the point where 20 or 30 instructions are at various stages of execution at one time. This type of processing is called *pipeline processing*. No difficulties arise during uninterrupted processing. When an interrupt does occur, however, it is difficult to determine which instruction has caused the interrupt since the interrupt may arise in a subsystem sometime after the IC has initiated action. In the meantime, the IC may have started a number of subtasks elsewhere by stepping through subsequent cycles. Operands within subunits may not be saved in an arbitrary intermediate state, since information is in the process of being generated for return to the main program. Because of the requirement that no further I cycles be started, interrupt is signaled when the pipeline is empty. At the time the interrupt is signaled, the IC does not point at the instruction causing the interrupt but somewhat past it. This type of interrupt is called *imprecise*.

Advanced Organizations

In addition to the von Neumann computer and its enhancements, a number of other computer organizations have been developed to provide alternative approaches to satisfying the needs for improved computational performance, increased throughput, and improved system reliability and availability. In addition, certain unique architectures have been proposed to solve specific problems or classes of problems.

TABLE 18.1.3 Classification Scheme for Computer Architectures

Acronym	Meaning	Instruction streams	Data streams	Examples
SISD	Single instruction stream, single data stream	1	1	IBM 370, DEC VAX, Macintosh
SIMD	Single instruction stream, multiple data stream	1	>1	ILLIAC IV, Connection Machine, NASA's MPP
MISD	Multiple instruction stream, single data stream	>1	1	Not used
MIMD	Multiple instruction stream, multiple data stream	>1	>1	Cray X/MP, Cedar, Butterfly

Computer organizations can be categorized according to the number of procedure (instruction) streams and the number of data streams processed: (1) a single-instruction-stream-single-data-stream (SISD) organization, which is the conventional computer; (2) a multiple-instruction-stream-multiple-data-stream (MIMD) organization, which includes multiprocessor or multicomputer systems; (3) a single-instruction-stream-multiple-data-stream (SIMD) organization; this uses a single control unit that executes a single instruction at a time, but the operation is applied across a number of processing units each of which acts in a synchronous, concurrent fashion on its own data set (parallel and associative processors fall into this category); and (4) a multiple-instruction-stream-single-data-stream (MISD) organization. (Pipeline processors fall into this category.) Table 18.1.3 summarizes the categories.

One way to achieve an improvement in performance and to improve reliability at the same time is to use multiprocessors. The American National Standard Vocabulary for Information Processing defines a multiprocessor as “a computer employing two or more processing units under integrated control.” Enslow^{61a} amplifies this definition by pointing out that a multiprocessor contains two or more processors of approximately comparable capabilities. Furthermore, all processors share access to common storage, to I/O channels, control units, and devices. Finally, the entire system is controlled by one operating system that provides interaction between processors and their programs.

A number of different multiprocessor system organizations have been developed: (1) time-shared, or common-bus, systems that use a communication path to connect all functional units, (2) crossbar-switch systems that use a crossbar switching matrix to interconnect various system elements, (3) multiport storage systems in which the switching and control logic is concentrated at the interface to the memory units, and (4) networking of computers interconnected via high-speed buses.

A number of large problems require high throughput rates on structured data, e.g., weather forecasting, nuclear-reactor calculations, pattern recognition, and ballistic-missile defense. Problems like these require high computation rates and may not be solved cost-effectively using a general-purpose (SISD) computer. Parallel processors, which are SIMD organization types, were designed to address problems of this nature. A parallel processor consists of a series of process elements (cells) each having data memories and operand registers. The cells are interconnected. A central control unit accesses a program, interprets each program step, and broadcasts the same instructions to all the processing elements simultaneously.

Distributed Processing

One of the newest concepts in computer organizations is that of *distributed processing*. The term distributed processing has been loosely applied to any computer system that has any degree of decentralization. The consensus seems to be that a distributed processing system consists of a number of processing elements (not necessarily identical), which are interconnected but which operate with a distributed, i.e., decentralized, control of all resources. With the advent of the less expensive micro- and miniprocessors, distributed processing is receiving much attention since it offers the potential for organizing these processors so that they can handle problems that would otherwise require more expensive supercomputers. Through resource sharing and decentralized

control, distributed processing also provides for reliability and extensibility since processors can be removed or added to the system without disrupting system operations. The types of distributed processing can be described by configurations in terms of the processing elements, paths, and switching elements: (1) loop, (2) complete interconnection, (3) central memory, (4) global bus, (5) star, (6) loop with central switch, (7) bus with central switch, (8) regular network, (9) irregular network, and (10) bus window. Distributed systems have been designed that fall into each of these categories. Hybrid forms use combinations of two or more of these architectural types.

Distributed and parallel processing systems can be thought of as being loosely coupled (each has its own CPU and memory) or tightly coupled (each has its own CPU and shares the same memory). Master–slave and client–server systems are part of the distributed and cooperative processing. In master–slave, one computer controls another, whereas in client–server, the requesting computer is the client and the requested resource is the server.

Stack Computers

In the CPUs discussed thus far, the instructions store all results, so that the next time an operand is used it has to be fetched. For example, a program to add A , B , and C and put result into E appears as

MOVE A to E	1 fetch, 1 store
ADD E to B store in E	2 fetch, 1 store
ADD E to C store in E	2 fetch, 1 store

In languages such as PL/I or FORTRAN this program might be written as the single statement

$$E = A + B + C$$

This equation describes a sequence of actions, as in the case of the program, but the specific sequence is not described. Since addition is commutative, a correct result is achieved by $E = [(A + B) + C]$, $E = [A + (B + C)]$, or $E = [(A + C) + B]$, each step occurring in any order. The computer, however, uses a specific program in achieving a result so that the method of writing the equation must generate a specific sequence of actions.

A method of writing an equation that specifies the order of operation is called *Polish notation*. For the above example of addition, one possible Polish string would be

$$AB + C + E =$$

In this string, the system would find A and B and, as determined by the plus sign *following* the two operands, add them. The result is then combined with C under addition called for by the second plus sign. The $E =$ symbols indicates that the result is to be stored in E . The plus sign appears *after* the A and B , and the specific string shown is called *postfixed*. An equivalent convention could place the operator first and would be called *prefixed*.

Any complex expression can be translated into a Polish string. For example in PL/I language, the statement

$$M = (A + B) * (C + D * E) - F;$$

means evaluate the right-hand side of the equation and store the result in the main-store location corresponding to variable M (asterisks indicate multiplication). The Polish string translation for this statement is

$$AB + DE * C + * F - M =$$

In translation from the types of expression permitted by higher-level languages, a machine can be programmed to analyze successively an arithmetic expression of the types shown above. In so doing, first, the outermost expressed or implied parentheses are aggregated and successively broken down until not more quantities remain. The first such quantities analyzed are generally the last computed, so that in the development of a Polish string from an algebraic expression, a first-in, last-out situation prevails.

Stacks

Evaluation of a Polish string in a machine is best performed using a *stack* (push-down list). A stack has the property that it holds numbers in order. A PUSH command places a value on the stack; i.e., it stores a number and an operation at the top of the stack and, in the process, lowers all previous items by one position. Numbers are retrieved from the stack by issuing a POP command. The number returned by the stack on a POP command is the most recently PUSHED one. The following example illustrates the behavior of a stack. The value in parentheses is the value *placed* on the stack for PUSH and returned by the stack for POP (assume the stack is initially empty):

PUSH (A)	stack contains	A
PUSH (B)	stack contains	B A
POP (B)	stack contains	A
PUSH (C)	stack contains	C A
POP (C)	stack contains	A
POP (A)	stack contains	nothing

Such a stack lends itself very well to the evaluation of Polish strings. The rules for evaluation are:

1. Scan the string from left to right.
2. If a variable (or constant) is encountered, fetch it from main store and place its value on the stack.
3. If an operator is encountered, POP the operands and PUSH the result.
4. Stop at the end of the string. If executed correctly, the stack is in the same state at the end of execution as it was at the start.

The advantage of using a stack is that intermediate results never need storing and therefore no intermediate variables are needed. In sequences of instructions where there are no branches, the operations can be stored in a stack. A program becomes a series of such stacks put together between branches.

This approach is called *stack processing*. In stack processing, a program consists of many Polish strings that are executed one after another. In some cases the entire program may be considered to be one long string.

Stacks are implemented by using a series of parallel shift registers, one per bit of the character code. The input is placed into the leftmost set of register positions. PUSH moves an entry to the right, and POP moves it to the left. The length of the shift registers is finite and fixed. The stack, however, usually must appear to the user as though it were infinitely deep. The stack is thus implemented so that the most active locations are in the shift register, and if the shift register overflows, the number shifted out at the right on a PUSH is placed in main storage. There the order is maintained by hardware, microprogramming, or a normal system program.

Trends in Computer Organization

Several trends in computer architecture and organization may have a significant impact on future computer systems. The first of these are the *data-flow computers*, which are data-driven rather than control-driven. In the data-flow computer, an instruction is ready for execution when its operands have arrived; there is no concept of control flow, and there is no program counter. A data-flow program can feature concurrent processing since many instructions can be ready for execution at the same time. In another area *capability systems* are receiving increased attention because their inherent protection facilities make them ideal for implementing secure operating systems. A capability is a protected token (key) authorizing the use of the object named in the token. One approach to implementing capabilities is through a *tagged* architecture, where tag bits are added to each word in storage and to each register. This tag specifies whether the contents represent a capability or not.

Special-Purpose Processors

Certain classes of problems require unique processing capabilities not found in general-purpose computers. Special-purpose processors have been designed to solve these problems. In some cases they have been designed

as stand-alone processors, but often they are designed to be attached to a general-purpose computer that acts as the host. One such class of special-purpose processors is the *associative processor*. It uses an associative store. Unlike the storage units described earlier, which require explicit addresses, an associative store retrieves data from memory locations based upon their content. The associative store does its searching in parallel over its entire storage in approximately the same time as required to access a single word in a conventional storage unit.

In digital signal processing (DSP), many repetitive mathematical operations must be performed, e.g., fast Fourier transforms, and require a large number of multiplications and summations. DSP algorithms are being used extensively in graphics processing and modem transmission. The *array processor* has been designed for these types of operations. It has a high-speed arithmetic processor and its own control unit and can operate on a number of operands in parallel. It attaches to a host CPU, from which it receives its initiation commands and data and to which it returns the finished results of its computation.

The *hybrid processor* uses a host digital CPU to which is attached an analog computer. These systems operate in a digital-analog mode and provide the advantages of both methods of computation. Hybrid processors are being replaced by very high-speed digital processors.

HARDWARE DESIGN

Design and Packaging of Computer Systems

Even a small computer may have as many as 3 million integrated circuits on a single chip, whereas a large system may have up to 100 million by the year 2000.

Nanosecond circuit speeds are common in high-performance computer systems. Since light travels approximately $\frac{1}{3}$ m in 1 ns, system configurations must be kept small to take advantage of the speed potential of available circuits. Thus the emphasis is on the use of microcircuit fabrication and packaging techniques. The layout of the system must minimize the length and complexity of these interconnections and must be realized, without error, from detailed manufacturing instructions. To permit these requirements to be met a *basic* circuit package must be available. The upper limit to the size of such a basic unit, e.g., an integrated circuit, is set by the number of crystal defects per unit area of silicon. If these defects are distributed at random, the selection of too large a chip size results in some inoperative circuits on a majority of chips. There is thus an economic balance between the number of circuits that can be fabricated in an integrated circuit and the yield of the manufacturing process.

Another limit on the size of the basic package is set by the number of interconnections between the integrated circuits. Reduced VLSI-chip power requirements and shrinking device dimensions have increased the number of circuits on a chip.

CHAPTER 18.2

COMPUTER STORAGE

BASIC CONCEPTS

The main memory attached to a processor represents the most crucial resource of the computing system. In most instances, the storage system determines the bulk of any general-purpose computer architecture. Once the word size and instruction set have been specified, the rest of computer architecture and design deals mainly with optimization of the attached memory and storage hierarchy. Early computers were designed by first choosing the main memory hardware. This not only specified much of the remaining architecture, e.g., serial or parallel machine, but also dictated the *processor cycle time*, which was chosen equal to the *memory cycle time*. As computer technology evolved, the logic circuits and hence processor cycle time* improved dramatically. This improved speed demanded more main-memory capacity to keep the processor busy, but the need for increasingly larger capacity at higher speed placed a difficult and usually impossible demand on memory technology. In the early 1960s, a gap appeared between the main-memory and processor cycle times, and the gap grew with time. Fundamentally, it is desirable that main-memory cycle time be approximately equal to the processor cycle time, so this gap could not continually widen without serious consequences. In the late 1960s, this gap became intolerable and was bridged by the “cache” concept, introduced by IBM in the System/36 Model 85.

The cache concept proved to be so useful and important that by the late 1970s it became quite common in small, medium, and large machine architectures. The *cache* is a relatively small high-speed random-access memory that is paged out of main memory and holds the most recently and frequently used instructions and data. The same fundamental concepts that provide the basis for cache design apply equally well to “virtual memory” systems; only the methods of implementation are different.

In terms of implementation methods, there are five types of storage systems used in computers.

1. *Random-access memory* is one for which any location (word, bit, byte, record) of relatively small size has a unique, physically wired-in addressing mechanism and is retrieved in one memory-cycle time interval. The time to retrieve from any given location is made to be the same for all locations.
2. *Direct-access storage* is a system for which any location (word, record, and so on) is not physically wired in and addressing is accomplished by a combination of direct access to reach a general vicinity plus sequential searching, counting, or waiting to find the final location. *Access time* depends on the physical location of the record at any given time; thus access time can vary considerably, from record to record and to a given record when accessed at a different time. Since addressing is not wired in, the storage medium must contain a certain amount of information to assist in the location of the desired data. This is referred to as *stored addressing information*.
3. *Sequential-access storage* designates a system for which the stored words or records do not have a unique address and are stored and retrieved entirely sequentially. Stored addressing information in the form of

*Processor cycle time is roughly 10 logic-gate delays with appropriate circuit and package loads.

simple interrecord gaps is used to separate records and assist in retrieval. Access time varies with the record being accessed, as with direct access, but sequentially accessing may require a search of every record in the storage medium before the correct one is located.

4. *Associative (content-addressable) memory* is a random-access type of memory that in addition to having a conventional wired-in addressing mechanism also has wired-in logic that makes possible a comparison of desired bit locations for a specified match for all words simultaneously during one memory-cycle time. Thus, the specific address of a desired word need not be known since a portion of its contents can be used to access the word. All words that match the specified bit locations are flagged and can then be addressed on subsequent memory cycles.
5. *Read-only memory (ROM)* is a memory that has permanently stored information programmed during the manufacturing process and can only be read and never destroyed. There are several variations of ROM. *Postable* or *programmable* ROM (PROM) is one for which the stored information need not be written in during the manufacturing process but can be written at any time, even while the system is in use, i.e., it can be posted at any time. However, once written, the medium cannot be erased and rewritten. Another variation is a *fast-read, slow-write* memory for which writing is an order of magnitude slower than reading. In one such case, the writing is done much as in random-access memory but very slowly to permit use of low-cost devices. Several types of ROM chips are available. The erasable programmable ROM (EPROM) allows the use of ultraviolet light (UV) to erase its contents. This UV-EPROM can take up to 20 min to erase its contents; a ROM burner may then be used to implant new data. An electrically erasable programmable ROM (EEPROM) allows the use of electrical energy to clear its memory. The flash memory EPROM is a high-speed erasable EPROM.

The various computer-storage types are related to each other through access time. An approximate rule of thumb for access time comparisons is as follows (where T = access time):

$$T_c = 10^{-1}T_m = 10^{-6}T_d = 10^{-9}T_t$$

where T_c = cache time

T_m = main time

T_d = disc time

T_t = tape time

STORAGE-SYSTEM PARAMETERS

In any storage system the most important parameters are the capacity of a given module, the access time to any piece of stored information, the data rate at which the stored information can be read out (once found), the cycle time (how frequently the system can be accessed for new information), and the cost to implement all these functions.

Capacity is simply the maximum number of bits (b), bytes (B), or words that can be assembled in one basic self-contained operating module.

Access time can vary depending on the type of storage. For random-access memory the *access time* is the time from the instant a request appears in an address register until the desired information appears in an output register, where it can subsequently be further processed. For nonrandom-access storage, the access time is the time from the instant an instruction is decoded asking for information until the desired information is found but not read. Thus, access time is a different quantity for random and nonrandom-access storage. In fact, it is the access time that distinguishes the two, as is evident by the definitions above. Access time is made constant on random-access memory whereas on nonrandom storage access time may vary substantially, depending on the location of information being sought and the current position of the storage system relative to that information.

Data rate is the rate (usually bits per second, bytes per second, or words per second) at which data can be read out of a storage device. *Data transfer time* for reading or writing equals the product of the data rate and the quantity of the information being transferred. Data rate is usually associated with nonrandom-access storage where large pieces of information are stored and read serially. Since an entire word is then read out of random-access memory in parallel, data rate has no significance for such memories.

Cycle time is the rate at which a memory can be accessed, i.e., the number of accesses per unit time, and is applicable primarily to random-access storage.

FUNDAMENTAL SYSTEM REQUIREMENTS FOR STORAGE AND RETRIEVAL

In order to be able to store and subsequently find and retrieve information, a storage system must have the following four basic requirements:

Medium for storing energy

Energy source for writing the information, i.e., write transducers on word and bit lines

Energy sources and sensors to read, i.e., read and sense transducers

Information addressing capability, i.e., address-selection mechanism for reading and writing

The fourth requirement implicitly includes some coincidence mechanisms within the system to bring the necessary energy to the proper position on the medium for writing and a coincidence mechanism for associating the sensed information with the proper location during reading. In random-access memory, it is provided by the coincidence of electric pulses within the storage cell, whereas in nonrandom-access storage, it is commonly provided by the coincidence of an electric signal with mechanical position. In many cases, the write energy source serves as the read energy source as well, thus leaving only sense transducers for the third requirement. Nevertheless, a read energy source is still a basic requirement.

The differences between storage systems lie only in how these four requirements are implemented and, more specifically, in the number of transducers required to achieve these necessary functions. Here a *transducer* denotes any device (such as magnetic head, laser, transistor circuits) that generates the necessary energies for reading and writing, senses restored energy and generates a sense signal, or provides the decoding for address selection.

Since random-access memory is so crucial to processor architecture, we discuss this type first and continue in the order defined above.

The organization of random-access memory systems is intimately dependent on the number of functional terminals inherent in the memory cells. The cell and overall array organization are so interwoven that a discussion of one is difficult without the other. We discuss first the fundamental building block, the memory cell, and subsequently build the array structure from this.

RANDOM-ACCESS MEMORY CELLS

To be useful in random-access memory, the cell must have at least two independent functional terminals consisting of a word line and a common bit/sense line, as shown in Fig 18.2.1a. For writing into the cell, the coincidence of a pulse on the word-select line with the desired data on the bit-select line places the cell into one of two stable binary states. For reading, only a pulse on the word-select line is applied, and a sense signal indicating the binary state of the cell is obtained on the sense line. A more versatile but more complex cell is one having three functional terminals, as in Fig. 18.2.1b. A coincidence of pulses on both the x and y lines is necessary to select the cell for both reading and writing. The appearance of data on the bit/sense line puts the cell in the proper binary state. If no data are applied, a sense signal indicating the binary state of the cell is obtained. The use of coincidence for reading as well as writing allows this cell to be used in complex array organizations.

Magnetic ferrite cores, which played a key role in the early history of computers, were first introduced as three-terminal cells. In fact, the first ferrite core cells used four wires through each core (separate bit and sense lines) to achieve a three-functional terminal cell as in Fig. 18.2.1b. Refinements gradually allowed the bit and sense line to be physically combined to give a three-wire cell and eventually even a two-wire two-terminal cell.

The introduction of *integrated-circuit cells* in the early 1970s for random-access memory led to the disuse of ferrite cores. There are two general types of integrated-circuit cells, static and dynamic. *Static cells* remain in the state they are set until they are reset or the power is removed and are read nondestructively; i.e., the information is not lost when read. A *dynamic cell* gradually loses its stored information and must be refreshed periodically. In addition, the cell state is destroyed when read, and the data must be rewritten after each read cycle. However, dynamic cells can be made much smaller than static cells, which gives a greater density of bits per semiconductor chip. The resulting lower cost more than compensates for the additional complexity.

FIGURE 18.2.1 Reading and writing operations for random-access memory cells having two and three functional terminals: (a) cell with two functional terminals, and (b) cell with three functional terminals.

STATIC CELLS

All static cells use the basic principles of the Eccles-Jordan flip-flop circuit to store binary information in a cross-coupled transistor circuit like that shown in Fig. 18.2.2. Either *junction (bipolar)* or *field-effect transistors (FET)* can be used in the same configuration; only the voltages, currents, and load resistors will be different. To store a 0, transistor T_0 is turned on and T_1 turned off. A stored 1 is just the opposite condition, T_0 off and T_1 on. To achieve these states, it is necessary to control the node voltages at A and B . For instance, if node A voltage V_A is made sufficiently low, the base of T_1 will be low enough to turn T_1 off, causing node B to rise in voltage. This turns the base and hence the collector of T_0 on and holds node A at a low voltage so that a 0 is stored in the flip-flop. If the voltage at node B is made sufficiently low, the opposite state occurs, giving a stored 1. For reading, it is only necessary to sample the voltages at nodes A or B to see which is high or low. This gives a nondestructive read cell since the state is not changed, only sampled. Hence, nodes A and B are the access ports to the cell for both reading and writing.

The basic difference between all *static* cells is in how nodes A and B are accessed. Note that although the flip-flop of Fig. 18.2.2 has two access nodes A and B , it is functionally only a one-terminal cell since nodes

FIGURE 18.2.2 Transistor flip-flop circuits: (a) stored 0, T_0 conducts, $V_A = 0$, $V_B = 1$ V; (b) stored 1, T_1 conducts, $V_A = 1$ V, $V_B = 0$.

FIGURE 18.2.3 MOSFET two-terminal storage cell.

A and B are not independent but operate in a cooperative mode. To make a cell suitable for a random-access array, at least another functional terminal must be added. This can be achieved by the addition of another FET to each node, A and B , as shown in Fig. 18.2.3. Although the two transistors provide a total of four physical connections to the cell, that is, T_2 provides one gate g_2 and one drain d_2 for node A and T_3 provides g_3 and d_3 for node B , the circuit operates in a symmetrical, balanced mode. Since these four terminals are not independent, only two functional terminals are present. The operation of the cell can be understood by tracing through the pulsing sequence of Fig. 18.2.3. The peripheral circuits used to obtain these pulse sequences are not shown. An equivalent two-terminal static cell can be achieved by using junction transistors with some charges, but the operating principles remain basically the same.

A two-terminal static cell that was very popular in early integrated-circuit memories used multiemitter transistors. The cell required high power, however, a condition that greatly limits chip density.

Higher density and lower power can be obtained with the Schottky diode flip-flop cell of Fig. 18.2.4, a very popular cell for high-speed, low-power junction transistor memories. Resistors R_c are part of the internal collector contact resistance of the devices and are much smaller than R_L . The pulses on the word and bit/sense lines are used to forward- or back-bias the diodes D_0 and D_1 , thus controlling or sensing the voltages and nodes A and B , as can be seen by tracing through the pulse sequence shown.

FIGURE 18.2.4 Schottky diode storage cell.

DYNAMIC CELLS

Since the static cells described above operate in a balanced, differential mode, it would seem reasonable that a nondifferential mode would be able to achieve at least a twofold reduction in component count per cell. This is indeed the case, and by sacrificing other properties of static cells, such as their inherent nondestructive read capability, a very significant reduction in cell size is possible. The most widely used such cell is the one-FET dynamic cell shown in a nonintegrated form in Fig. 18.2.5. The essential principle is simply the storing of charge on capacitor C_s for a 1 and no charge for a 0. A single capacitor by itself is sufficient to accomplish this, but an array of such devices requires a means of selecting the desired capacitors for reading and writing and of isolating nonselected capacitors from the array lines. If isolation is not provided, the charge stored on half-selected capacitors may inadvertently be removed, making the scheme inoperable. The isolation and selection means is provided by the simple one-FET device in series with the capacitor, as shown. For operation in an array, the terminal c can be either at ground or $+V_c$, depending on the technology and details of the cell. Assume that c is at $+V_c$, as indicated. To write either state, the word line is pulsed high to turn the FET on. If the bit/sense line is at ground, V_c will charge C_s to a stored 1 state. However, if the bit/sense line is at $+V_c$, any charge on C_s will be removed or no charge is stored if none was there originally, giving a stored 0. For reading, the word line is pulsed high to turn the FET on with the sense line at a normally high voltage. If there was

FIGURE 18.2.5 One-FET-device dynamic storage cell: (a) general equivalent circuit; (b) pulsing sequence.

charge on the capacitor, it will discharge through the bit/sense line to give a signal as shown. If there was no stored charge, no signal would be obtained.

Note that the reading is destructive since a stored 1 is discharged to a 0 and requires regeneration after each read operation in an array. Note also that the FET must carry current in both directions; i.e., the current charging C_s during writing is in the opposite direction of the current during reading. This cell has one further disadvantage: in an integrated structure, the charge on C_s will unavoidably leak off in a time typically measured in milliseconds. Hence the cell requires periodic refreshing, which necessitates additional peripheral circuits and complications. This feature gives rise to the term *dynamic cell*. Despite these disadvantages, this technique allows a very substantial improvement in cell density and cost, at very adequate cycle times and has become very popular.

RANDOM-ACCESS MEMORY ORGANIZATION

A memory is organized into bytes or byte groups known as words. If N is a word of fixed length, each word is assigned an address, or location, in memory. Each word has the same number of bits, called the word length. Each access usually retrieves the entire word. The addresses in memory run consecutively, from address 0 to the largest address.

In any memory system, if E units are to be selected, an address length of N bits is required which satisfies

$$2^N = E$$

In most cases of interest E is equal to W , the number of logical words in the system.

DIGITAL MAGNETIC RECORDING

Magnetic recording is attractive for data processing since it is inexpensive, easily transportable, unaffected by normal environments, and can be reused many times with no processing or developing steps.

The essential parts of a simplified but complete magnetic recording system are shown in Fig. 18.2.6. They consist of a *controller* to perform all the logic functions as well as write-current generation and signal detection; serial-to-parallel conversion registers; a read-write head with an air gap to provide a magnetic field for writing and sensing the flux during reading; and finally the medium. The wired-in cells, array, and transducers of random-access memory have been replaced by one read-write transducer, which is shared by all stored bits, and a shared controller. Coincident selection is still required for reading and writing, and this is obtained by the coincidence of electric signals in the read-write head with physical positioning of the medium under the head.

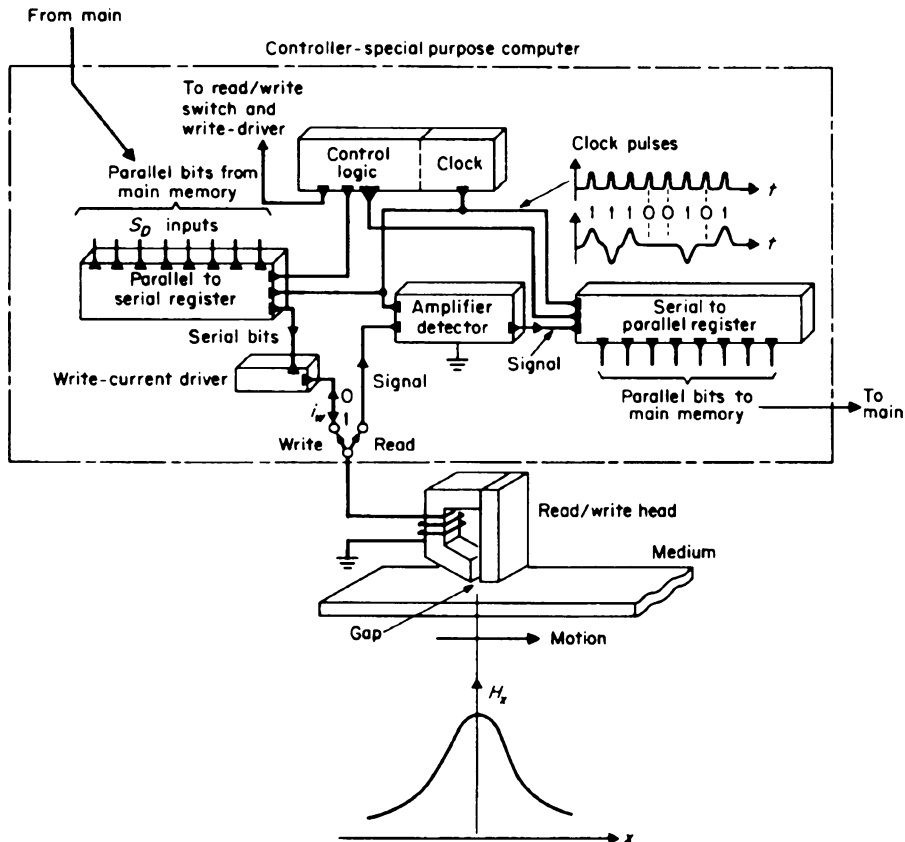

FIGURE 18.2.6 Schematic of simplified complete magnetic recording system.

The recording medium is very similar in principle to ferrite material used in cores. The common material for digital magnetic recording is ferric oxide, Fe_2O_3 . It has remained essentially unchanged for many years except for reductions in the particle size, smoother surfaces, and thinner, more uniform coating, all necessary for high density. This material remained the sole medium for discs and tapes until the late 1970s when NiCo (nickel cobalt) was introduced. These new materials have a higher coercive force and can be deposited thinner and smoother, allowing higher recording densities. Operation of these media requires a reasonably rectangular magnetic hysteresis loop with two stable residual states $+B_r$ and $-B_r$ for storing binary information. The media must be capable of being switched an infinite number of times by a magnetic field produced by the write head, which exceeds the coercive force. Stored information is sensed by moving the magnetized bits at constant velocity under the read head to provide time-changing flux and hence an induced sense signal.

The essence of magnetic recording consists of being able to write very small binary bits, to place these bits as close together as possible, to obtain an unambiguous read-back voltage from these bits, and to convert this continuously varying voltage into discrete binary signals. The writing is done by the trailing edge of the write field.

The minimum size of one stored bit is determined by the minimum transition length required within the medium to change from $+B_r$ to $-B_r$ without self-demagnetizing. The smaller the transition length, the larger the self-demagnetizing field. The minimum spacing at which adjacent bits can now be placed with respect to a given bit is governed mainly by the distortion of the sense signal when adjacent bits are too close, referred to as *bit crowding*. This results from the overlapping of the fringe field from adjacent bits when they are too close and this total, overlapped magnetic field is picked up in the read head as a different induced signal from that produced by a single transition. Conversion of the analog read-back signal to digital form requires accurate clocking; this means that clocking information must be built into the coded information, particularly at higher densities.

Neglecting clocking and analog-to-digital conversion problems for the moment, the signals obtained during a read cycle are just a continuous series of 1s and 0s. A precise means of identifying the exact beginning and end of the desired string of data is necessary, and furthermore, some means for identifying specific parts within the data string is often desirable. Since the only way to recognize particular pieces of stored information is through the sequence of pulse patterns, special sequences of patterns such as gaps, address markers, and numerous other coded patterns are inserted into the data. These can be recognized by the logic hardware built into the controller, which is a special-purpose computer attached to the storage unit. These special recorded patterns along with other types of aids are referred to as the *stored addressing information* and constitute at least a part of the addressing mechanism.

Coding schemes are chosen primarily to increase the linear bit density. The particular coding scheme used determines the frequency content of the write currents and read-back signals. Different codes place different requirements on the mode of operation and frequency response of various parts of the system such as clocking technique, timing accuracy, head time constant, medium response, and others. Each of these can influence the recording density in different ways, but in the overall design the trade-offs are made in the direction of higher density. Thus special coding schemes are not fundamentally necessary but only meet practical needs. For instance, it is possible to store bits by magnetizing the medium over a given region where say $+M_r$ (magnetization) is a stored 1 and $-M_r$ is a stored 0, as in Fig. 18.2.7a. The transition region in between 1s and 0s is assumed to have $M = 0$ except for the small regions of north and south poles on the edges as shown. As the medium is moved past the read head, a signal proportional to dM/dt or dM/dx is induced, so that the north poles induce, say, a positive signal and south poles a negative signal as shown (polarity arbitrary).

This code is known as *return to zero* (RZ) since the magnetization returns to zero after each bit. Each bit has one north- and one south-pole region, so that two pulses per bit result. Not only are two pulses per bit redundant, but considerable space is wasted on the medium for regions separating stored bits. It is possible to push these bits closer together, as in Fig. 18.2.7b, so that the magnetization does not return to 0 when two successive bits are identical, as shown for the first two 1s; hence the name *nonreturn to zero* (NRZ). The result is then only one transition region and one signal pulse per bit. By adjusting the clocking pulses to coincide with the signal peaks, we have a coding scheme in which 0s are always negative signals and 1s are always positive (Fig. 18.2.7b). The difficulty is that only a change from 1 to 0 or 0 to 1 produces a pulse; a string of only 1s or 0s produces no signals. This requires considerable logic and accurate clocking in the controller to avoid accumulated errors as well as to separate 1s from 0s.

FIGURE 18.2.7 Cross-sectional view of magnetic recording medium showing stored bits, signal patterns, and clocking for various codes.

One popular coding scheme is a slightly revised version of the above, namely, *nonreturn to zero inverted* (NRZI), in which all 1s are recorded as a transition (signal pulse) and all 0s as no transition, as shown in Fig. 18.2.7c. There is no ambiguity between 1s and 0s, but again a string of 0s produces no pulses. A *double-clock* scheme, with two clocks, each triggered by the peaks of alternate signals, is used to set the clock timing period to the following strobe point. NRZI is a common coding scheme for magnetic tapes used at medium density.

(e) Time diagram for encoding FM, MFM, and double density MFM (X indicates no flux transition)

FIGURE 18.2.7 (Continued)

For greater than density 1600 b/in. the clocking and sensing become critical, and *phase encoding* (PE), shown in Fig. 18.2.7d, is often used. Since 1s give a positive signal and 0s give a negative signal, a signal is available for every bit. Phase encoding requires additional transitions within the medium, e.g., between successive 1s or successive 0s, as shown. Density, however, is usually limited by sensing, clocking, and other problems rather than by the medium capability.

For magnetic-disc recording, a double-frequency NRZI code is often used. This is obtained from NRZI by adding an additional transition just before each stored bit. The additional transition generates an additional pulse to serve as a clocking pulse. Hence a well-specified window is provided between bits to avoid clocking problems when a string of 0s is encountered. Other popular and useful codes are frequency modulation (FM), modified frequency-modulation (MFM), which is derived from the DF code, and the run-length-limited code. Since the latter does not maintain a distinction between data and clock transitions, a special algorithm is required to retrieve the data.

FM encodes 1 and 0 in different frequencies, but entails a minimum of one pulse per digit for both. A pulse always appears at the beginning of a clock cycle. If the data are 0s, there are no further pulses; if the data are 1s, there is an additional pulse. MFM eliminates the automatic pulse for each digit, and so is more efficient. MFM retains the pulse for 1; for encoding 0, there is a pulse at the beginning of a period unless it was preceded by a 0. The encoding is illustrated in Fig. 18.2.7e. RLL is even more efficient. The run length is the number of no-flux transitions between two consecutive transitions. Figure 18.2.7e shows the encoding for 11000101. FM has 12 flux transitions, while MFM requires only six transitions. In personal computers, MFM is used to achieve *double density* recording, whereas FM is used for single density.

Writing the transition (north or south) in the medium is done by the trailing edge of the fringe field produced by the write head. Since writing is rather straightforward and is not a limiting factor, we dwell here on the more difficult problems of reading and clocking.

Read-back signals can best be understood in terms of the reciprocity theorem of mutual inductance. This theorem states that for any two coils in a linear medium, the mutual inductance from coil 1 to 2 is the same as that from coil 2 to 1. When applied to magnetic recording, the net result is that the signal, as a function of time observed across the read-head winding induced by a step-function magnetization transition, has a shape that is identical to the curve H_x versus x for the same position of the medium below the head gap (Fig. 18.2.6). It is necessary only to replace x by vt , where v = velocity, for the translation of the x scale on H_x to the time scale on V_{sig} versus t . The H_x -versus- x curve with a multiplication factor is often referred to as the *sensitivity function*.

FIGURE 18.2.8 Bit crowding on read-back showing amplitude reduction and peak shift.

The writing of a transition is done by only one small portion of the H_x -versus- x curve, whereas the sense signal is determined by the entire shape of H_x versus x ; that is, the signal is spread out.

This fact gives rise to *bit crowding*, which makes the read-back process more detrimental in limiting density than the writing process. To understand bit crowding, suppose there are two step-function transitions of north and south poles separated by some distance L , as in Fig. 18.2.8. When these transitions are far apart, their individual sense signals shown by the dashed lines appear at the read winding. However, as L becomes small, the signals begin to overlap and, in fact, subtract from each other,⁸ giving both a reduction in peak amplitude and a time shift in the peak position as shown. This represents, to a large extent, the actual situation in practice. The transitions can be written closer together than they can be read.

Clocking or strobing of the serial data as they come from the head to convert them into digital characters is another fundamental problem. If perfect clock circuits with no drift and hence no accumulated error could be made, the clocking problem would disappear. But all circuits have tolerances, and as the bit density increases, the time between bits becomes comparable to the drift in clock cycle times. Since the drift can be different during reading and writing, serious detection errors can result. For high density, it is necessary to have some clocking information contained within the stored patterns as in the PE and double-frequency NRZI codes discussed previously.

MAGNETIC TAPE

The most common use of magnetic tape systems is providing backup for hard disk drives.

Since there are either seven or nine tracks written across the width of the tape, either seven or nine read-write heads are required to store one complete character or byte at a time. The bit spacing along a track is approximately the reciprocal of the linear density, or 0.00125 for an 800 b/in. system. The actual transition lengths are generally about half this bit-cell spacing. In many systems there are separate read and write gaps in tandem to check the reliability of the recording by reading immediately after writing. The tape is mechanically moved back and forth in contact with the heads, all under the direction of a controller. Tape transports in digital systems must be able to start and stop quickly, and achieve high tape speed rapidly. The streaming tape drive used in PCs does not start and stop quickly; it is used to backup disk systems.

The stored addressing information in tapes is relatively simple, consisting of specially coded bits and tape marks in addition to *interrecord gaps* (IRG). The latter are black space on the tape to provide space to accelerate

⁸Linear superposition is possible since the air gap makes the read head linear.

and decelerate between records since reading and writing can only be done at constant velocity. The common gap sizes are 0.6 and 0.75 in. Typically, a tape recorded at 800 b/in. with eight tracks plus parity storing records of 1K B each and a gap of 0.6 in between each record can hold over 10^8 b of data. Even though this represents a large capacity, the gap spaces consume nearly 50 percent of the tape surface, a rather extravagant amount. In order to increase efficiency, records are often combined into groups known as blocks. Since the system can stop and start only at an interrecord gap, the entire block is read into main memory for further processing during one read operation. The highest-density tapes can hold nearly eight times the above amount. Half-inch reel tapes are beginning to be replaced by shorter reels mounted in self-contained cartridges. One tape drive can hold multiple cartridges, which can be mechanically selected and mounted. Typical cartridge tapes are 165 in. long and record 18 tracks on $\frac{1}{2}$ -in. tape at about 25K flux transitions per inch (972 flux transitions/mm).

DIRECT-ACCESS STORAGE SYSTEMS—DISCS

The major type of direct-access storage system is a disc. The system's recording head usually consists of one gap, which is used for both reading and writing. The head is "flown" on an air cushion above the disc surface at separations in the neighborhood of 5 to 100 $\mu\text{in.}$, depending on the system. A well-controlled separation is vital to reliable recording.

For discs, the medium consists of very thin coatings of about 10 $\mu\text{in.}$ or less of the same magnetic material used on tapes but applied to polished aluminum discs. Several discs are usually mounted on one shaft, all rotated in unison. Each surface is serviced by one head. The arms and heads are moved mechanically along a radial line, and each fixed position sweeps out a track on each surface, the entire group of heads sweeping out a cylinder. A typical bit cell is a rectangle 0.005 in. wide by 0.0005 in. long for a 2000 b/in. linear density. The transition length is about half this size.

The fundamental difference between various disc systems centers on the stored addressing information and addressing mechanisms built into the system. Some manufacturers provide a rather complex track format permitting the files to be organized in many different ways, using keys, identifying numbers, stored data, or other techniques for finding a particular word. Thus, the user can "program" the tracks and records to retrieve a particular word "on the fly." This provides a very versatile system but only with additional cost, since considerable function must be built into the controller. Other systems use a very simple track format consisting mainly of gaps and sector marks that do not permit the user to include programmable information about the data. This scheme is more suitable for well-organized data, such as scientific data; it still can be used in other applications with more user involvement.

Floppy discs are used in wide application as inexpensive high-density, medium-speed peripherals. Floppy discs often consist of the same flexible medium (hence the name floppy) as magnetic tape but cut in the form of a disc. Such discs straighten out when spun. The read-write mechanism is usually identical to that above except that the head is in contact with the medium, as in tape. This causes wear that is more significant than in ordinary discs, required frequent replacement of the disc and occasional replacement of the head, particularly when heavily used.

Floppy discs use tracks in concentric circles with movable heads and track-following servo. The systems record on both sides. The major deviations from flying-head discs are much smaller track density and data rate. The linear bit densities are quite comparable to those of tape. Typical parameters are 77 to 150 tracks per disc surface, 1600 to 6800 b/in., rotation from 90 to 3600 r/min.

Optical discs provide more storage than magnetic discs and are commonly in use. One optical disc can contain the same information as 20 or more floppy discs.

VIRTUAL-MEMORY SYSTEMS

Virtual memory is a term usually applied to the concept of paying a gain memory out of a disc. This concept makes the normal-sized main memory appear to the user as large as the virtual-address space* while still appearing to run at essentially the speed of the actual memory. Virtual memories are particularly useful

*Represented by a register holding the virtual address.

in multiprogrammed systems. On the average, virtual memory provides for better management of the memory resource with little wasted space because of fragmentation, which can otherwise be quite severe.

To understand *fragmentation*, suppose that a number of programs to be processed require small, medium, and large amounts of memory on a multiprogrammed machine. Suppose further that a small and a large program are both resident in main memory and that the small one has been completed. The operating system attempts to swap into memory a medium-sized program, to be processed, but it cannot fit in the space freed by the small program. If none of the other waiting programs is small enough to fit, this memory space is wasted until the large program has been completed. It can be seen that with many different-sized programs, fitting several of them into available memory space becomes difficult and leads to much unusable memory at any one time, i.e., fragmentation. Virtual memory avoids this by breaking all programs into *pages* of equal size, and dynamically paging them into main memory on demand. The identical concepts used in a virtual memory are applicable to a cache speed paged out of main memory; only the details of implementation are different, as shown later. We discuss first the basic concepts as applied to a main memory paged out of a disc and indicate, whenever possible, the differences applicable to a cache.

All virtual memories start with a *virtual address* that is larger than the address of the available main memory. Such being the case, the desired information may not be resident in the memory. Hence it is necessary to find out *if*, in fact, it is present. If the information is resident, it is necessary to determine *where* it is residing because the physical address cannot bear a one-to-one correspondence to the virtual address. In fact, in the most general case, there is no relationship between the two, so that an address translation scheme is necessary to find *where* the information does reside.

If the requested page is not resident in memory, a *page fault* results. This requires a separate process to find the page on the disc, remove some page from memory, and bring the new page into this open spot, called a *page frame*. Which page to remove from main storage is determined by a page-replacement algorithm that replaces some page "not recently used." The address-translation and page-replacement functions are shown conceptually in Fig. 18.2.9.

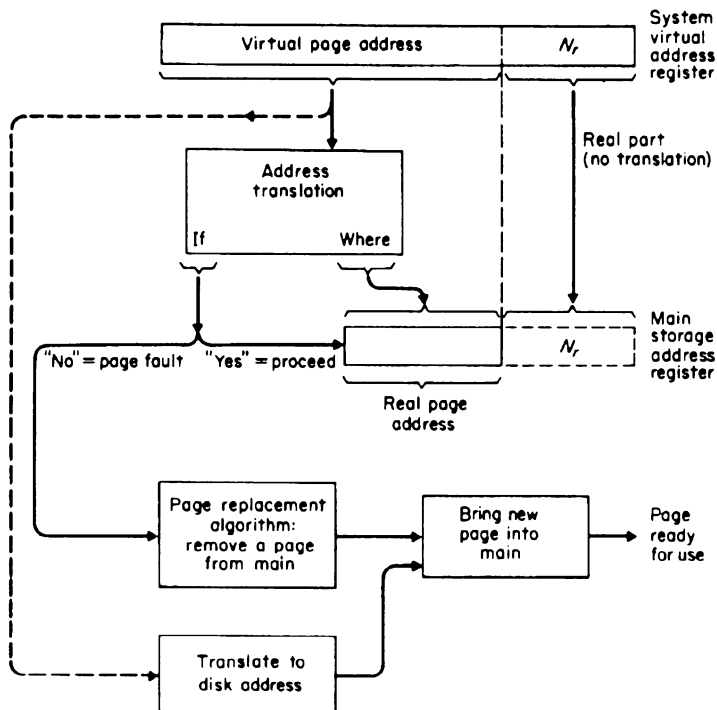

FIGURE 18.2.9 Block diagram of address-translation and page-replacement process.

Thus there are at least three fundamental requirements: (1) a mapping function to specify how pages from the disc are to be mapped into physical locations in memory, (2) an address translation function to determine *if* and *where* a virtual page is located in main memory, and (3) a replacement algorithm to determine which page in memory is to be removed when the *if* translation is a “no,” i.e., when a page fault occurs. These are the three fundamental requirements needed to implement a virtual memory system, either a virtual main memory as here described, or a cache.

MAPPING FUNCTION AND ADDRESS TRANSLATION

The mapping function is a logical construct, whereas the address-translation function is the physical implementation of the mapping function. Mapping functions cover a range from *direct mapping* to fully *associative mapping*, with a continuum of *set-associative* mapping functions in between. A very simple way to understand maps is to consider the example of building one’s own personal telephone directory “paged” out of larger telephone books. Assume that the personal directory is of fixed size, say $4(26) = 104$ names, addresses, and associated telephone numbers. A direct mapping from the large books to the personal directory is an alphabetical listing of the 104 names. Given any name, we can go directly to the directory entry, if present. Such an address translation could be hard-wired if desired. There are two difficulties with direct mapping: (1) it is very difficult to change, and (2) suppose we allow one entry for Jones. If later we wish to include another Jones, there is no room. If both Joneses are needed, there is a conflict unless we restructure the entire directory. Because of such conflicts, direct maps are seldom used.

At the other end of the spectrum is a *fully associative directory* in which 104 names in any combinations are placed in any positions of the directory. This directory is very easily changed because a name not frequently used can simply be removed and a new name entered in its place without regard to the logical (alphabetical) structure of the two names. For instance, if the directory is full and we wish to make a new entry Zeyer, we first find a name not used much recently. If Abas is in position 50 of the directory, remove Abas and replace the entry with Zeyer. The major difficulty, obviously, is in searching the directory. If we wish to know the number for Smith, we must associatively search the entire directory (worst case) to find the desired information. This is very time-consuming and impractical in most cases.

Imagine the usual telephone directory that is associatively organized. There are several ways to resolve the fundamental conflict between ease of search and ease of change. The fully associative directory can be augmented with a separate, directly organized and accessed table that contains a list of all names. However, the only other piece of data is a number indicating the entry this name now occupies in the associative directory. If a directory entry is changed, the new entry number must be placed in this table. If we wish to access a given name, a direct access to the table gives the entry number. A subsequent direct access to this entry number gives the desired address and telephone number.

The penalty is the two accesses plus the storage and maintenance of the translation table. Nevertheless, this is exactly the scheme used in all virtual main memories paged out of disc, drum, or tape. This table is typically broken into a hierarchy of two tables called *segment table* and *page table* to facilitate the sharing of segments among users and to allow the tables to also be pages as units of, say, 4K B. These tables are built, manipulated, and maintained by supervisory programs and generally are invisible to the user. Although these tables can consume large amounts of main memory and of system overhead, the saving greatly exceeds the loss.

An example of such a virtual memory with a fully associative mapping using a two-level table-translation scheme is illustrated in Fig. 18.2.10. Each user has a separate segment and page table (the two are, in principle, one table) stored in main memory along with the user’s data and programs. When an access is required to a virtual address, say $N_p N_s$, as in Fig. 18.2.10, a sequence of several accesses is required. The user ID register bits μ give a direct address to the origin of that user’s segment table in main memory. The higher-order segment-index bits (SI) of the virtual address (typically 4 to 8 b) specify the index (depth) into this table for the required entry. This segment table entry contains a flag specifying *if* this entry is valid or not, and a *where* specifying the origin of that user’s page table in memory, as shown. The lower-order page index bits (PI) of the virtual address specify the index into the page table as shown. The page-table entry so accessed contains an *if* bit to indicate whether the entry is valid (*if* page is present in main memory) and a *where* address that

FIGURE 18.2.10 Virtual-storage-address translation using a two-level table (segment and page) for each user.

gives the real main-memory address of the desired page. The lower-order N_r bits of the address, typically 11 or 12 b for 2K- or 4K-B pages, are real, representing the word or byte of the page and hence do not require translation.

In cache memories, speed is so important that a fully associative mapping with a table-translation scheme is impractical. Instead a set-associative mapping and address translation is implemented directly in hardware. Although it is not generally realized, set-associative mapping and translation is commonly used in everyday life. It is a combination of a partially direct mapping and selection, with a partially associative mapping and translation. Examples include the 4-way set associative organization in Fig. 18.2.11 and the most common type of personal telephone directory as shown in Fig. 18.2.12, where a small index knob is moved to the first letter of the name being sought. Suppose there is one known position on the directory for each letter of the alphabet and we organize it with a set associativity of four. This means that for each letter there are exactly four entries or names possible, and these four can be in any order, as shown by the insert of Fig. 18.2.12. To find the telephone number for any given name such as Becker, we first do a direct selection to the letter B followed by an associative search over the four entries. Thus it is apparent that a set-associative access is a combination of the two limiting cases, namely, part direct and part associative. Many different combinations are possible with various advantages and disadvantages.

This set-associative directory (Fig. 18.2.12) with four names or entries per set is exactly the same fundamental type used in many cache-memory systems. The directory is implemented in a random-access memory array as shown in Fig. 18.2.11, where there are 128(4) entries total, requiring nine total virtual page address bits. Each set of 4 is part of one physical word (horizontal) of the random-access array, so there are 128 such

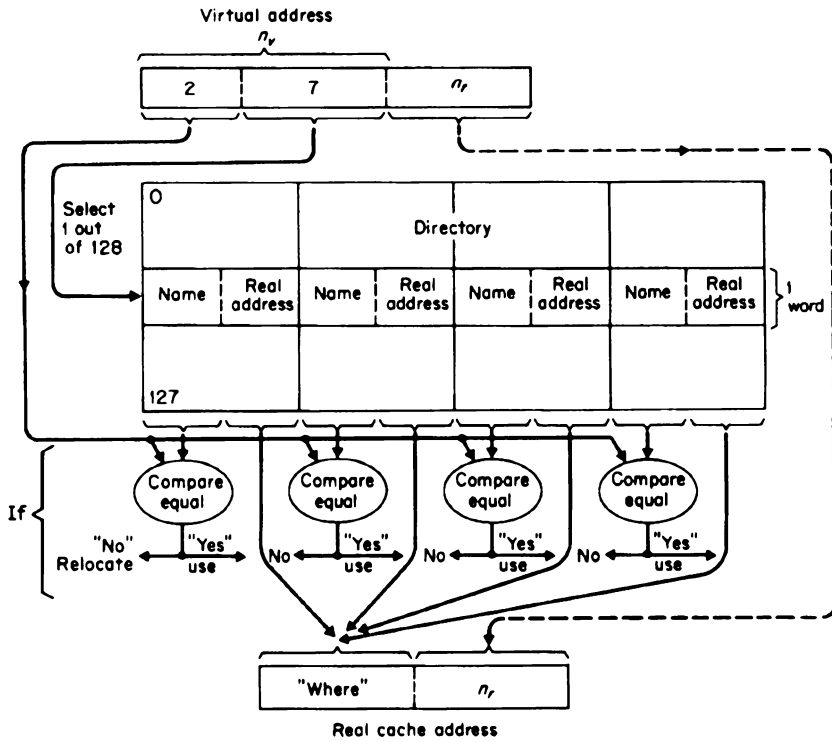

FIGURE 18.2.11 Cache directory using 4-way set associative organization.

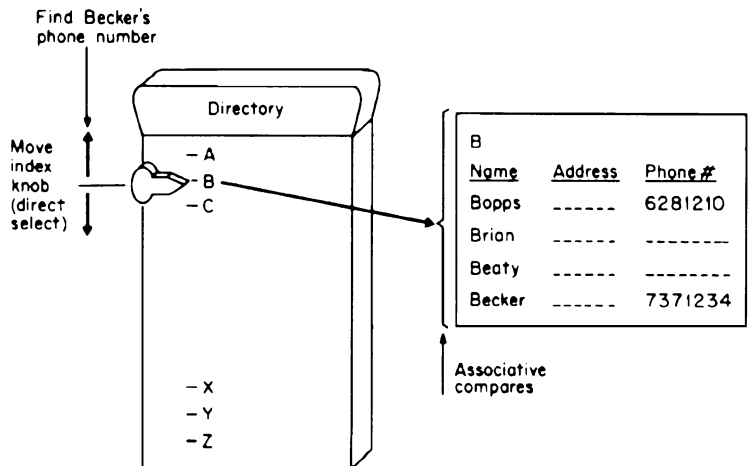

FIGURE 18.2.12 Fundamentals of a general set-associative directory showing direct and associative parts of the addressing process.

words, requiring seven address bits. The total virtual address $n_v = 9$ must be used in the address translation to determine *if* and *where* the cache page resides. As before, the lower-order bits n_r , which represent the byte within the page, need not be translated. Seven virtual bits are used to select directly one of the 128 sets as shown. This is analogous to moving the index knob in Fig. 18.2.12 and reads out all four names of the set. The NAME part is 2 b long, representing one of the four of the set. All four are compared simultaneously with the 2 b of the virtual address. *If* one of these gives a “yes” on compare equal, then the correct “real” address of the page in the cache, which resides in the directory with the correct NAME, is gated to the “real” cache-address register.

CHAPTER 18.3

INPUT/OUTPUT

INPUT-OUTPUT EQUIPMENT

Input-output (I/O) equipment includes cathode-ray tubes and other display devices; printers; keyboards; character, handwriting, voice, and other recognition devices; optical scanners and facsimile equipment; speech synthesizers; process control sensors and effectors; various pointing devices such as “mice,” wands, joysticks, and touch screens; card readers and punches; paper tapes; magnetic storage devices such as tape cassette units, floppy and hard disk drivers, drums, and various other types of tape drives; and several different types of optical storage devices, mainly disks.

Such equipment presents a wide range of characteristics that must be taken into account at their interface with the central processing unit (CPU) and its associated main memory. A magnetic tape unit usually operates serially by byte, writing or reading information of varying record length. Different types of printers deal with information on a character, line, or page basis, both in a coded (character) and noncoded mode. Most cathode-ray tube display devices build up the image in a bit-by-bit raster, but others handle data in the form of vectors or even directly coded as characters. Different types of I/O gear operate over widely different speed ranges, ranging from a few bytes per second to millions of bytes per second. Many I/O devices do little more than pass bits to a processor, while others have substantial internal processing power of their own.

In the many systems making use of telecommunications, an ever-growing array of I/O equipment can be attached to a variety of telecommunications links, ranging from twisted-pair copper wire to long-haul satellite and optical fiber links. Virtually any I/O device can be attached both locally and remotely to other elements of a system.

Data are entered by human operators, read from storage devices, or collected automatically from sensors or instruments.

Keyboards, wands, and character recognition equipment are typical *input devices*, while printers and displays are the most common *output devices*. Storage devices that can function in a read-write (R/W) mode naturally can fill both functions.

I/O CONFIGURATIONS

Input-output devices can be attached to other elements of the system in a wide variety of ways. When the attachment is *local*, the attachment may be an I/O bus, or a channel. Figures 18.3.1 and 18.3.2 show a typical bus attachment configuration of small systems such as personal computers. A program gains access to the I/O gear through the logic circuitry of the ALU. For example, to transfer information to I/O gear, a program might extract requested information from storage, edit and format it, add the address of the I/O device to the message, and deliver it to the bus, from which the proper I/O device can read it and deliver it to the requestor. In this simple

FIGURE 18.3.1 Machine organization with an I/O bus.

configuration, time must be spent by the CPU waiting for delivery of the information to the I/O gear and, if so programmed, for reception of an acknowledgement of the reception. If several types of I/O gear are used, the program or—more commonly—the operating system must take into account variations in formatting control, and speed of each type. A common method of improving the performance of the *I/O subsystem* is I/O buffering. A buffer may be part of the CPU or a segment of main memory, which accumulates information at machine speeds so that subsequent information transfers to the I/O gear can take place in an orderly fashion without holding up the CPU. In other cases, the I/O gear itself will be buffered, thus enabling, for example, syn-

chronous input devices to operate at maximum throughput without having to repeatedly interrupt the CPU. A buffered system is desirable in all but the simplest configurations and is all but essential in any case in which the speed of the I/O device is not matched to the data rate of the receiving communications link or I/O bus.

I/O MEMORY-CHANNEL METHODS

The arrangement shown in Fig 18.3.2 involves information transfer from the I/O gear into the ALU and thence to main store. With a modularized main store, I/O data can be directly entered in, and extracted from, main storage. Direct access to storage implies control interrelationships at the interface between the I/O and the CPU to ensure coordination of accesses between the two units. The basic configuration used for direct access of I/O into storage is shown in Fig. 18.3.2. The connecting unit between the main store and the I/O gear is called a *channel*. A channel is not merely a data path but a logical device that incorporates control circuits to fulfill the relatively complex functions of timing, editing, data preparation, I/O control, and the like.

TERMINAL SYSTEMS

Terminal systems use key-entry devices with a display and/or printer for direct access to a computer on a time-shared basis. The programming system in the CPU is arranged to scan a number of such terminals through a set of ports. Each character, line, or block of data from each terminal is entered into a storage area in the computer until an appropriate action signal is received. Then by means of an internal program the computer generates such responses as error signals, requests for data, or program outputs. Terminal systems extend the power of a large computer to many users and give each user the perception of using an independent system. Terminals remotely connected to host CPUs have the same overall description, except that communication is mediated by means of various network architectures and protocols (q.v.).

FIGURE 18.3.2 Machine organization with an I/O bus and I/O buffer.

A terminal that contains a high level of logic operational capability is often called an *intelligent terminal*. A personal computer with a communications adapter or modem is increasingly filling this description. If there are many terminals and a centralized computer or computer complex in a system, it is sometimes more economical to use simpler terminals and use the logic in the computer. More commonly, it has been the practice to attach a number of *dumb* terminals to an intelligent control unit, which, in turn, communicates with a host processor. Economic factors such as communication line cost and hardware cost, as well as such intangibles as system reliability and data security, are among those factors which influence the choice.

The proliferation of communicating personal computers has formed the basis of local and wide area networks (LANs and WANs). These networks provide both connectivity between sites and local processing power.

PROCESS-CONTROL ENTRY DEVICES

In process control, e.g., chemical plants and petroleum refineries, inputs to the computer generally come from sensors (see Sec. 8) that measure such physical quantities as temperature, pressure, rate of flow, or density. These units operate with a suitable analog-to-digital converter that forms direct inputs to the computer. The CPU may in turn communicate with such devices as valves, heaters, refrigerators, pump, and so forth, on a time-shared basis, to feed the requisite control information back to the process-control system.

MAGNETIC-INK CHARACTER-RECOGNITION EQUIPMENT

A number of systems have been developed to read documents by machine. *Magnetic-ink character recognition* is one. Magnetic characters are deposited on paper or other carrier materials in patterns designed to be recognized by machines and by operators. A change in reluctance, associated with the presence of magnetic ink, is sensed by a magnetic read head. The form of the characters is selected so that each yields a characteristic signature.

OPTICAL SCANNING

Information to be subjected to data processing comes from a variety of sources, and often it is not feasible to use magnetic-ink characters. To avoid the need for retranscription of such information by key-entry methods, devices to read documents optically have been developed.

Character recognition by optical means occurs in a number of sequential steps. First, the characters to be recognized must be located and initial starting points on the appropriate characters found. Unless the characters have been intentionally constrained to be placed in well-defined locations, it is then necessary to segment the characters, that is, to determine where one character leaves off and the next one begins. Third, the characters must be scanned to generate a sequence of bits that represents the character. The resulting bit pattern must then be compared with prestored reference patterns in order to identify the pattern in question.

The scanning can be performed in a number of ways. In one technique the pattern to be recognized is transported past a linear photodetector array and the output is sampled at periodic intervals to determine the bit pattern. A second way is to scan a laser beam across the page using a rotating mirror or holographic mirror device, with the light scattered from the document being detected by an assembly of photodetectors. Other approaches that use various combinations of arrays of sources and detectors with mechanical light deflection devices are also used.

As an alternative to comparing the scanned bit pattern with stored references, a *correlation function* between the input and stored functions can be computed. Optical spatial filtering is occasionally used, too.

Another common method of data entry is through the encoding of characters into a digital format, permitting scan by a wand or, alternatively, by moving the pattern past a "stationary" scanning laser pattern. Typical of this encoding scheme is the bar code, known as the *universal product code* (UPC), which has been standardized in the supermarket industry by industry agreement to the code selection by the Uniform Grocery Product Code Council, Inc.

BATCH-PROCESSING ENTRY

One computer can be used to enter information into another. For example, it is often advantageous for a small computer system to communicate with a larger one. The smaller system may receive a high-level language problem, edit and format it, and then transmit it to a larger system for translation. The larger system, in turn, may generate machine language that is executed at the remote location when it is transmitted back.

Remote systems may receive data, operate on them, and generate local output, with portions transmitted to a second unit for filing or incorporation into summary journals. In other cases, two CPUs may operate generally on data in an independent fashion but may be so interconnected that in the event of failure one system can assume the function of the other. In other cases, systems may be interconnected to share the work load. Computer systems that operate to share CPU functions are called *multiprocessing* systems.

PRINTERS

Much of the output of computers takes the form of printed documents, and a number of *printers* have been developed to produce them. The two basic types of printer are *impact printers*, which use mechanical motion of type slugs or dot-forming hammers driven against a carbon film or ink-loaded fabric ribbon to mark paper, and *nonimpact printers*, which use various physical and chemical phenomena to produce the characters.

Printers are additionally characterized by the sequence in which characters are placed on the page. *Serial printers* print one character at a time, by means of a moving print head. After a line of characters has been printed, the paper is indexed to the next print line. *Line or parallel printers* are designed such that they print all the characters on a print line at (nearly) the same time, after which the paper is indexed. Finally, *page printers* are limited by the technology to marking an entire piece of paper before the output is accessible to a user. Most such printers actually generate a page one dot at a time using some type of raster scanning means.

Printers may either be *fully formed character printers*, or *matrix* (or *all-points-addressable*) printers. Matrix printers build up characters and graphics images dot by dot; some matrix-printing mechanisms allow the dots to be placed anywhere on a page, while others are constrained to printing on a fixed grid. Dot size (resolution) ranges from 0.012 in. (0.3 mm) in many wire matrix printers to 0.002 in. (0.05 mm) in some nonimpact printers. Dot spacing (addressability) ranges from as few as 60 dots per inch (24 dots per centimeter) to more than 800 dots per inch.

The speed of serial printers typically ranges from 10 to over 400 characters per second. Line printer speeds range from 200 to about 4000 lines per minute. Page printers print from 4 to several hundred pages per minute.

IMPACT PRINTING TECHNOLOGIES

Figure 18.3.3 is a sketch of a band printer, the most common high speed impact line printer. Band printers are used where price and throughput (price/performance) are the dominant criteria. In this printer, the characters are engraved on a steel band, which is driven continuously past a bank of hammers—usually, 132—at speeds of the order of 500 cm/s. A ribbon is suspended between the band and the paper, behind which hammer bank is located. This is known as *back printing*. When a desired character is located at a specific print position, that hammer is actuated without stopping the band. Several characters may be printed simultaneously, although activating too many hammers at one time must be avoided, since that would slow or stop the band and overload the hammer power supply. Timing marks (and an associated sensor) provide precise positional information for the band.

Figure 18.3.4 is a schematic sketch of a print head for a wire matrix printer. These printers are most commonly used with personal computers. The print head contains nine hammers, each of which is a metal wire. The wires are activated in accordance with information received from a character generator so that a desired character can be printed in an array of dots. The wires strike a ribbon, and the print head is positioned on a carrier. Printing is done while the carrier is in continuous motion, and it is necessary to know the position to an

FIGURE 18.3.3 An engraved band print mechanism.

FIGURE 18.3.4 Schematic drawing of wire-matrix print head and print mechanism.

accuracy of a fraction of a dot spacing, that is, to much better than 0.1 mm. To do this, an optical grating is placed on the printer frame, and the motion of the carrier is detected by the combination of a simple light source and photodetector. Other sensing and control schemes are also used. Quite attractive printing can be generated with a wire matrix printer if the dots are more closely spaced. This can be done in the serial printer shown here by printing the vertical rows of dots in an overlapping fashion, and then indexing the page vertically only one-half or one-third the dot spacing in the basic matrix, so that the dots also overlap in the other direction. Many variations of this print mechanism are available. Among them are the use of 18 or 24 wires, and the use of multicolor ribbons to enable color printing.

NONIMPACT PRINTERS

Nonimpact printers use various mechanisms to imprint characters on a page. There are two major classes of such devices, those using *special paper* and those using *ordinary paper*. In one type of special-paper device, the paper is coated with chemicals that form a dark or colored dye when heated. Characters are formed by contact with selective heated wires or resistors that form a matrix character. Another type of special paper, known as *electro-erosion paper*, is coated with a thin aluminum metal film that can be evaporated when subjected to an intense electric spark, obtained from a suitably actuated array of wires.

Another method of nonimpact printing on special paper, called *electrography*, or, more often, *electrostatic printing*, uses a dielectric coated paper that is directly charged by ion generation. In this case an electrostatic latent image is generated by an array of suitably addressed styli. The charged paper can be toned and fixed as in *electrophotography*, also known as *xerography*. In the xerographic process, the image is developed by exposing the latent image to a toner, which may be very small solid powder particles or a suspension of solid particles or a dye in a neutral liquid. The toner particles, suitably charged, adhere either to the charged or the neutral portions of the image. This pattern is then fixed, by heat, pressure, or evaporation of the liquid carrier.

Most plain-paper nonimpact page printers combine laser and electrophotographic techniques to produce high-speed, high-quality computer printout. The printing process uses a light-sensitive photoconductive material (such as selenium, or various organic compounds) wrapped around a rotating drum. The photoconductor is electrically charged and then exposed to light images of alphanumeric or graphic (image) information). These images selectively discharge the photoconductor where there is light and leave it charged where there is no light. A powdered black toner material is then distributed over the photoconductor where it adheres to the unexposed areas and does not adhere to the exposed areas, thus forming a dry-powder image. This image is then electrostatically transferred to the paper where it is fixed by fusing it with heat or pressure. In some printers the toner is suspended in a liquid carrier, and the image is fixed by evaporation of the carrier liquid. A different choice of toner materials allows development of the unexposed rather than the exposed areas. The various elements of this process can all be quite complex and many variations are used. (See Fig. 18.3.5.)

IMAGE FORMATION

Electrophotography, transfer electrophotography, and thermal methods require that optical images of characters be generated. In some types of image generation, the images of the characters to be printed are stored. Other devices use a linear sweep arrangement with an on-off switch. The character image is generated from a digital storage device that supplies bits to piece together images. In the latter system any type of material can be printed, not just the character sets stored; the unit is said to have a *noncoded-information* (NCI) capability or *all-points-addressable* (APA) capability.

Patterns are generated either by scanning a single source of energy, usually a laser in printers and an electron beam in display devices, and selectivity modulating the output, or else by controlling an array of transducers. The array can be the actuators in a wire matrix printer, light-emitting diodes, ink-jet nozzles (see below), an array of ion sources, thermal elements, or magnetic or electrical styli.

FIGURE 18.3.5 Xerographic printer mechanism.

The output terminals for digital image processing are high-resolution monochrome or color monitors for real-time displays. For off-line processing, a high-resolution printer is required. The inputs to digital image-processing requirements are generally devices such as the vidicon, flying-spot scanner, or color facsimile scanner.

INK JETS

Another method of direct character formation, usually used on untreated paper, employs ink droplets.

An example of this technique is continuous-droplet ink-jet printers, which have been developed for medium- to high-quality serial character printing and is also usable for very high speed line printing. When a stream of ink emerges from a nozzle vibrated at a suitable rate, droplets tend to form in a uniform, serial manner. Figure 18.3.6 shows droplets emerging from a nozzle and being electrostatically charged by induction as they

FIGURE 18.3.6 Ink-jet printing. Ink under pressure is emitted from a vibrating nozzle, producing droplets that are charged by a signal applied to the charging electrodes. After charging, each drop is deflected by a fixed field, the amount of deflection depending on the charge previously induced by the charging electrodes.

FIGURE 18.3.7 Nozzle-per-spot binary ink-jet printer.

break off from the ink stream. In subsequent flight through an electrostatic field, the droplets are displaced according to the charge they received from the charging electrode. Droplets generated at high rates (of the order of 100,000 droplets per second) are guided in one dimension and deposited upon untreated paper. The second dimension is furnished by moving the nozzle relative to the paper. Since the stream of droplets is continuous, it is necessary to dispose of most of the ink before it reaches the paper. This is usually done by selectively charging only those drops that should reach the paper; uncharged drops are intercepted by a gutter and recirculated.

An array of nozzles can be used in combination with paper displacement to deposit characters. The simplest form of such a printer has a separate nozzle for each dot position extending across the page (Fig. 18.3.7). Uncharged droplets proceed directly to the paper, while unwanted drops are charged such that they are deflected into a gutter for recirculation. Moving the paper past the array of nozzles provides full two-dimensional coverage of the paper. Such a binary nozzle-per-spot printer can print tens of thousands of lines per minute. Ink-jet systems have also been developed using very fine matrices for character generation, producing high document quality.

VISUAL-DISPLAY DEVICES

Visual-display devices associated with a computer system range from console lights that indicate the internal state of the system to *cathode-ray-tube* displays that can be used for interactive problem solving. In the cathode-ray tube, a raster scan, in conjunction with suitable bit storage, generates the output image.

For certain graphics applications, it is preferable to write the vectors making up the image directly, rather than by means of raster deflection. Such a vector mode provides higher-quality output, but can be overcome by refresh limitations when there is a large number of vectors to be displayed. Such displays are usually used with a keyboard for information entry, so that the operator and computer can operate in an interactive mode. Graphic input devices such as mice, joysticks, touch panels, and the like are also often used.

A relatively low cost, low power, and high-performance display is the *liquid-crystal display* (LCD). Liquid crystals differ from most other displays in that they depend on external light sources for visibility; i.e., they

18.70 DIGITAL COMPUTER SYSTEMS

employ a *light-valve* principle. This type of display is composed of two parallel glass plates with conductive lines on their inner surfaces and a liquid-crystal compound (e.g., of the *nematic* variety) sandwiched between them. In the dynamic scattering display, the clear organic material becomes opaque and reflective when subjected to an electric field. As in other displays, the characters are built up from segments or dots.

Color LCDs are available. In one version, a dot triad is used, with thin-film color filters deposited directly on the glass. Again, the complexity and cost are such that where low power and the thin-form factors are not critical, the technology has been uncompetitive with CRTs.

CHAPTER 18.4

SOFTWARE

NATURE OF THE PROBLEM

Even though hardware costs have been declining dramatically over a 30-year period, the overall cost of developing and implementing new data processing systems and applications has not decreased. Because developing software is a predominantly labor-intensive effort, overall costs have been increasing. Furthermore, the problems being solved by software are becoming more and more complex. This creates a real challenge to achieve intellectual and management control over the software development process.

The successful development of software requires discipline and rigor coupled with appropriate management control arising from adequate visibility into the development process itself. This has led to the rise of *software engineering*, defined as the application of scientific knowledge to the design and construction of computer programs and the associated documentation and to the widespread use of standardized commercially available software packages. In addition, a set of software tools has been developed to assist in system analysis of designs. The tools, often called computer assisted systems engineering, or CASE tools, mechanize the graphic and textual descriptions of processes, test interrelationships, and maintain cross-referenced data dictionaries.

THE SOFTWARE LIFE-CYCLE PROCESS

In the earlier history of software the primary focus was on its development, but it has become evident that many programs are not one-shot consumables but are tools intended to be used repetitively over an extended time. As a result, it is obvious that the entire software life cycle must be considered. The software life cycle is that period of time over which the software is defined, developed, and used. Figure 18.4.1 shows the traditional model of the software life-cycle process and its five major phases. It begins with the *definition phase*, which is the key to everything that follows. During the definition phase, the system requirements to be satisfied by the system are developed and the system specifications, both hardware and software, are developed. These specifications describe *what* the software product must accomplish. At the same time, test requirements should also be developed as a requisite for systems acceptance testing.

The *design phase* is concerned with the design of a software structure that can meet the requirements. The design describes *how* the software product is to function. During the *development phase*, the software product is itself produced, implemented in a programming language, tested to a limited degree, and integrated. During the *test phase*, the product is extensively tested to show that it does in fact satisfy the user's requirements. The *operational phase* includes the shipment and installation of the data-processing system in the user's facility. The system is then employed by the user, who usually embarks on a maintenance effort, modifying the system to improve its performance and to satisfy new requirements. This effort continues for the remainder of the life of the system.

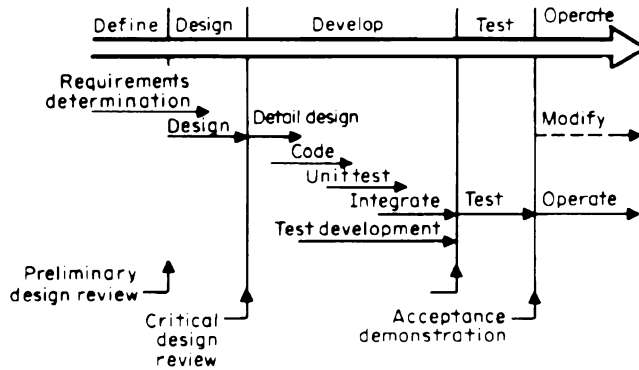

FIGURE 18.4.1 Traditional model of the software life-cycle process showing its five major phases.

PROGRAMMING

When a stored-program digital computer operates, its storage contains two types of information: the data being processed and program instructions controlling its operations. Both types of information are stored in binary form. The control unit accesses storage to acquire instructions; the ALU makes reference to storage to gain access to data and modify it. The set of instructions describing the various operations the computer is designed to execute is referred to as a *machine language*, and the act of constructing programs using the appropriate sequences of these computer instructions is called *machine-language programming*. It is possible but expensive to write them directly in machine languages, and maintenance and modification is virtually impossible. *Programming languages* have been created to make the code more accessible to its writers.

A programming language consists of two major parts: the language itself and a translator. The language is described by a set of *symbols* (the *alphabet*) and a *grammar* that tells how to assemble the symbols into correct strings. The *translator* is a machine-language program whose main function is to translate a program written in the *programming language* (the *source code*) into machine language (*object code*) that can be executed in the computer. Before describing some of the major programming languages currently in use, we consider two important programming concepts, *alternation and iteration*, and also see by examples some of the difficulties associated with machine-language programming.

ALTERNATION AND ITERATION

These techniques are illustrated here using a computer whose storage consists of 10,000 words each containing 4 bytes numbered 1 to 4. The instruction format is

1	2	3	4
op code	0	Address	

Op code	Name	Description
01	LOAD	Loads value from addressed word into data register
02	COMP	Compares value of addressed word with data-register value
03	ADD	Adds value of addressed word to data register
08	STORE	Copies value of data register into addressed storage word
20	BRLO	Branches if data-register value from last previously executed COMP was less than comparand

The computer used in this simplified example contains a separate nonaddressable data register that contains one word of data. Further, each instruction is accessed at an address 1 more than that of the previously executed instruction unless that instruction was BRLO instruction with a low COMP condition, in which case the address part of the BRLO instruction is the address at which the next instruction is to be accessed.

Consider the following program instructions (beginning at address 0100) to select the lower value of two items (in words 0950 and 0951) and place the selected value in a specific place (word 0800):

Address	Instruction	Effect
0100	01000950	Place first-item value in data register
0101	02000951	Compare second-item value with data-register value
0102	20000104	Branch to next instruction at address 0104 if data-register value was lower
0103	01000951	Place second item value in data register
0104	08000800	Store lower value in result (word 0800)

FLOWCHARTS

One way to depict the logical structure of a program graphically is by the use of *flowcharts*. Flowcharts are limited in what they can convey about a computer program, and with the advent of modern programming design languages they are becoming less widely used. However, they are used here to portray these simple programs graphically. The program of the preceding example is depicted by the flowchart shown in Fig. 18.4.2.

The flowchart contains boxes representing processes (rectangular boxes) and decisions (alternations—diamond-shaped boxes). The arrows connecting the boxes represent the paths and sequences of instruction execution. An alternation represents an instruction (or a sequence of instructions) with more than one possible successor depending on the result of some processing test (this is commonly a conditional branch). In the example, instruction 0103 is or is not executed depending on the values of the two items.

If the example is extended to require finding the least of four item values, the flowchart is that shown in Fig. 18.4.3. If the example is further extended to find the largest value of 1000 items (in locations 0336 through 0790 inclusive in hexadecimal), the flowchart and the corresponding program become very large if analogous extensions of the flowcharts are used.

The alternative is to use the technique known as the *program loop*. A program loop for this latter example is:

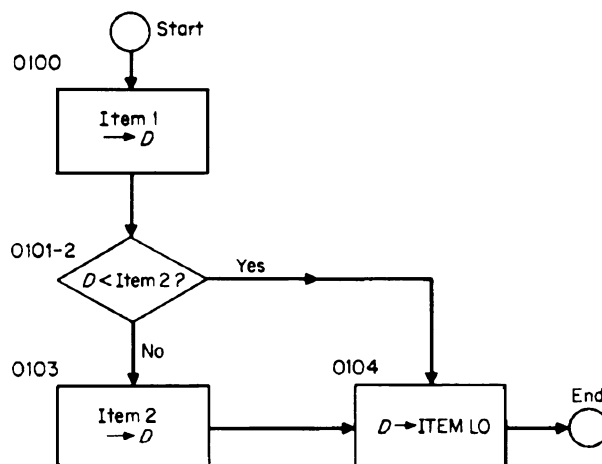

FIGURE 18.4.2 Flowchart of a simple program. The boxes represent processes; the diamonds represent decisions.

Address	Instruction	Effect
0100	01000950	Move first item as initial value of result (ITEMHI)
0101	08000800	
0102	01000900	Initialize loop to begin with item 2
0103	08000104	
0104	(00000000)	Loop, N th item to data register
0105	02000800	Compare with prior ITEMHI value
0106	20000108	Branch to 108 if N th item value low
0107	08000800	Store N th item value as ITEMHI
0108	01000104	Increment value, of N by 1
0109	03000901	
010A	08000104	
010B	02000902	Compare against $N = 1001$
010C	20000104	Branch for looping if $N < 1001$
010D	end	
0900	01000951	Load item 2; initial instruction
0901	00000001	Address increment of 1
0902	010003E9	Limit test; load 1001st item

FIGURE 18.4.3 Flowchart of a repetitive task.

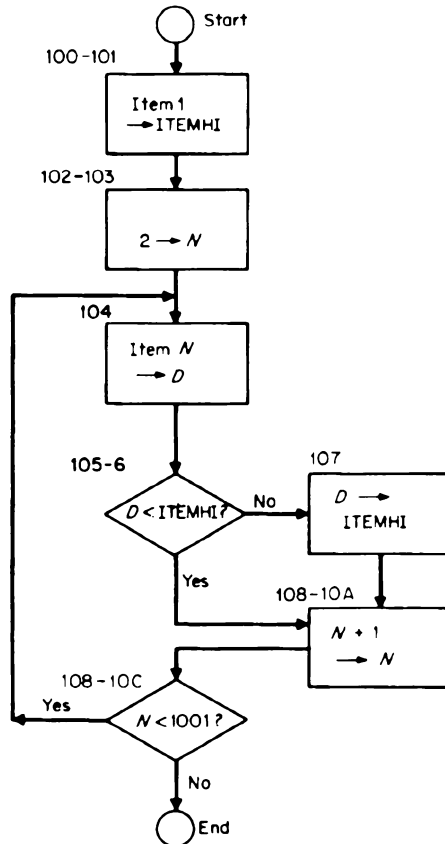

FIGURE 18.4.4 Flowchart showing a program loop.

The corresponding flowchart appears in Fig. 18.4.4. The loop proper (instructions 0104 to 010C) is executed 999 times. The instruction at 0104 accesses the N th item and is indexed each time the program flows through the loop so that on successive executions successive words of the item table are obtained. After each loop execution, a test is made to determine whether processing is complete or a branch should be made back to the beginning of the loop to repeat the loop program.

The loop proper is preceded by several instructions that *initialize* the loop, presetting ITEMHI and the instruction 0104 value for the first time through. A loop customarily has a *process* part, and an *induction* part to make changes for the next loop iteration, and an *exit test* or termination to determine whether an additional iteration is required.

ASSEMBLY LANGUAGES

The previous example illustrates the difficulty of preparing and understanding even simple machine-language programs. One help would be the ability to use a symbolic (or mnemonic) representation of the operations and addresses used in the program. The actual translation of these symbols to specific computer operations and addresses is a more or less routine clerical procedure. Since computers are well suited to performing such routine operations, it was quite natural that the first automatic programming aids, *assembly languages* and their associated assembly programs, were developed to take advantage of that fact. Assembly languages permit the critical addressing interrelations in a program to be described regardless of the storage arrangement, and they can produce therefrom a set of machine instructions suitable for the specific storage layout of the computer in use. An assembly-language program for the 1000-value program of Fig. 18.4.4 is shown in Fig. 18.4.5.

The program format illustrated is typical. Each line has four parts: location, operation, operand(s), and comments. The location part permits the programmer to specify a symbolic name to be associated with the address

LOC	OP	Operand	Comment
START	ORG LOAD STORE LOAD STORE CONST	100 ITEM 1 ITEM HI CONST 1 LOOP ST	Start at ADDR 100 Move first item value to ITEMHI Set LOOP to start with second item
LOOP ST	CONST COMP BRLO STORE	ITEM HI LOOP INC ITEM HI	* Load N TH item Compare with previous HI Skip if lower Store on equal or high
LOOP INC	LOAD ADD STORE COMP BRLO	LOOP ST ONE LOOP ST CONST 2 LOOP ST	Increment N by 1 Modify storage Exit test Repeat if $N < 1001$ (End of example)
CONST 1 ONE CONST 2	... ORG LOAD CONST LOAD	700 ITEM 1 + 1 + 1 ITEM 1 + 1000	Initial LOOP ST instruction Incrementation constant LOOP end test constant
ITEM HI	... ORG RESRV	800 1	Word where high value left
ITEM 1	... ORG RESRV RESRV	950 1 999	First item value Second through thousandth items

FIGURE 18.4.5 An assembly program. The program statements are in a one-to-one correspondence with machine instructions. Hence the procedure is fully supplied by the programmer according to the particular macroinstruction set of the system. The assembly language alleviates housekeeping routines, such as specific assignments, and makes user-oriented symbols possible instead of numeric or binary code.

of the instruction (or datum) defined on that line. The operation part contains a mnemonic designation of the instruction operation code. Alternatively, that line may be designated to be a datum constant, a reservation of data space, or a designation of an assembly *pseudo operation* (a specification to control the assembly process itself). Pseudo operations in the example are ORG for origin and END to designate the end of the program.

The operand field(s) give the additional information needed to specify the machine instruction, e.g., the name of a constant, the size of the data reservation, or a name associated with a pseudo operation. The comment part serves for documentation only; it does not affect the assembly-program operation.

After a program is written in assembly language, it is processed by an assembler. The assembly program reads the symbolic assembly-language input and produces (1) a machine instruction program with constants, usually in a form convenient for subsequent program loading, and (2) an assembly listing that shows in typed or printed form each line of the symbolic assembly-language input, together with any associated machine instructions or constants produced therefrom.

The assembly pseudo operation ORG specifies that the instructions and/or constant entries for succeeding lines are to be prepared for loading at successive addresses, beginning at the specified load origin (value of operand field or ORG entry). Thus the 13 symbolic instructions following the initial ORG line in Fig. 18.4.5 are prepared for loading at addresses 0100 through 010C inclusive, with the following symbolic associations established:

Location symbol	(Local) address
START	100
LOOP ST	104
LOOP INC	108

Four instructions of this group of 13 contain the symbol LOOP ST in the operand field, and the corresponding machine instructions will contain 0104 in their address parts.

The operation of a typical assembly program therefore consists of (1) collecting all location symbols and determining their values (addresses), called *building the symbol table*, and (2) building the machine instructions and/or constants by substituting op codes for the OP mnemonics and location symbol values for their positions in the operand field. The symbol table must be formed first since, as the first instruction in the example shows, a machine instruction may refer to a location symbol that appears in the location field near the program end. Thus most assembly programs process the program twice; the *first pass* builds the symbol table, and the *second pass* builds the machine-language program. Note in the example the use of the operation RESRV to reserve space (skipping in the load-address sequence) for variable data.

Assembly language is specific to a particular computer instruction repertoire. Hence, the basic unit of assembly language describes a single machine instruction (so-called one-for-one assembly process).

Most assembly languages have a *macroinstruction* facility. This permits the programmer to define *macros* that can generate desired sequences of assembly-language statements to perform specific functions. These macro definitions can be placed in macro libraries, where they are available to all programmers in the facility.

The term *procedure* (also *subroutine* and *subprogram*) is used to refer to a group of instructions that perform some particular function used repeatedly in essentially the same *context*. The quantities that vary between contexts may be regarded as parameters (or arguments) of the procedure. The method of adaptation of the procedure determines whether it is an *open* or *closed* procedure.

An open subroutine is adapted to its parameter values during code preparation (assembly or compilation) in advance of execution, and a separate copy of the subroutine code is made for each different execution context. A closed subroutine is written to adapt itself during execution to its parameter values; hence, a single copy suffices for several execution contexts in the same program. The open subroutine executes faster since tailoring to its parameter values occurs before execution begins. The closed subroutine not only saves storage space, since one copy serves multiple uses, but is more flexible, in that parameter values derived from the execution itself can be used.

A closed subroutine must be written to determine its parameter values in a standard way (including the return point after completion). The conventions for finding the values and/or addresses of values are called the subroutine linkage *conventions*. Quite commonly, a single address is placed in a particular register, and this address in turn points to a consecutively addressed list of addresses and/or values to be used. Subroutines commonly use (or *call*) other closed subroutines, so that there are usually a number of levels of subroutine control

available at any point during execution. That is, one routine is currently executing, and others are waiting at various points in partially executed condition.

HIGH-LEVEL PROGRAMMING LANGUAGES

On general-purpose digital computers, *high-level programming languages* have largely superseded assembly languages as the predominant method of describing application programs. Such programming languages are said to be *high-level* and *machine-independent*. High-level means that each program function is such that several or many machine instructions must be executed to perform that function. Machine-independent means that the functions are intended to be applied to a wide range of machine-instruction repertoires and to produce for each a specific machine representation of data.

The high-level language translator is known as a *compiler*, i.e., a program that converts an input program written in a particular high-level language (*source program*) to the machine language of a particular machine type (*object program*) each time the source code is executed.

HIGH-LEVEL PROCEDURAL LANGUAGES

Most of the high-level programming languages are said to be *procedural*. The programmer writing in a high-level procedural language thinks in terms of the precise sequence of operations, and the program description is in terms of sequentially executed *procedural statements*. Most high-level procedural languages have statements for *documentation*, *procedural execution*, *data declaration*, and various compiler and execution *control specifications*.

The program in Fig. 18.4.6, written in the FORTRAN high-level language, describes the program function given in Fig. 18.4.5 in assembly language. The first six lines are for documentation only, as indicated by C in the first column. The DIMENSION statement defines ITEM to consist of 1000 values. The assignment statement ITEMHI = ITEM (1) is read as “set the value of ITEMHI to the value of the first ITEM.” The next statement is a loop-control statement meaning: “do the following statements through the statement labeled 1 for the variable N assuming every value from 2 through 1000.” The statement labeled 1 causes a test to be made to “see if the Nth ITEM is greater than .GT. the value of ITEMHI, and if so, set the ITEMHI value equal to the value of the Nth item.

FIGURE 18.4.6 An example of a FORTRAN program, corresponding to the flowchart of Fig. 18.4.4 and assembly program of Fig. 18.4.5.

FORTRAN

The high-level programming languages most commonly used in engineering and scientific computation are C++, FORTRAN, ALGOL, BASIC, APL, PL/I, and PASCAL. FORTRAN, the first to appear, was developed during 1954 to 1957 by a group headed by Backus of IBM. Based on algebraic notation, it allows two types of numbers: integers (positive and negative) and floating point. Variables are given character names of up to six positions. All variables beginning with the letters I, J, K, L, M, or N are integers; otherwise they are floating point. Integer constants are written in normal fashion, 1, 0, -4, and so on. Floating-point constants must contain a decimal point, 3.1, -0.1, 2.0, 0.0, and so on. For example, 6.02×10^{24} is written 6.02E24. This standard notation was adopted to accommodate the limited capability of computer input-output equipment.

READ and WRITE statements permit values of variables to be read into or written from the ALU, from or to input, output, or intermediate storage devices. The latter may operate merely by transcribing values or may be accompanied by conversions or editing specified in a separate FORMAT statement. Some idea of the range of operations provided in FORTRAN is shown by the following value-assignment statement:

$$\text{ROOT} = (-(B/2.0) + \text{SQRT}((B/2.0)**2 - A*C))/A$$

This is the formula for the root of a quadratic equation with coefficients A , B , and C . The asterisk indicates multiplication, / stands for division, and ** exponentiation.

The notation: *name (expression)* and *name (Expression, expression)*, and so forth, is used in FORTRAN with two distinct meanings depending on whether or not the specific name appears in a DIMENSION statement. If so, the *expression(s)* are subscript values; otherwise the *name* is considered to be a function name, and the expressions are the values of the arguments of the function. SQRT((B/2.0)**2 - A*C) in the preceding assignment statement requires the expression (B/2.0)**2 - A*C to be evaluated, and then the function (square root here) of that value is determined. Square root and various other common trigonometric and logarithmic functions and their respective inverses are standardized in FORTRAN, typically as closed subroutines.

The same notations may be employed for a function defined by a FORTRAN programmer in the FORTRAN language. This operation is performed by writing a separate FORTRAN program headed by the statement

FUNCTION name (arg 1, arg 2, etc.)

where arg represents the name that stands for the actual argument value at each evaluation of that function. Similarly, any action or set of actions described by a closed FORTRAN subroutine is called for by "CALL subroutines (args)" together with a defining FORTRAN subroutine headed by "SUBROUTINE subroutine name (args)."

BASIC

BASIC is high-level programming language based on algebraic notation that was developed for solving problems at a terminal; it is particularly suitable for short programs and instructional purposes. The user normally remains at the terminal after entering his program in BASIC, while it compiles, executes, and types the output, a process that typically requires only a few seconds. Widely used in PCs, BASIC is usually bundled with PC operating systems. It is available in both interpretive and compiled versions, and may include an extensive set of programming capabilities. Visual BASIC is currently being used on display-oriented operating systems such as Windows.

APL

A programming language (APL) is high-level language that is often used because it is easy to learn and has an excellent interactive programming system supporting it. Its primitive objects are arrays (lists, tables, and so forth). It has a simple syntax, and its semantic rules are few. The usefulness of the primitive functions is

further enhanced by operations that modify their behavior in a systematic manner. The sequence control is simple because one statement type embraces all types of branches and the termination of the execution of any function always returns control to the point of use. External communication is established by variables shared between APL and other systems.

PASCAL

An early high-level programming language is PASCAL, developed by Niklaus Wirth. It has had widespread acceptance and use since its introduction in the early 1970s. The language was developed for two specific purposes: (1) to make available a language to teach programming as a systematic discipline and (2) to develop a language that supports reliable and efficient implementations. PASCAL provides a rich set of both control statements and data structuring facilities. Six control statements are provided: BEGIN-END, IF-THEN-ELSE, WHILE-DO, REPEAT-UNTIL, FOR-DO, and CASE-END. Similar control statements can be found in virtually all high-level languages.

In addition to the standard scalar data types, PASCAL provides the ability to extend the language via user-defined scalar data types. In the area of higher-level structured data types, PASCAL extends the array facility of ALGOL 60 to include the record, set, file, and pointer data types. In addition to these, PASCAL contains a number of other features that make it useful for programming and teaching purposes. In spite of this, PASCAL is a systematic language and modest in size, attributes that account for its popularity.

ADA PROGRAMMING LANGUAGE

(Ada is a registered trademark of the Department of Defense.) Ada is named after Lord Byron's daughter. This language was developed by the U.S. Department of Defense to be a single successor to a number of high-level languages in use by the armed forces of the United States. It was finalized in 1980.

The Ada language was designed to be a strongly typed language, with features from modern programming language theory and software engineering practices. It is a block-structured language providing mechanisms for data abstraction and modularization. It supports concurrent processing and provides user control over scheduling and interrupt handling.

C PROGRAMMING LANGUAGE

Research is continuing in the development of new languages that support the concepts growing out of modern software technology development. One such language is the C programming language (a registered trademark of AT&T). C is a general-purpose programming language designed to feature modern control flow and data structures and a rich set of operators, yet provide an economy of expression. Although it was not specialized for any one area of application, it has been found especially useful for implementing operating systems and is being more widely used in communications and other areas. C++ is a later version of this language. An extension of this language has been called JAVA, developed by Sun Microsystems.

OBJECT-ORIENTED PROGRAMMING LANGUAGES

A second area of programming language development has been the creation of object-oriented languages. These are used for message-object programming, which incorporates the concepts of objects that communicate by messages. An object includes data, a set of procedures (methods) that operate on the data, and a mechanism for

translating messages. These languages should contribute to improved reusability of software—a highly sought after goal to increase programming productivity and reduce software costs. These languages are based on the concept that “objects,” once defined, are henceforth available for reuse, without reprogramming. Programs can then be viewed as mechanisms that employ the appropriate object at the appropriate time to accomplish the task at hand.

COBOL AND RPG

High-level programming languages used for business data-processing applications emphasize description and handling of files for business record keeping. Two widely used programming languages for business applications are COBOL (*common business-oriented language*) and RPG (*report program generation*). Compilers for these languages, with generalized sorting programs, form the fundamental automatic programming aids of many computer installations primarily used for business data processing. COBOL and RPG have comparable file, record, and field-within-record descriptive capabilities, but the specification of processing and sequence control device from basically different concepts.

OPERATING SYSTEMS

There are many reasons for developing and using an *operating system* for a digital computer. One of the main reasons is to optimize the scheduling and use of computer resources, so as to increase the number of jobs that can be run in a given period. Creation of a multiprogramming environment means that the resources and facilities of the computing system can be shared by a number of different programs, each written as if it were the only program in the system.

FIGURE 18.4.7 The user's view of the operating system as an extension of the computing system yet an integral part of it.

Another major objective for an operating system is to provide the full capability of the computing system to the user while minimizing the complexity and depth of knowledge of the computer system required. This is accomplished by establishing standard techniques for handling system functions like *program calling* and *data management* and providing a convenient and effective interface to the user. In effect the user is able to deal with the operating system as an entity rather than having to deal with each of the computer's features. As indicated in Fig. 18.4.7 each

user will be thought of conceptually as a unit consisting of both the hardware and the programs and procedures that make up the operating system.

GENERAL ORGANIZATION OF AN OPERATING SYSTEM

There are many ways to structure operating systems, but for the purpose of this discussion the organization shown in Fig. 18.4.8 is typical. The operating system is composed of two major sets of programs, control (or supervision) programs and processing programs. *Control programs* supervise the execution of the support programs (including the user application programs), control the location, storage, and retrieval of data, handle interrupts, and schedule jobs and resources needed in processing. *Processing programs* consist of language translators, service programs, and user-written application programs, all of which are used by the programmer in support of program development.

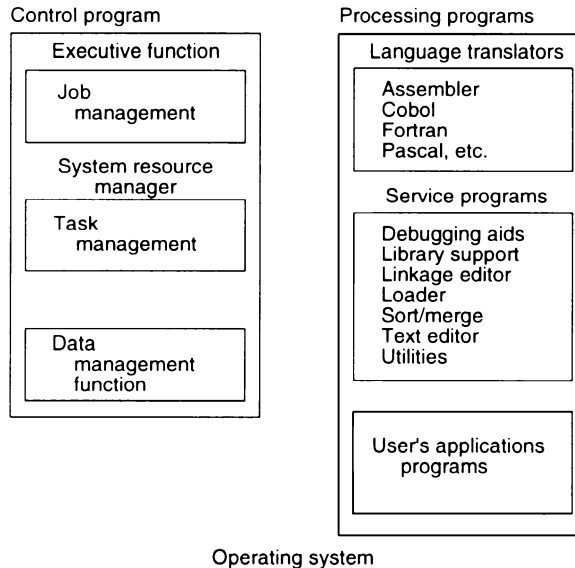

FIGURE 18.4.8 A typical operating system and its constituent parts.

The work to be processed by the computer can be viewed as a stack of jobs to be run under the management of the control program. A *job* is a unit of computational work that is independent of all other jobs concurrently in the system. A single job may consist of one or a number of *steps*.

TYPES OF OPERATING SYSTEMS

There are many basic types of operating systems including multiprogramming, time-sharing, real-time, and multiprocessing.

The multiprocessing system must schedule and control the execution of jobs that are distributed across two or more coupled processors. These processors may share a common storage, in which case they are said to be *tightly* (or *directly*) *coupled*, or they may have their own private storage and communicate via other means such as sending messages over networks, in which case they are said to be *loosely coupled*.

Operating systems were generally developed for a specific CPU architecture or for a family of CPUs. For example, MS-DOS and WINDOWS apply to x86-based systems. However, one operating system, the UNIX system (a registered trademark of AT&T), has been *transported* to a number of different manufactures' systems and is in very wide use today. UNIX was developed as a unified, interactive, multiuser system. It consists of a kernel that schedules tasks and manages data, a shell that executes user commands—one at a time or in a series called a pipe—and a series of utility programs.

TASK-MANAGEMENT FUNCTION

This function, sometimes called the *supervisor*, controls the operation of the system as it executes units of work known as *tasks* or *processes*. (The performance of a task is requested by a job step.) The distinction between a task and a program should be noted. A *program* is a static entity, a sequence of instructions, while a *task* is a dynamic entity, the work to be done in execution of the program. Task management initiates and controls the

execution of tasks. If necessary it controls their synchronization. It allocates system resources to tasks and monitors their use. In particular it is concerned with the dynamic allocation and control of main storage space.

Task management handles all interrupts occurring in the computer, which can arise from five different sources: (1) supervisor call interrupts occur when a task needs a service from the task-management function, such as initiating an I/O operation; (2) program interrupts occur when unusual conditions are encountered in the execution of a task; (3) I/O interrupts indicate that an I/O operation is complete or some unusual condition has occurred; (4) machine-check interrupts are initiated by the detection of hardware errors; and (5) external interrupts are initiated by the timer, by the operator's console, or other external devices.

DATA MANAGEMENT

This function provides the necessary I/O control system services needed by the operating system and the user application programs. It frees the programmer from the tedious and error-prone details of I/O programming and permits standardization of these services. It constructs and maintains various file organization structures, including the construction and use of index tables. It allocates space on disc (auxiliary) storage. It maintains a directory showing the locations of data sets (files) within the system. It also provides protection for data sets against unauthorized entry.

OPERATING SYSTEM SECURITY

One of the major concerns in the design of operating systems is to make certain that they are reliable and that they provide for the protection and the integrity of the data and programs stored within the system. Work is under way to develop secure operating systems. These systems use the concept of a security kernel—a minimal set of operating system programs that are formally specified and designed so that they can be proved to implement the desired security policy correctly. This assures the correctness of all access-controlling operations throughout the system.

SOFTWARE-DEVELOPMENT SUPPORT

There have been great strides in software engineering technology. Out of the research and development efforts in universities, industry, and government have emerged a number of significant ideas and concepts that can have significant and long-lasting influence on the way that software is developed and managed. Those concepts are just now starting to find their way into the software-development process but should become more widely used in the future. They are briefly reviewed below.

REQUIREMENTS AND SPECIFICATIONS

This has been one of the problem areas through the years. Analysis and design errors are, by far, the most costly and crucial types of errors, and a number of attempts are being made to develop methods for recording and analyzing software requirements and developing specifications. Most requirements and specifications documents are still recorded in English narrative form, which introduces problems of inconsistency, ambiguity, and incompleteness. These problems are addressed with CASE tools and structured programming.

SOFTWARE DESIGN

The work of Dijkstra, Hoare, and Mills (1968, 1976) had a major influence on software-design methodology by introducing a number of concepts that led to the development of *structured programming*. Structured programming is a methodology based on mathematical rigor. It uses the concept of top-down design and

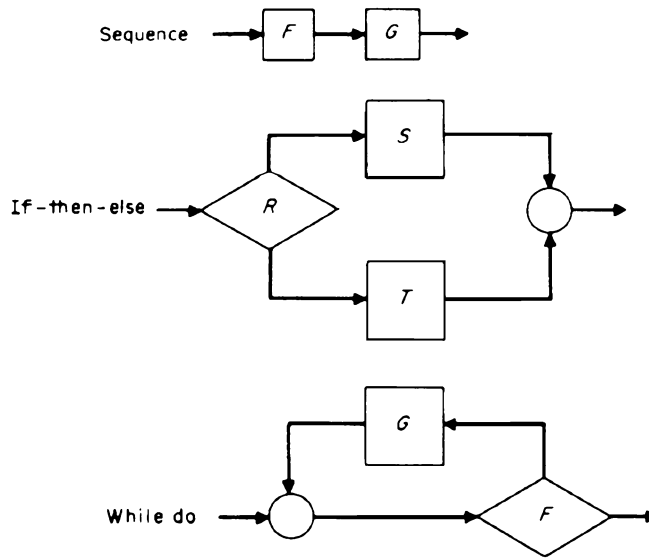

FIGURE 18.4.9 Basic set of structured control primitives.

implementation by describing the program at a high level of abstraction and then expanding (refining) this abstraction into more detailed representations through a series of steps until sufficient detail is present for implementation of the design in a programming language to be possible. This process is called *stepwise refinement*. The design is represented by a small, finite set of primitives, such as shown in Fig. 18.4.9. These three primitives are adequate for design purposes but for convenience several others have been introduced; namely, the *indexed alternation* or *case*, the *do-until*, and the *indexed sequence* or *for-do* structure.

It also recognized that the organization and representation of software systems are clearer if certain data and the operations permitted on those data are organized into data abstractions. The internal details of the organization of the data are hidden from the user.

The result of applying this methodology is the organization of a sequential software process into a hierarchical structure through the use of stepwise refinement. The software system structure is then defined at three levels—the *system*, the *module*, and the *procedure*. The system (or *job*) describes the highest level of program execution. The system is decomposed into modules. The module is composed of one or more procedures and data that persist between successive invocations of the module. The procedure is the lowest level of system decomposition, the executable unit of the stored program.

Another important aspect of the design process is its documentation. There is a critical need to record the design as it is being developed, from its highest level all the way to its lowest level of detail, before its implementation in a programming language, using language that can be used not only to communicate software designs between specialists in software development but also between specialists and nonspecialists in rigorous logical terms.

Important elements of the software development process are reviews, walk-throughs, and inspections, which can be applied to the products of the software-development process to ensure that they are complete, accurate, and consistent. They are applied to such areas as the design (design inspections), the software source code (code inspections), documentation, test designs, and test-results analysis. The goals of the software review and inspection process are to ensure that standards are met, to check on the quality of the product, and to detect and correct errors at the earliest possible point in the software life cycle. Another important value of the review process is that it permits progress against development-plan milestones to be measured more objectively and rework for error correction to be monitored more closely.

TESTING

An important activity in the software-development cycle that is often ignored until too late in the process is testing. It is also important to note what testing can and cannot do for the software product. Quality cannot be tested into the software; it must be designed into it. Test planning begins with the requirements analysis at the beginning of the project. Requirements should be testable; i.e., they should be stated in a form that permits the final product to be tested to assure that it satisfies the requirements. Test planning and test designs should be developed in parallel with the design of the software.

EXPERT SYSTEMS

One important area of research in computer science has been that of *artificial intelligence*. The most successful application of artificial intelligence techniques has been in the development of *expert systems*, or *knowledge-based systems*, as they are often called. These are human-machine interactive systems with specialized problem-solving expertise that are used to solve complex problems in such specific areas as medicine, chemistry, mathematics, and engineering. This expertise consists of knowledge about the particular problem domain that the expert system is designed to support (e.g., diagnosis and therapy for infectious diseases) and planning and problem-solving rules for processes used to identify and solve the particular problem at hand. The two main elements of an expert system are its knowledge base, which contains the domain knowledge for the problem area being addressed, and the inference engine, which contains the general problem-solving knowledge. A key task in constructing an expert system is knowledge acquisition: the extraction and formulation of knowledge (facts, concepts, rules) from existing sources, with special attention paid to the experience of experts in the particular problem domain being addressed.

CHAPTER 18.5

DATABASE TECHNOLOGY

DATABASE OVERVIEW

Around 1964 a new term appeared in the computer literature to denote a new concept. The term was “database,” and it was coined by workers in military information systems to denote collections of data shared by end users of time-sharing computer systems. The commercial data-processing world at the time was in the throes of “integrated data processing,” and quickly appropriated “database” to denote the data collection that results from consolidating the data requirements of individual applications. Since that time, the term and the concept have become firmly entrenched in the computer world. Today, computer applications in which users access a database are called *database applications*. The *database management system*, or DBMS, has evolved to facilitate the development of database applications. The development of DBMS, in turn, has given rise to new languages, algorithms, and software techniques, which together make up what might be called a *database technology*. An overview of a typical DBMS is shown in Fig. 18.5.1.

Traditional data-processing applications used *master files* to maintain continuity between program runs. Master files “belonged to” applications, and the master files within an enterprise were often designed and maintained independently of one another. As a result, common data items often appeared in different master files, and the values of such items often did not agree. There was thus a requirement to consolidate the various master files into a single database, which could be centrally maintained and shared among various applications. Data consolidation was also required for the development of certain types of “management information” applications that were not feasible with fragmented master files. There was a requirement to raise the level of languages used to specify application procedures, and also to provide software for automatically transforming high-level specifications into equivalent low-level specifications. In the database context, this property of languages has come to be known as *data independence*. The consolidation of master files into databases had the undesirable side effect of increasing the potential for data loss and unauthorized data use. The requirement for data consolidation thus carried with it a requirement for tools and techniques to control the use of databases and to protect against their loss.

A DBMS is characterized by its *data-structure class*, that is, the class of data structures that it makes available to users for the formulation of applications. Most DBMSs distinguish between structure *instances* and structure *types*, the latter being abstractions of sets of structure instances. A DBMS also provides an implementation of its data-structure class, which is conceptually a mapping of the structures of the class into the structures of a lower-level class. The structures of the former class are often referred to as *logical* structures, whereas those of the latter are called *physical* structures. The data-structure classes are early systems, were derived from punched-card technology, and thus tended to be quite simple. A typical class was composed of *files of records* of a single type, with the record type being defined by an ordered set of fixed-length fields. Because of their regularity, such files are now referred to as *flat files*.

Database technology has produced a variety of improved data-structuring methods, many of which have been embodied in DBMS. Although many specific data-structure classes have been produced (essentially one class per system), these classes have tended to cluster into a small number of families, the most important of which are the *hierarchical*, the *network*, the *relational*, and the *semantic* families. These families have evolved more or less in the

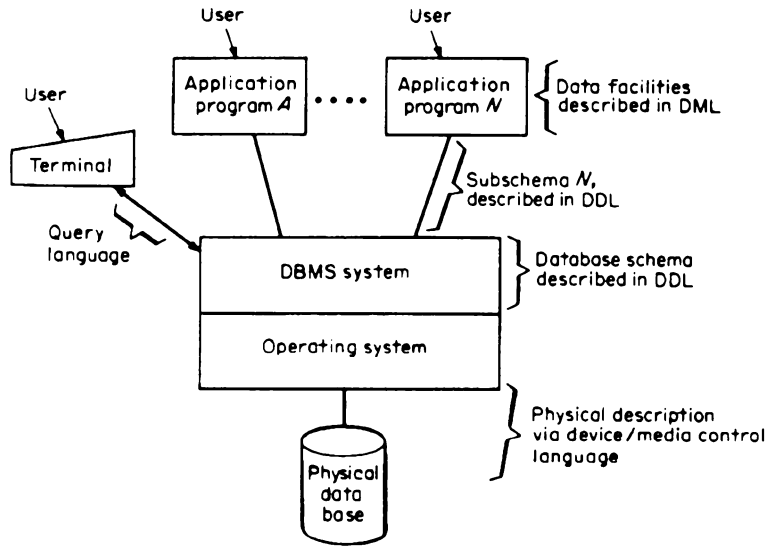

FIGURE 18.5.1 Overview of a typical database management system (DBMS).

order indicated, and all are represented in the data-structure classes of present-day DBMS. The use of large databases in distributed computing systems is sometimes called *Data Repository* or *Data Warehouse*.

HIERARCHIC DATA STRUCTURES

The *hierarchic data-structuring methods* that began to appear in the early 1960s provided some relief for the entity association problem. These methods were developed primarily to accommodate the variability that frequently occurs in the records of a file. For example, in the popular two-level hierarchic method, a record was divided into a *header* segment and a variable number of *trailer* segments of one or more types. The header segment represented attributes common to all entities of a set, while the trailer segments were used for the variably occurring attributes. The method was also capable of representing one-many associations between two sets of entities, by representing one set as header segments and the other as trailers and thus provided a primitive tool for data consolidation.

This two-level approach was expanded to *n*-level structures. These structures have also been implemented extensively on direct-access storage devices (DASD), which afford numerous additional representation possibilities. IMS was one of the first commercial systems to offer hierarchic data structuring and is often cited to illustrate the hierarchic structuring concept. The IMS equivalent of a file is the *physical database*, which consists of a set of hierarchical structured records of a single type. A record type is composed according to the following rules. The record type has a single type of *root* segment. The root segment type may have any number of *child* segment types. Each child of the root may also have any number of child segment types, and so on.

NETWORK DATA STRUCTURES

The first network structuring method to be developed for commercial data processing had its origins in the bill-of-materials application, which requires the representation of many-many associations between a set of parts and itself; e.g., a given part may simultaneously act as an assembly of other parts and as a component of other parts.

This concept was used as the basis of a database language developed by the database task group (DBTG) of CODASYL in the late 1960s and early 1970s. This language introduced some new terminology and generalized some features, and has been implemented in a number of DBMSs.

RELATIONAL DATA STRUCTURES

In the mid-1960s, a number of investigators began to grow dissatisfied with the hardware orientation of then extant data-structuring methods and, in particular, with the manner in which pointers and similar devices for implementing entity associations were being exposed to the users. These investigators sought a way of raising the perceived level of data structures and at the same time bringing them closer to the way in which people look at information. Their efforts resulted in an *entity-set*-structuring method, wherein information is represented in a set of tables, with each table corresponding to a set of entities of a single type. The rows of a table correspond to the entities in the set, and the columns correspond to the attributes that characterize the entity set type.

Tables can be used to represent associations among entities. In this case, each row corresponds to an association, and the columns correspond to entity identifiers, i.e., entity attributes that can be used to uniquely identify entities. Additional columns may be used to record attributes of the association itself (as opposed to attributes of the associated entities). The key new concepts in the entity set methods were the simplicity of the structures it provided and the use of entity identifiers (rather than pointers or hardware-dictated structures) for representing entity associations. These concepts represented a major step forward in meeting the general goal of *data independence*.

Codd (1971) noted that an entity set could be viewed as a mathematical relation on a set of domains, where each domain corresponds to a different property of the entity set. Associations among entities could be similarly represented, with the domains in this case corresponding to entity identifiers. Codd defined a (data) *relation* to be a time-varying subset of the cartesian product of the members of the set of domain *n*-tuples (or simply *tuples*). Codd proposed that relations be built exclusively on domains of elementary values—integers, character strings, and so forth. He called such relations *normalized relations* and the process of converting relations to normalized form, *normalization*. Virtually all work done with relations has been with normalized relations.

Codd postulated levels of normalization called *normal forms*. An unconstrained normalized relation is in *first normal form* (1NF). A relation in 1NF in which all nonkey domains are functionally dependent on (i.e., have their values determined by) the entire key are in *second normal form* (2NF), which solves the problem of parasitic entity representation. A relation in 2NF in which all nonkey domains are dependent *only* on the key is the *third normal form* (3NF), which solves the problem of masquerading entities. As part of the development of the relational method, Codd postulated a *relational algebra*, i.e., a set of operations on relations that is closed in the sense of a traditional algebra, and thereby provided an important formal vehicle for carrying out a variety of research in data structures and systems. In addition to the conventional set operations, the relational algebra provides such operations as *restriction*, to delete selected tuples of a relation; *projection*, to delete selected domains of a relation; and *join*, to join two relations into one. Codd also proposed a *relational calculus*, whose distinguishing feature is the method used to designate sets of tuples. The method is patterned after the predicate calculus and makes use of free and bound variables and the universal and existential quantifiers.

Codd characterized his methodology as a *data model*, and thereby provided a concise term for an important but previously unarticulated database concept, namely, the *combination* of a class of data structures and the operation allowed on the structures of the class. (A similar concept, the *abstract data type* or *data abstraction*, has evolved elsewhere in software technology.) The term “model” has been applied retroactively to early data-structuring methods, so that, for example, we now speak of hierarchic models and network models, as well as the relational model. The term is now generally used to denote an abstract data-structure class, although there is a growing realization that it should embrace operations as well as structures. The relational model has been implemented in a number of DBMSs.

SEMANTIC DATA STRUCTURES

During the evolution of the hierarchic, network, and relational methods, it gradually became apparent that building a database was in fact equivalent to building a model of an enterprise and that databases could be developed more or less independently of applications simply by studying the enterprise. The notion of a *conceptual schema*

for the application-independent modeling of an enterprise and various *external schemata* derivable from the conceptual schema for expressing data requirements of specific applications is the outgrowth of this view.

Application-independent modeling has produced a spate of *semantic* data models and debate over which of these is best for modeling “reality.” One of the most successful semantic models is the *entity-relationship model*, which provides data constructs at two levels: the *conceptual* level, whose constructs include entities, relationships (*n*-ary associations among entities), value sets, and attributes; and the *representation* level, in which conceptual constructs are mapped into tables.

DATA DEFINITION AND DATA-DEFINITION LANGUAGES

The history of computer applications has been marked by a steady increase in the level of the language used to implement applications. In database technology, this trend is manifested in the development of high-level data-definition languages and data-manipulation languages. A *data-definition language* (DDL) provides the DBMS user with a way to declare the attributes of structure types within the database, and thus enable the system to perform implicitly many operations (e.g., name resolution, data-type checking) that would otherwise have to be invoked explicitly. A DDL typically provides for the definition of both logical and physical data attributes as well as for the definition of different *views* of the (logical) data. The latter are useful in limiting or tailoring the way in which specific programs or end users look at the database. A *data-manipulation language* (DML) provides the user with a way to express operations on the data structure instances of a database, using names previously established through data definitions. Data-manipulation facilities are of two general types: host-language and self-contained.

A *host-language* facility permits the manipulation of databases through programs written in conventional procedural languages such as COBOL or PL/I. It provides statements that the user may embed in a program at the points where database operations are to be performed. When such a statement is encountered control is transferred to the database system, which performs the operation and returns the results (data and return codes) to the program in prearranged main-storage locations.

A *self-contained* facility permits the manipulation of the database through a high-level, nonprocedural language, which is independent of any procedural language, i.e., whose language is self-contained. An important type of self-contained facility is the *query facility*, which enables “casual” users to access a database without the mediation of a professional programmer. Other types of self-contained facility are available for performing generalizable operations on data, such as sorting report generation, and data translation.

REPORT PROGRAM GENERATORS

The use of fixed files for reporting is found in the *report program generator*, a software package intended primarily for the production of reports from formatted files. Attributes of the source files and the desired reports are described by the user in a simple declarative language, and this description is then processed by a compiler to generate a program that, when run, produces the desired reports. A key concept of the report program generator is the use of a fixed structure for the generated program, consisting of input, calculation, and output phases. Such a structure limits the transformations that can be carried out with a single generated program, but it has nevertheless proved to be remarkably versatile. (Report program generators are routinely used for file maintenance as well as for report generation.) The fixed structure of the generated program imposes a discipline on the user, which enables the user to produce a running program much more quickly than could otherwise be done with conventional languages. Report program generators were especially popular in smaller installations where conventional programming talent is scarce, and in some installations it was the only “programming language” used.

The report program generators and the formatted file systems were the precursors of the contemporary DBMS query facility. A query processor is in effect a generalized routine that is particularized to a specific application (i.e., the user’s query) by the parameters (data names, Boolean predicates, and so forth) appearing in the query. Query facilities are more advanced than most early generalized routines in that they provide online (as opposed to batch) access to databases (as opposed to individual files). The basic concept is unchanged, however, and the lessons learned in implementing the generalized routines, and especially in reconciling ease of use with acceptable performance, have been directly applicable to query-language processors.

PROGRAM ISOLATION

Most DBMSs permit a database to be accessed concurrently by a number of users. If this access is not controlled, the consistency of the data can be compromised (e.g., lost updates) or the logic of programs can be affected (e.g., nonrepeatable read operations). With program isolation, records are locked for a program upon updating any item within the record and unlocked when the program reaches a *synchpoint*, i.e., a point at which the changes made by the program are committed to the database. Deadlocks can occur and are resolved by selecting one of the deadlocked programs and restarting it at its most recent synchpoint.

AUTHORIZATION

Consolidated data often constitute sensitive information, which the user may not want divulged to other than authorized people, for reasons of national security, competitive advantage, or personal privacy. DBMSs, therefore, provide mechanisms for limiting data access to properly authorized persons. A system administrator can grant specific capabilities with respect to specific data objects to specific users. Grantable capabilities with respect to relations include the capability to read from the relation, to insert tuples, to delete tuples, to update specific fields, and to delete the relation. The holder of a capability may also be given authority to grant that capability to others, so that authorization tasks may be delegated to different individuals within an organization.

CHAPTER 18.6

ADVANCED COMPUTER TECHNOLOGY

BACKGROUND

Early computer systems were tightly integrated with locally attached I/O facilities, such as card readers and punches, tape readers and punches, tape drives, and discs. Data had to be moved to and from the site of the programming system physically. For certain systems, the turnaround time in such processes was considered excessive and it was not long before steps were taken to interconnect *remotely located* I/O devices to a computer site via telephone and telegraph facilities.

Telecommunications today means any form of communicating that exists to support the exchange of information between people and application programs in one of the three following combinations: person to person, person to process, or process to process. Thus, today, telecommunications encompasses telephony, facsimile transmission, television, and data communications. The impetus for this change has been continual advancement in digital technology, a common technological thread running through all the previously mentioned disciplines.

TERMINALS

Terminals are the mechanisms employed by individuals to interface to communications mechanisms and to represent them in their information exchange with other individuals or processes. Since the early advent of telecommunications, many terminal device types have come in the market. The earliest and most popular devices were the *keyboard printers* made by Teletype Corporation and other manufacturers. These electro-mechanical machines operated at speeds from 5 to 11 characters per second.

Another popular type of terminal device is the *cathode-ray-tube (CRT) visual display* and keyboard. This *dumb terminal* operates at speeds from 1200 to 9600 b/s across common-carrier telephone facilities or at megabit rates directly attached to the local channel of a processor. Displays generally are alphanumeric or graphic, the preponderance of terminals being alphanumeric. Many such displays can be attached to a single *control unit*, or *node*, which can greatly reduce the overall costs of the electronic devices required to drive the multiple devices. The control unit can also reduce communications cost by concentrating the multiple-terminal data traffic from the locally connected drives into a single data stream and sharing a single channel between the controller and a *host processor*. Some controllers support the attachment of hard-copy printers and have sufficient logic to permit printout of information of a display screen without communicating with a host computer. Displays are generally used in conversational or interactive modes of operation.

In recent years PCs have had a profound impact on the quantity of this type of display. Although the personal computer really is an *intelligent workstation*, most PCs can employ communications software subsystems to emulate nonintelligent visual display and keyboard devices. In this way, they can communicate with host software.

Many specialized *transaction-type terminals* are designed for specific industry applications and form another category of terminals. Special point-of-sale terminals for the retail industry, bank teller and cash dispensers, and airline ticketing terminals are examples of transaction-type terminals.

A category of terminals that incorporates many of the features of previous categories, the *intelligent workstation*, is really a remote mini- or microcomputer system that permits the distribution of application program functions to remote sites. Such *intelligent terminals* are capable of supporting a diversity of functions from interactive processing to remote batched job entry. Some of these terminals contain such a high level of processing capability that they are, in fact, true host processors. With the expanded scope of telecommunications, television and telephones are beginning to play an important role as terminals. Not that they were not terminals before, but rather, they are now recognized as an important part of the terminal types to be found in the world of information. Terminals now support voice, data, and video communications within one single integrated package.

HOSTS

When people communicate with machines via their terminals, they are communicating with application programs. These programs offer services to the user, such as data processing (computation, word processing, editing, and so forth) and data storage or retrieval. In such applications as message switching and conferencing, hosts often act as intermediates between two terminals. Thus they may contain application software that stores a sender's message until the designated receiver actively connects to the message application or to some program that has been made aware of the person's relationship to the host service.

Host applications also may have a need to cooperate with other host applications in *distributed processors*. Distributed processing and distributed database applications typically involve host-to-host communications. Host-to-host communications typically require much higher-speed communication channels than terminal-to-host traffic. Within recent years, host channel speeds have increased to tens of megabits per second, commensurate with the increased millions-of-instructions-per-second (MIPS) rate of processors.

Personal computers can also assume the role of a host. The difference between being a terminal or a host is defined by the telecommunications software supporting the PC. Acceptance of this statement should be easy when one recognizes that PCs today come with the processing power and storage capacity attributable to what was once viewed as a sizable host processor.

COMMUNICATIONS SYSTEMS

For communications to occur between end users, it is essential that two aspects be present: (1) There must be interconnectivity between the communicating parties to permit the transference of signals and bits that represent the information transfer, and (2) there must be commonality of representation and interpretation of the bits that represent the information.

In the early years of telecommunications, the world of *connectivity* was divided and classified as *local* and *remote*. Local implied limited distances from a host, usually with relatively high-speed connections (channel speeds). Terminals were connected to controllers that concentrated the data traffic. Remote connections depended on the services available from common carriers. These worlds were separate and distinct.

Evolving standards obscure the earlier distinction between local and remote and introduce the new concept of *networking*. In the telecommunications world, networking is the interconnection and interoperability of systems for the purpose of providing communications service. The types of communications services to be found in modern networks vary with the needs of subscribers and the service characteristics of the media available. The end users impose requirements in the form of service classifications. Examples of requirements are capacity, integrity, delay characterizations, acceptable cost, security, and connectivity. Each medium imposes constraints for which the systems may have to compensate. Thus a medium may have a limited capacity, it may be susceptible to error, it may introduce a propagation delay, it may also lack security, and it may limit connectivity.

FIGURE 18.6.1a ISO-OSI model.

Most early communications networks were designed to meet specific subscriber needs, as was the case with the early telephone system, airline reservation systems, and the early warning system. Computer and transmission technology have changed this concept. The introduction of digital technology introduces a common denominator to the field of information communications that eases the sharing of resources used in the creation of communications networks. However, the existence of millions of terminals and tens of thousands of processors designed to operate within the construct of their own private communications world, and the need for innovation to accommodate new and heretofore unanticipated subscriber needs, presents a formidable challenge to the information communications industry.

In an attempt to bring about order, the International Standards Organization (ISO) has developed standards recommendations for an *open system*. An open system is one that conforms to the standards defined by ISO and thus facilitates connectivity and interoperability between systems manufactured by different vendors. Figure 18.6.1 depicts the ISO open system interconnect (OSI) model.

OSI REFERENCE MODEL

The OSI reference model describes a communication system in the seven hierarchic layers shown in Fig. 18.6.1. Each layer provides services to the layer above and invokes services from the layer below. Thus the *end users* of a communications system interconnect to the *application layer*, which provides the user interface and interprets user service requests. This layer is often thought of as a *distributed operating system*, because it supports the interconnectivity and communicability between end users that are distributed. The model is a general one and even permits two end users to use the application layer interface of a common system to communicate, instead of a shared local operating system. By hiding the difference between locally connected and remotely connected end users, the interconnected and interrelated application layer entities assume the role of a *global operating system*, as shown in Fig. 18.6.2.

In a single system, the operating system contains *supervisory control logic* for the resources—both logical and physical—that are allocated to provide services to the end user. In a distributed system, such as a communications system, the global supervisory service for all the layers resides in the application layer, hence, the reason to view the layer as a global operating system.

Note that the model applies equally as well to telephony. An end user, in requesting a connection service from the communications system, communicates with a supervisory controller. This controller is in the local

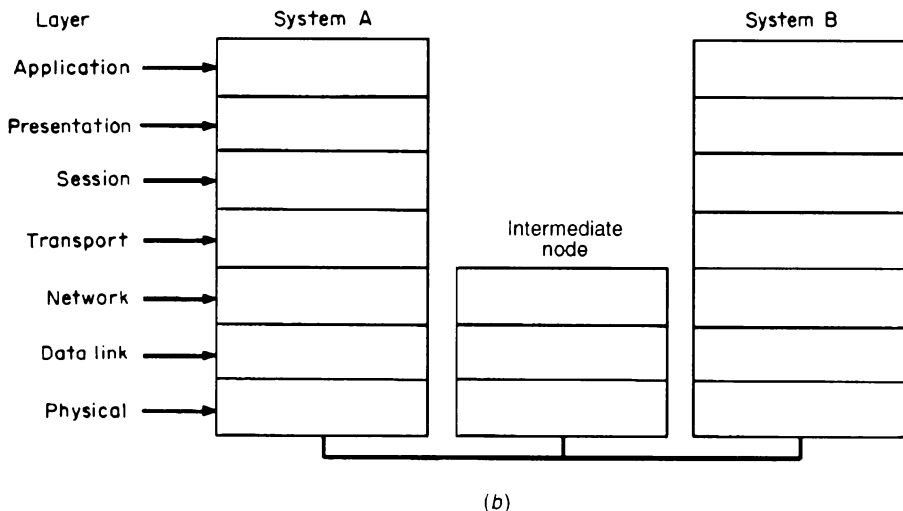

FIGURE 18.6.1b ISO-OSI model with an intermediate node.

exchange of a telephone operating company. The cooperating efforts of the distributed supervisory control components of the telephone systems are an analog of the distributed application layers of a data network, as shown in Fig. 18.6.1b.

A user views the application layer as a global server. Requests for service are passed from the user to the communications system through an interface that typically has been defined by the serving system. Even though systems differ in their programs and hardware architectures, there is a growing recognition of the necessity for the introduction of standardization at this critical interface. Consider the difficulty in making a telephone call when traveling, if every telephone company had chosen a different interface mechanism. This would require a knowledge of all the different methods, as is the case for persons who travel to foreign countries.

The services available from the communications systems can be quite varied. In telephony, a basic transport and connection service is prevalent. However, as greater intelligence was placed within the systems of

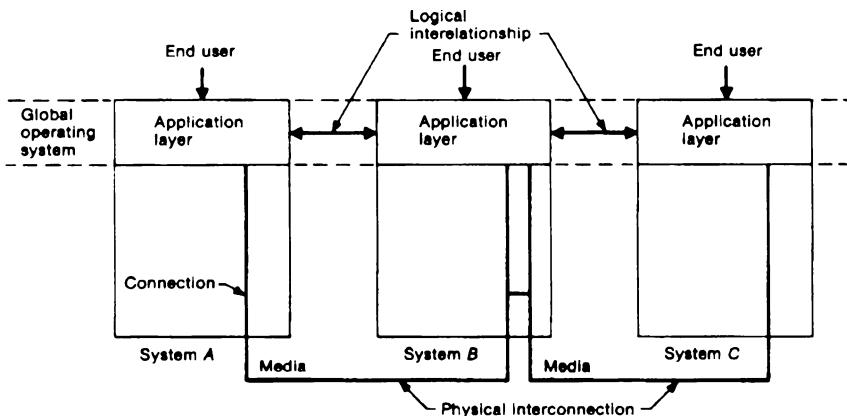

FIGURE 18.6.2 Application layers as a global operating system.

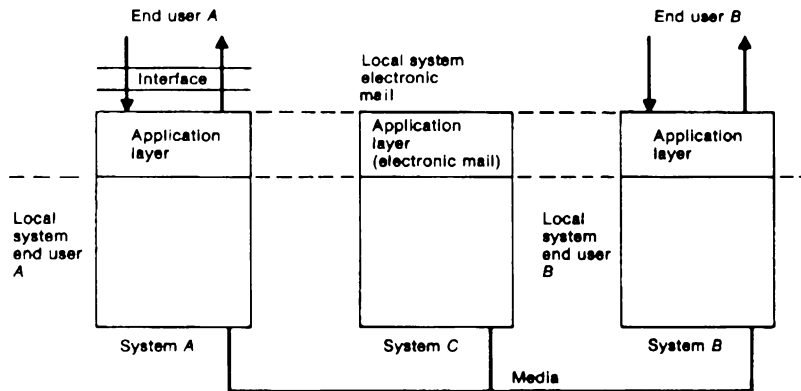

FIGURE 18.6.3 Example use of the application layer.

the telephone networks, the operating companies have increased the types of services they provide. Systems are operational in the United States, which integrate voice and data information through a common interface mechanism and across a shared medium. That medium is the existing twisted-pair wire that once carried only analog voice signals, or optical lines, which carry a much greater volume of data. Carrier networks offer *electronic mail, packet switching, telemetry services, videotex*, and many other services. The limit on what can or will be provided will be determined by either government regulations or market demand.

The layers that lie below the application layer exist to support communications between end users or the communications services of an application layer that exist in a distributed system, as is shown in Fig. 18.6.3. The application layer of system A can contain knowledge of the electronic mail server in system C and, on behalf of end user A (EUA), invoke that service. The application layer of system A can also support a connect service that enables it to create a communications path between system A and its equivalent partner (*functional pair*) in system B, for the purpose of supporting communications between EUA and EUB.

Each of the layers of the OSI model in Fig. 18.6.1 contributes some value to the communications service between communicating partners, be they end users or communication systems distributed entities.

The *application layer* is a user of the *presentation service layer* and is concerned with the differences that exist in the various processors and operating systems in which each of the distributed communications systems is implemented. The presentation service layer provides the service to overcome differences in coded representation, format, and the presentations of information. To use an analogy, if one system's machine talked and understood Greek and another system's machine talked and understood Latin, the presentation services layer would perform the necessary service to permit the comprehension of information exchanged between the two systems.

The *presentation service layer* is a user of the session layer which manages the dialogue between two communicating partners. The session layer assures that the information exchange conforms to the rules necessary to satisfy the end user needs. For example, if the exchange is to be by the *two-way alternate* mode, the session layer monitors and enforces this mode of exchange. It regulates the rate of flow to end users and assures that information is delivered in the same form and sequence in which it had been transmitted, if that had been a requirement. It is the higher layer's port into the transmission subsystem that encompasses the lower four layers of the OSI reference model in Fig. 18.6.1a.

The *session layer* is the user of the *transport layer*, which creates a logical pipe between the session layer of its system and that of any other system. The transport layer is responsible for selecting the appropriate lower-layer network to meet the service requirement of the session-layer entities, and where necessary, to enhance lower-level network services by providing system end-to-end integrity, information resequencing, and system-to-system flow control to assure no underrun or overrun of the receiving system's resources.

The transport layer uses the *network layer* to create a logical path between two systems. Systems may be attached to each other in many different ways. The simplest way is through a single point-to-point connection. The network layer in such an example is very simple. However, witness the topology depicted in Fig. 18.6.4. To go from system A to system B involves passing through several different networks, each of which exhibits

FIGURE 18.6.4 Creating a logical path between two systems.

different characteristics of transmission service and each of which may differ radically in its software and hardware design, topology, and *protocol* (rules of operation).

Such a network interconnection is rather typical. In fact, many interconnections can be far more complex. Consider the effect of the inclusion of an alternate packet-switch network PSB between local area network (LAN) A and PSA. The logic to decide which network or sequence of networks to employ must be dealt with within the network layer. This function is referred to as *routing*. However, to hide the presence of network complexity from the transport layer and thus provide the appearance of a single network, a unifying sublayer, called the *internet layer*, is inserted between the transport layer and subnetworks, as shown in Fig. 18.6.5.

Because networks differ with regard to the size of data units they can handle, the network layer must deal with the breaking of information frames into the size required by individual subnetworks within the path. The network layer must ultimately be capable of reassembling the information frames at the target system before passing them to that system's transport layer. The network layer must also address the problem of congestion caused by network sources being shared by large numbers of users attached to different systems. Because the end users of these

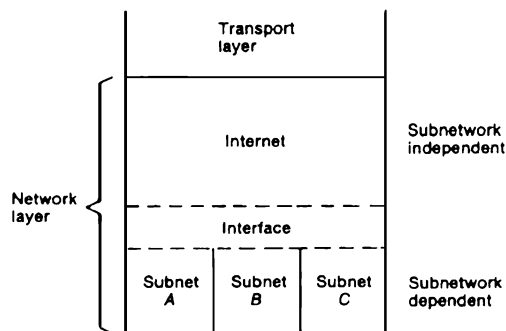

FIGURE 18.6.5 Network layer structure.

FIGURE 18.6.6 A new link control for each new channel.

different systems are independent of each other, it is possible they may all attempt to access and use the same network resources simultaneously. Congestion can result in deadlock, and such an occurrence can bring a network to a halt. Thus network layers must offer means of deadlock avoidance or detection and correction.

The network layer is a user of the *link-control layer*, which is responsible for building a point-to-point connection between two system nodes that share a common communications circuit. Link control is aware only of its neighboring node(s) on the shared channel. Each new circuit requires a new link control, as illustrated in Fig. 18.6.6.

It is possible to hide the existence of multiple circuits between two nodes by the inclusion of a multilink sublayer above the individual link-control layers. Link control performs such functions as error detection and correction, framing, flow-control sequencing, and channel-access control.

Link control is the user of the *physical layer*. The physical layer is responsible for transforming the information frame into a form suitable for transmission onto the medium. Thus its major function is signaling, i.e., putting information onto the medium, removing it, and retransforming it into the code structure understandable by the link control.

REAL SYSTEMS

It is important to understand that OSI describes a layered model that allocates functions necessary in the process of communications to each of the layers. However, the actual implementation of any system to attain conformance with the model is left to individual system vendors. Thus, whether there are layers and where a function is actually executed within a single system are matters beyond the scope of ISO. The test of conformance is the successful interoperability between systems. However, one can use the model to place in proper context existing communications protocols, associated entities, services, and products. For example, modems are entities of the physical layer. A data service unit is another such entity, and LAN adapter is still another.

For the network layer, the list is still growing. There are many different subnetworks, each with its own routing schemes to effect the switching of information through the nodes of its unique communications subnetwork. Thus, when one looks at some of the network service providers, such as Telenet or Tymnet, different logical and physical entities performing the same services are observed. Agreement exists among vendors and carriers that if systems are to interconnect, there is a need for a unifying network address structure to avoid ambiguity in identifying systems. There must also be a way of shielding the transport layer entities from various differences within the possible networks that could be involved in achieving end-to-end communications. Such shielding is implemented in the protocols of the Internet and associated software, such as TCP/IP.

PACKET SWITCH

A packet switch is designed to provide the three lower-layer services of the OSI model to its subscribers (physical, link, and network). The interface to access these services is X.25. (See Fig. 18.6.1b). When one observes the implementation of various vendor packet switches, it is difficult to see the layers. Most vendors tend to integrate their layers and thus do not clearly define the interfaces that would demonstrate the layer-to-layer independence required. However, because most packet-switched networks are in themselves closed systems, and each generally has its own unique routing algorithms and congestion and flow-control mechanisms, OSI is concerned only with conformance at the top-layer service interface (X.25) and at the gateway between different packet networks (X.75).

SECTION 19

CONTROL SYSTEMS

Control is used to modify the behavior of a system so it behaves in a specific desirable way over time. For example, we may want the speed of a car on the highway to remain as close as possible to 60 miles per hour in spite of possible hills or adverse wind; or we may want an aircraft to follow a desired altitude, heading, and velocity profile independent of wind gusts; or we may want the temperature and pressure in a reactor vessel in a chemical process plant to be maintained at desired levels. All these are being accomplished today by control methods and the above are examples of what automatic control systems are designed to do, without human intervention. Control is used whenever quantities such as speed, altitude, temperature, or voltage must be made to behave in some desirable way over time.

This section provides an introduction to control system design methods. D.C.

CHAPTER 19.1

CONTROL SYSTEM DESIGN

Panos Antsaklis, Zhiqiang Gao

INTRODUCTION

To gain some insight into how an automatic control system operates we shall briefly examine the speed control mechanism in a car.

It is perhaps instructive to consider first how a typical driver may control the car speed over uneven terrain. The driver, by carefully observing the speedometer, and appropriately increasing or decreasing the fuel flow to the engine, using the gas pedal, can maintain the speed quite accurately. Higher accuracy can perhaps be achieved by looking ahead to anticipate road inclines. An automatic speed control system, also called *cruise control*, works by using the difference, or error, between the actual and desired speeds and knowledge of the car's response to fuel increases and decreases to calculate via some algorithm an appropriate gas pedal position, so to drive the speed error to zero. This decision process is called a *control law* and it is implemented in the *controller*. The system configuration is shown in Fig. 19.1.1. The car dynamics of interest are captured in the *plant*. Information about the actual speed is fed back to the controller by *sensors*, and the control decisions are implemented via a device, the *actuator*, that changes the position of the gas pedal. The knowledge of the car's response to fuel increases and decreases is most often captured in a mathematical model.

Certainly in an automobile today there are many more automatic control systems such as the antilock brake system (ABS), emission control, and tracking control. The use of feedback control preceded control theory, outlined in the following sections, by over 2000 years. The first feedback device on record is the famous Water Clock of Ktesibios in Alexandria, Egypt, from the third century BC.

Proportional-Integral-Derivative Control

The proportional-integral-derivative (PID) controller, defined by

$$u = k_p e + k_i \int e + k_d \dot{e} \quad (1)$$

is a particularly useful control approach that was invented over 80 years ago. Here k_p , k_i , and k_d are controller parameters to be selected, often by trial and error or by the use of a lookup table in industry practice. The goal, as in the cruise control example, is to drive the error to zero in a desirable manner. All three terms in Eq. (1) have explicit physical meanings in that e is the current error, $\int e$ is the accumulated error, and \dot{e} represents the trend. This, together with the basic understanding of the causal relationship between the control signal (u) and the output (y), forms the basis for engineers to “tune,” or adjust, the controller parameters to meet the design specifications. This intuitive design, as it turns out, is sufficient for many control applications.

To this day, PID control is still the predominant method in industry and is found in over 95 percent of industrial applications. Its success can be attributed to the simplicity, efficiency, and effectiveness of this method.

FIGURE 19.1.1 Feedback control configuration with cruise control as an example.

The Role of Control Theory

To design a controller that makes a system behave in a desirable manner, we need a way to predict the behavior of the quantities of interest over time, specifically how they change in response to different inputs. Mathematical models are most often used to predict future behavior, and control system design methodologies are based on such models. Understanding control theory requires engineers to be well versed in basic mathematical concepts and skills, such as solving differential equations and using Laplace transform. The role of control theory is to help us gain insight on how and why feedback control systems work and how to *systematically* deal with various design and analysis issues. Specifically, the following issues are of both practical importance and theoretical interest:

1. Stability and stability margins of closed-loop systems.
2. How fast and how smoothly the error between the output and the set point is driven to zero.
3. How well the control system handles unexpected external disturbances, sensor noises, and internal dynamic changes.

In the following, modeling and analysis are first introduced, followed by an overview of the classical design methods for single-input single-output plants, design evaluation methods, and implementation issues. Alternative design methods are then briefly presented. Finally, for the sake of simplicity and brevity, the discussion is restricted to linear, time invariant systems. Results maybe found in the literature for the cases of linear, time-varying systems, and also for nonlinear systems, systems with delays, systems described by partial differential equations, and so on; these results, however, tend to be more restricted and case dependent.

MATHEMATICAL DESCRIPTIONS

Mathematical models of physical processes are the foundations of control theory. The existing analysis and synthesis tools are all based on certain types of mathematical descriptions of the systems to be controlled, also called plants. Most require that the plants are linear, causal, and time invariant. Three different mathematical models for such plants, namely, linear ordinary differential equations, state variable or state space descriptions, and transfer functions are introduced below.

Linear Differential Equations

In control system design the most common mathematical models of the behavior of interest are, in the time domain, linear ordinary differential equations with constant coefficients, and in the frequency or transform domain, transfer functions obtained from time domain descriptions via Laplace transforms.

Mathematical models of dynamic processes are often derived using physical laws such as Newton's and Kirchoff's. As an example consider first a simple mechanical system, a spring/mass/damper. It consists of a weight m on a spring with spring constant k , its motion damped by friction with coefficient f (Fig. 19.1.2).

FIGURE 19.1.2 Spring, mass, and damper system.

FIGURE 19.1.3 RLC circuit.

If $y(t)$ is the displacement from the resting position and $u(t)$ is the force applied, it can be shown using Newton's law that the motion is described by the following linear, ordinary differential equation with constant coefficients:

$$\ddot{y}(t) + \frac{f}{m} \dot{y}(t) + \frac{k}{m} y(t) = \frac{1}{m} u(t)$$

where $\dot{y}(t) \triangleq dy(t)/dt$ with initial conditions

$$y(t) \Big|_{t=0} = y(0) = y_0 \quad \text{and} \quad \frac{dy(t)}{dt} \Big|_{t=0} = \frac{dy(0)}{dt} = \dot{y}(0) = y_1$$

Note that in the next subsection the trajectory $y(t)$ is determined, in terms of the system parameters, the initial conditions, and the applied input force $u(t)$, using a methodology based on Laplace transform. The Laplace transform is briefly reviewed in the CD-ROM.

For a second example consider an electric RLC circuit with $i(t)$ the input current of a current source, and $v(t)$ the output voltage across a load resistance R (Fig. 19.1.3).

Using Kirchoff's laws one may derive:

$$\ddot{v}(t) + \frac{R}{L} \dot{v}(t) + \frac{1}{LC} v(t) = \frac{R}{LC} i(t)$$

which describes the dependence of the output voltage $v(t)$ to the input current $i(t)$. Given $i(t)$ for $t \geq 0$, the initial values $v(0)$ and $\dot{v}(0)$ must also be given to uniquely define $v(t)$ for $t \geq 0$.

It is important to note the similarity between the two differential equations that describe the behavior of a mechanical and an electrical system, respectively. Although the interpretation of the variables is completely different, their relations are described by the same linear, second-order differential equation with constant coefficients. This fact is well understood and leads to the study of mechanical, thermal, fluid systems via convenient electric circuits.

State Variable Descriptions

Instead of working with many different types of higher-order differential equations that describe the behavior of the system, it is possible to work with an equivalent set of standardized first-order vector differential equations that can be derived in a systematic way. To illustrate, consider the spring/mass/damper example. Let $x_1(t) = y(t)$, $x_2(t) = \dot{y}(t)$ be new variables, called *state variables*. Then the system is equivalently described by the equations

$$\dot{x}_1(t) = x_2(t) \quad \text{and} \quad \dot{x}_2(t) = -\frac{f}{m} x_2(t) - \frac{k}{m} x_1(t) + \frac{1}{m} u(t)$$

19.6 CONTROL SYSTEMS

with initial conditions $x_1(0) = y_0$ and $x_2(0) = y_1$. Since $y(t)$ is of interest, the output equation $y(t) = x_1(t)$ is also added. These can be written as

$$\begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -k/m & -f/m \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 1/m \end{bmatrix} u(t)$$

$$y(t) = [1 \quad 0] \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix}$$

which are of the general form

$$\dot{x}(t) = Ax(t) + Bu(t), \quad y(t) = Cx(t) + Du(t)$$

Here $x(t)$ is a 2×1 vector (a column vector) with elements the two state variables $x_1(t)$ and $x_2(t)$. It is called the *state vector*. The variable $u(t)$ is the *input* and $y(t)$ is the *output* of the system. The first equation is a vector differential equation called the *state equation*. The second equation is an algebraic equation called the *output equation*. In the above example $D = 0$; D is called the *direct link*, as it directly connects the input to the output, as opposed to connecting through $x(t)$ and the dynamics of the system. The above description is the *state variable* or *state space description* of the system. The advantage is that system descriptions can be written in a standard form (the state space form) for which many mathematical results exist. We shall present a number of them in this section.

A state variable description of a system can sometimes be derived directly, and not through a higher-order differential equation. To illustrate, consider the circuit example presented above, using Kirchoff's current law

$$i_c = C \frac{dv_c}{dt} = i - i_L$$

and from the voltage law

$$L \frac{di_L}{dt} = -Ri_L + v_c$$

If the state variables are selected to be $x_1 = v_c$, $x_2 = i_L$, then the equations may be written as

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & -1/C \\ 1/L & -R/L \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 1/C \\ 0 \end{bmatrix} i$$

$$v = [0 \quad R] \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$$

where $v = Ri_L = Rx_2$ is the output of interest. Note that the choice of state variables is not unique. In fact, if we start from the second-order differential equation and set $\bar{x}_1 = v$ and $\bar{x}_2 = \dot{v}$, we derive an equivalent state variable description, namely,

$$\begin{bmatrix} \dot{\bar{x}}_1 \\ \dot{\bar{x}}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1/LC & -R/L \end{bmatrix} \begin{bmatrix} \bar{x}_1 \\ \bar{x}_2 \end{bmatrix} + \begin{bmatrix} 0 \\ R/LC \end{bmatrix} i$$

$$v = [1 \quad 0] \begin{bmatrix} \bar{x}_1 \\ \bar{x}_2 \end{bmatrix}$$

Equivalent state variable descriptions are obtained by a change in the basis (coordinate system) of the vector state space. Any two equivalent representations

$$x = Ax + Bu, \quad y = Cx + Du \quad \text{and} \quad \bar{x} = \bar{A}\bar{x} + \bar{B}u, \quad y = \bar{C}\bar{x} + \bar{D}u$$

are related by $\bar{A} = PAP^{-1}$, $\bar{B} = PB$, $\bar{C} = CP^{-1}$, $\bar{D} = D$, and $\bar{x} = Px$ where P is a square and nonsingular matrix. Note that state variables can represent physical quantities that may be measured, for instance, $x_1 = v_c$ voltage, $x_2 = i_L$ current in the above example; or they can be mathematical quantities, which may not have direct physical interpretation.

FIGURE 19.1.4 The transfer function model.

Linearization. The linear models studied here are very useful not only because they describe linear dynamical processes, but also because they can be approximations of nonlinear dynamical processes in the neighborhood of an operating point. The idea in linear approximations of nonlinear dynamics is analogous to using Taylor series approximations of functions to extract a linear approximation. A simple example is that of a simple pendulum $x_1 = x_2$, $\dot{x}_2 = -k \sin x_1$, where for small excursions from the equilibrium at zero, $\sin x_1$ is approximately equal to x_1 and the equations become linear, namely, $\dot{x}_1 = x_2$, $\dot{x}_2 = -kx_1$.

Transfer Functions

The *transfer function* of a linear, time-invariant system is the ratio of the Laplace transform of the output $Y(s)$ to the Laplace transform of the corresponding input $U(s)$ with all initial conditions assumed to be zero (Fig. 19.1.4).

From Differential Equations to Transfer Functions. Let the equation

$$\frac{d^2 y(t)}{dt^2} + a_1 \frac{dy(t)}{dt} + a_0 y(t) = b_0 u(t)$$

with some initial conditions

$$y(t)|_{t=0} = y(0) \quad \text{and} \quad \left. \frac{dy(t)}{dt} \right|_{t=0} = \frac{dy(0)}{dt} = y'(0)$$

describe a process of interest, for example, a spring/mass/damper system; see previous subsection. Taking the Laplace transform of both sides we obtain

$$[s^2 Y(s) - sy(0) - y'(0)] + a_1 [sY(s) - y(0)] + a_0 Y(s) = b_0 U(s)$$

where $Y(s) = L\{y(t)\}$ and $U(s) = L\{u(t)\}$. Combining terms and solving with respect to $Y(s)$ we obtain:

$$Y(s) = \frac{b_0}{s^2 + a_1 s + a_0} U(s) + \frac{(s + a_1)y(0) + y'(0)}{s^2 + a_1 s + a_0}$$

Assuming the initial conditions are zero,

$$Y(s)/U(s) = G(s) = \frac{b_0}{s^2 + a_1 s + a_0}$$

where $G(s)$ is the *transfer function of the system* defined above.

We are concerned with transfer functions $G(s)$ that are rational functions, that is, ratios of polynomials in s , $G(s) = n(s)/d(s)$. We are interested in *proper* $G(s)$ where $\lim_{s \rightarrow \infty} G(s) < \infty$. Proper $G(s)$ have degree $n(s) \leq$ degree $d(s)$.

19.8 CONTROL SYSTEMS

In most cases degree $n(s) < \text{degree } d(s)$, in which case $G(s)$ is called *strictly proper*. Consider the transfer function

$$G(s) = \frac{b_m s^m + b_{m-1} s^{m-1} + \dots + b_1 s + b_0}{s^n + a_{n-1} s^{n-1} + \dots + a_1 s + a_0} \quad \text{with } m \leq n$$

Note that the system described by this $G(s)$ ($Y(s) = G(s)U(s)$) is described in the time domain by the following differential equation:

$$y^{(n)}(t) + a_{n-1} y^{(n-1)}(t) + \dots + a_1 y^{(1)}(t) + a_0 y(t) = b_m u^{(m)}(t) + \dots + b_1 u^{(1)}(t) + b_0 u(t)$$

where $y^{(n)}(t)$ denotes the n th derivative of $y(t)$ with respect to time t . Taking the Laplace transform of both sides of this differential equation, assuming that all initial conditions are zero, one obtains the above transfer function $G(s)$.

From State Space Descriptions to Transfer Functions. Consider $\dot{x}(t) = Ax(t) + Bu(t)$, $y(t) = Cx(t) + Du(t)$ with $x(0)$ initial conditions; $x(t)$ is in general an n -tuple, that is, a (column) vector with n elements. Taking the Laplace transform of both sides of the state equation:

$$sX(s) - x(0) = AX(s) + BU(s) \quad \text{or} \quad (sI_n - A)X(s) = BU(s) + x(0)$$

where I_n is the $n \times n$ identity matrix; it has 1 on all diagonal elements and 0 everywhere else, e.g.,

$$I_2 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

Then

$$X(s) = (sI_n - A)^{-1}BU(s) + (sI_n - A)^{-1}x(0)$$

Taking now the Laplace transform on both sides of the output equation we obtain $Y(s) = CX(s) + DU(s)$. Substituting we obtain,

$$Y(s) = [C(sI_n - A)^{-1}B + D]U(s) + C(sI_n - A)^{-1}x(0)$$

The response $y(t)$ is the inverse Laplace of $Y(s)$. Note that the second term on the right-hand side of the expression depends on $x(0)$ and it is zero when the initial conditions are zero, i.e., when $x(0) = 0$. The first term describes the dependence of $Y(s)$ on $U(s)$ and it is not difficult to see that the transfer function $G(s)$ of the systems is

$$G(s) = C(sI_n - A)^{-1}B + D$$

Example Consider the spring/mass/damper example discussed previously with state variable description $\dot{x} = Ax + Bu$, $y = Cx$. If $m = 1$, $f = 3$, $k = 2$, then

$$A = \begin{bmatrix} 0 & 1 \\ -2 & -3 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad C = [1 \quad 0]$$

and its transfer function $G(s)$ ($Y(s) = G(s)U(s)$) is

$$\begin{aligned} G(s) &= C(sI_2 - A)^{-1}B = [1 \quad 0] \left[\begin{bmatrix} s & 0 \\ 0 & s \end{bmatrix} - \begin{bmatrix} 0 & 1 \\ -2 & -3 \end{bmatrix} \right]^{-1} \begin{bmatrix} 0 \\ 1 \end{bmatrix} \\ &= [1 \quad 0] \begin{bmatrix} s & -1 \\ 2 & s+3 \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 1 \end{bmatrix} = [1 \quad 0] \frac{1}{s^2 + 3s + 2} \begin{bmatrix} s+3 & 1 \\ -2 & s \end{bmatrix} \begin{bmatrix} 0 \\ 1 \end{bmatrix} \\ &= \frac{1}{s^2 + 3s + 2} \end{aligned}$$

as before.

Using the state space description and properties of the Laplace transform an explicit expression for $y(t)$ in terms of $u(t)$ and $x(0)$ may be derived. To illustrate, consider the *scalar case* $\dot{z} = az + bu$ with $z(0)$ initial condition. Using the Laplace transform:

$$Z(s) = \frac{1}{s-a} z(0) + \frac{b}{s-a} U(s)$$

from which

$$z(t) = L^{-1}\{Z(s)\} = e^{at} z(0) + \int_0^t e^{a(t-\tau)} bu(\tau) d\tau$$

Note that the second term is a convolution integral. Similarly in the *vector case*, given

$$\dot{x}(t) = Ax(t) + Bu(t), \quad y(t) = Cx(t) + B(t)u(t)$$

it can be shown that

$$x(t) = e^{At} x(0) + \int_0^t e^{A(t-\tau)} Bu(\tau) d\tau$$

and

$$y(t) = Ce^{At} x(0) + \int_0^t Ce^{A(t-\tau)} Bu(\tau) d\tau + Du(t)$$

Notice that $e^{At} = L^{-1}\{(sI - A)^{-1}\}$. The *matrix exponential* e^{At} is defined by the (convergent) series

$$e^{At} = I + e^{At} + \frac{A^2 t^2}{2!} + \frac{A^k t^k}{k!} + \dots = I + \sum_{k=1}^{\infty} \frac{t^k}{k!} A^k$$

Poles and Zeros. The n roots of the denominator polynomial $d(s)$ of $G(s)$ are the *poles* of $G(s)$. The m roots of the numerator polynomial $n(s)$ of $G(s)$ are (finite) *zeros* of $G(s)$.

Example (Fig. 19.1.5)

$$G(s) = \frac{s+2}{s^2+2s+2} = \frac{s+2}{(s+1)^2+1} = \frac{s+2}{(s+1-j)(s+1+j)}$$

$G(s)$ has one (finite) zero at -2 and two complex conjugate poles at $-1 \pm j$. In general, a transfer function with m zeros and n poles can be written as

$$G(s) = k \frac{(s-z_1) \dots (s-z_m)}{(s-p_1) \dots (s-p_n)}$$

where k is the *gain*.

Frequency Response

The *frequency response* of a system is given by its transfer function $G(s)$ evaluated at $s = j\omega$, that is, $G(j\omega)$. The frequency response is a very useful means characterizing a system, since typically it can be determined experimentally, and since control system specifications are frequently expressed in terms of the frequency response. When the poles of $G(s)$ have negative real parts, the system turns out to be bounded-input/bounded-output

FIGURE 19.1.5 Complex conjugate poles of $G(s)$.

(BIBO) stable. Under these conditions the frequency response $G(j\omega)$ has a clear physical meaning, and this fact can be used to determine $G(j\omega)$ experimentally. In particular, it can be shown that if the input $u(t) = k \sin(\omega_o t)$ is applied to a system with a stable transfer function $G(s)$ ($Y(s) = G(s)U(s)$), then the output $y(t)$ at steady state (after all transients have died out) is given by

$$y_{ss}(t) = k |G(\omega_o)| \sin[\omega_o t + \theta(\omega_o)]$$

where $|G(\omega_o)|$ denotes the magnitude of $G(j\omega_o)$ and $\theta(\omega_o) = \arg G(j\omega_o)$ is the argument or phase of the complex quantity $G(j\omega_o)$. Applying sinusoidal inputs with different frequencies ω_o and measuring the magnitude and phase of the output at steady state, it is possible to determine the full frequency response of the system $G(j\omega_o) = |G(\omega_o)| e^{j\theta(\omega_o)}$.

ANALYSIS OF DYNAMICAL BEHAVIOR

System Response, Modes, and Stability

It was shown above how the response of a system to an input and under some given initial conditions can be calculated from its differential equation description using Laplace transforms. Specifically, $y(t) = L^{-1}\{Y(s)\}$ where

$$Y(s) = \frac{n(s)}{d(s)}U(s) + \frac{m(s)}{d(s)}$$

with $n(s)/d(s) = G(s)$, the system transfer function; the numerator $m(s)$ of the second term depends on the initial conditions and it is zero when all initial conditions are zero, i.e., when the system is initially at rest.

In view now of the partial fraction expansion rules, $Y(s)$ can be written as follows:

$$Y(s) = \frac{c_1}{s-p_1} + \dots + \frac{c_{i1}}{s-p_i} + \frac{c_{i2}}{(s-p_i)^2} + \dots + \frac{b_1 s + b_0}{s^2 + a_1 s + a_0} + \dots + I(s)$$

This expression shows real poles of $G(s)$, namely, p_1, p_2, \dots , and it allows for multiple poles p_i ; it also shows complex conjugate poles $a \pm jb$ written as second-order terms. $I(s)$ denotes the terms due to the input $U(s)$; they are fractions with the poles of $U(s)$. Note that if $G(s)$ and $U(s)$ have common poles they are combined to form multiple-pole terms.

Taking now the inverse Laplace transform of $Y(s)$:

$$y(t) = L^{-1}\{Y(s)\} = c_1 e^{p_1 t} + \dots + c_{i1} e^{p_i t} + (\cdot) t e^{p_i t} + \dots + e^{at} [(\cdot) \sin bt + (\cdot) \cos bt] + \dots + i(t)$$

where $i(t)$ depends on the input. Note that the terms of the form $c t^k e^{p_i t}$ are the *modes of the system*. The system behavior is the aggregate of the behaviors of the modes. Each mode depends primarily on the location of the pole p_i ; the location of the zeros affects the size of its coefficient c .

If the input $u(t)$ is a *bounded signal*, i.e., $|u(t)| < \infty$ for all t , then all the poles of $I(s)$ have real parts that are negative or zero, and this implies that $I(t)$ is also bounded for all t . In that case, the response $y(t)$ of the system will also be bounded for any bounded $u(t)$ if and only if all the poles of $G(s)$ have strictly negative real parts. Note that poles of $G(s)$ with real parts equal to zero are not allowed, since if $U(s)$ also has poles at the same locations, $y(t)$ will be unbounded. Take, for example, $G(s) = 1/s$ and consider the bounded step input $U(s) = 1/s$; the response $y(t) = t$, which is not bounded.

Having all the poles of $G(s)$ located in the open left half of the s -plane is very desirable and it corresponds to the system being stable. In fact, a system is *bounded-input, bounded-output (BIBO) stable* if and only if all poles of its transfer function have negative real parts. If at least one of the poles has positive

real parts, then the system is *unstable*. If a pole has zero real parts, then the term *marginally stable* is sometimes used.

Note that in a BIBO stable system if there is no forcing input, but only initial conditions are allowed to excite the system, then $y(t)$ will go to zero as t goes to infinity. This is a very desirable property for a system to have, because nonzero initial conditions always exist in most real systems. For example, disturbances such as interference may add charge to a capacitor in an electric circuit, or a sudden brief gust of wind may change the heading of an aircraft. In a stable system the effect of the disturbances will diminish and the system will return to its previous desirable operating condition. For these reasons a control system should first and foremost be guaranteed to be stable, that is, it should always have poles with negative real parts. There are many design methods to stabilize a system or if it is initially stable to preserve its stability, and several are discussed later in this section.

Response of First- and Second-Order Systems

Consider a system described by a first-order differential equation, namely, $\dot{y}(t) + a_0y(t) = a_0u(t)$ and let $y(0) = 0$. In view of the previous subsection, the transfer function of the system is

$$G(s) = \frac{a_0}{s + a_0}$$

and the response to a *unit step input* $q(t)$ ($q(t) = 1$ for $t \geq 0$, $q(t) = 0$ for $t < 0$) may be found as follows:

$$\begin{aligned} y(t) &= L^{-1}\{Y(s)\} = L^{-1}\{G(s)U(s)\} = L^{-1}\left\{\frac{a_0}{s + a_0} \frac{1}{s}\right\} \\ &= L^{-1}\left\{\frac{1}{s} + \frac{-1}{s + a_0}\right\} = [1 - e^{-a_0t}]q(t) \end{aligned}$$

Note that the pole of the system is $p = -a_0$ (in Fig. 19.1.6 we have assumed that $a_0 > 0$). As that pole moves to the left on the real axis, i.e., as a_0 becomes larger, the system becomes faster. This can be seen from the fact that the steady state value of the system response

FIGURE 19.1.6 Pole location of a first-order system.

$$y_{ss} = \lim_{t \rightarrow \infty} y(t) = 1$$

is approached by the trajectory of $y(t)$ faster, as a_0 becomes larger. To see this, note that the value $1 - e^{-1}$ is attained at time $\tau = 1/a_0$, which is smaller as a_0 becomes larger. τ is the *time constant* of this first-order system; see below for further discussion of the time constant of a system.

We now derive the response of a second-order system to a unit step input (Fig. 19.1.7). Consider a system described by $\ddot{y}(t) + a_1\dot{y}(t) + a_0y(t) = a_0u(t)$, which gives rise to the transfer function:

$$G(s) = \frac{a_0}{s^2 + a_1s + a_0}$$

Here the steady-state value of the response to a unit step is

$$y_{ss} = \lim_{s \rightarrow 0} sG(s) \frac{1}{s} = 1$$

Note that this normalization or scaling to 1 is in fact the reason for selecting the constant numerator to be a_0 . $G(s)$ above does not have any finite zeros—only poles—as we want to study first the effect of the poles on the system behavior. We shall discuss the effect of adding a zero or an extra pole later.

FIGURE 19.17 Step response of a first-order plant.

It is customary, and useful as we will see, to write the above transfer function as

$$G(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}$$

where ζ is the *damping ratio* of the system and ω_n is the (*undamped*) *natural frequency* of the system, i.e., the frequency of oscillations when the damping is zero.

The poles of the system are

$$p_{1,2} = -\zeta\omega_n \pm \omega_n\sqrt{\zeta^2 - 1}$$

When $\zeta > 1$ the poles are real and distinct and the unit step response approaches its steady-state value of 1 without overshoot. In this case the system is *overdamped*. The system is called *critically damped* when $\zeta = 1$ in which case the poles are real, repeated, and located at $-\zeta\omega_n$.

The more interesting case is when the system is *underdamped* ($\zeta < 1$). In this case the poles are complex conjugate and are given by

$$p_{1,2} = -\zeta\omega_n \pm j\omega_n\sqrt{1 - \zeta^2} = \sigma + j\omega_d$$

The response to a unit step input in this case is

$$y(t) = \left[1 - \frac{e^{-\zeta\omega_n t}}{\sqrt{1 - \zeta^2}} \sin(\omega_d t + \theta) \right] q(t)$$

where $\theta = \cos^{-1} \zeta = \tan^{-1} (\sqrt{1 - \zeta^2} / \zeta)$, $\omega_d = \omega_n \sqrt{1 - \zeta^2}$, and $q(t)$ is the step function. The response to an *impulse input* ($u(t) = \delta(t)$) also called the *impulse response* $h(t)$ of the system is given in this case by

$$h(t) = \left[\omega_n \frac{e^{-\zeta\omega_n t}}{\sqrt{1 - \zeta^2}} \sin \omega_n (\sqrt{1 - \zeta^2} t) \right] q(t)$$

The second-order system is parameterized by the two parameters ζ and ω_n . Different choices for ζ and ω_n lead to different pole locations and to different behavior of (the modes of) the system. Fig. 19.1.8 shows the relation between the parameters and the pole location.

FIGURE 19.1.8 Relation between pole location and parameters.

Time Constant of a Mode and of a System. The time constant of a mode ce^{pt} of a system is the time value that makes $|pt| = 1$, i.e., $\tau = 1/|p|$. For example, in the above first-order system we have seen that $\tau = 1/a_0 = RC$. A pair of complex conjugate poles $p_{1,2} = \sigma \pm j\omega$ give rise to the term of the form $Ce^{\sigma t} \sin(\omega t + \theta)$. In this case, $\tau = 1/|\sigma|$, i.e., τ is again the inverse of the distance of the pole from the imaginary axis. The time constant of a system is the time constant of its dominant modes.

Transient Response Performance Specifications for a Second-Order Underdamped System

For the system

$$G(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}$$

and a unit step input, explicit formulas for important measures of performance of its transient response can be derived. Note that the steady state is

$$y_{ss} = \lim_{s \rightarrow 0} sG(s) \frac{1}{s} = 1$$

The *rise time* t_r shows how long it takes for the system's output to rise from 0 to 66 percent of its final value (equal to 1 here) and it can be shown to be $t_r = (\pi - \theta)/\omega_n$, where $\theta = \cos^{-1} \zeta$ and $\omega_d = \omega_n \sqrt{1 - \zeta^2}$. The *settling time* t_s is the time required for the output to settle within some percentage, typically 2 or 5 percent, of its final value. $t_s \cong 4/\zeta\omega_n$ is the 2 percent settling time ($t_s \cong 3/\zeta\omega_n$ is the 5 percent settling time). Before the underdamped system settles, it will overshoot its final value. The *peak time* t_p measures the time it takes for the output to reach its first (and highest) peak value. M_p measures the actual *overshoot* that occurs in percentage terms of the final value. M_p occurs at time t_p , which is the time of the first and largest overshoot.

$$t_p = \frac{\pi}{\omega_d}, \quad M_p = 100e^{-\zeta\pi/\sqrt{1-\zeta^2}} \%$$

It is important to notice that the overshoot depends only on ζ . Typically, tolerable overshoot values are between 2.5 and 25 percent, which correspond to damping ratio ζ between 0.8 and 0.4.

Effect of Additional Poles and Zeros

The addition of an extra pole in the left-half s -plane (LHP) tends to slow the system down—the rise time of the system, for example, will become larger. When the pole is far to the left of the imaginary axis, its effect tends to be small. The effect becomes more pronounced as the pole moves toward the imaginary axis.

The addition of a zero in the LHP has the opposite effect, as it tends to speed the system up. Again the effect of a zero far away to the left of the imaginary axis tends to be small. It becomes more pronounced as the zero moves closer to the imaginary axis.

The addition of a zero in the right-half s -plane (RHP) has a delaying effect much more severe than the addition of a LHP pole. In fact a RHP zero causes the response (say, to a step input) to start toward the wrong direction. It will move down first and become negative, for example, before it becomes positive again and starts toward its steady-state value. Systems with RHP zeros are called *nonminimum phase systems* (for reasons that will become clearer after the discussion of the frequency design methods) and are typically difficult to control. Systems with only LHP poles (stable) and LHP zeros are called *minimum phase systems*.

CLASSICAL CONTROL DESIGN METHODS

In this section, we focus on the problem of controlling a single-input and single-output (SISO) LTI plant. It is understood from the above sections that such a plant can be represented by a transfer function $G_p(s)$. The closed-loop system is shown in Fig. 19.1.9.

The goal of feedback control is to make the output of the plant, y , follow the reference input r as closely as possible. Classical design methods are those used to determine the controller transfer function $G_c(s)$ so that the closed-loop system, represented by the transfer function:

$$G_{CL}(s) = \frac{G_c(s)G_p(s)}{1 + G_c(s)G_p(s)}$$

has desired characteristics.

Design Specifications and Constraints

The design specifications are typically described in terms of step response, i.e., r is the set point described as a step-like function. These specifications are given in terms of transient response and steady-state error, assuming the feedback control system is stable. The transient response is characterized by the rise time, i.e., the time it takes for the output to reach 66 percent of its final value, the settling time, i.e., the time it takes for the output to settle within 2 percent of its final value, and the percent overshoot, which is how much the output exceeds the set-point r percentagewise during the period that y converges to r . The steady-state error refers to the difference, if any, between y and r as y reaches its steady-state value.

There are many constraints a control designer has to deal with in practice, as shown in Fig. 19.1.10. They can be described as follows:

1. *Actuator Saturation:* The input u to the plant is physically limited to a certain range, beyond which it “saturates,” i.e., becomes a constant.
2. *Disturbance Rejection and Sensor Noise Reduction:* There are always disturbances and sensor noises in the plant to be dealt with.

FIGURE 19.1.9 Feedback control configuration.

FIGURE 19.1.10 Closed-loop simulator setup.

3. *Dynamic Changes in the Plant:* Physical systems are almost never truly linear nor time invariant.
4. *Transient Profile:* In practice, it is often not enough to just move y from one operating point to another. How it gets there is sometimes just as important. Transient profile is a mechanism to define the desired trajectory of y in transition, which is of great practical concern. The smoothness of y and its derivatives, the energy consumed, the maximum value, and the rate of change required of the control action are all influenced by the choice of transient profile.
5. *Digital Control:* Most controllers are implemented today in digital forms, which makes the sampling rate and quantization errors limiting factors in the controller performance.

Control Design Strategy Overview

The control strategies are summarized here in ascending order of complexity and, hopefully, performance.

FIGURE 19.1.11 Open-loop control configuration.

1. *Open-Loop Control:* If the plant transfer function is known and there is very little disturbance, a simple open loop controller, where $G_c(s)$ is an approximate inverse of $G_p(s)$, as shown in Fig. 19.1.11, would satisfy most design requirements. Such control strategy has been used as an economic means in controlling stepper motors, for example.
2. *Feedback Control with a Constant Gain:* With significant disturbance and dynamic variations in the plant, feedback control, as shown in Fig. 19.1.9, is the only choice; see also the Appendix. Its simplest form is $G_c(s) = k$, or $u = ke$, where k is a constant. Such proportional controller is very appealing because of its simplicity. The common problems with this controller are significant steady-state error and overshoot.
3. *Proportional-Integral-Derivative Controller:* To correct the above problems with the constant gain controller, two additional terms are added:

$$u = k_p e + k_i \int e + k_d \dot{e} \quad \text{or} \quad G_c(s) = k_p + k_i / s + k_d s$$

This is the well-known PID controller, which is used by most engineers in industry today. The design can be quite intuitive: the proportional term usually plays the key role, with the integral term added to reduce/eliminate the steady-state error and the derivative term the overshoot. The primary drawbacks of PID are that the integrator introduces phase lag that could lead to stability problems and the differentiator makes the controller sensitive to noise.

FIGURE 19.1.12 Loop-shaping.

4. *Root Locus Method*: A significant portion of most current control textbooks is devoted to the question of how to place the poles of the closed-loop system in Fig. 19.1.9 at desired locations, assuming we know where they are. Root locus is a graphical technique to manipulate the closed-loop poles given the open-loop transfer function. This technique is most effective if disturbance rejection, plant dynamic variations, and sensor noise are not to be considered. This is because these properties cannot be easily linked to closed-loop pole locations.
5. *Loop-Shaping Method*: Loop-shaping [5] refers to the manipulation of the *loop gain* frequency response, $L(j\omega) = G_p(j\omega)G_c(j\omega)$, as a control design tool. It is the only existing design method that can bring most of design specifications and constraints, as discussed above, under one umbrella and systematically find a solution. This makes it a very useful tool in understanding, diagnosing, and solving practical control problems. The loop-shaping process consists of two steps:
 - a. Convert all design specifications to loop gain constraints, as shown in Fig. 19.1.12.
 - b. Find a controller $G_c(s)$ to meet the specifications.

Loop-shaping as a concept and a design tool helped the practicing engineers greatly in improving the PID loop performance and stability margins. For example, a PID implemented as a lead-lag compensator is commonly seen in industry today. This is where the classical control theory provides the mathematical and design insights on why and how feedback control works. It has also laid the foundation for modern control theory.

FIGURE 19.1.13 A Digital servo control design example.

Example Consider a motion control system as shown in Fig. 19.1.13. It consists of a digital controller, a dc motor drive (motor and power amplifier), and a load of 235 lb that is to be moved linearly by 12 in. in 0.3 s with an accuracy of 1 percent or better. A belt and pulley mechanism is used to convert the motor rotation a linear motion. Here a servo motor is used to drive the load to perform a linear motion. The motor is coupled with the load through a pulley.

The design process involves:

1. Selection of components including motor, power amplifier, the belt-and-pulley, the feedback devices (position sensor and/or speed sensor)
2. Modeling of the plant
3. Control design and simulation
4. Implementation and tuning

The first step results in a system with the following parameters:

1. *Electrical:*

- Winding resistance and inductance: $R_a = 0.4$ mho $L_a = 8$ mH (the transfer function of armature voltage to current is $(1/R_a)/[(L_a/R_a)s + 1]$)
- back emf constant: $K_E = 1.49$ V/(rad/s)
- power amplifier gain: $K_{pa} = 80$
- current feedback gain: $K_{cf} = 0.075$ V/A

2. *Mechanical:*

- Torque constant: $K_t = 13.2$ in-lb/A
- Motor inertia $J_m = .05$ lb-in. 2
- Pulley radius $R_p = 1.25$ in.
- Load weight: $W = 235$ lb (including the assembly)
- Total inertia $J_t = J_m + J_l = 0.05 + (W/g)R_p^2 = 1.0$ lb-in. 2

With the maximum armature current set at 100 A, the maximum torque = $K_t I_{a,\max} = 13.2 \times 100 = 1320$ in.-lb; the maximum angular acceleration = $1320/J_t = 1320$ rad/s 2 , and the maximum linear acceleration = $1320 \times R_p = 1650$ in./s $^2 = 4.27$ g's (1650/386). As it turned out, they are sufficient for this application.

The second step produces a simulation model (Fig. 19.1.14).

A simplified transfer function of the plant, from the control input, v_c (in volts), to the linear position output, x_{out} (in inches), is

$$G_p(s) = \frac{206}{s(s+3)}$$

An open loop controller is not suitable here because it cannot handle the torque disturbances and the inertia change in the load. Now consider the feedback control scheme in Fig. 19.1.9 with a constant controller, $u = ke$. The root locus plot in Fig. 19.1.15 indicates that, even at a high gain, the real part of the closed-loop poles does not exceed -1.5 , which corresponds to a settling time of about 2.7 s. This is far slower than desired.

In order to make the system respond faster, the closed-loop poles must be moved further away from the $j\omega$ axis. In particular, a settling time of 0.3 s or less corresponds to the closed-loop poles with real parts smaller than -13.3 . This is achieved by using a PD controller of the form

$$G_c(s) = K(s+3); \quad K \geq 13.3/206$$

will result in a settling time of less than 0.3 s.

The above PD design is a simple solution in servo design that is commonly used. There are several issues, however, that cannot be completely resolved in this framework:

1. Low-frequency torque disturbance induces steady-state error that affects the accuracy.
2. The presence of a resonant mode within or close to the bandwidth of the servo loop may create undesirable vibrations.
3. Sensor noise may cause the control signal to be very noisy.
4. The change in the dynamics of the plant, for example, the inertia of the load, may require frequency tweaking of the controller parameters.
5. The step-like set point change results in an initial surge in the control signal and could shorten the life span of the motor and other mechanical parts.

These are problems that most control textbooks do not adequately address, but they are of significant importance in practice. The first three problems can be tackled using the loop-shaping design technique introduced above. The tuning problem is an industrywide design issue and the focus of various research and development efforts. The last problem is addressed by employing a smooth transient as the set point, instead of a step-like set point. This is known as the "motion profile" in industry.

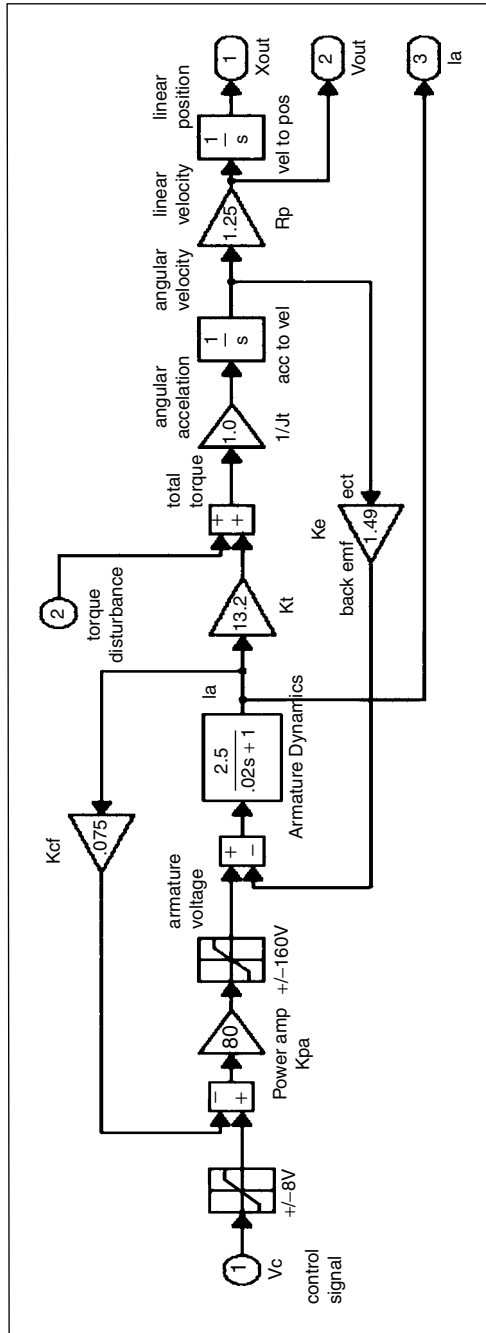

FIGURE 19.1.14 Simulation model of the motion control system.

FIGURE 19.1.15 Root locus plot of the servo design problem.

Evaluation of Control Systems

Analysis of control system provides crucial insights to control practitioners on why and how feedback control works. Although the use of PID precedes the birth of classical control theory of the 1950s by at least two decades, it is the latter that established the control engineering discipline. The core of classical control theory are the frequency-response-based analysis techniques, namely, Bode and Nyquist plots, stability margins, and so forth.

In particular, by examining the loop gain frequency response of the system in Fig. 19.1.9, that is, $L(j\omega) = G_c(j\omega)G_p(j\omega)$, and the sensitivity function $1/[1 + L(j\omega)]$, one can determine the following:

1. How fast the control system responds to the command or disturbance input (i.e., the bandwidth).
2. Whether the closed-loop system is stable (Nyquist Stability Theorem); if it is stable, how much dynamic variation it takes to make the system unstable (in terms of the gain and phase change in the plant). It leads to the definition of gain and phase margins. More broadly, it defines how robust the control system is.
3. How sensitive the performance (or closed-loop transfer function) is to the changes in the parameters of the plant transfer function (described by the sensitivity function).
4. The frequency range and the amount of attenuation for the input and output disturbances shown in Fig. 19.1.10 (again described by the sensitivity function).

Evidently, these characteristics obtained via frequency-response analysis are invaluable to control engineers. The efforts to improve these characteristics led to the lead-lag compensator design and, eventually, loop-shaping technique described above.

Example: The PD controller in Fig. 19.1.10 is known to be sensitive to sensor noise. A practical cure to this problem is to add a low pass filter to the controller to attenuate high-frequency noise, that is,

$$G_c(s) = \frac{13.3(s+3)}{206\left(\frac{s}{133}+1\right)^2}$$

FIGURE 19.1.16 Bode plot evaluation of the control design.

The loop gain transfer function is now

$$L(s) = G_p(s)G_c(s) = \frac{13.3}{s\left(\frac{s}{133} + 1\right)^2}$$

The bandwidth of the low pass filter is chosen to be one decade higher than the loop gain bandwidth to maintain proper gain and phase margins. The Bode plot of the new loop gain, as shown in Fig. 19.1.16, indicates that (a) the feedback system has a bandwidth 13.2 rad/s, which corresponds to a 0.3 s settling time as specified and (b) this design has adequate stability margins (gain margin is 26 dB and phase margin is 79°).

Digital Implementation

Once the controller is designed and simulated successfully, the next step is to digitize it so that it can be programmed into the processor in the digital control hardware. To do this:

1. Determine the sampling period T_s and the number of bits used in analog-to-digital converter (ADC) and digital-to-analog converter (DAC).
2. Convert the continuous time transfer function $G_c(s)$ to its corresponding form in discrete time transfer function $G_{cd}(z)$ using, for example, Tustin's method, $s = (1/T)(z - 1)/(z + 1)$.
3. From $G_{cd}(z)$, derive the difference equation, $u(k) = g(u(k - 1), u(k - 2), \dots, y(k), y(k - 1), \dots)$, where g is a linear algebraic function.

After the conversion, the sampled data system, with the plant running in continuous time and the controller in discrete time, should be verified in simulation first before the actual implementation. The quantization error and sensor noise should also be included to make it realistic.

The minimum sampling frequency required for a given control system design has not been established analytically. The rule of thumb given in control textbooks is that $f_s = 1/T_s$ should be chosen approximately 30 to 60 times the bandwidth of the closed-loop system. Lower-sampling frequency is possible after careful tuning but the aliasing, or signal distortion, will occur when the data to be sampled have significant energy above the

Nyquist frequency. For this reason, an antialiasing filter is often placed in front of the ADC to filter out the high-frequency contents in the signal.

Typical ADC and DAC chips have 8, 12, and 16 bits of resolution. It is the length of the binary number used to approximate an analog one. The selection of the resolution depends on the noise level in the sensor signal and the accuracy specification. For example, the sensor noise level, say 0.1 percent, must be below the accuracy specification, say 0.5 percent. Allowing one bit for the sign, an 8-bit ADC with a resolution of $1/2^7$, or 0.8 percent, is not good enough; similarly, a 16-bit ADC with a resolution of 0.003 percent is unnecessary because several bits are “lost” in the sensor noise. Therefore, a 12-bit ADC, which has a resolution of 0.04 percent, is appropriate for this case. This is an example of “error budget,” as it is known among designers, where components are selected economically so that the sources of inaccuracies are distributed evenly.

Converting $G_c(s)$ to $G_{cd}(z)$ is a matter of numerical integration. There have been many methods suggested; some are too simple and inaccurate (such as the Euler’s forward and backward methods), others are too complex. Tustin’s method suggested above, also known as trapezoidal method or bilinear transformation, is a good compromise. Once the discrete transfer function $G_{cd}(z)$ is obtained, finding the corresponding difference equation that can be easily programmed in C is straightforward. For example, given a controller with input $e(k)$ and output $u(k)$, and the transfer function

$$G_{cd}(z) = \frac{z+2}{z+1} = \frac{1+2z^{-1}}{1+z^{-1}}$$

the corresponding input-output relationship is

$$u(k) = \frac{1+2q^{-1}}{1+q^{-1}} e(k)$$

or equivalently, $(1+q^{-1})u(k) = (1+2q^{-1})e(k)$. [$q^{-1}u(k) = u(k-1)$, i.e., q^{-1} is the unit time delay operator.] That is, $u(k) = -u(k-1) + e(k) + 2e(k-1)$.

Finally, the presence of the sensor noise usually requires that an antialiasing filter be used in front of the ADC to avoid distortion of the signal in ADC. The phase lag from such a filter must not occur at the crossover frequency (bandwidth) or it will reduce the stability margin or even destabilize the system. This puts yet another constraint on the controller design.

ALTERNATIVE DESIGN METHODS

Nonlinear PID

Using a nonlinear PID (NPID) is an alternative to PID for better performance. It maintains the simplicity and intuition of PID, but empowers it with nonlinear gains. An example of NPID is shown in Fig. 19.1.17. The need for the integral control is reduced, by making the proportional gain larger, when the error is small. The limited

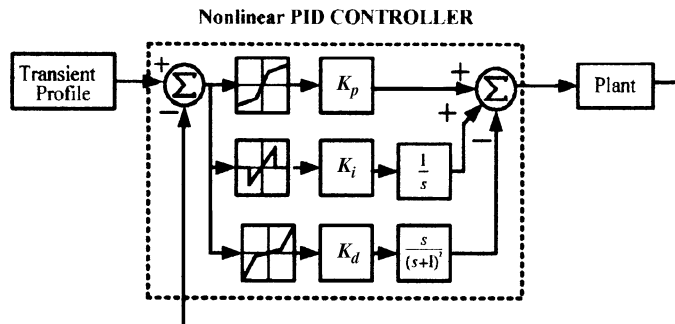

FIGURE 19.1.17 Nonlinear PID for a power converter control problem.

authority integral control has its gain zeroed outside a small interval around the origin to reduce the phase lag. Finally the differential gain is reduced for small errors to reduce sensitivities to sensor noise. See Ref. 8.

State Feedback and Observer-Based Design

If the state space model of the plant

$$\begin{aligned}\dot{x} &= Ax + Bu \\ y &= Cx + Du\end{aligned}$$

is available, the pole-placement design can be achieved via state feedback

$$u = r + Kx$$

where K is the gain vector to be determined so that the eigenvalues of the closed-loops system

$$\begin{aligned}\dot{x} &= (A + BK)x + Br \\ y &= Cx + Du\end{aligned}$$

are at the desired locations, assuming they are known. Usually the state vector is not available through measurements and the state observer is of the form

$$\begin{aligned}\dot{\hat{x}} &= A\hat{x} + Bu + L(y - \hat{y}) \\ \hat{y} &= C\hat{x} + Du\end{aligned}$$

where \hat{x} is the estimate of x and L is the observer gain vector to be determined.

The state feedback design approach has the same drawbacks as those of Root Locus approach, but the use of the state observer does provide a means to extract the information about the plant that is otherwise unavailable in the previous control schemes, which are based on the input-output descriptions of the plant. This proves to be valuable in many applications. In addition, the state space methodologies are also applicable to systems with many inputs and outputs.

Controllability and Observability. Controllability and observability are useful system properties and are defined as follows. Consider an n th order system described by

$$x = Ax + Bu, \quad y = Cx + Du$$

where A is an $n \times n$ matrix. The system is *controllable* if it is possible to transfer the state to any other state in finite time. This property is important as it measures, for example, the ability of a satellite system to reorient itself to face another part of the earth's surface using the available thrusters; or to shift the temperature in an industrial oven to a specified temperature. Two equivalent tests for controllability are:

The system (or the pair (A, B)) is *controllable* if and only if the controllability matrix $C = [B, AB, \dots, A^{n-1}B]$ has full (row) rank n . Equivalently if and only if $[s_i I - A, B]$ has full (row) rank n for all eigenvalues s_i of A .

The system is *observable* if by observing the output and the input over a finite period of time it is possible to deduce the value of the state vector of the system. If, for example, a circuit is observable it may be possible to determine all the voltages across the capacitors and all currents through the inductances by observing the input and output voltages.

The system (or the pair (A, C)) is *observable* if and only if the observability matrix

$$\theta = \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{n-1} \end{bmatrix}$$

has full (column) rank n . Equivalently if and only if

$$\begin{bmatrix} s_i I - A \\ C \end{bmatrix}$$

has full (column) rank n for all eigenvalues s_i of A .

Consider now the transfer function

$$G(s) = C(sI - A)^{-1}B + D$$

Note that, by definition, in a transfer function all possible cancellations between numerator and denominator polynomials are assumed to have already taken place. In general, therefore, the poles of $G(s)$ are some (or all) of the eigenvalues of A . It can be shown that when the system is both controllable and observable no cancellations take place and so in this case the poles of $G(s)$ are exactly the eigenvalues of A .

Eigenvalue Assignment Design. Consider the equations: $\dot{x} = Ax + Bu$, $y = Cx + Du$, and $u = r + Kx$. When the system is controllable, K can be selected to assign the closed-loop eigenvalues to any desired locations (real or complex conjugate) and thus significantly modify the behavior of the open-loop system. Many algorithms exist to determine such K . In the case of a single input, there is a convenient formula called Ackermann's formula

$$K = -[0, \dots, 0, 1] C^{-1} \alpha_d(A)$$

where $C = [B, \dots, A^{n-1}B]$ is the $n \times n$ controllability matrix and the roots of $\alpha_d(s)$ are the desired closed-loop eigenvalues.

Example Let

$$A = \begin{bmatrix} 1/2 & 1 \\ 1 & 2 \end{bmatrix}, \quad B = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$$

and the desired eigenvalues be $-1 \pm j$.

Here

$$C = [B, AB] = \begin{bmatrix} 1 & 3/2 \\ 1 & 3 \end{bmatrix}$$

Note that A has eigenvalues at 0 and 5/2. We wish to determine K so that the eigenvalues of $A + BK$ are at $-1 \pm j$, which are the roots of $\alpha_d(s) = s^2 + 2s + 2$.

Here

$$C = [B, AB] = \begin{bmatrix} 1 & 3/2 \\ 1 & 3 \end{bmatrix}$$

and

$$\alpha_d(A) = A^2 + 2A + 2I = \left(\begin{bmatrix} 1/2 & 1 \\ 1 & 2 \end{bmatrix}^2 + 2 \begin{bmatrix} 1/2 & 1 \\ 1 & 2 \end{bmatrix} + 2 \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \right) = \begin{bmatrix} 17/4 & 9/2 \\ 9/2 & 11 \end{bmatrix}$$

Then

$$K = -[0 \quad 1] C^{-1} \alpha_d(A) = [-1/6 \quad -13/3]$$

Here

$$A + BK = \begin{bmatrix} 1/3 & -10/3 \\ 5/6 & -7/3 \end{bmatrix}$$

which has the desired eigenvalues.

Linear Quadratic Regulator (LQR) Problem. Consider

$$\dot{x} = Ax + Bu, \quad y = Cx$$

We wish to determine $u(t)$, $t \geq 0$, which minimizes the quadratic cost

$$J(u) = \int_0^{\infty} \left[x^T(t)(M^T Q M)x + u^T(t)Ru(t) \right] dt$$

for any initial state $x(0)$. The weighting matrices Q and R are real, symmetric ($Q = Q^T$, $R = R^T$), Q and R are positive definite ($R > 0$, $Q > 0$) and $M^T Q M$ is positive semidefinite ($M^T Q M \geq 0$). Since $R > 0$, the term $u^T R u$ is always positive for any $u \neq 0$, by definition. Minimizing its integral forces $u(t)$ to remain small. $M^T Q M \geq 0$ implies that $x^T M^T Q M x$ is positive, but it can also be zero for some $x \neq 0$; this allows some of the states to be treated as “do not care states.” Minimizing the integral of $x^T M^T Q M x$ forces the states to become smaller as time progresses. It is convenient to take Q (and R in the multi-input case) to be diagonal with positive entries on the diagonal. The above performance index is designed so that the minimizing control input drives the states to the zero state, or as close as possible, without using excessive control action, in fact minimizing the control energy. When $(A, B, Q^{1/2}M)$ is controllable and observable, the solution $u^*(t)$ of this optimal control problem is a state feedback control law, namely,

$$u^*(t) = K^* x(t) = -R^{-1} B^T P_c^* x(t)$$

where P_c^* is the unique symmetric positive definite solution of the *algebraic Riccati equation*:

$$A^T P_c + P_c A - P_c B R^{-1} B^T P_c + M^T Q M = 0$$

Example. Consider

$$\dot{x} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} x + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u, \quad y = [1 \quad 0]x$$

And let

$$J = \int_0^{\infty} (y^2(t) + 4u^2(t)) dt$$

Here

$$M = C, \quad Q = 1, \quad M^T Q M = C^T C = \begin{bmatrix} 1 \\ 0 \end{bmatrix} [1 \quad 0] = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \quad R = 4$$

Solving the Riccati equation we obtain

$$P_c^* = \begin{bmatrix} 2 & 2 \\ 2 & 2\sqrt{2} \end{bmatrix}$$

and

$$u^*(t) = K^* x(t) = -\frac{1}{4} [0 \quad 1] \begin{bmatrix} 2 & 2 \\ 2 & 2\sqrt{2} \end{bmatrix} x(t) = -\frac{1}{2} [1, \sqrt{2}] x(t)$$

Linear State Observers. Since the states of a system contain a great deal of useful information, knowledge of the state vector is desirable. Frequently, however, it may be either impossible or impractical to obtain measurements of all states. Therefore, it is important to be able to estimate the states from available measurements, namely, of inputs and outputs.

Let the system be

$$x = Ax + Bu, \quad y = Cx + Du$$

An asymptotic state estimator of the full state, also called *Luenberger observer*, is given by

$$\dot{\hat{x}} = A\hat{x} + Bu + L(y - \hat{y})$$

where L is selected so that all eigenvalues of $A - LC$ are in the LHP (have negative real parts). Note that a L that arbitrarily assigns the eigenvalues of $A - LC$ exists if and only if the system is observable. The observer may be written as

$$\dot{\hat{x}} = (A - LC)\hat{x} + [B - LD, K] \begin{bmatrix} u \\ y \end{bmatrix}$$

which clearly shows the role of u and y ; they are the inputs to the observer. If the error $e(t) = x(t) - \hat{x}(t)$ then $e(t) = e^{(A-LC)t}e(0)$, which shows that $e(t) \rightarrow 0$ or $\hat{x}(t) \rightarrow x(t)$ as $t \rightarrow \infty$.

To determine appropriate L , note that $(A - LC)^T = A^T + C^T(-L) = \bar{A} + \bar{B}\bar{K}$, which is the problem addressed above in the state feedback case. One could also use the following observable version of Ackermann's formula, namely,

$$L = \alpha_d(A) O^{-1}[0, \dots, 0, 1]^T$$

where

$$O = \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{n-1} \end{bmatrix}$$

The gain L in the above estimator may be determined so that it is optimal in an appropriate sense. In the following, some of the key equations of such an optimal estimator (*Linear Quadratic Gaussian* (LQG)), also known as the *Kalman-Bucy filter*, are briefly outlined.

Consider

$$x = Ax + Bu + \Gamma w, \quad y = Cx + v$$

where w and v represent process and measurement noise terms. Both w and v are assumed to be white, zero-mean Gaussian stochastic processes, i.e., they are uncorrelated in time and have expected values $E[w] = 0$ and $E[v] = 0$. Let $E[ww^T] = W$, $E[vv^T] = V$ denote the covariances where W , V are real, symmetric and positive definite matrices. Assume also that the noise processes w and v are independent, i.e., $E[wv^T] = 0$. Also assume that the initial state $x(0)$ is a Gaussian random variable of known mean, $E[x(0)] = x_0$, and known covariance $E[(x(0) - x_0)(x(0) - x_0)^T] = P_{e0}$. Assume also that $x(0)$ is independent of w and v .

Consider now the estimator

$$\dot{\hat{x}} = (A - LC)\hat{x} + Bu + Ly$$

and let $(A, \Gamma, W^{1/2}, C)$ be controllable and observable. Then the error covariance $E[(x - \hat{x})(x - \hat{x})^T]$ is minimized when the filter gain $L^* = P_e^* C^T V^{-1}$, where P_e^* denotes the symmetric, positive definite solution of the (dual to control) *algebraic Riccati equation*

$$P_e A^T + A P_e - P_e C^T V^{-1} C P_e + \Gamma W \Gamma^T = 0$$

The above Riccati is the *dual* to the Riccati equation for optimal control and can be obtained from the optimal control equation by making use of the substitutions:

$$A \rightarrow A^T, B \rightarrow C^T, M \rightarrow \Gamma^T, R \rightarrow V, Q \rightarrow W$$

In the state feedback control law $u = Kx + r$, when state measurements are not available, it is common to use the estimate of state \hat{x} from a Luenberger observer. That is, given

$$x = Ax + Bu, \quad y = Cx + Du$$

the control law is $u = K\hat{x} + r$, where \hat{x} is the state estimate from the observer

$$\hat{x} = (A - LC)\hat{x} + [B - KD, K] \begin{bmatrix} u \\ y \end{bmatrix}$$

The closed-loop system is then of order $2n$ since the plant and the observer are each of order n . It can be shown that in this case, of linear output feedback control design, the design of the control law and of the gain K (using, for example, LQR) can be carried out independent of the design of the estimator and the filter gain L (using, for example, LQG). This is known as the *separation property*.

It is remarkable to notice that the overall transfer function of the compensated system that includes the state feedback and the observer is

$$T(s) = (C + DK)[sI - (A + BK)]^{-1} B + D$$

which is exactly the transfer function one would obtain if the state x were measured directly and the state observer were not present. This is of course assuming zero initial conditions (to obtain the transfer function); if nonzero initial conditions are present, then there is some deterioration of performance owing to observer dynamics, and the fact that at least initially the state estimate typically contains significant error.

ADVANCED ANALYSIS AND DESIGN TECHNIQUES

The foregoing section described some fundamental analysis and design methods in classical control theory, the development of which was primarily driven by engineering practice and needs. Over the last few decades, vast efforts in control research have led to the creation of modern mathematical control theory, or advanced control, or control science. This development started with optimal control theory in the 50s and 60s to study the optimality of control design; a brief glimpse of optimal control was given above. In optimal control theory, a cost function is to be minimized, and analytical or computational methods are used to derive optimal controllers. Examples include minimum fuel problem, time-optimal control (Bang-Bang) problem, LQ, H_2 , and H_∞ , each corresponding to a different cost function. Other major branches in modern control theory include multi-input multi-output (MIMO) control systems methodologies, which attempt to extend well-known SISO design methods and concepts to MIMO problems; adaptive control, designed to extend the operating range of a controller by adjusting automatically the controller parameters based on the estimated dynamic changes in the plants; analysis and design of nonlinear control systems, and so forth.

A key problem is the robustness of the control system. The analysis and design methods in control theory are all based on the mathematical model of the plants, which is an approximate description of physical processes. Whether a control system can tolerate the uncertainties in the dynamics of the plants, or how much uncertainty it takes to make a system unstable, is studied in robust control theory, where H_2 , H_∞ , and other analysis and design methods were originated. Even with recent progress, open problems remain when dealing with real world applications. Some recent approaches such as in Ref. 8 attempt to address some of these difficulties in a realistic way.

APPENDIX: OPEN- AND CLOSED-LOOP STABILIZATION

It is impossible to stabilize an unstable system using open-loop control, owing to system uncertainties. In general, closed-loop or feedback control is necessary to control a system—stabilize if unstable and improve performance—because of uncertainties that are always present. Feedback provides current information about the system and so the controller does not have to rely solely on incomplete system information contained in a nominal plant model. These uncertainties are system parameter uncertainties and also uncertainties induced on the system by its environment, including uncertainties in the initial condition of the system, and uncertainties because of disturbances and noise.

Consider the plant with transfer function

$$G(s) = \frac{1}{s - (1 + \epsilon)}$$

where the pole location at 1 is inaccurately known.

The corresponding description in the time domain using differential equations is $\dot{y}(t) - (1 + \epsilon)y(t) = u(t)$. Solving, using Laplace transform, we obtain $sY(s) - y(0) - (1 + \epsilon)Y(s) = U(s)$ from which

$$Y(s) = \frac{y(0)}{s - (1 + \epsilon)} + \frac{1}{s - (1 + \epsilon)}U(s)$$

Consider now the controller with transfer function

$$G_c(s) = \frac{s - 1}{s + 2}$$

The corresponding description in the time domain using differential equations is $\dot{u}(t) + 2u(t) = \dot{r}(t) - r(t)$. Solving, using Laplace transform, we obtain $sU(s) - u(0) + 2U(s) = sR(s) - R(s)$ from which

$$U(s) = \frac{u(0)}{s + 2} + \frac{s - 1}{s - 2}R(s)$$

Connect now the plant and the controller in series (open-loop control)

Connecting in Series - Open loop

19.28 CONTROL SYSTEMS

The overall transfer function is

$$T = GG_c = \frac{s-1}{[s-(1+\varepsilon)](s+2)}$$

Including the initial conditions

$$Y(s) = \frac{(s+2)y(0) + u(0)}{[s-(1+\varepsilon)](s+2)} + \frac{s-1}{[s-(1+\varepsilon)](s+2)} R(s)$$

It is now clear that open-loop control cannot be used to stabilize the plant:

1. First, because of the uncertainties in the plant parameters. Note that the plant pole is not exactly at +1 but at $1 + \varepsilon$ and so the controller zero cannot cancel the plant pole exactly.
2. Second, even if we had knowledge of the exact pole location, that is, $\varepsilon = 0$, and

$$Y(s) = \frac{(s+2)y(0) + r(0)}{(s-1)(s+2)} + \frac{1}{s+2} R(s)$$

still we cannot stabilize the system because of the uncertainty in the initial conditions. We cannot, for example, select $r(0)$ so as to cancel the unstable pole at +1 because $y(0)$ may not be known exactly.

We shall now stabilize the above plant using a simple feedback controller.

Consider a unity feedback control system with the controller being just a gain k to be determined. The closed-loop transfer function is

$$T(s) = \frac{kG(s)}{1+kG(s)} = \frac{k}{s-(1+\varepsilon)+k}$$

Working in the time domain,

$$\dot{y} - (1 + \varepsilon)y = u = k(r - y)$$

from which

$$\dot{y} + [k - (1 + \varepsilon)]y = kr$$

Using Laplace transform we obtain

$$sY(s) - y(0) + [k - (1 + \varepsilon)]Y(s) = kR(s)$$

and

$$Y(s) = \frac{y(0)}{s + k - (1 + \varepsilon)} + \frac{k}{s + k - (1 + \varepsilon)} R(s)$$

It is now clear that if the controller gain is selected so that $k > 1 + \varepsilon$, then the system will be stable. In fact, we could have worked with the nominal system to derive $k > 1$ for stability. For stability robustness, we take k somewhat larger than 1 to have some safety margin and satisfy $k > 1 + \varepsilon$ for some unknown small ε .

ON THE CD-ROM:

"A Brief Review of the Laplace Transform Useful in Control Systems," by the authors of this section, examines its usefulness in control systems analysis and design.

SECTION 20

AUDIO SYSTEMS

Although much of this section contains fundamental information on basic audio technology, extensive information on new evolving digital audio formats and recording and reproduction systems has been added since the last edition.

As noted herein, DVD-Audio, for example, is based on the same DVD technology as DVD-Video discs and DVD-ROM computer discs. It has a theoretical sampling rate of 192 kHz with 24-bit processing and can store 4.7 gigabytes on a disc with a choice of two- or six-channel audio tracks or a mix of both. Super Audio CD (SACD) has the same storage capacity. It uses direct stream digital (DSD) with 2.8 MHz sampling in three possible disc types. The first two contain only DSD data (4.7 gigabytes of data on a single-layer disc and slightly less than 9 gigabytes on the dual layer disc). The third version, the SACD hybrid, combines a single 4.7 gigabyte layer with a conventional CD that can be played back on conventional CD players.

MPEG audio coding variations continue to evolve. For example:

- MPEG-1 is a low-bit-rate audio format.
- MPEG-2 extends MPEG-1 toward the audio needs of digital video broadcasting.
- MPEG-2 Advanced Audio Coding (AAC) is an enhanced multichannel coding system.
- MP3 is the popular name for MPEG-1 Layer III.
- MPEG-4 adds object-based representation, content-based interactivity, and scalability.
- MPEG-7 defines a universal standardized mechanism for exchanging descriptive data.
- MPEG-21 defines a multimedia framework to enable transparent and augmented use of multimedia services across a wide range of networks and devices used by different communities. R.J.

CHAPTER 20.1

SOUND UNITS AND FORMATS

Daniel W. Martin, Ronald M. Aarts

STANDARD UNITS FOR SOUND SPECIFICATION^{1,2}

Sound Pressure

Airborne sound waves are a physical disturbance pattern in the air, an elastic medium, traveling through the air at a speed that depends somewhat on air temperature (but not on static air pressure). The instantaneous magnitude of the wave at a specific point in space and time can be expressed in various ways, e.g., displacement, particle velocity, and pressure. However, the most widely used and measured property of sound waves is *sound pressure*, the fluctuation above and below atmospheric pressure, which results from the wave.

An *atmosphere* (atm) of pressure is typically about 10^5 pascals (Pa) in the International System of units. Sound pressure is usually a very small part of atmospheric pressure. For example, the minimum audible sound pressure (threshold of hearing) at 2000 Hz is $20 \mu\text{Pa}$, or $2(10)^{-10}$ atm.

Sound-Pressure Level

Sound pressures important to electronics engineering range from the weakest noises that can interfere with sound recording to the strongest sounds a loudspeaker diaphragm should be expected to radiate. This range is approximately 10^6 . Consequently, for convenience, sound pressures are commonly plotted on a logarithmic scale called *sound-pressure level* expressed in *decibels* (dB).

The decibel, a unit widely used for other purposes in electronics engineering, originated in audio engineering (in telephony), and is named for Alexander Graham Bell. Because it is logarithmic, it requires a reference value for comparison just as it does in other branches of electronics engineering. The reference pressure for sounds in air, corresponding to 0 dB, has been defined as a sound pressure of $20 \mu\text{Pa}$ (previously 0.0002 dyn/cm^2). This is the reference sound pressure p_0 used throughout this section of the handbook. Thus the sound-pressure level L_p in decibels corresponding to a sound pressure p is defined by

$$L_p = 20 \log (p/p_0) \text{ dB} \quad (1)$$

The reference pressure p_0 approximates the weakest audible sound pressure at 2000 Hz. Consequently most decibel values for sound levels are positive in sign. Figure 20.1.1 relates sound-pressure level in decibels to sound pressure in micropascals.

Sound power and sound intensity (power flow per unit area of wavefront) are generally proportional to the square of the sound pressure. Doubling the sound pressure quadruples the intensity in the sound field, requiring four times the power from the sound source.

FIGURE 20.1.1 Relation between sound pressure and sound-pressure level.¹

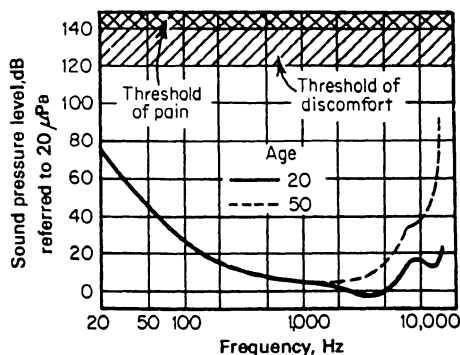

FIGURE 20.1.2 The auditory area.

Audible Frequency Range

The international abbreviation Hz (hertz) is now used (instead of the former cps) for audible frequencies as well as the rest of the frequency domain. The limits of audible frequency are only approximate because tactile sensations below 20 Hz overlap aural sensations above this lower limit. Moreover, only young listeners can hear pure sounds near or above 20 kHz, the nominal upper limit.

Frequencies beyond both limits, however, have significance to audio-electronics engineers. For example, near-infrasonic (below 20 Hz) sounds are needed for classical organ music but can be noise in turntable rumble. Near-ultrasonic (above 20 kHz) intermodulation in audio circuits can produce undesirable difference-frequency components, which are audible.

The *audible sound-pressure level range* can be combined with the audible frequency range to describe an *auditory area*, shown in Fig. 20.1.2. The lowest curve shows the weakest audible sound-pressure level for listening with both ears to a pure tone while facing the sound source in a free field. The minimum level depends greatly on the frequency of the sound. It also varies somewhat among listeners. The levels that quickly produce discomfort or pain for listeners are only approximate, as indicated by the shaded and cross-hatched areas of Fig. 20.1.2. Extended exposure can produce temporary (or permanent) loss of auditory area at sound-pressure levels as low as 90 dB.

Wavelength effects are of great importance in the design of sound systems and rooms because wavelength varies over a 3-decade range, much wider than is typical elsewhere in electronics engineering. Audible sound waves vary in length from 1 cm to 15 m. The dimensions of the sound sources and receivers used in electroacoustics also vary greatly, e.g., from 1 cm to 3 m.

Sound waves follow the principles of geometrical optics and acoustics when the wavelength is very small relative to object size and pass completely around obstacles much smaller than a wavelength. This wide range of physical effects complicates the typical practical problem of sound production or reproduction.

Loudness Level

The simple, direct method for determining experimentally the loudness *level* of a sound is to match its observed loudness with that of a 1000-Hz sinewave reference tone of calibrated, variable sound-pressure level. (Usually this is a group judgment, or an average of individual judgments, in order to overcome individual observer differences.)

When the two loudnesses are matched, the *loudness level* of the sound, expressed in *phons*, is defined as numerically equal to the sound-pressure level of the reference tone in decibels. For example, a series of observers, each listening alternately to a machine noise and to a 1000-Hz reference tone, judge them (on the average) to be equally loud when the reference tone is adjusted to 86 dB at the observer location. This makes the loudness level of the machine noise 86 phons.

FIGURE 20.1.3 Equal-loudness-level contours.

At 1000 Hz the decibel and phon levels are numerically identical, by definition. However, at other frequencies sine-wave tones may have numerically quite different sound- and loudness-levels, as seen in Fig. 20.1.3. The dashed contour curves show the decibel level at each frequency corresponding to the loudness level identifying the curve at 1000 Hz. For example, a tone at 80 Hz and 70 dB lies on the contour marked 60 phons. Its sound level must be 70 dB for it to be as loud as a 60-dB tone at 1000 Hz. Such differences at low frequencies, especially at low sound levels, are a characteristic of the sense of hearing. The fluctuations above 1000 Hz are caused by sound-wave diffraction around the head of the listener and resonances in his ear canal. This illustrates how human physiological and psychological characteristics complicate the application of purely physical concepts.

Since loudness level is related to 1000-Hz tones defined physically in magnitude, the loudness-level scale is not really psychologically based. Consequently, although one can say that 70 phons is louder than 60 phons, one cannot say *how much* louder.

Loudness

By using the phon scale to overcome the effects of frequency, psychophysicists have developed a true loudness scale based on numerous experimental procedures involving relative-loudness judgments. *Loudness*, measured in *sones*, has a direct relation to loudness level in phons, which is approximated in Fig. 20.1.4. (Below 30 phons the relation changes slope. Since few practical problems require that range, it is omitted for simplicity.) A loudness of 1 sone has been defined equivalent to a loudness level of 40 phons. It is evident in Fig. 20.1.4 that a 10-phon change doubles the loudness in sones, which means *twice as loud*. Thus a 20-phon change in loudness level quadruples the loudness.

Another advantage of the sone scale is that the loudness of components of a complex sound are additive on the sone scale as long as they are well separated on the frequency scale. For example (using Fig. 20.1.4), two tonal components at 100 and 4000 Hz having loudness levels of 70 and 60 phons, respectively, would have individual loudnesses of 8 and 4 sones, respectively, and a total loudness of 12 sones.

FIGURE 20.14 Relation between loudness in sones and loudness level in phons.³

FIGURE 20.15 Typical line spectrum.¹

FIGURE 20.16 Continuous-level spectrum curve for a motor and blower.¹

Detailed loudness computation procedures have been developed for highly complex sounds and noises, deriving the loudness in sones directly from a complete knowledge of the decibel levels for individual discrete components or noise bands. The procedures continue to be refined.

TYPICAL FORMATS FOR SOUND DATA

Sound and audio electronic data are frequently plotted as functions of frequency, time, direction, distance, or room volume. Frequency characteristics are the most common, in which the ordinate may be sound pressure, sound power, output-input ratio, percent distortion, or their logarithmic-scale (level) equivalents.

Sound Spectra

The frequency spectrum of a sound is a description of its resolution into components of different frequency and amplitude. Often the abscissa is a logarithmic frequency scale or a scale of octave (or fractional-octave) bands with each point plotted at the geometric mean of its band-limiting frequencies. Usually the ordinate scale is sound-pressure level. Phase differences are often ignored (except as they affect sound level) because they vary so greatly with measurement location, especially in reflective environments.

Line spectra are bar graphs for sounds dominated by discrete frequency components. Figure 20.1.5 is an example.

Continuous spectra are curves showing the distribution of sound-pressure level within a frequency range densely packed with components. Figure 20.1.6 is an example. Unless stated otherwise, the ordinate of a continuous-spectrum curve, called *spectrum level*, is assumed to represent sound-pressure level for a band of 1-Hz width. Usually level measurements L_{band} are made in wider bands, then converted to spectrum level L_{ps} by the bandwidth correction

$$L_{ps} = L_{\text{band}} - 10 \log(f_2 - f_1) \text{ dB} \quad (2)$$

in which f_1 and f_2 are the lower- and upper-frequency limits of the band.

When a continuous-spectrum curve is plotted automatically by a level recorder synchronized with a heterodyning filter or with a sequentially switched set of narrow-bandpass filters, any effect of *changing* bandwidth on curve slope must be considered.

Combination spectra are appropriate for many sounds in which strong line components are superimposed over more diffuse continuous spectral backgrounds. Bowed or blown musical tones and motor-driven fan noises are examples.

Octave spectra, in which the ordinate is the sound-pressure level for bands one octave wide, are very convenient for measurements and for specifications but lack fine spectrum detail.

Third-octave spectra provide more detail and are widely used. One-third of an octave and one-tenth of a decade are so nearly identical that substituting the latter for the former is a practical convenience, providing a 10-band pattern that repeats every decade. Placing third-octave band zero at 1 Hz has conveniently made the band numbers equal 10 times the logarithm (base 10) of the band-center frequency; e.g., band 20 is at 100 Hz and band 30 at 1000 Hz.

Visual proportions of spectra (and other frequency characteristics) depend on the ratio of ordinate and abscissa scales. There is no universal or fully standard practice, but for ease of visual comparison of data and of specifications, it has become rather common practice in the United States for 30 dB of ordinate scale to equal (or slightly exceed) 1 decade of logarithmic frequency on the abscissa. Available audio and acoustical graph papers and automatic level-recorder charts have reinforced this practice. When the entire 120-dB range of auditory area is to be included in the graph, the ordinate is often compressed 2:1.

Response and Distortion Characteristics

Output-input ratios versus frequency are the most common data format in audio-electronics engineering. The audio-frequency scale (20 Hz to 20 kHz) is usually logarithmic. The ordinate may be sound- or electric-output

20.8 AUDIO SYSTEMS

level in decibels as the frequency changes with a constant electric or sound input; or it may be a ratio of the output to input (expressed in decibels) as long as they are linearly related within the range of measurement.

When the response-frequency characteristic is measured with the input frequency filtered from the output, a distortion-frequency characteristic is the result. It can be further filtered to obtain curves for each harmonic if desired.

Directional Characteristics

Sound sources radiate almost equally in all directions when the wavelength is large compared to source dimensions. At higher frequencies, where the wavelength is smaller than the source, the radiation becomes quite directional.

Time Characteristics

Any sound property can vary with time. It can build up, decay, or vary in magnitude periodically or randomly. A reverberant sound field decays rather logarithmically. Consequently the sound level in decibels falls linearly when the time scale is linear. The rate of decay in this example is 33 dB/s.

CHAPTER 20.2

SPEECH AND MUSICAL SOUNDS

Daniel W. Martin, Ronald M. Aarts

SPEECH SOUNDS

Speech Level and Spectrum

Both the sound-pressure level and the spectrum of speech sounds vary continuously and rapidly during connected discourse. Although speech may be arbitrarily segmented into elements called phonemes, each with a characteristic spectrum and level, actually one phoneme blends into another.

Different talkers speak somewhat differently, and they sound different. Their speech characteristics vary from one time or mood to another. Yet in spite of all these differences and variations, statistical studies of speech have established a typical “idealized” speech spectrum. The spectrum level rises about 5 dB from 100 to 600 Hz, then falls about 6, 9, 12, and 15 dB in succeeding higher octaves.

Overall sound-pressure levels, averaged over time and measured at a distance of 1 m from a talker on or near the speech axis, lie in the range of 65 and 75 dB when the talkers are instructed to speak in a “normal” tone of voice. Along this axis the speech sound level follows the inverse-square law closely to within about 10 cm of the lips, where the level is about 90 dB. At the lips, where communication microphones are often used, the overall speech sound level typically averages over 100 dB.

The peak levels of speech sounds greatly exceed the long-time average level. Figure 20.2.1 shows the difference between short peak levels and average levels at different frequencies in the speech spectrum. The difference is greater at high frequencies, where the sibilant sounds of relatively short duration have spectrum peaks.

Speech Directional Characteristics

Speech sounds are very directional at high frequencies. Figure 20.2.2 shows clearly why speech is poorly received behind a talker, especially in nonreflective environments. Above 4000 Hz the directional loss in level is 20 dB or more, which particularly affects the sibilant sound levels so important to speech intelligibility.

Vowel Spectra

Different vowel sounds are formed from approximately the same basic laryngeal tone spectrum by shaping the vocal tract (throat, back of mouth, mouth, and lips) to have different acoustical resonance-frequency combinations. Figure 20.2.3 illustrates the spectrum filtering process. The spectral peaks are called *formants*, and their frequencies are known as formant frequencies.

The shapes of the vocal tract, simplified models, and the acoustical results for three vowel sounds are shown in Fig 20.2.4. A convenient graphical method for describing the combined formant patterns is shown in Fig 20.2.5. Traveling around this vowel loop involves progressive motion of the jaws, tongue, and lips.

FIGURE 20.2.1 Difference in decibels between peak pressures of speech measured in short (1/8-s) intervals and rms pressure averaged over a long (75-s) interval.

Speech Intelligibility

More intelligibility is contained in the central part of the speech spectrum than near the ends. Figure 20.2.6 shows the effect on articulation (the percent of syllables correctly heard) when low- and high-pass filters of various cutoff frequencies are used. From this information a special frequency scale has been developed in which each of 20 frequency bands contributes 5 percent to a total *articulation index* of 100 percent. This distorted frequency scale is used in Fig. 20.2.7. Also shown are the spectrum curves for speech peaks and for speech minima, lying approximately 12 and 18 dB, respectively, above and below the average-speech-spectrum curve. When all the shaded area (30-dB range between the maximum and minimum curves) lies above threshold and below overload, in the absence of noise, the articulation index is 100 percent.

If a noise-spectrum curve were added to Fig 20.2.7, the figure would become an articulation-index computation chart for predicting communication capability. For example, if the ambient-noise spectrum coincided with the average-speech-spectrum curve, i.e., the signal-to-noise ratio is 1, only twelve-thirtieths of the shaded area would lie above the noise. The articulation index would be reduced accordingly to 40 percent.

Figure 20.2.8 relates monosyllabic word articulation and sentence intelligibility to articulation index. In the example above, for an articulation index of 0.40 approximately 70 percent of monosyllabic words and 96 percent of sentences would be correctly received.

However, if the signal-to-noise ratio were kept at unity and the frequency range were reduced to 1000 to 3000 Hz, half the bands would be lost. Articulation index would drop to 0.20, word articulation to 0.30, and sentence intelligibility to 70 percent. This shows the necessity for wide frequency range in a communication system when the signal-to-noise ratio is marginal. Conversely a good signal-to-noise ratio is required when the frequency range is limited.

The articulation-index method is particularly valuable in complex intercommunication-system designs involving noise disturbance at both the transmitting and receiving stations. Simpler effective methods have also been developed, such as the *rapid speech transmission index* (RASTI).

FIGURE 20.2.2 The directional characteristics of the human voice in a horizontal plane passing through the mouth.

Speech Peak Clipping

Speech waves are often affected inadvertently by electronic-circuit performance deficiencies or limitations. Figure 20.2.9 illustrates two types of amplitude distortion, center clipping and peak clipping. Center clipping, often caused by improper balancing or biasing of a push-pull amplifier circuit, can greatly interfere with speech quality and intelligibility. In a normal speech spectrum the consonant sounds are higher in frequency and lower in level than the vowel sounds. Center clipping tends to remove the important consonants.

FIGURE 20.2.3 Effects on the spectrum of the laryngeal tone produced by the resonances of the vocal tract.⁵

By contrast peak clipping has little effect on speech intelligibility as long as ambient noise at the talker and system electronic noise are relatively low in level compared with the speech.

Peak clipping is frequently used intentionally in speech-communication systems to raise the average transmitted speech level above ambient noise at the listener or to increase the range of a radio transmitter of limited power. This can be done simply by overloading an amplifier stage. However, it is safer for the circuits and it produces less intermodulation distortion when back-to-back diodes are used for clipping ahead of the overload point in the amplifier or transmitter. Figure 20.2.10 shows intelligibility improvement from speech peak clipping when the talker is in quiet and listeners are in noise. Figure 20.2.11 shows that caution is necessary when the talker is in noise, unless the microphone is shielded or is a noise-canceling type.

Tilting the speech spectrum by differentiation and flattening it by equalization are effective preemphasis treatments before peak clipping. Both methods put the consonant and vowel sounds into a more balanced relationship before the intermodulation effects of clipping affect voiced consonants.

Caution must be used in combining different forms of speech-wave distortion, which individually have innocuous effects on intelligibility but can be devastating when they are combined.

FIGURE 20.2.4 Phonetic symbols, shapes of vocal tract, models, and acoustic spectra for three vowels.⁶

MUSICAL SOUNDS

Musical Frequencies

The accuracy of both absolute and relative frequencies is usually much more important for musical sounds than for speech sounds and noise. The international frequency standard for music is defined at 440.00 Hz for A_4 , the A above C_4 (middle C) on the musical keyboard. In sound recording and reproduction, the disc-rotation and tape-transport speeds must be held correct within 0.2 or 0.3 percent error (including both recording and playback mechanisms) to be fully satisfactory to musicians.

The mathematical musical scale is based on an exact octave ratio of 2:1. The subjective octave slightly exceeds this, and piano tuning sounds better when the scale is stretched very slightly.

The equally tempered scale of 12 equal ratios within each octave is an excellent compromise between the different historical scales based on harmonic ratios. It has become the standard of reference, even for individual musical performances, which may deviate from it for artistic or other reasons.

Different musical instruments play over different ranges of *fundamental* frequency, shown in Fig.20.2.12. However, most musical sounds have many harmonics that are audibly significant to their tone spectra. Consequently high-fidelity recording and reproduction need a much wider frequency range.

FIGURE 20.2.5 The center frequencies of the first two formants for the sustained English vowels plotted to show the characteristic differences.⁷

Sound Levels of Musical Instruments

The sound level from a musical instrument varies with the type of instrument, the distance from it, which note in the scale is being played, the dynamic marking in the printed music, the player's ability, and (on polyphonic instruments) the number of notes (and stops) played at the same time.

FIGURE 20.2.6 Syllable articulation score vs. low- or high-pass cutoff frequency.⁸

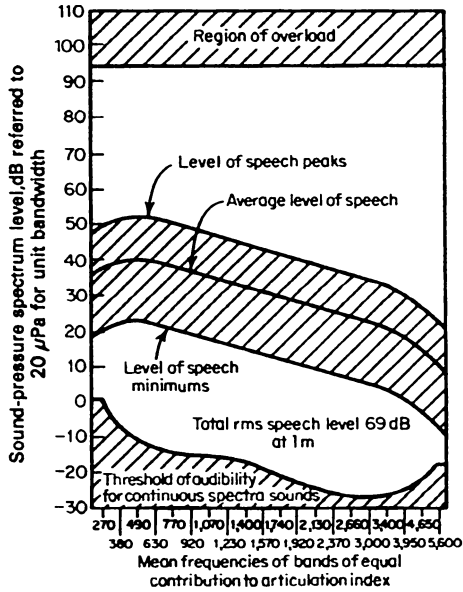

FIGURE 20.2.7 Speech area, bounded by speech peak and minimum spectrum-level curves, plotted on an articulation-index calculation chart.⁹

FIGURE 20.2.8 Sentence- and word-intelligibility prediction from calculated articulation index.¹⁰

Orchestral Instruments. The following sound levels are typical at a distance of 10 ft in a nonreverberant room. Soft (pianissimo) playing of a weaker orchestral instrument, e.g., violin, flute, bassoon, produces a typical sound level of 55 to 60 dB. Fortissimo playing on the same instrument raises the level to about 70 to 75 dB. Louder instruments, e.g., trumpet or tuba, range from 75 dB at pianissimo to about 90 dB at fortissimo.

Certain instruments have exceptional differences in sound level of low and high notes. A flute may change from 42 dB on a soft low note to 77 dB on a loud high note, a range of 35 dB. The French horn ranges from 43 dB (soft and low) to 93 dB (loud and high).

Sound levels are about 10 dB higher at 3 ft (inverse-square law) and 20 dB higher at 1 ft. The louder instruments, e.g., brass, at closer distances may overload some microphones and preamplifiers.

FIGURE 20.2.9 Two types of amplitude distortion of speech waveform.⁵

FIGURE 20.2.10 Advantages of peak clipping of noise-free speech waves, heard by listeners in ambient aircraft noise.¹⁰

FIGURE 20.2.11 Effects of speech clipping with both the talker and the listener in simulated aircraft noise. Note that excessive peak clipping is detrimental.¹⁰

average about 85 to 90 dB with peaks of 105 to 110 dB. A full concert band will go higher. At a similar distance from the sound sources of an organ (pipe or electronic) the full-organ (or crescendo-pedal) condition will produce a level of 95 to 100 dB. By contrast the softest stop with expression shutters closed may be 45 dB or less.

Growth and Decay of Musical Sounds

These characteristics are quite different for different instruments. Piano or guitar tones quickly rise to an initial maximum, then gradually diminish until the strings are damped mechanically. Piano tones have a more rapid decay initially than later in the sustained tone. Orchestral instruments can start suddenly or smoothly, depending on the musician's technique, and they damp rather quickly when playing ceases. Room reverberation affects both growth and decay rates when the time constants of the room are greater than those of the instrument vibrators. This is an important factor in organ music, which is typically played in a reverberant environment.

Many types of musical tone have characteristic transients which influence timbre greatly. In the "chiff" of organ tone the transients are of different fundamental frequency. They appear and decay before steady state is reached. In percussive tones the initial transient is the cause of the tone (often a percussive noise), and the final transient is the result.

These transient effects should be considered in the design of audio electronics such as "squelch," automatic gain control, compressor, and background-noise reduction circuits.

Spectra of Musical Instrument Tones

Figure 20.2.13 displays time-averaged spectra for a 75-piece orchestra, a theater pipe organ, a piano, and a variety of orchestral instruments, including members of the brass, woodwind, and percussion families. These vary from one note to another in the scale, from one instant to another within a single tone or chord, and from one instrument or performer to another. For example, a concert organ voiced in a baroque style would have lower spectrum levels at low frequencies and higher at high frequencies than the theater organ shown.

The organ and bass drum have the most prominent low-frequency output. The cymbal and snare drum are strongest at very high frequencies. The orchestra and most of the instruments have spectra which diminish gradually with increasing frequency, especially above 1000 Hz. This is what has made it practical to preemphasize the high-frequency components, relative to those at low frequencies, in both disc and tape recording. However, instruments that differ from this spectral tendency, e.g., coloratura sopranos, piccolos, cymbals, create problems of intermodulation distortion, and overload.

Spectral peaks occurring only occasionally, for example, 1 percent of the time, are often more important to sound recording and reproduction than the peaks in the average spectra of Fig. 20.2.13. The frequency

Percussive Instruments. The sound levels of shock-excited tones are more difficult to specify because they vary so much during decay and can be excited over a very wide range. A bass drum may average over 100 dB during a loud passage with peaks (at 10 ft) approaching 120 dB. By contrast a triangle will average only 70 dB with 80-dB peaks. A single tone of a grand piano played forte will initially exceed 90 dB near the piano rim, 80 dB at the pianist, and 70 dB at the conductor 10 to 15 ft away. Large chords and rapid arpeggios will raise the level about 10 dB.

Instrumental Groups. Orchestras, bands, and polyphonic instruments produce higher sound levels since many notes and instruments (or stops) are played together. Their sound levels are specified at larger distances than 10 ft because the sound sources occupy a large area; 20 ft from the front of a 75-piece orchestra the sound level will

FIGURE 20.2.12 Range of the fundamental frequencies of voices and various musical instruments. (Ref. 8).

ranges shown in Table 20.2.1 have been found to have relatively large instantaneous peaks for the instruments listed.

Directional Characteristics of Musical Instruments

Most musical instruments are somewhat directional. Some are highly so, with well-defined symmetry, e.g., around the axis of a horn bell. Other instruments are less directional because the sound source is smaller than the wavelength, e.g., clarinet, flute. The mechanical vibrating system of bowed string instruments is complex, operating differently in different frequency ranges, and resulting in extremely variable directivity. This is significant for orchestral seating arrangements both in concert halls and recording studios.

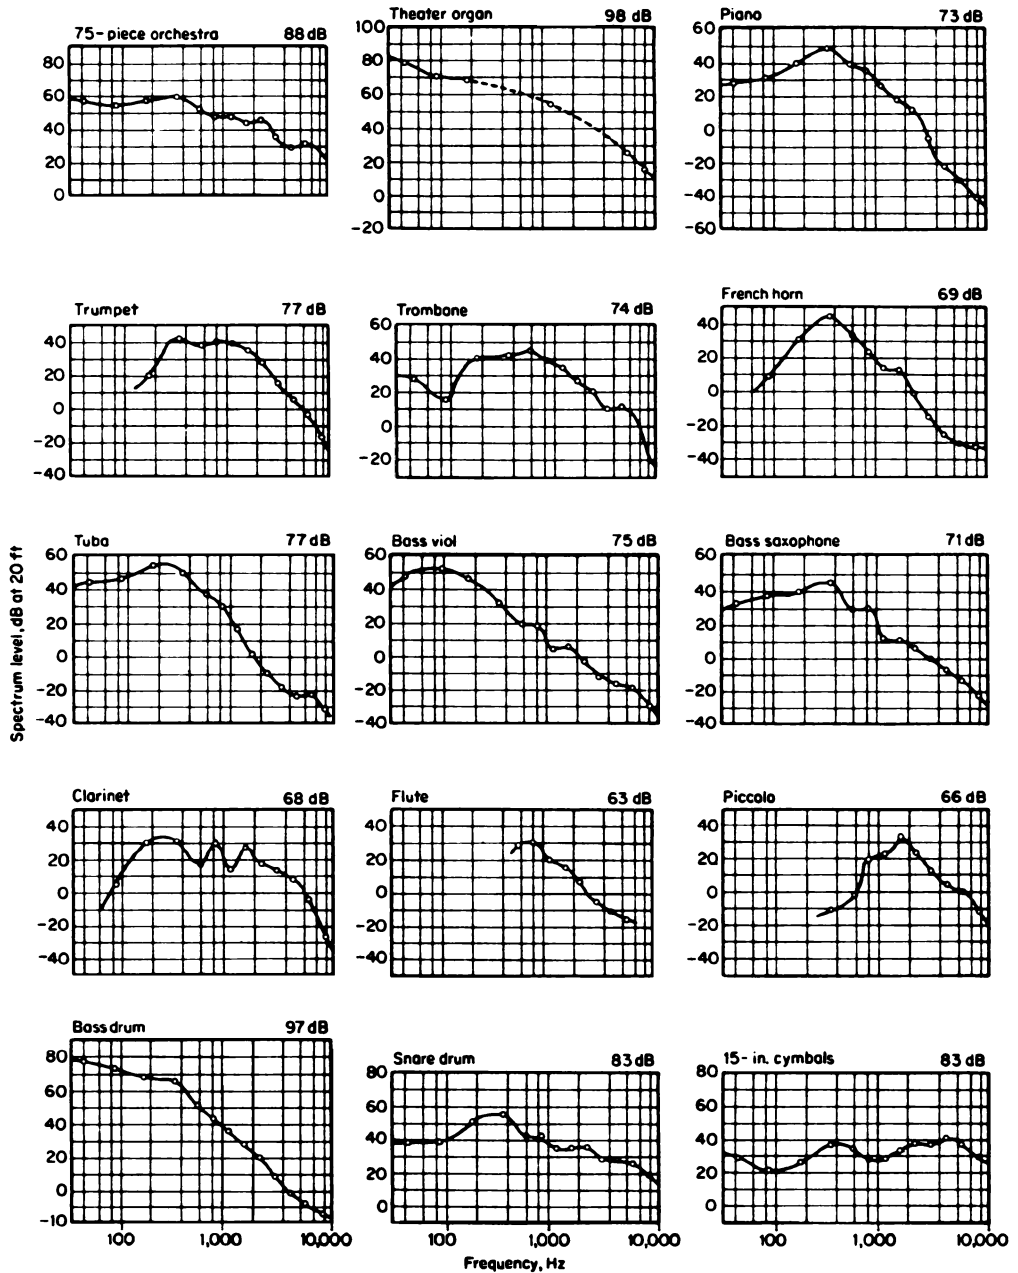

FIGURE 20.2.13 Time-averaged spectra of musical instruments.

TABLE 20.2.1 Frequency Band Containing Instantaneous Spectral Peaks

Band limits, Hz	Instruments
20–60	Theater organ
60–125	Bass drum, bass viol
125–250	Small bass drum
250–500	Snare drum, tuba, bass saxophone, French horn, clarinet, piano
500–1,000	Trumpet, flute
2,000–3,000	Trombone, piccolo
5,000–8,000	Triangle
8,000–12,000	Cymbal

Audible Distortions of Musical Sounds

The quality of musical sounds is more sensitive to distortion than the intelligibility of speech. A chief cause is that typical music contains several simultaneous tones of different fundamental frequency in contrast to typical speech sound of one voice at a time. Musical chords subjected to nonlinear amplification or transduction generate intermodulation components that appear elsewhere in the frequency spectrum.

Difference tones are more easily heard than summation tones because the summation tones are often hidden by harmonics that were already present in the undistorted spectrum and because auditory masking of a high-frequency pure tone by a lower-frequency pure tone is much greater than vice versa.

When a critical listener controls the sounds heard (an organist playing an electronic organ on a high-quality amplification system) and has unlimited opportunity and time to listen, even lower distortion (0.2 percent, for example) can be perceived.

CHAPTER 20.3

MICROPHONES, LOUDSPEAKERS, AND EARPHONES

Daniel W. Martin

MICROPHONES

Sound-Responsive Elements

The sound-responsive element in a microphone may have many forms (Fig. 20.3.1). It may be a stretched membrane (*a*), a clamped diaphragm (*b*), or a magnetic diaphragm held in place by magnetic attraction (*c*). In these the moving element is either an electric or magnetic conductor, and the motion of the element creates the electric or magnetic equivalent of the sound directly.

Other sound-responsive elements are straight (*d*) or curves (*e*) conical diaphragms with various shapes of annular compliance rings, as shown. The motion of these diaphragms is transmitted by a drive rod from the conical tip to a mechanical transducer below.

Other widely used elements are a circular piston (*f*) bearing a circular voice coil of smaller diameter and a corrugated-ribbon conductor (*g*) of extremely low mass and stiffness suspended in a magnetic field.

Transduction Methods

Microphones have a great variety of transduction methods shown in Fig. 20.3.2.

The loose-contact transducer (Fig. 20.3.2*a*) was the first achieved by Bell in magnetic form and later made practical by Edison's use of carbonized hard-coal particles. It is widely used in telephones. Its chief advantage is its self-amplifying function, in which diaphragm amplitude variations directly produce electric resistance and current variations. Disadvantages include noise, distortion, and instability.

Moving-iron transducers have great variety, ranging from the historic pivoted armature (Fig. 20.3.2*b*) to the modern ring armature driven by a nonmagnetic diaphragm (Fig. 20.3.2*h*). In all these types a coil surrounds some portion of the magnetic circuit. The reluctance of the magnetic circuit is varied by motion of the sound-responsive element, which is either moving iron itself (Fig. 20.3.2*c* and *d*) or is coupled mechanically to the moving iron (Fig. 20.3.2*e-h*). In some of the magnetic circuits that portion of the armature surrounded by the coil carries very little steady flux, operating on differential magnetic flux only. Output voltage is proportional to moving-iron velocity.

Electrostatic transducers (Fig. 20.3.2*i*) use a polarizing potential and depend on capacitance variation between the moving diaphragm and a fixed electrode for generation of a corresponding potential difference. The *electret microphone* is a special type of electrostatic microphone that holds polarization indefinitely without continued application of a polarizing potential, an important practical advantage for many applications.

FIGURE 20.3.1 Sound-responsive elements in microphones.¹

Piezoelectric transducers (Fig. 20.3.2j) create an alternating potential through the flexing of crystalline elements which, when deformed, generate a charge difference proportional to the deformation on opposite surfaces. Because of climatic effects and high electric impedance the rochelle salt commonly used for many years has been superseded by polycrystalline ceramic elements and by piezoelectric polymer.

Moving-coil transducers (Fig. 20.3.2k) generate potential by oscillation of the coil within a uniform magnetic field. The output potential is proportional to coil velocity.

FIGURE 20.3.2 Microphone transduction methods.¹

FIGURE 20.3.3 Equivalent basic elements in electrical, acoustical, and mechanical systems.²

FIGURE 20.3.4 Helmholtz resonator in (a) perspective and (b) in section and (c) equivalent electric circuit.²

Equivalent Circuits

Electronics engineers understand electroacoustic and electromechanical design better with the help of equivalent or analogous electric circuits. Microphone design provides an ideal base for introduction of equivalent circuits because microphone dimensions are small compared with acoustical wavelengths over most of the audio-frequency range. This allows the assumption of lumped circuit constants.

Figure 20.3.3 shows equivalent symbols for the three basic elements of electrical, acoustical, and mechanical systems. In acoustical circuits the resistance is air friction or viscosity, which occurs in porous materials or narrow slots. Radiation resistance is another form of acoustical damping. Mechanical resistance is friction. Mass in the mechanical system is analogous to electric inductance. The acoustical equivalent is the mass of air in an opening or constriction divided by the square of its cross-sectional area. The acoustical analog of electric capacitance and mechanical-spring compliance is acoustical capacitance. It is the inverse of the stiffness of an enclosed volume of air under pistonlike action. Acoustical capacitance is proportional to the volume enclosed.

Figure 20.3.4 is an equivalent electric circuit for a Helmholtz resonator. Sound-pressure and air-volume current are analogous to electric potential and current, respectively. Other analog systems have been proposed. One frequently used has advantages for mechanical systems.

Microphone Types and Equivalent Circuits

Different types of microphone respond to different properties of the acoustical *input* wave. Moreover, the electric *output* can be proportional to different internal mechanical variables.

Pressure Type, Displacement Response. Figure 20.3.5 shows a microphone responsive to the sound-pressure wave acting through a resonant acoustical circuit upon a resonant diaphragm coupled to a piezoelectric element responsive to displacement. (The absence of sound ports in the case or in the diaphragm keeps the microphone pressure responsive.) In the equivalent circuit the sound pressure is the generator. L_a and R_a represent

FIGURE 20.3.5 Pressure microphone, displacement response.¹

FIGURE 20.3.6 Pressure microphone, velocity response.¹

the radiation impedance. L_s and R_s are the inductance and acoustical resistance of the holes; C_s is the capacitance of the volume in front of the diaphragm; L_m , C_m , and R_m are the mass, compliance, and resistance of the piezoelectric element and diaphragm lumped together; and C_b is the capacitance of the entrapped back volume of air. The electric output is the potential differential across the piezoelectric element. It is shown across the capacitance in the equivalent circuit because microphones of this type are designed to be stiffness-controlled throughout most of their operating range.

Pressure Type, Velocity Response. Figure 20.3.6 shows a moving-coil pressure microphone, which is a velocity-responsive transducer. In this microphone three acoustical circuits lie behind the diaphragm. One is behind the dome and another behind the annular rings. The third acoustical circuit lies beyond the acoustical resistance at the back of the voice-coil gap and includes a leak from the back chamber to the outside. This microphone is resistance-controlled throughout most of the range, but at low frequencies its response is extended by the resonance of the third acoustical circuit. Output potential is proportional to the velocity of voice-coil motion.

Pressure-Gradient Type, Velocity Response. When both sides of the sound-responsive element are open to the sound wave, the response is proportional to the *gradient* of the pressure wave. Figure 20.3.7 shows a ribbon conductor in a magnetic field with both sides of the ribbon open to the air. In the equivalent circuit there are two generators, one for sound pressure on each side.

FIGURE 20.3.7 Gradient microphone, velocity response.¹

Radiation resistance and reactance are in series with each generator and the circuit constants of the ribbon. Usually the ribbon resonates at a very low frequency, making its mechanical response mass-controlled throughout the audio-frequency range. The electric output is proportional to the conductor velocity in the magnetic field. Gradient microphones respond differently to distant and close sound sources.

Directional Patterns and Combination Microphones

Because of diffraction, a pressure microphone is equally responsive to sound from all directions as long as the wavelength is larger than microphone dimensions (see Fig. 20.3.8a). (At high frequencies it is somewhat directional along the forward axis of diaphragm or ribbon motion.)

By contrast a pressure-gradient microphone has a figure-eight directional pattern (Fig. 20.3.8b), which rotates about the axis of ribbon or diaphragm motion. A sound wave approaching a gradient microphone at 90° from the axis produces balanced pressure on the two sides of the ribbon and consequently no response.

FIGURE 20.3.8 Directional patterns of microphones: (a) nondirectional; (b) bidirectional; (c) unidirectional.²

This defines the *null plane* of a gradient microphone. Outside this plane the microphone response follows a cosine law.

If the pressure and gradient microphones are combined in close proximity (see Fig. 20.3.9) and are connected electrically to add in equal (half-and-half) proportions, a heart-shaped cardioid pattern (Fig. 20.3.8c) is obtained. (The back of the ribbon in the pressure microphone is loaded by an acoustical resistance line.) By combining the two outputs in other proportions other limaçon directional patterns can be obtained.

Phase-Shift Directional Microphones

Directional characteristics similar to those of the combination microphones can also be obtained with a single moving element by means of equivalent circuit analysis using acoustical phase-shift networks. Figure 20.3.10 shows a moving-coil, phase-shift microphone and its simplified equivalent circuit. The phase-shift network is composed of the rear-port resistance R_2 and inductance L_2 , the capacitance of the volume under the diaphragm and within the magnet, and the impedance of the interconnecting screen. The microphone has a cardioid directional pattern.

Special-Purpose Microphones

Special-purpose microphones include two types that are superdirectional, two that overcome noise, and one without cables.

Line microphones use an approximate line of equally spaced pickup points connected through acoustically damped tubes to a common microphone diaphragm. The phase relationships at these points for an incident plane wave combine to give a sharply directional pattern along the axis if the line segment is at least one wavelength.

Parabolic microphones face a pressure microphone unit toward a parabolic reflector at its focal point, where sounds from distant sources along the axis of the parabola converge. They are effective for all wavelengths smaller than the diameter of the reflector.

Noise-canceling microphones are gradient microphones in which the mechanical system is designed to be stiffness-controlled rather than mass-controlled. For distant sound sources the resulting response is greatly attenuated at low frequencies. However, for a very close sound source, the response-frequency characteristic is uniform because the *gradient* of the pressure wave near a point source decreases with increasing frequency. Such a microphone provides considerable advantage for nearby speech over distant noise on the axis of the microphone.

FIGURE 20.3.9 Combination unidirectional microphone.¹

FIGURE 20.3.10 Phase-shift unidirectional microphone.¹

Contact microphones are used on string and percussion musical instruments, on seismic-vibration detectors, and for pickup of body vibrations including speech. The throat microphone was noted for its convenience and its rejection of airborne noise. Most types of throat microphone are inertia-operated, the case receiving vibration from the throat walls actuated by speech sound pressure in the throat. The disadvantage is a deficiency of speech sibilant sounds received back in the throat from the mouth.

Wireless microphones have obvious operational advantages over those with microphone cords. A wireless microphone contains a small, low-power radio transmitter with a nearby receiver connected to an audio communication system. Any of the microphone types can be so equipped. The potential disadvantage is in rf interference and field effects.

Microphone Use in Recordings

The choice of microphone type and placement greatly affects the sound of a recording. For speech and dialogue recordings pressure microphones are usually placed near the speakers in order to minimize ambient-noise pickup and room reverberation. Remote pressure microphones are also used when a maximum room effect is desired.

In the playback of monophonic recordings room effects are more noticeable than they would have been to a listener standing at the recording microphone position because single-microphone pickup is similar to single-ear (monaural) listening, in which the directional clues of localization are lost. Therefore microphones generally need to be closer in a monophonic recording than in a stereophonic recording.

In television pickup of speech, where a boom microphone should be outside the camera angle, unidirectional microphones are often used because of their greater ratio of direct to generally reflected sound response.

Both velocity (gradient) microphones and unidirectional microphones can be used to advantage in broadcasting and recording. Figure 20.3.11a shows how instruments may be placed around a figure-eight directivity pattern to balance weaker instruments 2 and 5 against stronger instruments 1 and 3 with a potential noise source at point 4. In Fig. 20.3.11b source 2 is favored, with sources 1 and 3 somewhat reduced and source 4 highly discriminated against by the cardioid directional pattern. In Fig. 20.3.11c an elevated unidirectional microphone aimed downward responds uniformly to sources on a circle around the axis while discriminating against mechanical noises at ceiling level. Figure 20.3.11d places the camera noise in the null plane of a figure-eight pattern, and Fig. 20.3.11e shows a similar use for the unidirectional microphone. Camera position is less critical for the cardioid microphone than for the gradient microphone.

Early classical stereo recordings used variations of two basic microphone arrangements. In one scheme two unidirectional microphones were mounted close together with their axes angled toward opposite ends of the sound field to be recorded. This retained approximately the same arrival time and phase at both microphones, depending chiefly on the directivity patterns to create the sound difference in the two channels.

In the second scheme the two microphones (not necessarily directional) were separated by distances of 5 to 25 ft, depending on the size of the sound field to be recorded. Microphone axes (if directional) were again directed toward the ends of the sound field or group of sound sources. In this arrangement the time of arrival and phase differences were more important, and the effect of directivity was lessened. Each approach had its advantages and disadvantages.

FIGURE 20.3.11 Use of directional microphones.²

20.24 AUDIO SYSTEMS

With the arrival of tape recorders having many channels a trend has developed toward the use of more microphones and closer microphone placement. This offers much greater flexibility in mixing and rerecording, and it largely removes the effect of room reverberation from the recording. This may be either an advantage or a disadvantage depending on the viewpoint. Reverberation can be added later.

In sound-reinforcement systems for dramatic productions and orchestras the use of many microphones again offers operating flexibility. However, it also increases the probability of operating error, increased system noise, and acoustical feedback, making expert monitoring and mixing of the microphone outputs necessary.

An attractive alternative for multimicrophone audio systems is the use of independent voice-operated electronic control switches in each microphone channel amplifier, in combination with an automatic temporary reduction of overall system gain as more channels switch on, in order to prevent acoustical feedback. Automatic mixers have been devised to minimize speech signal dropouts, and to prevent the inadvertent operation of channel control switches by background noises.

Microphone Mounting

On podiums and lecterns microphones are typically mounted on fixed stands with adjustable arms. On stages they are mounted on adjustable floor stands. In mobile communication and in other situations where microphone use is occasional, handheld microphones are used during communication and are stowed on hangers at other times. For television and film recording, where the microphone must be out of camera sight, the microphones are usually mounted on booms overhead and are moved about during the action to obtain the best speech-to-noise ratio possible at the time. In two-way communication situations which require the talker to move about or to turn his head frequently, the microphone can be mounted on a boom fastened to his headset. This provides a fixed close-talking microphone position relative to the mouth, a considerable advantage in high-ambient-noise levels.

Microphone Accessories

Noise shields are needed for microphones in ambient noise levels exceeding 110 dB. Noise shields are quite effective at high frequencies, where the random-noise discrimination of noise-canceling microphones diminishes. Noise shields and noise-canceling microphones complement each other.

Windscreens are available for microphone use in airstreams or turbulence. Without them aerodynamically induced noise is produced by turbulence at the microphone grille or openings. Large windscreens are more effective than small ones because they move the turbulence region farther from the microphone.

Special sponge-rubber mountings for the microphone and cable to reduce extraneous vibration of the microphone are often used. Many microphone stands and booms have optional suspension mounting accessories to reduce shock and vibration transmitted through the stand or boom to the microphone.

Special Properties of Microphones

The source impedance of a microphone is important not only to the associated preamplifier but also to the allowable length of microphone cable and the type and amount of noise picked up by the cable. High-impedance microphones (10 k Ω or more) cannot be used more than a few feet from the preamplifier without pickup from stray fields. Microphones having an impedance of a few ohms or less are usually equipped with stepup transformers to provide a line impedance in the range of 30 to 600 Ω , which extensive investigation has established as the most noise-free line-impedance range.

The microphone unit itself can be responsive to hum fields at power-line frequencies unless special design precautions are taken. Most microphones have a hum-level rating based on measurement in a standard alternating magnetic field.

For minimum electrical noise balanced and shielded microphone lines are used, with the shield grounded only at the amplifier end of the line.

Microphone linearity should be considered when the sound level exceeds 100 dB, a frequent occurrence for loud musical instruments and even for close speech. Close-talking microphones, especially of the gradient type, are particularly susceptible to noise from breath and plosive consonants.

Specifications

Microphone specifications typically include many of the following items: type or mode of operation, directivity pattern, frequency range, uniformity of response within the range, output level at one or more impedances for a standard sound-pressure input (for example, 1 Pa or 10 dyn/cm²), recommended load impedance, hum output level for a standard magnetic field (for example, 10⁻³ G), dimensions, weight, finish, mounting, power supply (if necessary), and accessories.

LOUDSPEAKERS

Introduction

A loudspeaker is an electroacoustic transducer intended to radiate acoustic power into the air, with the acoustic waveform equivalent to the electrical input waveform. An earphone is an electroacoustic transducer intended to be closely coupled acoustically to the ear. Both the loudspeaker and earphone are receivers of audio-electronic signals. The principal distinction between them is the acoustical loading. An earphone delivers sound to air in the ear. A loudspeaker delivers sound indirectly to the ear through the air.

The transduction methods of loudspeakers and earphones are historically similar and are treated together. An overview of loudspeaker developments of the closing 50 years of the last millennium is given by Gander.³ However, since loudspeakers operate primarily into radiation resistance and earphones into acoustical capacitance, the design, measurement, and use of the two types of electroacoustic transducers will be discussed separately.

Transduction Methods

Early transducers for sound reproduction were of the mechanoacoustic type. Vibrations received by a stylus in the undulating groove of a record were transmitted to a diaphragm, placed at the throat of a horn for better acoustical impedance matching to the air, all without the aid of electronics. Electro-acoustics and electronics introduced many advantages and a variety of transduction methods including moving-coil, moving-iron, electrostatic, magnetostrictive, and piezoelectric (Fig. 20.3.12).

Most loudspeakers are moving-coil type today, although moving-iron transducers were once widely used. Electrostatic loudspeakers are used chiefly in the upper range of audio frequencies, where amplitudes are small. Magnetostrictive and piezoelectric loudspeakers are used for underwater sound. All the transducer types are used in earphones except magnetostrictive.

FIGURE 20.3.12 Loudspeaker (and earphone) transduction methods: (a) moving-coil; (b) moving-iron; (c) electrostatic; (d) magnetostrictive; (e) piezoelectric.⁴

The output force along the axis of the circular coil is applied to a sound radiator.

Moving-iron transducers reverse the mechanical roles of the coil and the iron. The iron armature surrounded by the stationary coil is moved by mechanical forces developed within the magnetic circuit. Moving-iron

Moving-Coil. The mechanical force on the moving coil of Fig. 20.3.12a is developed by the interaction of the current in the coil and the transverse magnetic field disposed radially across the gap between the magnet

magnetic circuits have many forms. As an example in the balanced armature system (Fig. 20.3.12*b*) the direct magnetic flux passes only transversely through the ends of the armature centered within the two magnetic gaps. Coil current polarizes the armature ends oppositely, creating a force moment about the pivot point. The output force is applied from the tip of the armature to an attached sound radiator. In a balanced-diaphragm loudspeaker the armature is the radiator.

Electrostatic. In the electrostatic transducer (Fig. 20.3.12*e*) there is a dc potential difference between the conductive diaphragm and the stationary perforated plate nearby. Audio signals applied through a blocking capacitor superimpose an alternating potential, resulting in a force upon the diaphragm, which radiates sound directly.

Magnetostrictive transducers (Fig. 20.3.12*d*) depend on length fluctuations of a nickel rod caused by variations in the magnetic field. The output motion may be radiated directly from the end of the rod or transmitted into the attached mechanical structure.

Piezoelectric transducers are of many forms using crystals or polycrystalline ceramic materials. In simple form (Fig. 20.3.12*e*) an expansion-contraction force develops along the axis joining the electrodes through alternation of the potential difference between them.

Sound Radiators

The purpose of a sound radiator is to create small, audible air-pressure variations. Whether they are produced within a closed space by an earphone or in open air by a loudspeaker, the pressure variations require air motion or current.

Pistons, Cones, Ports. Expansion and contraction of a sphere is the classical configuration but most practical examples involve rectilinear motion of a piston, cone, or diaphragm. In addition to the primary direct radiation from moving surfaces, there is also indirect or secondary radiation from enclosure ports or horns to which the direct radiators are acoustically coupled.

Attempts have been made to develop other forms of sound radiation such as oscillating airstreams and other aerodynamic configurations with incidental use, if any, of moving mechanical members.

Directivity. Figure 20.3.13 shows the directional characteristics of a rigid circular piston for different ratios of piston diameter and wavelength of sound. (In three dimensions these curves are symmetrical around the axis of piston motion.) For a diameter of one-quarter wavelength the amplitude decreases 10 percent (approximately

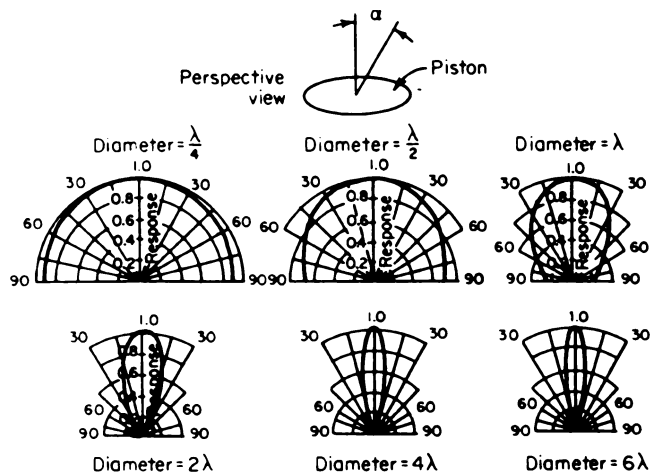

FIGURE 20.3.13 Directional characteristics of rigid circular pistons of different diameters or at different sound wavelengths.²

FIGURE 20.3.14 Directional characteristics of two equal small in-phase sound sources separated by different distances or different sound wavelengths.²

1 dB sound level) at 90° off axis. For a four-wavelength diameter the same drop occurs in only 5° . (The beam of an actual loudspeaker cone is less sharp than this at high frequencies, where the cone is not rigid.) Note that all the polar curves are smooth when the single-source piston vibrates as a whole.

Radiator Arrays. When two separate, identical small-sound sources vibrate in phase, the directional pattern becomes narrower than for one source. Figure 20.3.14 shows that for a separation of one-quarter wavelength the two-source beam is only one-half as wide as for a single piston. At high frequencies the directional pattern becomes very complex. (In three dimensions these curves become surfaces of revolution about the axis joining the two sources.)

Arrays of larger numbers of sound radiators in close proximity are increasingly directional. Circular-area arrays have narrow beams which are symmetrical about an axis through the center of the circle. Line arrays, e.g., column loudspeakers, are narrowly directional in planes containing the line and broadly directional in planes perpendicular to the line.

Direct-Radiator Loudspeakers

Most direct-radiator loudspeakers are of the moving-coil type because of simplicity, compactness, and inherently uniform response-frequency trend. The uniformity results from the combination of two simple physical principles: (1) the radiation resistance increases with the square of the frequency, and hence the radiated sound power increases similarly for constant velocity amplitude of the piston or cone; (2) for a constant applied force (voice-coil current) the mass-controlled (above resonance) piston has a velocity amplitude which decreases with the square of the frequency. Consequently a loudspeaker designed to resonate at a low frequency combines decreasing velocity with increasing radiation resistance to yield a uniform response within the frequency range where the assumptions hold.

FIGURE 20.3.15 (a) Structure, (b) electric circuit, and (c) equivalent mechanical circuit for a direct-radiator moving-coil loudspeaker in a baffle.⁴

Equivalent Electric Circuits. Figure 20.3.15 shows a cross-sectional view of a direct-radiator loudspeaker mounted in a baffle, the electric voice-coil circuit, and the equivalent electric circuit of the mechanoacoustic system. In the voice-coil circuit e is the emf and R_{EG} the resistance of the generator, e.g., power-amplifier output, L and R_{EC} are the inductance and resistance of the voice coil. Z_{EM} is the motional electric impedance from the mechanoacoustic system.

FIGURE 20.3.16 Components of a mechanical impedance of a typical 4-in loudspeaker.⁴

All this has assumed that the cone moves as a whole. Actually wave motion occurs in the cone. Consequently at high frequencies the mass reactance is somewhat reduced (as shown in the dashed curve of Fig. 20.3.16), tending to improve efficiency beyond the frequency where radiation resistance becomes uniform.

Magnetic Circuit. Most magnets now are a high-flux, high-coercive permanent type, either an alloy of aluminum, cobalt, nickel, and iron, or a ferrite of iron, cobalt, barium, and nickel. The magnet may be located in the core of the structure or in the ring, or both. However, magnetization is difficult when magnets are oppositely polarized in the core and ring.

Air-gap flux density varies widely in commercial designs from approximately 3000 to 20,000 G. Since most of the reluctance in the magnetic circuit resides in the air gap, the minimum practical voice-coil clearance in the gap compromises the maximum flux density. Pole pieces of heat-treated soft nickel-iron alloys, dimensionally tapered near the gap, are used for maximum flux density.

Voice Coils. The voice coil is a cylindrical multilayer coil of aluminum or copper wire or ribbon. Aluminum is used in high-frequency loudspeakers for minimum mass and maximum efficiency. Voice-coil impedance varies from 1 to 100 Ω with 4, 8, and 16 Ω standard. For maximum efficiency the voice-coil and cone masses are equal. However, in large loudspeakers the cone mass usually exceeds the voice-coil mass. Typically the voice-coil mass ranges from tenths of a gram to 5 g or more.

Cones. Cone diameters range from 1 to 18 in. Cone mass varies from tenths of a gram to 100 g or more. Cones are made of a variety of materials. The most common is paper deposited from pulp on a wire-screen form in a felting process. For high-humidity environment cones are molded from plastic materials, sometimes with a cloth or fiber-glass base. Some low-frequency loudspeaker cones are molded from low-density plastic foam to achieve greater rigidity with low density.

So far piston action has been assumed in which the cone moves as a whole. Actually at high frequencies the cone no longer vibrates as a single unit. Typically there is a major dip in response resulting from quarter-wave

F_M is the driving force resulting from interaction of the voice-coil current field with the gap magnetic field. M_C is the combined mass of the cone and voice coil. C_{MS} is the compliance of the cone-suspension system. R_{MS} is the mechanical resistance. The mass M_A and radiation resistance R_{MA} of the air load complete the circuit.

Figure 20.3.16 summarizes these mechanical impedance factors for a 4-in direct-radiator loudspeaker of conventional design. Above resonance (where the reactance of the suspension system equals the reactance of the cone-coil combination) the impedance-frequency characteristic is dominated by M_C . From the resonance frequency of about 150 Hz to about 1500 Hz the conditions for uniform response hold.

Efficiency. Since R_{MA} is small compared to the magnitudes of the reactive components, the efficiency of the loudspeaker in this frequency range can be expressed as

$$\text{Efficiency} = \frac{100(Bl)^2 R_{MA}}{R_{EC}(X_{MA} + X_{MC})^2} \text{ percent} \quad (1)$$

where B = gap flux density (G)

l = voice-coil conductor length (cm)

R_{EC} = voice-coil electric resistance (abohms)

Since R_{MA} is proportional to the square of the frequency and both X_{MA} and X_{MC} increase with frequency, the efficiency is theoretically uniform.

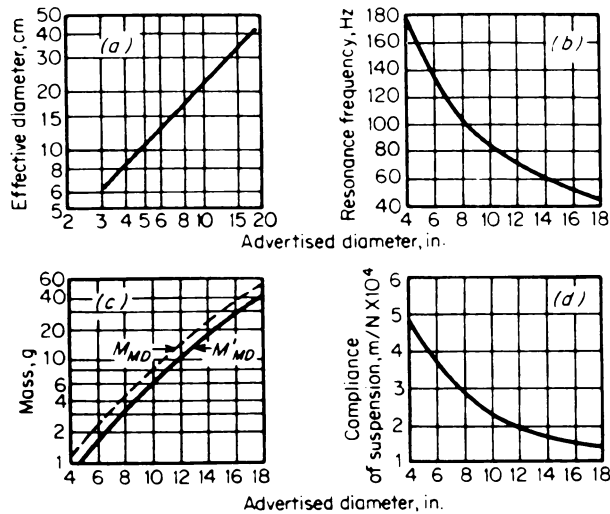

FIGURE 20.3.17 Typical cone and coil design values.⁵

reflection from the circular rim of the cone back to the voice coil. For loudspeaker cones in the range of 8 to 15 in. diameter this dip usually occurs in the range of 1 to 2 kHz.

Typical Commercial Design Values. Figure 20.3.17 shows typical values for several cone and voice-coil design parameters for a range of loudspeaker diameters. These do not apply to extreme cases, such as high-compliance loudspeakers or high-efficiency horn drivers. The effective piston diameter (Fig. 20.3.17a) is less than the loudspeaker cone diameter because the amplitude falls off toward the edges. A range of resonance frequencies is available for any cone diameter, but Fig. 20.3.17b shows typical values. In Fig. 20.3.17c typical cone mass is M including the voice coil and M' excluding the voice coil. Figure 20.3.17d shows typical cone-suspension compliance.

Impedance. A major peak results from motional impedance at primary mechanical resonance. Impedance is usually uniform above this peak until voice-coil inductance becomes dominant over resistance.

Power Ratings. Different types of power rating are needed to express the performance capabilities of loudspeakers. The large range of typical loudspeaker efficiency makes the acoustical power-delivering capacity quite important. The electrical power-receiving capacity (without overload or damage) determines the choice of power amplifier.

Loudspeaker efficiencies are seldom measured but are often compared by measuring the sound-pressure level at 4 ft on the loudspeaker axis for 1-W audio input. High-efficiency direct radiators provide 95 to 100 dB. Horn loudspeakers are typically higher by 10 dB or more, being both more efficient and more directional.

Loudspeakers are also rated by the maximum rms power output of amplifiers which will not damage the loudspeaker or drive it into serious distortion on peaks. Such ratings usually assume that the amplifier will seldom be driven to full power. For example, a 30-W amplifier will seldom be required to deliver more than 10 W rms of music program material. Otherwise music peaks would be clipped and sound distorted.

However, in speech systems for high-ambient-noise levels the speech peaks may be clipped intentionally, causing the loudspeaker to receive the full 30 W much of the transmission time. Then the loudspeaker must handle large excursions without mechanical damage to the cone suspension and without destroying the cemented coil or charring the form.

Distortion. Nonlinear distortion in a loudspeaker is inherently low in the mass-controlled range of frequencies. However, distortion is produced by nonlinear cone suspension at low frequencies, voice-coil motion

beyond the limits of uniform air-gap flux, Doppler shift modulation of high-frequency sound by large cone velocity at low frequencies, and nonlinear distortion of the air near the cone at high powers (particularly in horn drivers). Methods for controlling these distortions follow.

1. When a back enclosure is added to a loudspeaker, the acoustical capacitance of the enclosed volume is represented by an additional series capacitor in the mechanical circuit of Fig. 20.3.15. Insufficient volume stiffens the cone acoustically, raising the resonance frequency and limiting the low-frequency range of the loudspeaker. It is convenient to reduce nonlinear distortion at low frequencies by increasing the cone-suspension compliance and depending on the back enclosure to provide the system stiffness. Since an enclosed volume is more linear than most mechanical springs, this lowers low-frequency distortion.
2. Distortion from inhomogeneity of the air-gap flux can be reduced by making the voice-coil length either considerably smaller or larger than the gap width. This stabilizes the total number of lines passing through the coil, but it also reduces loudspeaker efficiency.
3. Doppler distortion can be eliminated only by separating the high and low frequencies in a multiple loudspeaker system.
4. Air-overload distortion can be avoided by increasing the radiating area.

Loudspeaker Mountings and Enclosures

Figure 20.3.18 shows a variety of mountings and enclosures. An un baffled loudspeaker is an acoustic doublet for wavelengths greater than the rim diameter. In this frequency range the acoustical power output for constant cone velocity is proportional to the fourth power of the frequency.

Baffles. In order to improve efficiency at low frequencies it is necessary to separate the front and back waves. Figure 20.3.18a is the simplest form of baffle. The effect of different baffle sizes is given in Fig. 20.3.19. Response dips occurring when the acoustic path from front to back is a wavelength are eliminated by irregular baffle shape or off-center mounting.

Enclosures. The widely used open-back cabinet (Fig. 20.3.18b) is noted for a large response peak produced by open-pipe acoustical resonance. A closed cabinet (Fig. 20.3.18c) adds acoustical stiffness at low frequencies where the wavelength is larger than the enclosure. At higher frequencies the internal acoustical resonances create response irregularities requiring internal acoustical absorption.

FIGURE 20.3.18 Mountings and enclosures for direct-radiator loudspeaker: (a) flat baffle; (b) open-back cabinet; (c) closed cabinet; (d) ported closed cabinet; (e) labyrinth; (f) folded horn.⁴

FIGURE 20.3.19 Response frequency for loudspeaker in 2-, 3-, 4-, and 6-ft square baffles.⁶

FIGURE 20.3.20 Response frequency for loudspeaker in closed (A) and ported (B) cabinets.⁶

Ported Enclosures (Fig. 20.3.18d). Enclosure volume can be minimized without sacrificing low-frequency range by providing an appropriate port in the enclosure wall. Acoustical inertance of the port should resonate with the enclosure capacitance at a frequency about an octave below cone-resonance frequency. *B*, Fig. 20.3.20, shows that this extends the low-frequency range. This is most effective when the port area equals the cone-piston area. Port inertance can be increased by using a duct. An extreme example of ducting is the acoustical labyrinth (Fig. 20.3.18e). When duct work is shaped to increase cross section gradually, the labyrinth becomes a low-frequency horn (Fig. 20.3.18f).

Direct-radiator loudspeaker efficiency is typically 1 to 5 percent. Small, highly damped types with miniature enclosures may be only 0.1 percent. Transistor amplifiers easily provide the audio power for domestic loudspeakers. However, in auditorium, outdoor, industrial, and military applications much higher efficiency is required.

Horn Loudspeakers

Higher efficiency is obtained with an acoustic horn, which is a tube of varying cross section having different terminal areas to provide a change of acoustic impedance. Horns match the high impedance of dense diaphragm material to the low air impedance. Horn shape or taper affects the acoustical transformer response. Conical, exponential, and hyperbolic tapers have been widely used. The potential low-frequency cutoff of a horn depends on its taper rate. Impedance transforming action is controlled by the ratio of mouth to throat diameter.

Horn Drivers. Figure 20.3.21 shows horn-driving mechanisms and straight and folded horns of large- and small-throat types. A large-throat driver (Fig. 20.3.21a) resembles a direct-radiator loudspeaker with a voice-coil diameter of 2 to 3 in. and a flux density around 15,000 G. A small-throat driver (Fig. 20.3.21b) resembles a moving-coil microphone structure. Radiation is taken from the back of the diaphragm into the horn throat through passages which deliver in-phase sound from all diaphragm areas. Diaphragm diameters are 1 to 4 in. with throat diameters of $\frac{1}{4}$ to 1 in. Flux density is approximately 20,000 G.

Large-Throat Horns. These are used for low-frequency loudspeaker systems. A folded horn (Fig. 20.3.21c) is preferred over a straight horn (Fig. 20.3.21d) for compactness.

Small-Throat Horns. A folded horn (Fig. 20.3.21e) with sufficient length and gradual taper can operate efficiently over a wide frequency range. This horn is useful for outdoor music reproduction in a range of 100 to 5000 Hz. Response smoothness is often compromised by segment resonances. Extended high-frequency range requires a straight-axis horn (Fig. 20.3.21f).

FIGURE 20.321 Horns and horn drivers: (a) large-throat driver; (b) small-throat driver; (c) folded large-throat horn; (d) straight large-throat horn; (e) folded small-throat horn; (f) straight small-throat horn.⁴

Horn Directivity. Large-mouth horns of simple exponential design produce high-directivity radiation that tends to narrow with increasing frequency (as in Fig. 20.3.13). In applications requiring controlled directivity over a broad angle and a wide frequency range, a horn array (shown in Fig. 20.3.22a) can be used, with numerous small horn mouths spread over a spherical surface and throats converging together. Figure 20.3.22b shows the directional characteristics. Single sectoral horns with radial symmetry can provide cylindrical wavefronts with smoother directional characteristics which are controlled in one plane. Recent rectangular or square-mouth “quadric” horns, designed by computer to have different conical expansion rates in horizontal and vertical planes, provide controlled directivity in both planes over a wide frequency range.

Special Loudspeakers

Special types of loudspeakers for limited applications include the following.

Electrostatic high-frequency units have an effective spacing of about 0.001 in. between a thin metalized coating on plastic and a perforated metal backplate. This spacing is necessary for sensitivity comparable to moving-coil loudspeakers, but it limits the amplitude and the frequency range. Extension of useful response to the lower frequencies can be obtained with larger spacing, for example, $1/16$ in., with a polarizing potential of several thousand volts. This type of unit employs push-pull operation.

FIGURE 20.3.22 Horn array (cellular) and directional characteristics: (a) array; (b) horizontal directional curves.⁶

Modulated-airflow loudspeakers have an electromechanical mechanism for modulating the airstream from a high-pressure pneumatic source into a horn. Low audio power controls large acoustical power in this system. A compressor is also needed. Nonlinear distortion in the air and reduced speech intelligibility have been limitations of this high-power system.

Loudspeaker Specifications and Measurements

Typical loudspeaker specifications are shown in Table 20.3.1 for a variety of loudspeaker types.

Loudspeaker impedance is proportional to the voltage across the voice coil when driven by a high-impedance constant-current source. Continuous power ratings are obtained from sustained life tests with

typical audio-program material restricted to the frequency range appropriate for the loudspeaker type. Sensitivity, response-frequency characteristics, frequency range, and directivity are most effectively measured under anechoic conditions using calibrated laboratory microphones and high-speed level recorders. However, data so measured should not be expected to be exactly reproducible under room-listening conditions.

Distortion measurements in audio-electronic systems are generally of three types shown in Fig. 20.3.23. For harmonic distortion a single sinusoidal signal A is supplied to the loudspeaker and wave analysis at the harmonic frequencies determines the percent distortion.

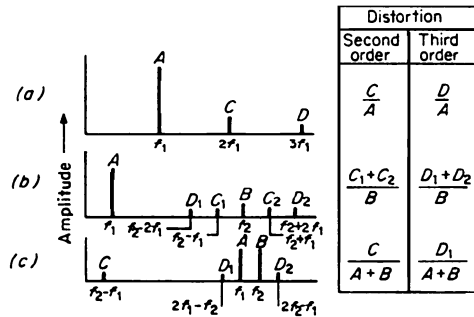

FIGURE 20.3.23 Methods of measuring nonlinear distortion: (a) harmonic; (b) intermodulation method of SMPTE; (c) intermodulation method of CCIF.⁷

inputs, with a 4:1 amplitude ratio, and observing the multiple sum- and difference-frequency components added to the output spectrum.

Both intermodulation methods supply two sinusoidal signals of different frequency to the loudspeaker. In the older Society of Motion Picture and Television Engineers (SMPTE) method the frequencies are widely separated, and the distortion is expressed in terms of sum and difference frequencies around the higher test frequency. This method is meaningful for wide-range loudspeaker systems.

The CCIF (International Telephone Consultative Committee) method is more applicable to narrow-range systems and loudspeakers receiving input at high frequencies. It supplies two high frequencies to the loudspeaker and checks the low difference frequency.

Transient intermodulation distortion, resulting from nonlinear response to steep wavefronts, is measured by adding square-wave (3.18-kHz) and sine-wave (15-kHz)

EARPHONES

The transduction methods are the same as for loudspeakers. Telephone and hearing aid receivers are usually moving-iron. Most military headsets are now moving-coil. Piezoelectric, moving-coil, and electrostatic types are used for listening to recorded music.

Equivalent Electric Circuits

Figure 20.3.24 shows a cross section of a moving-coil earphone and the equivalent electric circuit. The voice-coil force drives the voice coil and diaphragm. (Mechanical resonance of earphone diaphragms occurs at a high audio frequency in contrast to loudspeakers.) Diaphragm motion creates sound pressure in several spaces behind the diaphragm and the voice coil and between the diaphragm and the earcup. Inertance and resistance of the connecting holes and clearances combine with the capacitance of the spaces to add acoustical resonances. Z is the acoustical impedance of the ear.

Idealized Ear Loading

The ear is approximately an acoustical capacitance. However, acoustical leakage adds a parallel resistance-inertance path affecting low-frequency response. At high frequencies the ear canal-length resonance is a factor.

Since the ear is a capacitance, the goal of earphone design is a constant diaphragm amplitude throughout the frequency range. This requires a stiffness-controlled system or a high-resonance frequency. The potential across the ear is analogous to sound pressure within the ear cavity. This sound pressure is proportional to

FIGURE 20.3.24 Moving-coil earphone cross section and equivalent electric circuit.⁸

diaphragm area and inversely proportional to enclosed volume. Earphone loading conditions are extremely varied for different types of earphone mountings.

Earphone Mountings

The most widely used earphone is the single receiver unit on a telephone handset. It is intended to be held against the ear but is often tilted away, leaving considerable leakage.

Headsets provide better communication than handsets because they supply sound to both ears and shield them.

A remote earphone can drive the ear canal through a small acoustic tube. The length may be an inch or two for hearing aids and several feet for music listening on aircraft.

Efficiency, Impedance, and Driving Circuits

Moving-iron earphones and microphones can be made efficient enough to operate as sound-powered (battery-less) telephones. Efficient magnet structures, minimum mechanical and acoustical damping, and minimum volume of acoustical coupling are required for this purpose. In some earphone applications overall efficiency is less critical, and wearer comfort is important.

Insert earphones need less efficiency than external earphones because the enclosed volume is much smaller; however, they require moderate efficiency to save the amplifier batteries.

Circumaural earphones are frequently driven by amplifiers otherwise used for loudspeakers. Here efficiency is less important than power-delivering capacity.

Typically 1 mW of audio power to an earphone will produce 100 to 110 dB in a standard 6-cm³ coupler. The same earphone will produce less sound level in an earmuff than in an ear cushion and more when coupled to an ear insert.

The shape of the enclosed volume also affects response. The farther the driver is from the eardrum the lower the frequency of standing-wave resonance. Small tube diameters produce high-frequency attenuation.

The response-frequency characteristic of moving-iron or piezoelectric earphones is quite dependent on source impedance. A moving-iron earphone having uniform response when driven at constant power will have a rising response (with increasing frequency) at constant current and a falling response at constant voltage (Fig. 20.3.25).

FIGURE 20.3.25 Effect of source impedance upon earphone response curve: (a) constant current; (b) constant voltage; (c) constant power.⁹

A moving-iron earphone having uniform response when driven at constant power will have a rising response (with increasing frequency) at constant current and a falling response at constant voltage (Fig. 20.3.25).

Real-Ear Response

The variety of earphone-coupling methods and the variability of outer-ear geometry (among different listeners) make response data from artificial ears only indicative, not definitive. Out of necessity a real-ear response-measuring technique was developed. A listener adjusts headset input to match headset loudness to an external calibrated sound wave in an anechoic chamber. From matching data at numerous frequencies an equivalent free-field sound-pressure level can be plotted for constant input to the earphone. This curve usually differs from a sound-level curve on a simple earphone coupler. The reason is that probe measurements of sound at the eardrum and outside the ear in a free field differ because of ear amplification and diffraction about the head (Fig. 20.3.26).

FIGURE 20.3.26 Relative level of sound pressures at the listener's eardrum and in the free sound field.¹⁰

Acoustic attenuation by earphones can be measured either by threshold shift or by matching the loudness of tones heard from an external loudspeaker, with and without the headset on. The sound-level difference is plotted as attenuation in decibels.

Monaural, Diotic, and Binaural Listening

A handset earphone provides monaural listening. Diotic listening with the same audio signal in both earphones localizes sound within the head. This is not unpleasant and may actually be an aid to concentration. In natural-binaural listening the ears receive sound differently from the same source unless it is directly on the listening axis. Usually there are differences in phase, arrival time, and spectrum (because of diffraction about the head).

Recordings provide true binaural effects only if the two recording microphones are on an artificial head. Stereophonic microphones are usually separated much farther, so that headset listening gives an exaggerated effect. For some listeners this is an enhancement.

CHAPTER 20.4

DIGITAL AUDIO RECORDING AND REPRODUCTION

Daniel W. Martin, Ronald M. Aarts

INTRODUCTION

A digital revolution has occurred in audio recording and reproduction that has made some previous techniques only of historical interest. Although analog recording and reproduction systems have been greatly improved (Fig. 20.4.1), their capabilities are still short of ideal. For example, they could not provide the dynamic range of orchestral instrument sounds (e.g., from 42 dB on a soft low flute note to 120 dB for a bass drum peak), plus a reasonable ratio of weakest signal to background noise. Mechanical analog records are still limited by inherent nonlinear distortions as well as surface noise, and magnetic analog recording is limited by inherent modulation noise.

Digital audio signal transmission, recording, and playback have numerous potential advantages, which, with appropriate specifications and quality control, can now be realized as will now be shown.

DIGITAL ENCODING AND DECODING

There is much more to digital audio than encoding the analog signal and decoding the digital signal, but this is basic. The rest would be largely irrelevant if it were not both advantageous and practically feasible to convert analog audio signals to digital for transmission, storage, and eventual retrieval.

A digital audio signal is a discrete-time, discrete-amplitude representation of the original analog audio signal. Figure 20.4.2 is a simple encoding example using only 4 bits. The amplitude of the continuous analog audio signal wavetrain *A* is sampled at each narrow pulse in the clock-driven pulse train *B*, yielding for each discrete abscissa (time) value a discrete ordinate (voltage) value represented by a dot on or near the analog curve. The vertical scale is subdivided (in this example) into 16 possible voltage values, each represented by a binary number or “word.” The first eight words can be read out either in parallel

1000, 1010, 1011, 1011, 1010, 1000, 0110, 0101, ...

on four channels, or in sequence

10001010101110111010100001100101 ...

on a single channel for transmission, optional recording and playback, and decoding into an approximation of the original wavetrain. Unless intervening noise approaches the amplitude of the digit 1, the transmitted or played-back digital information matches the original digital information.

The degree to which digitization approximates the analog curve is determined by the number of digits chosen and the number of samplings per second. Both numbers are a matter of choice, but the present specifications for digital audio systems generally use 16 bits for uniform quantization (65,536 identifiable values),

FIGURE 20.4.1 Dynamic range of analog tape cartridges and cassettes. (After Ref. 1)

corresponding to a theoretical dynamic range of $16(6 \text{ dB}) = 96 \text{ dB}$. The sampling frequency, according to the Nyquist criterion, must be at least twice the highest audio frequency to be transmitted or recorded. Three different sampling frequencies are being used, 48 kHz “for origination, processing, and interchange of program material”; 44.1 kHz “for certain consumer applications”; and 32 kHz “for transmission-related applications.”

Figure 20.4.3 shows the main electronic blocks of a 5-bit digital system for encoding and decoding audio signals for various transmitting and receiving purposes. The digital audio signal may be transmitted and

FIGURE 20.4.2 Digital encoding of an analog waveform: (a) continuous analog signal wavetrain; (b) clock-driven pulse train. At equal time intervals, sample values are encoded into nearest digital word.

FIGURE 20.4.3 The basic electronic system components for encoding and decoding digital audio signals for (a) transmitting (or recording) and (b) receiving (or playback). (Ref. 2)

received conductively or electromagnetically. Alternatively, it may be stored and later retrieved by recording and playback. Or transmission may simply be into and out of a digital signal processing system, which purposely alters or enhances the signal in a manner not easily accomplished by analog means.

In any case the frequency range of the analog input signal must be limited, by the first low-pass filter of Fig. 20.4.3, to less than one-half the sampling frequency. For 16-bit accuracy in digitization this filter probably needs a stop-band attenuation greater than 60 dB, a signal-to-noise ratio of 100 dB, bandpass ripple less than 0.2 dB, and differential nonlinearity less than 0.0075 percent.

The next block is a sample-and-hold analog circuit which tracks the input voltage and samples it during a very short portion of the sampling period; it then holds that value during the remainder of the sampling period until the next sampling begins. Possible faults in sampling include timing “jitter,” which adds modulation noise, and “droop” in the held voltages during digitization.

The analog-to-digital converter quantizes each of the succession of held voltages shown and turns them into a sequence of binary numbers, the first of which (1000, corresponding to 16) is shown at the outputs of the converter. For practical reasons the parallel output information from the converter is put into sequential form in the transmitting system by multiplexing, for example, before transmission or recording occurs.

Demultiplexing in the receiving system puts the data back into parallel form for digital-to-analog conversion. Possible faults in the conversion include gain errors, which increase quantizing error, and nonlinearity or relative nonuniformity, which cause distortion. The second low-pass filter removes the scanning frequency and its harmonics, which, although inaudible themselves, can create audible distortion in the analog output system.

TRANSMISSION AND RECEPTION OF THE DIGITAL AUDIO SIGNAL

As previously stated, other digital functions and controls are required to assist in the encoding and decoding. Figure 20.4.4 complements Fig. 20.4.3 by showing in a block diagram that analog-to-digital (A/D) conversion and transmission (or storage) have intervening digital processing and that all three are synchronized under digital clock control. In reception (or playback), equivalent digital control is required for reception, digital reprocessing, and digital-to-analog (D/A) conversion. Examples of these functions and controls are multiplexing of the A/D output, digital processing to introduce redundancy for subsequent error detection and correction, servo system control when mechanical components are involved, and digital processing to overcome inherent transmission line or recording media characteristics. The digitization itself may be performed in any of a number of ways: straightforward, uniform by successive approximations, companding, or differential methods such as delta modulation. Detailed design of much of this circuitry is in the domain of digital-circuit and

FIGURE 20.4.4 Block diagram of the basic functions in a digital audio system.

FIGURE 20.4.5 Subframe format recommended for serial transmission of linearly represented digital audio data.

integrated-circuit engineering, beyond the scope of this chapter. However, the audio system engineer is responsible for the selection, specification, and (ultimately) standardization of sampling rate, filter cutoff frequency and rate, number of digits, digitization method, and code error-correction method, in consultation with broadcast, video, and transmission engineers with whose systems compatibility is necessary.

Compatibility should be facilitated by following the “Serial Transmission Format for Linearly Represented Digital Audio Data” recommended by the Audio Engineering Society, in which digital audio sample data within a subframe (Fig. 20.4.5) is accompanied by other data bits containing auxiliary information needed for functions and controls such as those listed above. Two 32-bit subframes in sequence, one for each channel (of stereo, for example), comprise a frame transmitted in any one period of the sampling frequency. A channel (or modulation) code of the biphase mark, self-clocking type is applied to the data prior to transmission, in order to embed a data-rate clock signal which enables correct operation of the receiver. In this code all information is contained in the transitions, which simplifies clock extraction and channel decoder synchronization.

The audio signal data may occupy either 20 or 24 bits of the subframe, preceded by 4 bits of synchronizing and identifying preamble for designating the start of a frame and block, or the start of the first or the second subframe. If the full 24 bits are not needed for the audio sample, the first four can be auxiliary audio data.

Following the audio data are four single bits that indicate (*V*) whether the previous audio sample data bits are valid; (*U*) any information added for assisting the user of the data; (*C*) information about system parameters; and (*P*) parity for detection of transmission errors for monitoring channel reliability.

Within the audio field it is the Audio Engineering Society (AES) that has determined many standards. Among these there are a few digital interconnect standards [<http://www.aes.org/standards/>]. The AES30-1985 document has formed the basis for the international standards documents concerning a two-channel digital audio interface. The society has been instrumental in coordinating professional equipment manufacturers’ views on interface standards although it has tended to ignore consumer applications to some extent, and this is perhaps one of the principal roots of confusion in the field.³ The consumer interface was initially developed in 1984 by Sony and Philips for the CD system and is usually called Sony-Philips digital interface (SPDIF). The interface is serial and self-clocking. The two audio channels are carried in a multiplexed fashion over the same channel and the data are combined with a clock signal in such a way that the clock may be extracted at the receiver side.

A further standard was devised, originally called multichannel audio digital interface (MADI), which is based on the AES3 data format and has been standardized as AES10-1991. It is a professional interface that can accommodate up to 56 audio channels.

Bluetooth

Bluetooth is a low-cost, low-power, short-range radio technology, originally developed as a cable replacement to connect devices.⁴ An application of Bluetooth is as a carrier of audio information. This functionality allows to build devices such as wireless headsets, microphones, headphones, and cellular phones. The audio quality provided by Bluetooth is the same as one would expect from a cellular telephone.

IEEE1394

IEEE1394 is a standard defining a high-speed serial bus. This bus is also named FireWire or i.Link. It is a serial bus similar in principle to UBS, but runs at speeds of up to 400 Mbit/s, and is not centered around a PC (i.e., there may be none or multiple PCs on the same bus). It has a mode of transmission that guarantees bandwidth that makes it ideal for audio transmission digital video cameras and similar devices.

DIGITAL AUDIO TAPE RECORDING AND PLAYBACK

The availability of adaptable types of magnetic tape video recorders accelerated digital-audio-recording development in the tape medium. Nippon Columbia had developed a video-type recorder into a PCM tape recorder for eight channels of audio information with each channel sampled at 47.25 kHz. Now numerous manufacturers produce audio tape recorders for professional recording studios, and some large recording companies have developed digital master tape recording systems including digital editors and mixers.

An inherent disadvantage of digital recording and playback, especially in the tape medium, has been dropout caused by voids or scratches in the tape. Some dropouts are inevitable, so protective or corrective means are used such as interlacing the encoded signal with redundancy, or reserving and using bits for error-detection schemes, e.g., recording sums of words, for comparison with sums simultaneously calculated from playback of the words. Such error detection can trigger the substitution of adjacent data, for example, into the dropout gap.

Digital audio tape recorders are of two different types, helical-scan and multitrack using rotary and stationary heads, respectively. Helical-scan systems already had the needed bandwidth, but improved recording densities and multitrack head stacks allowed multitrack systems to become competitive. A variety of tape formats has been developed. Table 20.4.1 shows part of the specifications for a multitrack professional digital recorder, the Sony PCM-3324.

Two new modes of recording on magnetic tape have permitted large increases in lineal density of recording and signal-to-noise ratio, both great advantages for digital magnetic recording. Perpendicular (or vertical) recording (see Fig. 20.4.6a) uses a magnetic film (e.g., CoCr crystallites), which has a preferred anisotropy normal to the surface. In contrast to conventional longitudinal magnetic recording, demagnetization is weak at short wavelengths, increasing the signal amplitude at high frequencies. Another advantage is that sharp transitions between binary states is possible. Vector field recording (Fig. 20.4.6b) with isotropic particles and micro-gap heads has also led to higher bit densities.

TABLE 20.4.1 Specifications for the PCM-3324

Number of channels (one track per channel):	
digital audio 24, analog audio 2, time code 1, control 1; total 28	
Tape speed, sampling rate:	
70.01 cm, 44.1 kHz	} with $\pm 12.5\%$ vernier
76.20 cm/s, 48.0 kHz	
(selectable at recording, automatic switching in playback)	
Tape: 0.5-in. (12.7-mm) digital audio tape	
Quantization: 16-bit linear per channel	
Dynamic range: more than 90 dB	
Frequency response: 20 Hz to 20 kHz, +0.5, -1.0 dB	
Total harmonic distortion: less than 0.05%	
Wow and flutter: undetectable	
Emphasis: 50 μ s/15 μ s (EIAJ format and compact disc compatible)	
Format: DASH-F (fast)	
Channel coding: HDM-1	
Error control: cross-interleave code

Digital Compact Cassette (DCC)

After intensive research on digital audio tape (DAT), Philips built on this research to develop the digital compact cassette (DCC) recorder (Fig. 20.4.7). To make DCC mechanically (and dimensionally) compatible with analogue cassettes, and their tape mechanisms, the same tape speed of 4.76 cm/s (1⁷/₈ in./s) was adopted. At

FIGURE 20.4.7 DCC recorder block diagram (Ref. 5).

that tape speed, matching the quality of CD reproduction required compression of the digital audio data stream (1.4 million bits/s) by at least 4 to 1. DCC's coding system, called precision adaptive sub-band coding (PASC) achieves the compression after digitally filtering the audio frequency range into 32 sub-bands of equal bandwidth. The PASC signal processor adapts its action dynamically in each sub-band (a) by omitting data for sounds lying below the hearing threshold at that frequency and time, and (b) by disregarding data for weak sounds in any sub-band that would be masked (rendered inaudible) at that time by the presence of stronger sounds in adjacent or nearby sub-bands. Bits are reallocated to sub-bands when needed for accuracy, from sub-bands where not needed at the time, to optimize coding accuracy overall. The PASC sequential data, together with error correction codes and other system information are multiplexed into eight channels for recording on eight 185μ m-wide tracks. The 3.78 mm wide tape accommodates two sets of eight tracks, one forward and one reverse, alongside auxiliary code data on a separate track providing track and index numbers, time codes, and so forth. In playback the tape output signals are amplified, equalized, demodulated, with error detection and correction. The PASC processor reconstructs the input data that are fed to the digital-to-analogue converter. PASC is compatible with all three existing sampling frequencies, 32, 44.1, and 48 kHz with sub-band widths of 500, 690, and 750 Hz, respectively, and corresponding frame periods of 12, 8.7, and 8 msec.

The 18-channel thin-film playback head has magnetoresistive sensors having resistance that varies with the angle between the sensor's electrical bias current vector and the magnetization vector. Although the recorded digital track is 185μ m wide, the playback sensor is only 70μ m wide, allowing considerable azimuth tolerance. When playing analog audio cassette tapes each audio track uses more than one sensor, as shown, to improve S/N ratio.

DIGITAL AUDIO DISC RECORDING AND PLAYBACK

As in video discs, two general types of digital audio discs were developed. One type recorded binary information mechanically or electrically along a spiral groove that provides guidance during playback for a lightly contacting pickup. The second type used optical laser recording of the digital information in a spiral pattern and optical playback means which track the pattern without contacting the disc directly. The optical type now appears to be dominant.

Optical Digital Discs

The compact disc optical digital storage and reproduction system, a milestone in consumer electronics, was made possible by the confluence of significant progress in each of a number of different related areas of technology. Optical media capable of high storage density had long been available at high cost, but more durable optical surfaces of lower costs, integrated solid-state lasers, and mass-producible optical light pens were all required to permit economical optical recording and playback. Mechanical drive systems of higher accuracy were needed under servocontrol by digital signals. Advanced digital signal processing algorithms, complex electronic circuitry, and very large-scale integration (VLSI) implementation were part of the overall system development. Many research organizations contributed to the state of the art, and in 1980 two of the leaders, Philips and Sony, agreed on standardization of their compact disc optical systems which had been developing along similar but independent paths.

On the reflective surface of the compact optical disc is a spiral track of successive shallow depressions or pits. The encoded digital information is stored in the length of the pits and of the gaps between them, with the transitions from pit to gap (or vice versa) playing a key role. The disc angular rotation is controlled for constant linear velocity of track readout on the order of 1.3 m/s. A beam from a solid-state laser, focused on the disc, is reflected, after modulation by the disc track information, to a photodiode that supplies input to the digital processing circuitry. Focusing of the laser spot on the spiral track is servocontrolled.

In the compact disc system, as in most storage or transmission of digital data, the A/D conversion data are transformed to cope with the characteristics of the storage medium. Such transformation, called modulation, involves (1) the addition of redundant information to the data, and (2) modulation of the combined data to compensate for medium characteristics (e.g., high-frequency losses). The modulation method for the compact disc system, called eight-to-fourteen modulation (EFM), is an 8-data-bit to 14-channel-bit conversion block code

FIGURE 20.4.8 Formats in the compact disc encoding system.

with a space of 3 channel bits (called merging bits) for every converted 14 channel bits for connecting the blocks. Figure 20.4.8 shows the format in the compact disc encoding, and Table 20.4.2 the disc specification.

The purpose of the redundant information is to be able to detect and correct errors that occur because of storage medium imperfections. It is important to minimize the probability of occurrence of such imperfections. The use of optical noncontacting readout from a signal surface protected by a plastic layer allows most of the signal errors at the surface to be reduced to random errors of several bits or larger burst errors. The error-correcting code, the cross-interleave Reed-Solomon code (CIRC), adopted in the standardization provides highly efficient detection and correction for errors of these types. It happens that the EFM modulation method and the CIRC error-correction method used in the compact disc system are well matched. This combination is credited with much of the system's success.

Between tape mastering and replication lies a complex and sophisticated disc mastering process which gets the information into the CD standard format and onto the surface of the CD disc master. Optical disc preparation, recording, development, electroplating, stamping, molding, and protection film coating are the major steps in the highly technological production process.

MiniDisc (MD) System

For optical digital discs to compete more favorably with digital audio tape, a recordable, erasable medium was needed. Magneto-optical discs combined the erasability of magnetic storage with the large capacity and long life of optical storage. An optical disc, with its digital data stream recordable in a tight spiral pattern, provides rapid track access for selective playback or re-recording.

TABLE 20.4.2 Specifications for a Compact Disc

Playing time: 75 min
Rotating speed: 1.2–1.4 m/s (constant linear velocity)
Track pitch: 1.6 μ m
Disc diameter: 120 mm
Disc thickness: 1.2 mm
Center hole: 15 mm
Signal surface: 50–116 ϕ mm (signal starts from inside)
Channel number: 2
Quantization: 16-bit linear per channel
Sampling rate: 44.1 kHz
Data rate: 2.0338 Mb/s
Channel bit rate: 4.3218 Mb/s
Error protection: CIRC (cross-interleave Reed-Solomon code), redundancy 25% ($4/3$)
Modulation: EFM (eight-to-fourteen modulation)

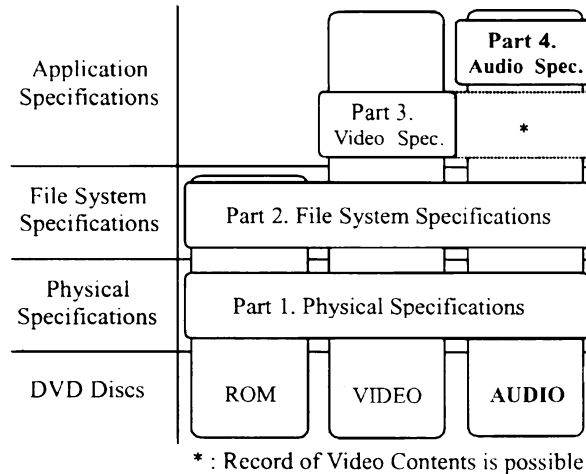

FIGURE 20.4.9 DVD specifications for DVD-ROM, DVD-video, and DVD-audio read only disks, parts 1 to 4.

On the blank disc is a thin film of magneto-optic material embedded within a protective layer, with all of the magnetic domains pointing north pole down (a digital zero). The magnetic field needed for reversal of polarity (to convert from zero to one) is very temperature dependent. At room temperature reversal requires a very strong magnetic field. However, at about 150°C only a small coercive force, provided by a dc magnetic bias field, is needed. During recording, a high-power laser beam, modulated by the digital data stream, heats microscopic spots on the rotating magneto-optic surface (within nanoseconds) to temperatures that allow the dc magnetic bias field to convert zeroes to ones. When the laser beam is off, the spots on the medium cool very rapidly, leaving the desired pattern of magnetic polarity. Erasure can be effected by repeating the procedure with the dc bias reversed.

Playback uses a low-power laser beam, which, because of the Kerr magneto-optic effect, has its plane of polarization rotated one way or the other depending on the magnetic polarity of the recorded bit. An optoelectronic playback head senses the polarization and delivers the digital playback signal.

The Sony magneto-optic MiniDisc is 6.4 cm (2½ in.) in diameter, half that of a CD. To compensate for reduced recording area, a digital audio compression technique called *adaptive transform acoustic coding* (ATRAC) is used. The analog signal is digitized at 44.1 kHz sampling frequency with 16-bit quantization. Waveform segments of about 20 ms and 1000 samples are converted to frequency components that are analyzed for magnitude by the encoder and compressed. Threshold and masking effects are used as criteria for disregarding enough data for an overall reduction of about 5 to 1. During playback, the ATRAC decoder regenerates an analog signal by combining the frequency components recorded on the magneto-optic disc. An added feature of the compression circuit is storage of 3 s of playback time when potential interruptions could occur owing to system shock or vibration.

Digital Versatile Disc-Audio (DVD-A)

DVD-Audio is a HiFi music format based on the same DVD technology as the DVD-Video discs and DVD-ROM computer discs, see Fig. 20.4.9. The disc structure is basically the same.

Recorded with current CD recording methods (PCM), DVD-Audio has a theoretical sampling rate of 192 kHz with 24-bit processing. Like Super Audio CD (SACD) and normal DVD-Video and DVD-Data formats, DVD-Audio discs can store 4.7-GB with a choice of 2-channel and 6-channel audio tracks or a mix of both (see Table 20.4.3).

Like SACD, information such as track names, artists' biographies, and still images can be stored. The format is supported by DVD-Video players made after about November 2000. Manufacturers are making audio machines compatible with playing both types of disc. Titles are available in both Dolby digital mix (so they are compatible on all DVD-Video players) and specific DVD-Audio (requiring the separate player).

TABLE 20.4.3 Specification of DVD-A

Audio combination	Configuration	Playing time in minutes (single layer)		Playing time in minutes (dual layer)	
		PCM	MLP	PCM	MLP
2 channels	48 kHz, 24 bits, 2 ch	258	409	469	740
2 channels	192 kHz, 24 bits, 2 ch	64	119	117	215
6 channels	96 kHz, 16 bits, 6 ch	64	201	117	364
5 channels	96 kHz, 20 bits, 5 ch	61	137	112	248
2 channels & 5 channels	96 kHz, 24 bits, 2 ch + 96 kHz, 24 bits, 3 ch & 48 kHz, 24 bits, 2 ch	43 each	79 each	78 each	144 each

Note: MLP is an acronym for Meridian Lossless Packing, a lossless coding scheme (see Lossless Coding section).

Super Audio CD

Super Audio CD is a new format. It uses direct stream digital (DSD) and a 4.7-GB disc with 2.8 MHz sampling frequency (i.e., 64 times the 44.1 kHz used in CD) enabling a very high quality audio format. Technical comparison between conventional CD and SACD is detailed in Table 20.4.4.

The main idea of the hybrid disc format (see Fig. 20.4.10) is to combine both well-known technologies, CD and DVD, respectively, to keep compatibility with the CD players in the market, and to use the existing DVD-video process tools to make a two-layer disc, i.e., to add a high-density layer to a CD reflective layer. As shown in Table 20.4.4, the storage capacity of the high-density layer is 6.9 times higher than the storage capacity of a conventional CD.

Direct Stream Digital

The solution came in the form of the DSD signal processing technique. Originally developed for the digital archiving of priceless analog master tapes, DSD is based on a 1-bit sigma-delta modulation together with a fifth-order noise-shaping filter and operates with a sampling frequency of 2.8224 MHz (i.e., 64 times the 44.1 kHz used in CD), resulting in an ultrahigh signal-to-noise ratio in the audio band.

TABLE 20.4.4 Comparison Between Conventional CD and SACD

	Conventional compact disc	Super Audio CD
Diameter	120 mm (4–3/4 in.)	120 mm (4–3/4 in.)
Thickness	1.2 mm (1/20 in.)	2 × 0.69 mm = 1.2 mm (1/20 in.)
Max. substrate thickness error	+/-100 μm	+/-30 μm
Signal sides	1	1
Signal layers	1	2: CD-density reflective layer + high-density semitransmissive layer
Data capacity		
Reflective layer	680 MB	680 MB
Semitransmissive layer	—	4.7 GB
Audio coding		
Standard CD audio	16-bit/44.1 kHz	16-bit/44.1 kHz
Super Audio	—	1-bit DSD/2.8224 MHz
Multichannel	—	6 channels of DSD
Frequency response	5–20,000 Hz	DC(0)–100,000 Hz (DSD)
Dynamic range	96 dB across the audio bandwidth	120 dB across the audio bandwidth (DSD)
Playback time	74 min	74 min
Enhanced capability	CD text	Text, graphics, and video

Hybrid Disc Content

Hybrid Disc Construction

Hybrid Disc Signal Reading

FIGURE 20.4.10 Hybrid disc content of the Super Audio CD (a), hybrid disc construction (b), and hybrid disc signal reading (c).

The Three Type of Super Audio CD

The SACD standard, published by Philips and Sony in March 1999, defines three possible disc types (see Fig. 20.4.10). The first two types are discs containing only DSD data; the single layer disc can contain 4.7 GB of data, while the dual layer disc contains slightly less than 9 GB. The third version—the SACD Hybrid—combines

a single 4.7 GB layer with a conventional CD that can be played back on standard CD players. (For more information see <http://www.sacd.philips.com/>)

RDAT

Rotary head digital audio tape (RDAT) is a semiprofessional recording format, an instrumentation recorder, and a computer data recorder.⁶ Mandatory specifications are:

- 2 channels (optional more)
- 48 or 44.1 kHz sampling rate
- 16 bits quantization
- 8.15 mm/s tape speed
- 2 h playing time (13 μ m tape)
- The cassette has a standardized format of $73 \times 54 \times 10.5$ mm, which is rather smaller than the compact cassette.

OTHER APPLICATIONS OF DIGITAL SIGNAL PROCESSING

The main applications of audio DSP are high-quality audio coding and the digital generation and manipulation of music signals. They share common research topics including perceptual measurement techniques and knowledge and various analysis and synthesis methods.⁷ Chen⁸ gives a review of the history of research in audio and electroacoustics, including electroacoustic devices, noise control, echo cancellation, and psychoacoustics.

Reverberation. For some years digital processing of audio signals has been used for special purposes (e.g., echo and reverberation effects) in systems that were otherwise analog in nature. The possibility was suggested by computer-generated “colorless” artificial reverberation experiments. When high-quality A/D and D/A conversion became economical, digital time-delay and reverberation units followed. Figure 20.4.11a is a block diagram of a digital audio reverberation system in which the complete musical impulse sound reaching a listener (Fig. 20.4.11b) consists of slightly delayed direct signal, followed by a group of simulated early reflections from a tapped digital delay line and a “reverberant tail” added to its envelope by a reverberation processor using multiple recursive structures to produce a high time density of simulated reflections.

Dither is used to prevent perceptually annoying errors like quantizers. It is a random “noise” process added to a signal prior to its (re)quantization in order to control the statistical properties of the quantization error.^{9,10} A common stage to perform dithering is after the various digital signal processing stages just ahead of the quantization before storing the signal or sending it to a digital-to-analog converter (DAC).

A special topic in signal processing for sound reproduction is overcoming the limitations of the reproduction set-up, e.g., reproduction of bass frequencies through small loudspeakers.¹¹ Another limitation is the distance between the two loudspeakers of a stereophonic setup. If one likes to increase the apparent distance, frequency dependent cross talk between the channels can be applied.¹²

Lossless Coding. Lossless compression is a technique to recode digital data in such a way that the data occupy fewer bits than before. In the PC world these programs are widely used and known under various names such as PkZip. For digital audio these programs are not very well suited, since they are optimized for text data and programs. Figure 20.4.12 shows a block diagram representing the basic operations in most lossless compression algorithms involved in compressing a single audio channel.¹³

All of the techniques studied are based on the principle of first removing redundancy from the signal and then coding the resulting signal with an efficient coding scheme. First the data are divided into independent frames of equal time duration in the range of 13 to 26 ms, which results in a frame of 576 to 1152 samples if a sampling rate of 44.1 kHz is used. Then the bits in each frame are decorrelated by some prediction algorithm as shown in Fig. 20.4.13.

The value of a sample $x[n]$ is predicted using the preceding samples $x[n-1]$, $x[n-2]$, ..., by using the filters A , B and quantizer Q . The error signal $e(n)$ that remains after prediction is in general smaller than x , and will therefore require fewer bits for its exact digital representation. The coefficients of the filters A and B are transmitted as well, which makes an exact reconstruction of $x[n]$ possible.

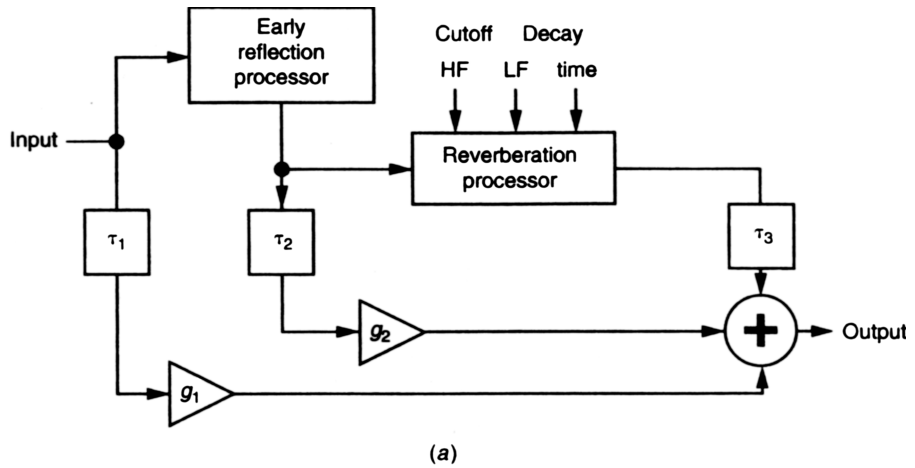

FIGURE 20.4.11 The basic operations in most lossless compression algorithms.

The third stage is an entropy coder, which removes further redundancy from the residual signal $e[n]$, and again in this process no information is lost. Most coding schemes use one of these three algorithms:

- Huffman, run length, and Rice coding, see Ref. 13 for more details
- Meridian Lossless Packing (MLP) for DVD-A
- Direct Stream Transfer for SACD

FIGURE 20.4.12 The basic operations in most lossless compression algorithms.

Watermarking. The advantages of digital processing and distribution of multimedia, such as noise-free transmission and the possibility of digital signal processing on these media, are obvious. The disadvantage, from the viewpoint of media producers and content providers, can be the possibility of unlimited copying of digital data without loss of quality. Digital copy protection is a way to overcome these problems. Another method is the embedding of digital watermarks into the multimedia.¹⁴

The watermark is an unremovable digital code, robustly and imperceptibly embedded in the host data and typically contains information about the origin, status, and/or destination of the data. While copyright protection is the most prominent application of watermarking techniques, other methods exist, including data authentication by means of fragile watermarks that are impaired or destroyed by manipulations, embedded transmission of value-added services, and embedded data labeling for other purposes than copyright protection such as monitoring and tracking.

Multimedia Content Analysis

Multimedia content analysis refers to the computerized understanding of semantic meanings of multimedia documents such as a video sequence with an accompanying audio track. There are many features that can be used to characterize audio signals. Usually audio features are extracted in two levels: short-term frame level and long-term clip level, where a frame is about 10 to 40 ms. To reveal the semantic meaning of an audio signal, analysis over a much longer period is necessary, usually from 1 to 10 s.¹⁵

Special Effects. If a single variably delayed echo signal ($\tau > 40$ ms) is added to direct signal at a low frequency (< 1 Hz), a sweeping comb filter sound effect is produced called *flanging*. When multiple channels of lesser delay (e.g., 10 to 25 ms) are used, a “chorus” effect is obtained from a single input voice or tone.

Time-Scale Modification. Minor adjustment of the duration of prerecorded programs to fit available program time can be accomplished digitally by loading a random-access memory with a sampled digital input signal and then outputting the signal with waveform sections of the memory repeated or skipped as needed under

FIGURE 20.4.13 General structure for prediction.

computer control, in order to approximate a continuous output signal of different duration. A related need, to change the fundamental (pitch) frequency of recorded speech or music without changing duration, involves the use of different input and output clock frequencies, along with repeating or skipping waveform segments as needed to retain constant duration.

Other digital audio components that offer advantages, or indeed are essential, once the system goes digital, include filters, equalizers, level controllers, background-noise reducers, mixers, and editors.

The compact disc, developed especially for audio uses, provides a multimegabyte storage technique, which is very attractive in many other applications for read-only memories. Conversely, in the evolution of telecommunication networks, new techniques for signal decomposition and reconstruction, and for echo cancellations, suggest further audio improvements in conference pickup and transmission, for example. The interchange between digital audio and other branches of digital communication continues.

MPEG Audio Coding General

Moving Picture Experts Group (MPEG) is well known for its developments of a series of standards for the coding of audiovisual content [<http://www.cseit.it/mpeg/>]. Initially targeted at the storage of audiovisual content on compact disc media, the MPEG-1 standard was finalized in 1992 and included the first generic standard for low-bit-rate audio within the audio part. Then the MPEG-2 standard was completed and extended MPEG-1 technology toward the needs of digital video broadcast. On the audio side, these extensions enabled coder operation at lower sampling rates (for multimedia applications) and coding of multichannel audio. In 1997 the standard of an enhanced multichannel coding system (MPEG-2 Advanced Audio Coding, AAC) was defined. The so-called MP3 is the popular name for MPEG-1 Layer III. Then the MPEG-4 standard was developed, with new functionalities such as object-based representation, content-based interactivity, and scalability; the MPEG-4 standard was developed in several steps (called versions), adding extensions to the basic technology for audio. Reference 16 describes in some detail the key technologies and main features of MPEG-1 and MPEG-2 audio coders. In 1996 the effort behind MPEG-7 was started. MPEG-7 defines a universal standardized mechanism for exchanging descriptive data that are able to characterize many aspects of multimedia content with a worldwide interoperability,¹⁷ or as the official name says, a “multimedia content description interface.” Work on the new standard MPEG-21 “Multimedia Framework” was started in June 2000. The vision for MPEG-21 is to define a multimedia framework to enable transparent and augmented use of multimedia resources across a wide range of networks and devices used by different communities.

SECTION 21

VIDEO AND FACSIMILE SYSTEMS

Although much of this section describes basic video and facsimile technologies that have not changed over the years, newer material is also included. For example, international agreement was reached recently on the use of 1920×1080 as a common image format for high-definition (HD) production and program exchange. The 1920×1080 format has its roots in the CCIR (Consultative Committee in International Radio) sampling standard and brings international compatibility to a new level.

Set-top boxes and high-definition or digital-ready TV sets will be the mechanism that brings digital technology to the consumer for the next several years as the transition from analog to digital takes place. In the United States, three modulation techniques have become “standards” in a particular application: vestigial sideband (VSB) for terrestrial, quadrature amplitude modulation (QAM) for cable, and quaternary phase-shift keying (QPSK) for direct-to-home satellite.

With Internet facsimile, store-and-forward facsimile occurs when the sending and receiving terminals are not in direct communication with one another. The transmission and reception takes place via the store-and-forward mode on the Internet using Internet e-mail. In this mode, the facsimile protocol “stops” at the gateway to the Internet. It is reestablished at the gateway leaving the Internet. Real-time facsimile is covered by Recommendation T.38 approved by the International Telecommunications Union, Telecommunications (ITU-T) in 2002. R.J.

CHAPTER 21.1

TELEVISION FUNDAMENTALS AND STANDARDS

James J. Gibson, Glenn Reitmeier

INTRODUCTION

This chapter summarizes analog and digital television signal standards and the principles on which they are based.

The technical standards for color television developed in 1953 for the United States by the National Television System Committee (NTSC) are described on a few pages in the rules of the Federal Communications Commission (FCC Rule Part 73). The rules only specify the radiated signal in sufficient detail for a receiver manufacturer to produce receivers, which convert this signal into a television picture with sound. This traditional approach to formulating standards leaves implementation to competitive forces. Since 1953 many international standards and recommended practices have evolved. A similar philosophy was used in the FCC's adoption of the Advanced Television System Committee (ATSC) digital television standards in 1996.

All color television standards are based on the same principles:

- The psychophysics of the human visual system (HVS).
- Picture-signal conversion by sampling/display, at field rate, of three primary colors in a flat rectangular dynamic picture on a raster of horizontal scan lines, scanned from left to right and top to bottom.
- The signals are conveyed as three components: one luminance signal, which essentially provides brightness information, and two chrominance signals which essentially provide hue and color saturation information.
- For radio frequency transmission these three signals and audio signals are multiplexed to form a single r.f. signal, which occupies a channel in the frequency spectrum.

Some of these principles are illustrated in Fig. 21.1.1, which shows a block diagram of a standard analog television system for terrestrial broadcasting. The figure shows that the video and audio signals are multiplexed separately to form *composite video and audio signals*, which are subsequently delivered to separate picture and sound transmitters generating signals, which are diplexed to form a radiated signal that occupies a 6, 7, or 8 MHz band in the radio frequency spectrum from 40 to 900 MHz. This is the usual practice in broadcasting of analog television signals in the NTSC, PAL (Phase Alternation Line), and SECAM (Séquentiel à mémoire) systems. These systems, which are compatible with black and white reception, use frequency division multiplex: The chrominance signals are bandlimited and modulate one or two subcarriers that are “inconspicuously” added to (multiplexed with) the luminance signal. Besides analog television terrestrial broadcast standards, there are many standards for analog television production, storage, and distribution (terrestrial, satellite, and cable) developed by several organizations. In analog television there are two picture scanning standards specified as N/F_v where N = total number of scanning lines and F_v = number of picture fields per second. These standards are 625/50 and 525/60 (including

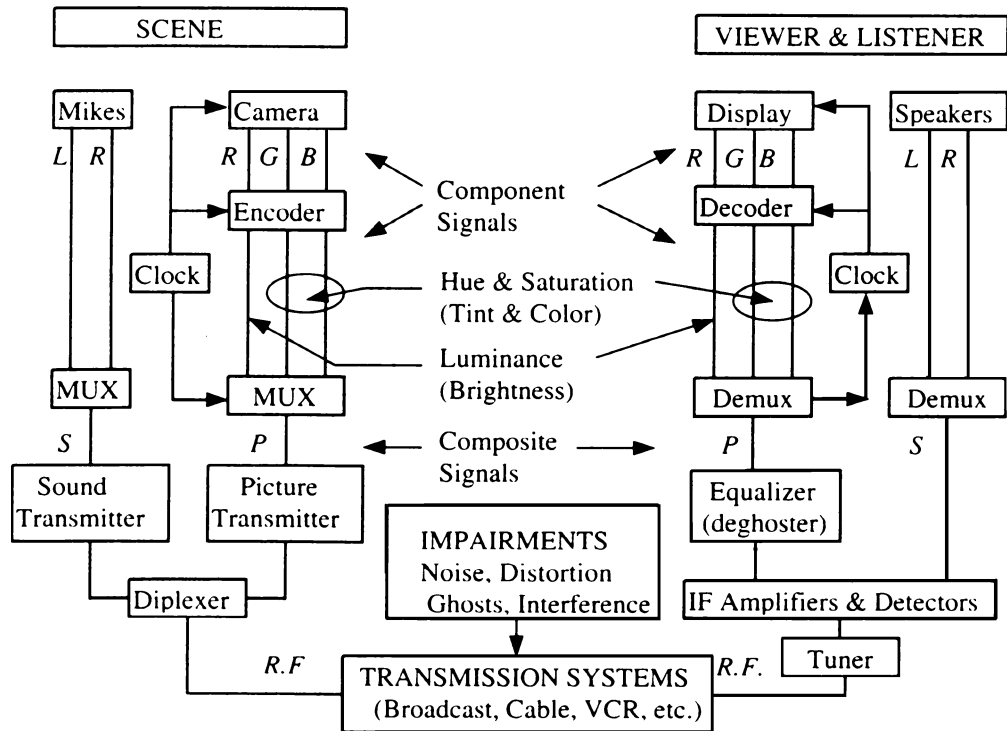

FIGURE 21.1.1 Functional block diagram of a standard analog television broadcast system. Some systems may multiplex sound and picture before delivery to a transmitter.

525/59.94). There are three basic *composite color video signal standards* that carry all the color information in one signal: NTSC, PAL, and SECAM. In addition there are nine standards (with variations) describing the radiated signal carrying the composite color video signals with various types of r.f. modulation and bandwidths and with various standards for audio signals and audio signal modulation. These nine standards are referred to as B, G, H, I, K, K1, L, M, N. Only system M is of type 525/60.

In digital television (DTV), the three component signals and audio are sampled, digitized, and data compressed to eliminate redundant and psychophysically irrelevant data. Digital signals use available spectrum more effectively than analog signals. Digital television standards have been developed with consideration for flexibility, extensibility (for future applications), and interoperability with other systems for information production and distribution (e.g., computers).

In 1982 the Radio Consultative Committee of the International Telecommunications Union (ITU-R), formerly called the International Radio Consultative Committee (CCIR) adopted an international digital television component standard, ITU-R Recommendation 601. In this chapter this important standard is referred to by its popular old designation: CCIR601. This standard was primarily intended for production and for tape recording (SMPTE format D-1), but is now used in many applications, including DTV transmission.

In digital television (DTV), including high-definition television (HDTV), digital techniques are used for video compression, data transport, multiplexing, and r.f. transmission. DTV promises to be more than television, in the sense that it delivers to homes a digital channel with high data rate which may carry more than high quality pictures and sound. Of particular importance are the standards developed by the Moving Picture Expert

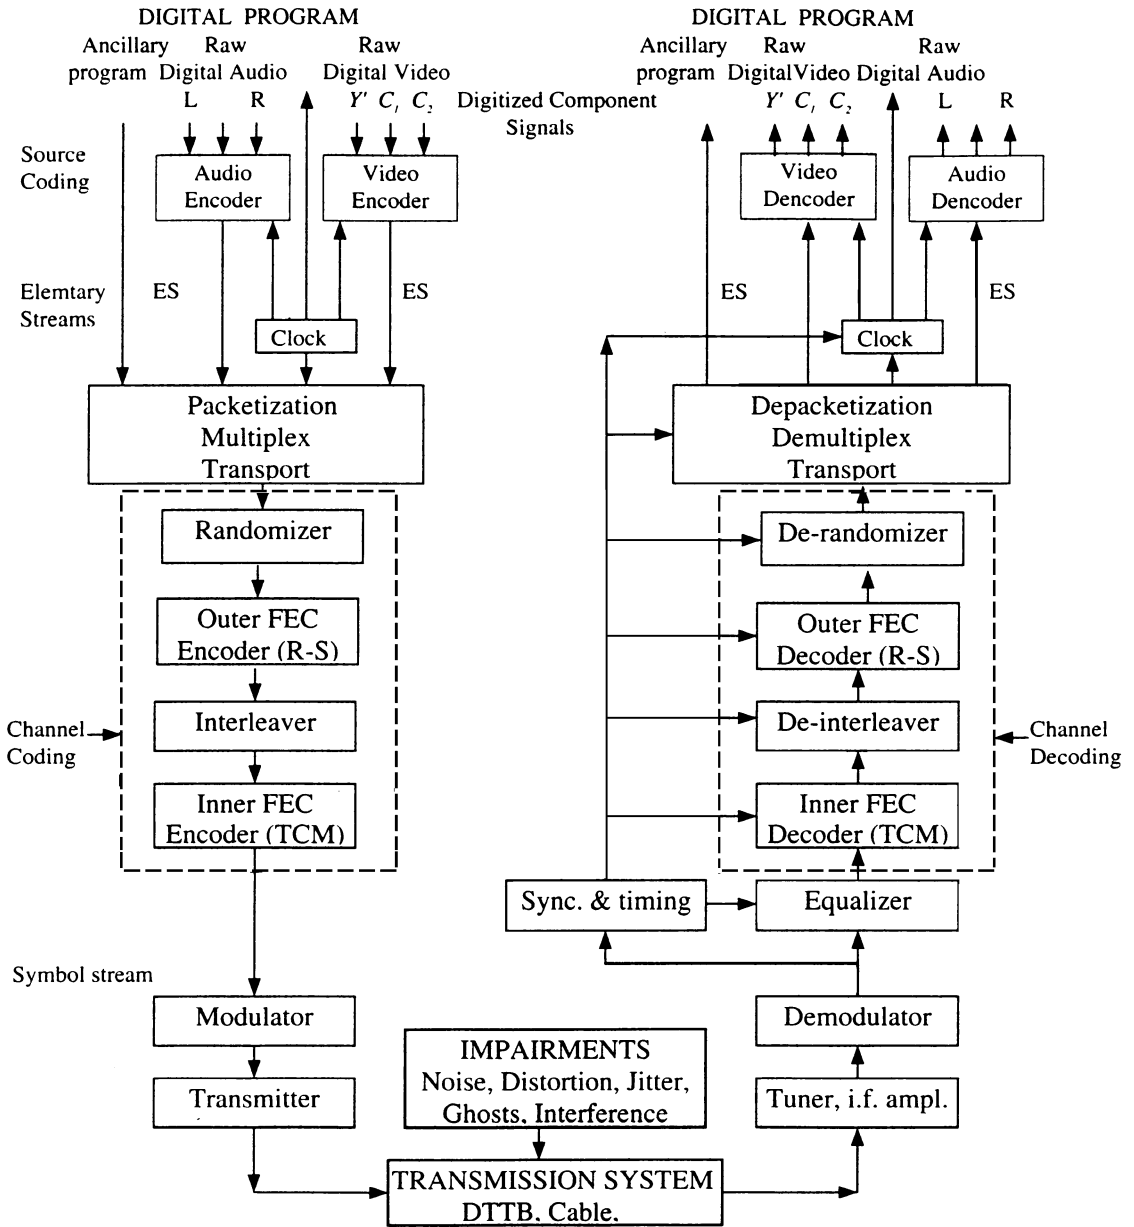

FIGURE 21.1.2 Functional block diagram of a standard television broadcast system. Different modulation techniques and signal bandwidths are used for different transmission media.

Group (MPEG) of ITU. MPEG standards are quite flexible, but include specific approaches to television data compression and packetization. MPEG standards have been adopted by the International Standards Organization (ISO) and the International Electro-technical Committee (IEC). Based on the MPEG-2 format, the FCC Advisory Committee on Advanced Television Systems (ACATS) provided oversight for the development

21.6 VIDEO AND FACSIMILE SYSTEMS

of a “Grand Alliance,” a system for high-definition digital television (HDTV) for North America. The Grand Alliance itself was comprised of AT&T, General Instrument, Massachusetts Institute of Technology, Philips, Sarnoff, Thomson, and Zenith, which joined forces to forge a single best-of-the-best system from four competing system proposals. The Grand Alliance system is the basis of the ATSC digital television standard and the FCC digital broadcast standards for the United States adopted in 1996.

Figure 21.1.2 shows basic functional blocks of the “Grand Alliance” HDTV system. The basic principles listed above for analog systems still apply to this digital system. The video and audio components are basically the same as in the analog system shown in Fig. 21.1.1, but source coding (removal of irrelevant and redundant data), ancillary signals, multiplexing, transport, packetization, channel coding (for error management), and modems are entirely different.

In both analog and digital systems, the relation between the picture, as observed by a viewer, and the signals is not a simple one. Signal quality measures are not easily related to the subjective quality of pictures. In fact, there are very few objective measures of picture quality, while there are many objective measures of signal quality and signal tolerances. The selection of television standards, including recent HDTV standards, are based on subjective picture quality evaluations. Relations between signal quality and picture quality in NTSC, PAL, and SECAM are fairly well known. Numerous measurement and monitoring techniques using test signals have been developed for these signals. Relations between objective measures of signal quality and picture and sound quality are not as well correlated in digital television and HDTV.

Ongoing work on digital TV standardization is carried out by numerous committees. ATSC continues to develop its terrestrial transmission standard. The Society of Cable Telecommunications Engineers (SCTE) develops standards for cable transmission. The Digital Video Broadcast (DVB) group also continues to develop its standards for terrestrial (DVB-T), cable (DVB-C), and satellite (DVB-S) transmission. The Society of Motion Picture and Television Engineers (SMPTE) is involved in standards for related professional production equipment. The Consumer Electronics Association (CEA) establishes industry standards for consumer equipment.

PHOTOMETRY, COLORIMETRY, AND THE HUMAN VISUAL SYSTEM

Radiance and Luminance

The HVS is sensitive to radiation over a 2:1 bandwidth of wavelengths extending from 380 to 760 nm, i.e., from extreme blue to extreme red. When adapted to daylight it is most sensitive to green light at 555 nm. As the wavelength of monochromatic light departs from 555 nm, the *radiance* (radiation from a surface element in a given direction defined by the angle Θ from the normal and measured in watts/steradian per unit projected area = the actual surface of the radiating element times $\cos\Theta$) must be increased for constant perception of brightness. The International Commission on Illumination (CIE) has standardized the response versus wavelength of the HVS $\bar{y}(\lambda)$ of a standard observer adapted to daylight vision (photopic vision). Figure 21.1.3 shows $\bar{y}(\lambda)$ versus λ . Luminance, sometimes referred to as brightness and measured in cd/m^2 , *Candelas per projected area in m^2* , is defined as

$$Y = 680 \int_0^{\infty} E(\lambda) \bar{y}(\lambda) d\lambda \quad \text{cd}/\text{m}^2 \quad E(\lambda) = \text{spectral density of radiance in } (\text{W}/\text{nm})/\text{m}^2 \quad (1)$$

where λ is the wavelength in nanometers. Older units for luminance are: a footlambert (ft.L) = 3.42626 cd/m^2 and a millilambert (mL) = 3.18310 cd/m^2 .

A surface is *diffuse* at a wavelength λ if $E(\lambda)$ is independent of the direction Θ . The face plate of a TV tube is essentially diffuse for all wavelengths of visible light, but this may not be the case for a projection screen. Thus the luminance of the face-plate of a picture tube is roughly independent of the direction from where it is seen. Typically the peak luminance levels of picture tubes is about 120 cd/m^2 , but bright displays may have luminance levels exceeding 250 cd/m^2 . The luminance of bright outdoor scenes may well exceed 10,000 cd/m^2 .

FIGURE 21.1.3 Tristimulus values of the CIE nonphysical primaries, $\bar{z}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{x}(\lambda)$. Note that $\bar{y}(\lambda)$ is the CIE standard luminosity function.

while a motion picture screen may be 30 cd/m^2 . *Equal Energy Radiation*, $E(\lambda) = \text{constant}$, appears to have the color “white.” Corresponding radiometric and photometric units are:

Radiant flux	Watt	Luminous flux	Lumens
Irradiance	Watt/m ²	Illuminance	Lux = lumens/m ²
Radiant intensity	Watt/steradian	Luminous intensity	Candela = lumens/steradian
Radiance	(Watt/steradian)/m ²	Luminance	Candela/m ²

At $\lambda = 555 \text{ nm}$ there are 680 lm/w . Without a color filter, the illuminance I of a target in a camera or of the retina of an eye is proportional to the luminance Y of the scene (theoretically $I \cong \pi Y/4(\text{f-number of the lens})^2$).

Contrast and Resolution

The HVS is sensitive to relative changes in luminance levels. The just noticeable difference (JND) between the luminance $Y + \Delta Y$ of a small area and the luminance Y of a surrounding large area can be expressed by the ratio

$$F = \Delta Y/Y \quad (2)$$

where F is the *Fechner ratio*.

The Fechner ratio is remarkably constant over the large range of the high luminance levels used in TV displays. It ranges from 1 percent for $Y > 10 \text{ cd/m}^2$ up to 2 percent at $Y = 1 \text{ cd/m}^2$. Assuming a constant Fechner ratio, the number of distinguishable small area gray levels between a “black” level Y_b and a highlight “white” level Y_w is

$$n \cong (\ln Y_w/Y_b)/F \quad \text{or} \quad Y_w/Y_b \cong \exp(nF) \cong (1 + F)^n = \text{contrast} \quad (3)$$

For example, for $n = 255$ levels (8-bit quantization of log luminance) and $F = 1.5$ percent, the contrast is 45. With 9 bits (511 levels @ 1 percent) the contrast is 165. Contrast rarely exceeds 50:1 in TV displays owing to ambient light and light scattered within the picture tube. Thus, due to the contrast available in consumer displays, DTV systems use 8-bit luminance (and chrominance) signals.

21.8 VIDEO AND FACSIMILE SYSTEMS

More relevant test patterns for measuring the contrast sensitivity of the HVS are luminance sinewave gratings added to a uniform background luminance level. The contrast ratio of a sinewave grating, also referred to as *modulation*, is defined as:

$$m = (Y_{\max} - Y_{\min}) / (Y_{\max} + Y_{\min}) = (\text{luminance amplitude/average luminance}) \quad (4)$$

The just perceptible modulation (JPM) of a stationary sinewave grating is sensitively dependent on a large number of factors: the spatial frequency ν of the grating expressed in cycles per degree (cpd), the average luminance level, the orientation of the wavefront, the adaptation of the pupil of the eye, and ambient factors. If the line from the eye to the observed point is perpendicular to the picture, ν cycles per degree can be converted into k cycles per picture height (cph) by multiplication with $57.3/D$, where D is the viewing distance in picture height. The most sensitive m is 0.3 percent at about $3.5 \text{ cpd} = 200/D \text{ cph}$ and increases to 100 percent at about $35 \text{ cpd} = 2000/D \text{ cph}$ (500 cph @ $D = 4$). This upper limit can be taken as an estimate of the resolution limit of the HVS. TV systems have been designed with HVS characteristics in mind. Analog and standard definition (SD) digital systems assume $D = 6$; therefore, the HVS resolution limit is approximately 383 cph. HDTV systems assume a larger display or closer viewing, $D = 2$; therefore, the HVS resolution limit is approximately 1000 cph.

The ratio of the perceived to the displayed modulation is the modulation transfer function (MTF) of the HVS. It rolls off with spatial frequency depending on a number of parameters including the adaptation of the pupil of the eye. It is down about 6 dB at $750/D \text{ cph}$ for a luminance of 140 cd/m^2 . One performance measure of a TV system is its MTF = ratio of displayed $m(k)$ to input $m(k)$ versus spatial frequency for various orientations of the wavefront of the grating.

The eye has high resolution only within a sustained angle of about 2° . For $D = 6$ this is 2.5 percent of a TV display area. The remaining area is viewed with low resolution rod vision which is sensitive to flicker.

Gamma "Pre-Correction"

Since the HVS is sensitive to contrast, it can tolerate more noise and larger luminance errors in bright areas than in dark areas. Since noise and errors are added to the luminance signal during transmission, the visibility of the added noise is reduced if the luminance signal is compressed at the source and expanded in the receiver. A constant Fechner ratio suggests logarithmic compression and exponential expansion of the luminance, a proposal that was recommended by the NTSC in 1941 and is still allowed in the FCC rules for black and white TV. In the early days of black and white TV, it was found, however, that the picture tube itself acted as a good and inexpensive expander. The displayed luminance Y on the face plate of a picture tube in response to an applied signal voltage V is approximately equal to:

$$Y = \text{const.} \times V^\gamma \quad (5)$$

where γ is *gamma* ranges from 2 to 3. Assuming that the output signal Y from a TV camera is proportional to the illuminance of the target (a fair assumption for modern cameras), the luminance signal Y delivered by such a linear camera is compressed right at the output of the camera to yield a *gamma* "corrected" luminance signal, which, in black and white TV, is approximately proportional to $Y^{1/\gamma}$. In DTV systems, the same practice continues to be employed, both for reducing the visibility of compression-related artifacts as well as maintaining compatibility with legacy analog systems, which is an economic consideration in dual digital/analog receivers. Table 21.1.1 shows standards for gamma and modifications of Eq. (5) in recent standards.

Flicker

The human visual system is quite sensitive to large area luminance fluctuations at frequencies below 100 Hz (flicker). The critical flicker frequency f_f Hz (threshold of perception) is determined by on-off modulation of the luminance of a large area. The critical frequency increases, according to the "Ferry-Porter law," in proportion to the logarithm of the highlight $Y \text{ cd/m}^2$ of the luminance:

$$f_f = 30 + 12.5 \log_{10}(Y \text{ cd/m}^2) \quad \text{Hz} \quad (6)$$

TABLE 21.1.1 Standards for Electro-Optical Transfer Characteristic: $V = F(L)$, $L = F^{-1}(V)$ Example: $R' = F(R = R)$ in “gamma corrector;” $R = F^{-1}(R')$ in display

SYSTEM	γ (gamma)	V_o (bias)	k (slope)	L^*	V^*
NTSC	2.2	0	0	0	0
PAL/SECAM	2.8	0	0	0	0
TU R-709, SMPTE170M, SMPTE274M	1/0.45	0.099	4.5	0.018	0.081
SMPTE 240M	1/0.45	0.1115	4	0.0228	0.0912

$V = \text{normalized electric signal level}$ and $L = \text{normalized optical stimulus level (at Maximum level } V = L = 1 \text{ by definition)}$:
 $V = F(L) : V = kL$ for $0 \leq L < L^*$ and for $L^* \leq L \leq 1$ $V = (1 + V_o)L^{1/\gamma} - V_o$
 $L = F^{-1}(V) : L = V/k$ for $0 \leq V < V^* = kL^*$ and for $V^* \leq V \leq 1$ $L = [(V + V_o)/(1 + V_o)]^\gamma$

The result varies with individuals and with the adaptation of the eye. It shows that f_f increases by about 12.5 Hz when Y increases by a factor of 10. For example, f_f is 48, 50, and 60 Hz for a peak luminance $Y = 25.4, 36.6,$ and 227.6 cd/m^2 . The HVS is more sensitive to flicker for light entering the eye at an angle (rod vision). In motion pictures the picture frame rate is 24 pictures per second. To avoid flicker at acceptable luminance levels, every picture is shown at least twice, when the film is projected (this is referred to as double-shuttering). In television the frame rate is 25 Hz in most of the world and 30 Hz in the United States, Japan, and some other countries. In all analog TV systems, large area flicker rates are doubled by using two fields with interlaced scan lines to complete a frame.

DTV systems decouple the display frame rate and the transmitted frame rate. DTV systems generally support the legacy analog frame rates and interlaced scanning formats, and additionally provide new capabilities for progressive scan formats and film-related frame rates.

Color Space, Color Primaries, and CIE Chromaticities

It is a fact that a wide range of colors can be reproduced with only three sources of light, e.g., red, green, and blue. The basic laws of *colorimetry*, the science devoted to color vision are:

- The HVS can only perceive three attributes of color: *brightness*, *hue*, and *saturation*, more precisely defined as *luminance*, *dominant wavelength*, and *purity*.
- Colors can be represented as vectors in a three-dimensional linear vector space referred to as *color space*. Colors add and subtract as vectors, but a distance in color space is not a measure of perceived difference in colors. In color space the luminance component $Y \geq 0$ traditionally points up from a horizontal chrominance plane $Y = 0$.

Figure 21.1.4 shows a color vector $\mathbf{A} = Y\mathbf{W} + \mathbf{C}$ as the sum of a white vector $Y\mathbf{W}$ with the same luminance (brightness) Y as \mathbf{A} and a chrominance vector \mathbf{C} in a constant luminance plane with an orientation related to hue (tint) and a magnitude related to saturation (color).

Based on experiments with hundreds of observers matching colors composed of monochromatic light of different wavelengths, the CIE standardized X- and Z-axes at right angles in the chrominance plane, such that all color vectors have nonnegative components X, Y, Z, and that $X = Y = Z$ for equal energy light. Thus, basis-vectors $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ with unit length along the XYZ-axes are *artificial or nonphysical primary vectors*. The X, Y, Z components of monochromatic colors all having the same radiance are $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ (Fig. 21.1.3). Given a color with a radiance having a spectral power density $E(\lambda)$ (radiance per nm), the relative X, Y, Z components are

$$X = \int_0^\infty E(\lambda)\bar{x}(\lambda)d\lambda \quad Y = \int_0^\infty E(\lambda)\bar{y}(\lambda)d\lambda \quad Z = \int_0^\infty E(\lambda)\bar{z}(\lambda)d\lambda \quad (7)$$

FIGURE 21.14 Representation of a color as a vector \mathbf{A} with three attributes luminance (brightness), hue (tint), and saturation. \mathbf{A} has a vertical luminance component Y . \mathbf{A} is the sum of a white vector $Y\mathbf{W}$, which has the same luminance as \mathbf{A} , and a chrominance vector \mathbf{C} , which is in the constant luminance plane.

Since $X = Y = Z$ for equal energy white ($E = \text{const.}$), the areas under the curves $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ are the same. Clearly lights with different spectral content $E(\lambda)$ can have the same color. The direction of a color vector is specified by the point $[x, y, z]$ where the vector or its extension penetrates the unit plane $X + Y + Z = 1$.

$$[x, y, z] = [X, Y, Z]/(X + Y + Z) \quad (8)$$

thus $x + y + z = 1$ and $Y/y = X/x = Z/z = X + Y + Z = \text{“gain.”}$

The coordinates x, y, z are referred to as the *CIE chromaticities* of the color. Clearly $z = 1 - x - y$ is redundant. It is common and practical to specify a color vector \mathbf{A} by chromaticities x and y and luminance Y as

$$\mathbf{A} = [X, Y, Z] = (Y/y)[x, y, 1 - x - y] \quad (9)$$

Figure 21.1.5 shows the CIE color space and the CIE chromaticity plane penetrated by color vectors or their extensions. Figure 21.1.6 shows the horseshoe-shaped locus of the xy -chromaticities of monochromatic light $[x(\lambda), y(\lambda)] = [\bar{x}(\lambda), \bar{y}(\lambda)]/[\bar{x}(\lambda) + \bar{y}(\lambda) + \bar{z}(\lambda)]$. All realizable chromaticities are within the horseshoe. The magenta colors along the straight line from extreme blue to extreme red are not monochromatic, but are obtained as red-blue mixtures. Areas in the CIE chromaticity chart of just noticeable differences in chromaticities (JNDs) are shaped like ellipses which are larger in the green area than in the red area, which in turn are larger than in the blue area. The number of chromaticities (color vector directions) required for perfect color reproduction has been estimated to range from 8000 (13 bits) to 130,000 (17 bits). The number of chromaticity JNDs within the color gamuts of current display devices has been estimated to be about 5000. In television standards all color vectors are defined in CIE color space.

The CIE components, X, Y, Z are not practical. Television standards specify realizable red, green, and blue *primary colors* $\mathbf{R}, \mathbf{G}, \mathbf{B}$, which are not in the same plane. In terms of these primaries a color is represented as a vector

$$\mathbf{A} = [X, Y, Z] = \mathbf{R}\mathbf{R} + \mathbf{G}\mathbf{G} + \mathbf{B}\mathbf{B} = \mathbf{Y}\mathbf{W} + \mathbf{C} \quad (10)$$

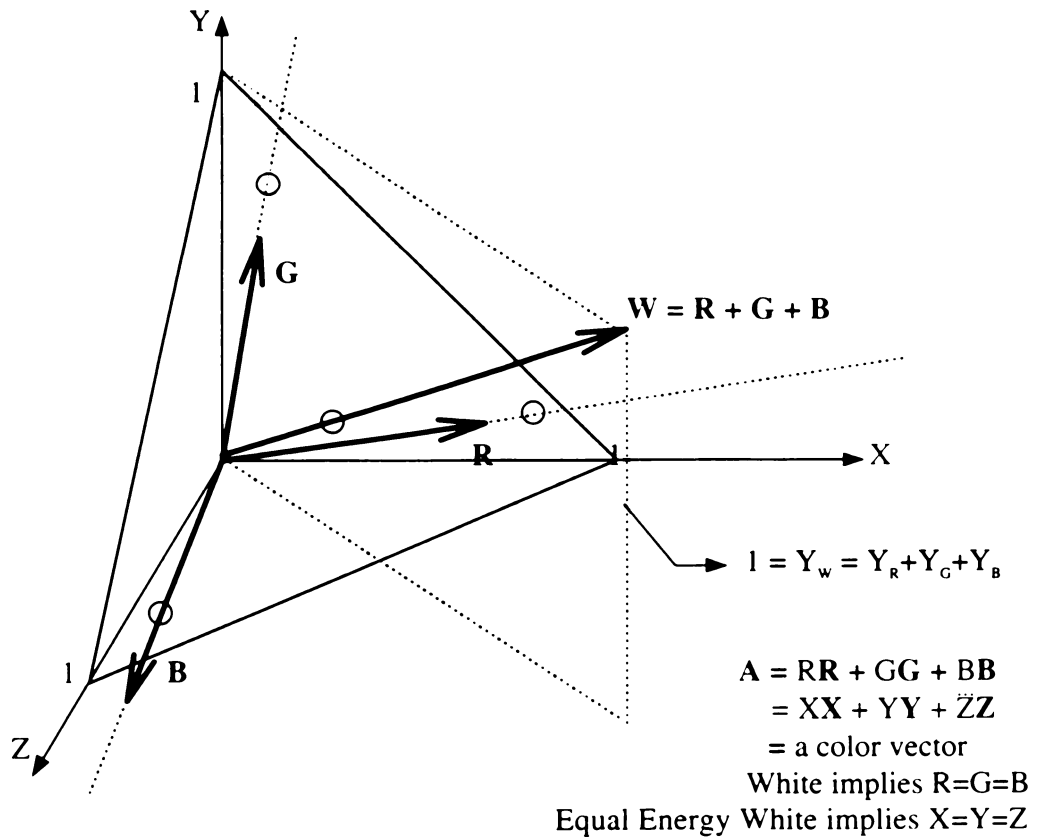

FIGURE 21.15 CIE color space with CIE chromaticity plane $X + Y + Z = 1$. The CIE chromaticities of a color vector are the coordinates x , y , and $z = 1 - x - y$, where the vector or its extension penetrates the CIE chromaticity plane. These points are shown for a set of R , G , B basis vectors and the associated white vector W , which by definition has a luminance of unity. X , Y , Z are unit vectors along the X , Y , Z axes.

where R , G , B are *tristimulus values* = quantity of each primary color in the mixture. The luminance Y of A multiplies a “reference white vector” $W = R + G + B$, which, by definition, has a luminance component normalized to unity ($Y_w = 1$). Thus *chrominance vector* C is in a *constant luminance plane* ($Y_c = 0$). The luminance components of R , G , and B are Y_r , Y_g , and Y_b , respectively. Consequently:

$$Y = Y_r R + Y_g G + Y_b B = \text{the luminance component of } A \quad (11a)$$

$$1 = Y_r + Y_g + Y_b = \text{normalized luminance component of the white vector } W \quad (11b)$$

$$W = R + G + B = \text{white vector with luminance component } Y_w = 1 \quad (11c)$$

$$C = M(R - Y) + N(B - Y) = \text{chrominance vector with luminance component } Y_c = 0 \quad (12a)$$

$$M = R - (Y_r/Y_g)G = \text{the } R - Y \text{ basis vector in the chrominance plane} \quad (12b)$$

$$N = B - (Y_b/Y_g)G = \text{the } B - Y \text{ basis vector in the chrominance plane} \quad (12c)$$

FIGURE 21.1.6 The xy -chromaticity diagram of the CIE system. Also shown are television standard rgb chromaticities and white illuminants. *The EBU x -coordinate for green is 0.29.

A white vector implies $C = 0$ and $R = G = B = Y$. Equation (12) is derived from Eqs. (10) and (11). Figure 21.1.5 shows vectors \mathbf{R} , \mathbf{G} , \mathbf{B} , and \mathbf{W} . Figure 21.1.7 shows the vectors \mathbf{M} and \mathbf{N} . Given the X, Y, Z components of the primaries $\mathbf{R}, \mathbf{G}, \mathbf{B}$ the R, G, B tristimuli can be related to the CIE tristimuli X, Y, Z by a matrix P as:

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = P \begin{pmatrix} R \\ G \\ B \end{pmatrix} = \begin{pmatrix} X_r & X_g & X_b \\ Y_r & Y_g & Y_b \\ Z_r & Z_g & Z_b \end{pmatrix} \begin{pmatrix} R \\ G \\ B \end{pmatrix} \quad (13)$$

RGB components of two different basis systems (e.g., NTSC and PAL) specified by matrices P_1 and P_2 are related by a matrix $P_1 P_2^{-1}$ where P^{-1} is the inverse of P . In television standards the $\mathbf{R}, \mathbf{G}, \mathbf{B}$ primaries

FIGURE 21.1.7 The rgb chromaticity plane goes through the tips of the basis vectors **R**, **G**, and **B**. It intersects the chrominance plane along the alychne. Also shown are the CIE basis vectors **X**, **Y**, and **Z** and the basis vectors used in television **Y**, **M**, and **N**. The chrominance values defined by the chrominance basis vectors **M** and **N** are the “color difference” values $M = R - Y$ and $N = B - Y$.

are specified by their CIE chromaticities and by the chromaticity of **W** (illuminant). The luminance values of the primaries Y_r, Y_g, Y_b can be derived from these eight standardized chromaticities by inverting the matrix **P** for the white vector $R = G = B = Y_w = 1$ and noting that $X/Y = x/y$ and $Z/Y = z/y$ and that $Y_r + Y_g + Y_b = 1$:

$$\begin{pmatrix} X_w \\ Y_w \\ Z_w \end{pmatrix} = \begin{pmatrix} x_w/y_w \\ 1 \\ z_w/y_w \end{pmatrix} = \begin{pmatrix} x_r/y_r & x_g/y_g & x_b/y_b \\ z_r/y_r & z_g/y_g & z_b/y_b \end{pmatrix} \begin{pmatrix} Y_r \\ Y_g \\ Y_b \end{pmatrix} \tag{14}$$

Given the **Y** values of the primaries, the **X** and **Z** values can be determined by Eq. (9). Table 21.1.2 lists the *xy*-chromaticities and the luminance values of the primaries in standard TV systems. Figure 21.1.6 shows the NTSC, ITU-R709 (SMPTE274M), EBU, and the SMPTE170M (SMPTE240M) chromaticities in the CIE diagram. Television programs are produced with the assumption that display devices have (phosphors with) these chromaticities. The chromaticities of the primaries of a display device can be marked as corners of a triangle in Fig. 21.1.6. Since the tristimuli **R**, **G**, **B** are nonnegative (see Figs. 21.1.5 and 21.1.7, only colors with chromaticities within the triangle can be displayed.

TABLE 21.1.2 Chromaticities and Luminance Components in Standard Television Systems. White Illuminant (last row) is C in NTSC, Otherwise D₆₅. Note that ITU-R709 is Almost the Same as EBU, and That NTSC Accommodates More Green Colors

	NTSC (FCC) System M			ITU-R709 & SMPTE274 EBU* (PAL* & SECAM*)			SMPTE 170M & 240M		
	x	y	Y	x	y	Y	x	y	Y
Red	0.67	0.33	0.299	0.64	0.33	0.2125 0.222*	0.630	0.340	0.212
Green	0.21	0.71	0.587	0.30	0.60	0.7154 0.29* 0.707*	0.310	0.595	0.701
Blue	0.14	0.08	0.114	0.15	0.06	0.0721 0.071*	0.155	0.070	0.087
White	0.3101	0.3162	1	0.3127	0.3291	1	0.3127	0.3291	1

In television the key components are R - Y, Y, and B - Y of the **M, W, N** primaries. They are related to the tristimuli *R, G, B* by the matrix *H*:

$$\begin{pmatrix} R - Y \\ Y \\ B - Y \end{pmatrix} = H \begin{pmatrix} R \\ G \\ B \end{pmatrix} = \begin{pmatrix} 1 - Y_r & -Y_g & -Y_b \\ Y_r & Y_g & Y_b \\ -Y_r & -Y_g & 1 - Y_b \end{pmatrix} \begin{pmatrix} R \\ G \\ B \end{pmatrix}, \quad \begin{pmatrix} R \\ G \\ B \end{pmatrix} = \begin{pmatrix} 1 & 1 & 0 \\ -Y_r + Y_g & 1 & -Y_b - Y_g \\ 0 & 1 & 1 \end{pmatrix} \begin{pmatrix} R - Y \\ Y \\ B - Y \end{pmatrix} \quad (15)$$

Two colors are said to be *complementary* if some weighted mixture of them results in a white color **WW**. Saturated complementary colors to the primaries **R, G, B** are Cyan **CY = G + B**, Magenta **MA = B + R** and Yellow **YE = R + G**. If a primary has components M, Y, N, the saturated complementary color has components -M, 1 - Y, -N. The RGB and MYN values of these basic colors in NTSC, ITU-R709 & SMPTE274M, and SMPTE240M are listed in Table 21.1.3. The EBU colors in PAL & SECAM differ only slightly (third decimal) from ITU-R709. These saturated colors can be seen on TV as color bars.

The rgb-Chromaticities and the Color Triangle

Figure 21.1.7 shows a plane connecting the tips of the primary vectors **R, G, B**. This plane is referred to as the *rgb-chromaticity plane*, not to be confused with the CIE *xyz-chromaticity plane*. A color vector **A = RR + GG + BB = (R + G + B)(rR + gG + bB)** has *rgb-chromaticities* = [r,g,b] = [R,G,B]/(R + G + B). Clearly g = 1 - r - b is redundant. An *rgb-chromaticity vector* is conveniently represented as **G + r(R - G) + b(B - G)**.

TABLE 21.1.3 Values of Y, M = R - Y and N = B - Y for Saturated Colors

COLOR	R G B	NTSC			ITU-R709 & SMPTE 274M			SMPTE 240M & 170M

Red	1 0 0	0.299	+0.701	-0.299	0.213	+0.787	-0.213	0.212	+0.788	-0.212
Blue	0 0 1	0.114	-0.114	+0.886	0.072	-0.072	+0.928	0.087	-0.087	+0.913

The rgb-chromaticity of the white vector \mathbf{W} is $r = g = b = 1/3$. Figure 21.1.7 also shows that the \mathbf{GR} and \mathbf{GB} planes intersect the chrominance plane along the $M = R - Y$ and $N = B - Y$ axes. The xyz chromaticities are nonlinearly related to the rgb chromaticities. The relations are easily determined with Eq. 13, given $[R,G,B] = [r,g,b]$ or $[X,Y,Z] = [x,y,z]$. The figure also shows a line, the *alychne* (no light), which is the intersection of the rgb-chromaticity plane and the chrominance plane $Y = 0$.

The tips of the \mathbf{R} , \mathbf{G} , and \mathbf{B} primary vectors are the corners of the *color triangle*. The rgb-chromaticities of the saturated complementary colors, cyan, magenta, and yellow, are midpoints on the sides of the triangle. The color triangle can be mapped to take more convenient shapes, for example, in a right angle or coordinate system. Figure 21.1.6 shows color triangles for some television standards first polar-projected onto the CIE chromaticity plane and subsequently parallel projected onto CIE xy -chromaticity diagram. Display devices using the standard chromaticities can only display colors with chromaticities inside the color triangle (nonnegative R, G, B tristimuli).

Relation Between Chromaticities and Chrominance-to-Luminance Ratios

Since $R - Y, Y, B - Y$ are related to signals in TV transmission, it is of interest to relate the ratios R/Y and B/Y to the xyz (CIE) chromaticities. In the CIE chromaticity diagram (Fig. 21.1.6) all lines $R/Y = \text{constant}$ go through the intersection of the projection of the green-blue side ($R/Y = 0$) of the color triangle with the x -axis and all $B/Y = \text{constant}$ lines go through the intersection of the projection of the green-red side ($B/Y = 0$) of the color triangle with the x -axis. Linear scales of R/Y and B/Y can be made on any line parallel with the x -axis. The scales are easily calibrated since lines $R/Y = 1$ and $B/Y = 1$ for lines going through the illuminant white point. The intersection between the pivoting R/Y and B/Y lines determines the chromaticity. Errors in the $(R - Y)/Y$ and $(B - Y)/Y$ ratios cause errors in the slope of these pivoting lines and may require the display device to produce negative light if they intersect outside the color triangle. Chroma noise and incorrect chroma gain ("color" on TV sets) may cause such errors. Errors in the chrominance cause large chromaticity errors when Y is small, which it is in the blue-magenta-red areas, especially in dark areas.

Implications of Chromaticity Standards

Television standards specify the chromaticities that are expected to be used in the display devices at the receivers. Receiver manufacturers do not have to meet these standards, and in fact, in the United States, more efficient phosphors are used, which do not have the standard FCC chromaticities. The SMPTE has recommended other chromaticities to be used at the source which better match the more efficient phosphors now used in most receivers. Various chromaticity standards are shown in Table 21.1.2. SMPTE 170M is proposed as NTSC broadcast studio standards and ITU-R709 (equal to SMPTE 274M) and 240M for DTV standard. White illuminant D_{65} is becoming universal. Figure 21.1.6 shows that the "old" NTSC gamut of colors (triangle) is substantially larger in the green-cyan area than the gamuts of the newer chromaticities. However, the gamuts of the new phosphors cover almost the gamut of paints, pigments, and dyes, and there are few complaints about the green color. Future displays may provide larger gamuts and force a change in *de facto* standards.

The implications of chromaticity standards or of *de facto* standards are that in production of television programs it is expected that most displays in the receivers have luminous phosphors and a reference white illuminant with chromaticities close to the standards. Cameras usually have sensors with nonstandard chromaticities. The output signals from a camera can be matrixed to conform with a large gamut of chromaticity standards. A cameraman can adjust this matrix and process the output signals (linearly as well as nonlinearly) to produce an artistically desirable picture on the faceplate of displays with standard or *de facto* standard primaries. The chromaticities listed in television standards are not enforceable, but are taken as guidelines for designing receivers and displays.

Progress in Psychophysics of the Human Visual and Aural Systems

Current television standards are based on an understanding of psychophysics which dates back a number of decades. Although current standard analog television systems are clever, economical, and robust, it is clear that

they make inefficient use of channel capacity. In a 6-MHz transmission channel, over 90 percent of the energy of the visual information occupies a bandwidth of a few hundred kHz. With the advent of digital television, methods for effective *reduction of irrelevancy and redundancy* in communication of moving pictures and audio benefit from a new technology basis in digital compression.

PICTURE SIZE, SCANNING PROCESS, AND RESOLUTION LIMITS

Picture Size and Scanning Raster

In analog TV systems, the transmitted signal was designed to be directly related to the image representation of the camera and the display. The white rectangular area in Fig. 21.1.8 shows the *active area* of the picture, i.e., the area containing pictorial information. The active area is assumed to be flat. The height of the active area is the length unit ph (picture height) and the width A of the active area is the *aspect ratio*. In current standard television systems the aspect ratio is $4/3$ and in HDTV it is $16/9$. The viewing distance D is commonly assumed to be 6 to 8 ph in standard TV and 3 to 4 ph in HDTV.

Also shown in Fig. 21.1.8 is an imaginary *total picture area* that includes inactive areas representing durations used in the scanning process for synchronization and retrace blanking. These durations are referred to as the *vertical blanking interval VBI* and the *horizontal blanking interval HBI*. The *total vertical height* including the VBI is $1/\eta_v$ and the *total horizontal width* including the HBI is A/η_H where η_v and η_H are vertical and horizontal scanning efficiencies. They are shown in Table 21.1.4 for analog TV systems and their standard definition DTV equivalents.

In all television systems the total picture is scanned along horizontal *lines* from left to right while the scan lines progress downward from the top of the picture. The duration of a horizontal scan line including the duration of the HBI is $H = 1/F_H$, where F_H = line rate in Hz. The duration of a *field* including the VBI is $V = 1/F_v$, where F_v = field rate in Hz. In television standards a scanning system is specified as N/F_v where $\eta_v N = N_0$ = number of nonoverlapping lines displayed in the visible picture area (active lines). In *progressive scan* ("proscan" or "1:1 scan") displayed lines in successive fields are co-located (overlap) and consequently the total number of scan lines is $N = F_H/F_v = V/H$. In 2:1 *interlaced scan*, displayed lines in even numbered fields are interlaced with the lines in odd-numbered fields and consequently $N = 2F_H/F_v = 2V/H$. When referring to "interlaced scan" it is generally assumed to be 2:1 interlaced. Multiple interlace without storage causes visible

FIGURE 21.1.8 Active picture area and the total area that includes the horizontal and vertical blanking intervals. η_v and η_H are scanning efficiencies.

TABLE 21.1.4 Scanning Parameters and Scanning Efficiencies in Interlaced Analog TV Systems and Their Digital Equivalents

	Analog		Digital CCIR601	
	525/60	625/50	525/60	625/50
A	4/3	4/3	4/3	4/3

$N_o = N\eta_v$	483	575	480	576
$V_v = F_v/\eta_v$ ph/s	65.152	54.348	65.559	54.253
$V_H = F_H A/\eta_H$ ph/s	25,321	25,641	25,000	25,000
$V_T = F_v/N_o$ ph/s	0.1241	0.0870	0.1249	0.0868

line-crawl. In interlaced scan *one frame comprises an odd-numbered field followed by an even-numbered field*. The frame rate is $F_V/2$ Hz. In proscan a frame and a field is the same thing. Automatic interlace can be obtained if N = number of lines per frame is odd, as shown in Fig. 21.1.9. Interlaced scan can be achieved with an even number of lines per frame and proscan can be achieved with an odd number of half lines per field. The PAL/SECAM systems are 625/50(2:1) systems and the NTSC system is a 525/59.94(2:1) system or simply as a 525/60(2:1) system (although the field rate is exactly 60/1.001 Hz). Figure 21.1.9 shows the scanning raster for the interlaced 525/60 system. The scanning raster shown in Fig. 21.1.9 covers the total area including the blanking intervals. Interlaced scan has been used in all analog television systems to achieve good vertical resolution and little large area flicker, given available transmission bandwidth.

**FIGURE 21.1.9** Interlaced scanning raster covering the total picture (including blanking intervals) for a 525/60 system (NTSC). Retrace during horizontal blanking is not shown.

Table 21.1.4 shows scanning parameters for various raster formats including the number of visible scan lines $N_o = \eta_v N$, the *vertical scanning velocity* $v_v = F_v/\eta_v$ ph/s, and the *horizontal scanning velocity* $v_H = F_H A/\eta_H$ ph/s in interlaced scan (v_H must be doubled for proscan). Velocities of moving objects in the picture are conveniently expressed relative to the reference velocity $v_T = F_v/N_o$ ph/s (= one line-spacing per field). In digitized systems η_H = ratio of active samples per line to total samples per line.

The Video Signal Spectrum. The dynamic image on the target of a TV camera is a three-dimensional message: two spatial and one temporal. In the scanning process this message is converted into a one-dimensional signal. Consider first a stationary image having a property, e.g., a response to exposure, which can be specified as a function $g(x,y)$ defined over the total picture area shown in Fig. 21.1.8. This is a rectangular area of width $A/\eta_H = v_H/F_H$ and a height $1/\eta_v = v_v/F_v$. The scanning beam can be represented as progressing with time along a straight line $x = v_H t$ and $y = v_v t$ over the periodically repeated image as shown in Fig. 21.1.10. The figure shows an interlaced scan with five lines per frame. A two-dimensional Fourier series component of the periodically repeated function $g(x,y)$ is sampled by the scanning beam to yield a one-dimensional signal:

$$C_{mn} \cos 2\pi[(mF_H/v_H)x + (nF_v/v_v)y + c_{mn}] = C_{mn} \cos 2\pi[(mF_H + nF_v)t + c_{mn}] \quad (16)$$

where $n = 0, \pm 1, \pm 2$, when $m = 1, 2, 3, \dots$, and $n = 0, 1, 2, 3, \dots$, when $m = 0$. A Fourier component in the picture is a sinewave grating with a constant phase wavefront perpendicular to the spatial frequency vector $\mathbf{k}_{mn} = [(mF_H/v_H), (nF_v/v_v)] = \text{cycles per picture height (cph)}$. In the scanning process this grating generates a spectral component in the signal at the discrete frequency $mF_H + nF_v$ Hz. A grating that cannot be expressed with m and n as integers has “kinks” at the borders of the total pictures shown in Fig. 21.1.10 and consists of several gratings of the type shown in Eq. (16).

Figure 21.1.11 shows a part of the spectrum of an interlaced system with $N = 9$ lines. Spectral components for $n > 0$ interleave with components for $n < 0$. The figure shows that a frequency component can be generated in more than one way (*aliasing*) if $|nl| > N/2$. Thus, as expected, the highest vertical spatial frequency that can be conveyed without aliasing is $N_o/2$ cph. Aliasing shows in certain pictures: venetian blinds, striped shirts, resolution test-patterns. If the horizontal scan frequency is doubled to $2F_H$ (progressive scan with N lines per field), the spectral components shown as dotted lines in Fig. 21.1.11 disappear. The components are spaced F_v in proscan and $F_v/2$ in interlaced scan, but aliasing occurs in both systems if $|nl| > N/2$. Optical defocusing and vertical defocusing of the scanning beam reduces aliasing at the expense of sharpness.

As the picture changes with time the parameters C_{mn} and c_{mn} in Eq. (14) become functions of time. As a consequence the frequency components of the signal shown in Fig. 21.1.11 develop sidebands just as amplitude and phase modulated carriers. A sideband with a frequency $f = mF_H + nF_v + f_{mn}$ could have been generated by the sinewave grating defined by Eq. (16) with $C_{mn} = \text{constant}$ and $c_{mn} = f_{mn}t + \text{constant}$. This moving

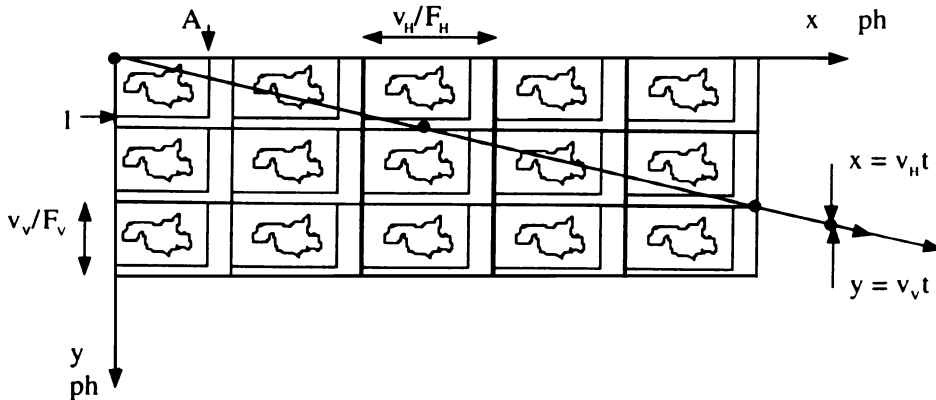

FIGURE 21.1.10 Interlaced scan of a stationary picture with $N = 5$ lines per frame.

FIGURE 21.1.11 Part of the frequency spectrum generated by interlaced scan of a stationary picture with $N = (4p + 1) = 9$ lines per frame. In proscan at line-rate $2F_H$, dotted line components disappear. Motion directions up, down, left, right are for sidebands associated with “carriers” at the endpoints of the $F_V/2$ intervals.

grating causes the amplitude at every active point x, y in the picture to oscillate with a frequency f_{mn} . The constant phase front of the grating moves in a direction opposite to \mathbf{k}_{mn} with a phase velocity

$$v_{mn} = f_{mn}/|\mathbf{k}_{mn}| = f_{mn} \lambda_{mn} \quad \text{ph/s} \quad \lambda_{mn} = \text{wavelength in ph} \quad (17)$$

A component at a frequency f in the video signal can, however, be generated by a number of moving sinewave gratings with different velocities and spatial frequencies, and it is up to the viewer to interpret and choose between $f = mF_H + nF_V + f_{mn}$ and $f = pF_H + qF_V + f_{pq}$. More often than not this ambiguity causes little confusion, because a moving object generates sidebands to a large number of carriers, including low-frequency carriers, with the consequence that the viewer will choose a good fit to his or her expectation of the motion. This psychophysical phenomenon is also taken advantage of in a 24 frame per second motion picture (aliasing: wagon wheels appearing as rotating the wrong way). In television, however, the confusion is accentuated by the scanning raster.

Figure 21.1.11 indicates perceived direction of motion (up, down, left, right) of a spectral component, under the assumption that the viewer interprets it as a sideband to either the nearest carrier to the left or the nearest carrier to the right. The motion designation (u, d, l, r) of these frequency intervals of width $F_V/2$ remain in proscan. Viewers tend to choose a carrier with the lowest spatial resolution, i.e., with the lowest value of $|\mathbf{l}_n|$. As the velocity of a grating increases and $|\mathbf{l}_n|$ goes through $F_V/2$ the grating may appear to reverse direction of motion. This may cause visible aliasing effects, e.g., when busy pictures are panned. However, confusion is not likely if $|\mathbf{k}_{mn}| < (dF_V/2)/|v_{mn}|$ ph/s, where $d = 1$ in proscan and $d = 1 - 2|\mathbf{l}_n|/(N - 1)$ in interlaced scan. Thus, for a given velocity, the highest nonaliasing spatial frequency depends only on d times the frame rate, which is the same for HDTV and standard TV. For example, for $d = 1$ and $v = 1$ ph/s, the maximum nonaliasing spatial frequency is 30 cph in N/60 systems and 25 cph in N/50 systems. Motion is handled better in progressive scan ($d = 1$) than in interlaced scan ($d < 1$). If C_{mn} varies with time but c_{mn} is constant there is level variation but no motion.

Resolution

Resolution is expressed in terms of the highest spatial frequencies k_{\max} in cycles per (picture) height (cph), which can be conveyed by the television system and displayed given a scanning process and a transmission bandwidth. Sometimes resolution is still expressed in the old unit “TV lines,” which should mean $2k_{\max}$ cph. Sometimes

horizontal resolution is expressed in cycles or in TV lines per picture width, which is misleading. Sometimes it means number of “perceived” lines of a square wave test signal. Specification of resolution in terms of TV lines and measurements of resolution with square waves should be avoided. Square waves may have lost some harmonics.

In the vertical direction, stationary information is sampled at N_0 active lines per picture height. The corresponding Nyquist bandwidth $N_0/2$ cph is theoretically the maximum *vertical resolution* for stationary pictures. The vertical resolution in the NTSC system is $k_v = N_0/2 = 241.5$ cph. The “perceived” vertical resolution of stationary pictures is less than $N_0/2$ because of many factors: aliasing, source processing, scanning spot sizes, contrast, brightness, ambient conditions, test signals, viewing distance, line flicker, luminance-chrominance cross talk, and confusion caused by the display of the scanning raster (display of high spatial frequency repeat spectra). The combination of all these factors on perceived vertical resolution is sometimes expressed in terms of some perceived vertical resolution $KN_0/2$, where $K = \text{Kell factor} < 1$. The Kell factor, which has been quoted to range from 0.7 to 1. must be used with many qualifications and a great deal of caution. It is not a basic system parameter. It should preferably be avoided. In interlaced scan *line flicker* can be very disturbing in busy slow-moving pictures. In some receivers line flicker is eliminated by converting interlaced scan into progressive scan (“line doubling”) by motion-adaptive interpolation.

The *horizontal resolution* of stationary pictures is $k_H = B/v_H$ cph, where B is the highest frequency in Hz of the information, which can theoretically be conveyed and which modulates “the scanning beam.” For example, in the NTSC system the highest frequency of the luminance signal is $B = 4,200,000$ Hz. Consequently the horizontal resolution of luminance in NTSC is $k_H = 4,200,000/25,321 = 166$ cph. The “perceived” horizontal resolution is less than k_H depending on many factors: video filter transfer functions, luminance-chrominance cross talk, type of test signal, contrast, and so forth. The horizontal resolution of the NTSC chrominance signals are $k_I = 52$ and $K_Q = 24$ cph, which are much less than the vertical chrominance resolution (241.5 cph).

When the NTSC system was developed it was observed that horizontal and vertical *chrominance resolution* can be reduced to about half the luminance resolution without significantly reducing perceived quality. This observation was crucial for the success of NTSC.

Table 21.1.5 shows the theoretical maximum bandwidth and resolution of luminance and chrominance in various systems. In the analog TV systems chrominance resolution is significantly reduced in the horizontal

TABLE 21.1.5 Potential Resolutions in cph in the Interlaced Systems Listed in Table 21.1.2 and the HDTV Common Usage Format (The Digital CCIR System is a 4:2:2 System with a Luminance Sample Rate 13.5 MHz and Chrominance Sample Rate 6.75 MHz. In the 1125/60 System, Luminance is Sampled at 74.25 MHz and in the 1250/50 System Luminance is Sampled at 72 MHz Nyquist Maximum Frequencies and Resolutions Are Shown for all Sampled Systems)

(1) Applies to $I = (R - Y)\cos 33^\circ - (B - Y)\sin 33^\circ$ (2) Applies to $Q = (R - Y)\sin 30^\circ + (B - Y)\cos 33^\circ$ (3) 5.5 MHz in PAL/I and 6 MHz in SECAM. The corresponding max resolutions of Y are 214.5 and 234 cph, respectively. *144 in SECAM. (4) *Standard CCIR601* luminance and chrominance bandwidths are 5.75 and 2.75 MHz respectively and $A = 4/3$. Corresponding resolutions are 230 and 115 cph. (5) In the HDTV systems the resolution of R – Y and B – Y is half the luminance resolution horizontally as well as vertically. (6) Progressive scan.

direction, but it is not reduced in the vertical direction. In digital TV with rectangular pixels the maximum resolution is the Nyquist bandwidth in cph determined by the horizontal and vertical distances between neighboring samples. The meaning of 4:2:2 is that for every four samples of the luminance signal Y along a horizontal line there are two samples of $B - Y$ and $R - Y$. In 4:2:2 systems the chrominance resolution is half the luminance resolution in the horizontal direction. In 4:2:0 systems the chrominance resolution is half the luminance resolution both horizontally and vertically. Tables 21.1.4 and 21.1.5 show a 4:2:2 version of CCIR601, while HDTV systems are 4:2:0 versions. The resolutions shown in Table 21.1.5 can be related to the luminance resolution of the HVS, which is at most 250 cph and 500 cph at viewing distances of 8 and 4 ph, respectively. It should be emphasized that the resolutions shown in Table 21.1.5 are theoretical maxima. The resolutions of the pictures displayed by a receiver depend on many factors and are usually much lower than the maximum resolutions shown in Table 21.1.5. One reason is that the signals conveyed by the system are not proportional to the tristimuli Y , $R - Y$, $B - Y$. In all systems the tristimuli are nonlinearly compressed before matrixed and bandlimited to form video signals Y' , $B' - Y'$, and $R' - Y'$. Whatever the resulting resolutions are in cph, the displayed resolution in cycles per visible height is usually lower owing to the overscan needed to allow for deflection tolerances.

In summary, the critical resolutions in cph, given the number of visible scan lines N_o , a maximum horizontal frequency B Hz, a grating phase velocity v , and a viewing distance D ph are:

$$k_{\max}(\text{hor.}) = B/v_H, \quad k_{\max}(\text{vert.}) = N_o/2, \quad k_{\max}(\text{move}) = dF_v/2v, \quad k_{\max}(\text{HVS}) \cong 2000/D \quad (18)$$

where $d = 1$ in proscan and $1 - 2lk_v/N_z$ in interlaced scan ($k_v =$ vertical spatial frequency of grating in cph).

Table 21.1.5 summarizes the static resolutions of the interlaced systems listed in Table 21.1.4 and the ATSC (Grand Alliance) HDTV system formats. The IQ chrominance axes in NTSC were chosen because the HVS can better resolve chrominance detail in the I direction (approximately red-cyan) than in the Q direction (approximately blue-yellow).

Standard Frequencies in Color Television Systems

Figure 21.1.12 shows that the key frequencies used in worldwide color television systems are related to a common frequency = 2.25 MHz. Multiples of this frequency are used as international standards for sample rates in HDTV and in the digital CCIR601 standard used in production and in the professional tape recording in the D1 format. The horizontal line rate in NTSC is $F_H = 2.25/143$ MHz and in PAL and SECAM it is $F_H = 2.25/144$ MHz. The field rate in NTSC is 60/1.001 Hz and in PAL and SECAM it is 50 Hz. ATSC Grand Alliance HDTV formats when operating with 60 Hz field rates have frequencies related to 2.25 MHz, but when operating with 60/1.001 they are related 2.25/1.001 MHz.

In the NTSC, PAL, and SECAM systems, which are *compatible* with black and white reception, most of the chrominance information $R - Y$ and $B - Y$ is conveyed by modulating one or two subcarriers to form a *chrominance subchannel*, which is added to (multiplexed with) the signal that carries most of the luminance information Y . The resulting signal is a *composite video signal*. In the FCC rules the NTSC color subcarrier frequency is specified to be $f_c = 315/88$ MHz = $227.5 F_H = 3.58 \dots$ MHz. In PAL the color subcarrier is specified to be $f_c = 283.75 F_H + F_v/2 = 4,433,618.75$ MHz. SECAM operates with two frequency modulated subcarriers: $f_{ob} = 4.25$ MHz and $f_{or} = 4.40625$ MHz. The subcarriers are chosen to provide acceptable compatibility with black and white reception and to minimize visible cross talk between luminance and chrominance in color reception.

The peculiar frequencies in NTSC resulted from a slight modification of the monochrome standards (60 Hz and 15.75 kHz) for the purpose of reducing the visibility of a beat between the color subcarrier and the 4.5 MHz sound carrier. F_H was chosen to be $4.5/286$ MHz to make the beat fall at an odd multiple of $F_H/2$ ($(286 - 227.5)F_H = 920$ kHz). This is how the 2.25 MHz frequency came about. In digital processing of NTSC and PAL signals, including professional recording in the D2 format as well as in signal processing in consumer products, $4f_c$ is often used as the sample rate. This sample rate exceeds the Nyquist rate somewhat in most applications, but it is readily available and phase-locked to F_H and F_v . It is particularly well suited for sampling composite video signals because it performs the function of a synchronous detector separating the in-phase and quadrature chrominance component which modulate the color subcarrier.

Some frequencies used or proposed for use in television are not well related to the frequencies shown in Fig. 21.1.12. One is 24 frames per second used in motion pictures. In NTSC broadcasting the movie frame rate

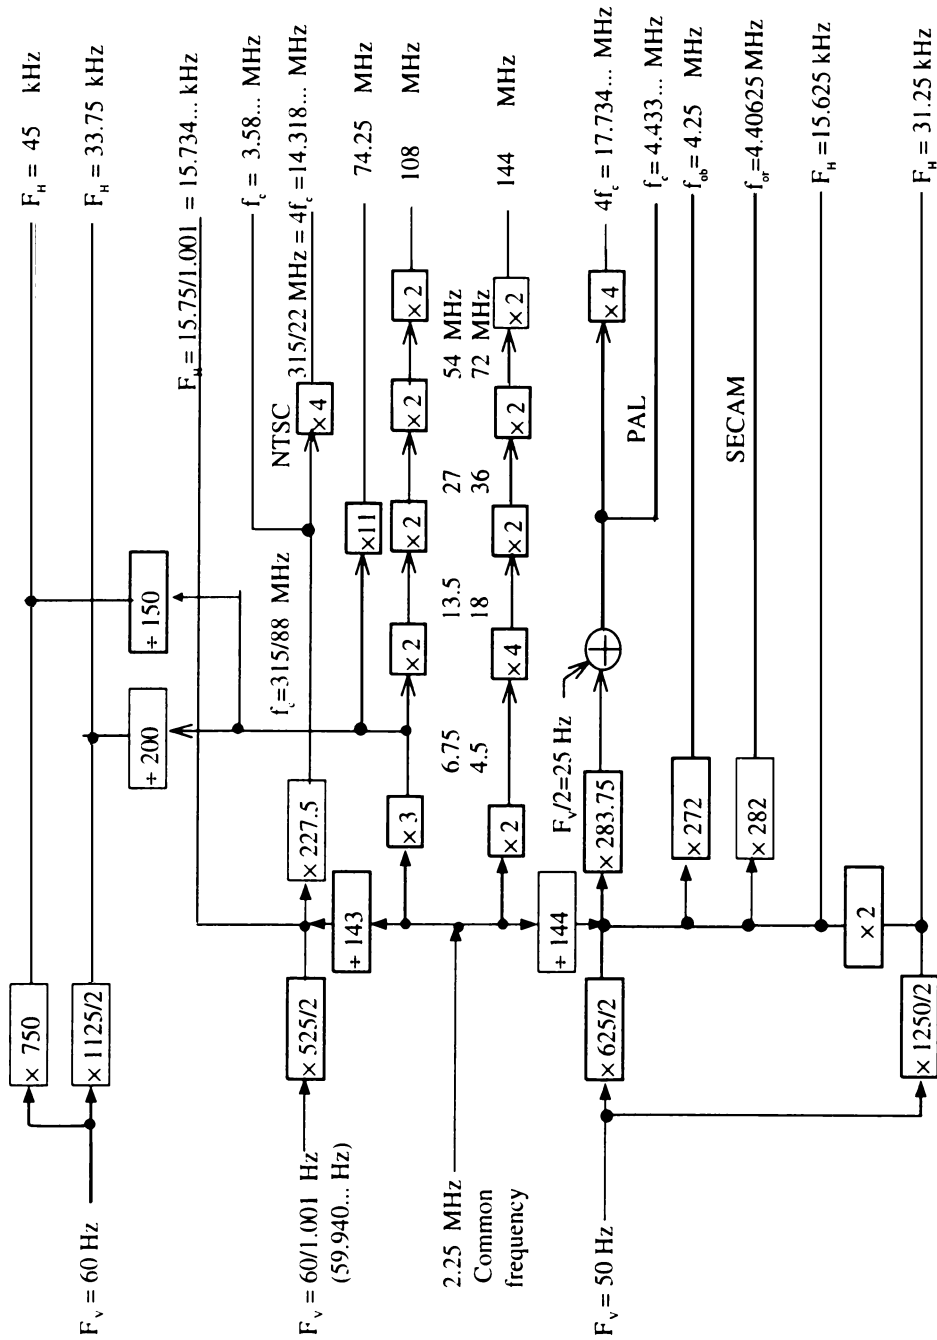

FIGURE 21.1.12 Relations between frequencies in standard analog and digital television systems.

is first reduced to 24/1.001 Hz. This is followed by a so-called 3-2 pull-down used to fit four movie frames to 10 NTSC fields, alternating three fields and two fields per movie frame. In Europe it has been common to speed up the movie by a ratio 25/24, but this increases the pitch of the sound unless digital pitch-preserving nonlinear time base techniques are used to accomplish the audio speedup. With digital techniques, better frame conversions can now be made. Other frequencies that are not well related to 2.25 MHz are: digital audio sample rates 48 and 44.1 kHz (8/375 and 49/2500 times 2.25 MHz).

ANALOG VIDEO SIGNALS

Gamma Pre-Correction

Three signals R , G , and B emerge from the camera amplifiers and associated signal processing circuits (aperture correction, peaking, correction for camera nonlinearity, and so forth). These signals are assumed to be proportional to the tristimulus values R , G , B defined by standard or *de facto* standard chromaticities and the illuminant of receiver display devices (see Photometry, Colorimetry, and the Human Visual System in this chapter). These signals and the tristimuli are all normalized so that

$$R = R \quad G = G \quad B = B \quad \text{and} \quad R = G = B = 1 \quad \text{for reference white highlight} \quad (19)$$

In television standards the signals R , G , B are usually denoted E_r , E_g , E_b to distinguish them from tristimulus values. Simplified notations are used in what follows: italics for signals and romans for optical tristimulus values.

True luminance and chrominance signals are:

$$Y = Y_r R + Y_g G + Y_b B \quad M = R - Y \quad N = B - Y \quad (20)$$

$$R = G = B = Y \quad \text{for white with luminance } Y = Y \quad (21)$$

The signals M , Y , N are related to the signals R , G , B by the matrix H [Eq. (5) and Table 21.1.3]. It is noted that only the luminance values Y_r , Y_g , Y_b appear in this matrix. Tristimuli components X and Z as well as chromaticities, while implicit in the significance of M , Y , and N in electro-optical conversion in the display are of no concern in video signal analysis.

The original intent of the NTSC was to convey the “true” signals M , Y , N over separate channels. This was referred to as the *constant luminance principle*, because all the luminance would be conveyed by the luminance signal. Reasons for this approach are:

- compatibility with black and white receivers
- luminance information requires more picture detail than chrominance
- noise is more visible in luminance than in chrominance. To minimize the visibility of noise added in transmission, the luminance signal was companded in black and white television using the nonlinear transfer characteristic of the picture tube as expander in the receivers. The idea of using the picture tube as an expander has also been adopted in color television

To display a red color with a tristimulus value R , a nonlinear display must be driven by a “gamma corrected” signal R' which is a function of R . It is assumed that green and blue have the same electro-optical transfer functions and must be driven by “gamma corrected” signals

$$R' = F(R) \quad G' = F(G) \quad B' = F(B) \quad \text{where} \quad F(0) = 0 \quad \text{and} \quad F(1) = 1 \quad (22)$$

assuming display systems with inverse electro-optical transfer functions

$$R = F^{-1}(R') \quad G = F^{-1}(G') \quad B = F^{-1}(B') \quad \text{where} \quad F^{-1}(0) = 0 \quad \text{and} \quad F^{-1}(1) = 1 \quad (23)$$

In NTSC and PAL/SECAM standards, these functions are as in black and white television:

$$R' = R^{1/\gamma}, \quad G' = G^{1/\gamma} \quad \text{and} \quad B' = B^{1/\gamma} \quad (24)$$

21.24 VIDEO AND FACSIMILE SYSTEMS

In NTSC, $\gamma = 2.2$ ("but not enforced"). In PAL and SECAM, the recommendation is $\gamma = 2.8$. Recent standards are listed as electro-optical transfer characteristics in Table 21.1.1.

The nonlinear transfer characteristics of picture tubes usually differ from the production standards $L = F^{-1}(V)$ listed in Table 21.1.1. It is often assumed that they are close to $L = V^{2.5}$.

The Luminance Signal

In all current analog and digital standard television systems the gamma-corrected primary signals R' , G' , B' are matrixed in a matrix T to form signals for transmission which are proportional to:

$$Y' = T_R R' + T_G G' + T_B B' \quad M' = R' - Y' \quad N' = B' - Y' \quad (25a)$$

$T_R + T_G + T_B = 1$. When the color is gray $R' = G' = B' = Y'$ and $M' = N' = 0$. Conversely

$$G' = Y' - (T_R/T_G)M' - (T_B/T_G)N' \quad R' = Y' + M' \quad B' = Y' + N' \quad (25b)$$

Y' is called the *luminance signal*, while signals proportional to M' and N' are called *chrominance signals*. In standard definition television (SDTV), including NTSC, PAL, SECAM, CCIR601, and SMPTE170M, the transmission coefficients T_R, T_G, T_B , are equal to the luminance components Y_r, Y_g, Y_b of the NTSC primaries (Table 21.1.2), i.e.,

$$Y' = 0.299R' + 0.587G' + 0.114B' \quad (25c)$$

The coefficient should *not* be rounded to two decimals as they unfortunately are in the official FCC standards. In HDTV, the transmission coefficients are equal to the luminance components of the primaries associated with the system (Table 21.1.2), i.e.,

$$Y' = 0.2125R' + 0.7154G' + 0.0721B' \dots \text{SMPTE274M and ITU-4 709} \quad (25d)$$

$$Y' = 0.212R' + 0.701G' + 0.087B' \dots \text{SMPTE240M} \quad (26e)$$

While the signal Y' is traditionally referred to as the luminance signal or just "the luminance" it is not a function of true luminance Y only. This happens only when the color is gray. For all other colors, part of the true luminance information is conveyed by the chrominance signals. When the chrominance (color) in a color receiver is turned off, the displayed luminance in the resulting black-and-white picture is less than in the color picture in all but originally gray areas. The ratio of the displayed luminance when the chrominance signals are turned off (compatible monochrome TV) to the displayed luminance when they are turned on can be taken as a viewer's perception of how much true luminance is conveyed by luminance signal Y' . This ratio is $G(Y')/Y$, where $G(V)$ is the transfer characteristic of the display. The ratio can be calculated given $G(V)$, Eqs. (20) and (25), and parameters for various systems given in Table 21.1.2. The ratio becomes smaller with increased saturation of the colors, and becomes exceptionally small for saturated blue. For a display with $G(V) = V^{2.5}$ the ratio for saturated blue is 3.8 percent in NTSC, 6.2 percent in PAL/SECAM, and 2 percent in ITU-R709. For $G(V) = F^{-1}(V)$ according to Table 21.1.1, corresponding numbers are 7.4, 3.2, and 22.2 percent. While saturated blue is an extreme case and the ratios are sensitive to the transfer function of the display at low signal levels, it is clear that a significant amount of luminance information is conveyed by the chrominance channels. Since the chrominance channels have less bandwidth, and in HDTV also less vertical resolution than the luminance channel, luminance resolution is lost, particularly in saturated colors. Another consequence is that noise (including various coding and transmission errors and defects) in the chrominance channels is displayed as luminance noise. The HVS is more sensitive to luminance noise than to chrominance noise. These effects are consequences of the violation of the constant luminance principle caused by pre-gamma correction of the R, G, B primaries.

The Chrominance Signals

The chrominance signals, also referred to as the *color difference signals*, are proportional to $M' = R' - Y'$ and $N' = B' - Y'$ and defined in Eq. 25a, b, c, d, and e. The N' blue-yellow range $\pm(1 - T_B)$ is larger than the M'

TABLE 21.1.6 Chrominance Scale (gain) Factors K_R and K_B Multiplying the Basic Chrominance Signals $M' = R' - Y'$ and $N' = B' - Y'$ to Yield Transmitted Chrominance Signals

SYSTEM	$K_R(R' - Y')$	$K_B(B' - Y')$	K_R	K_B

ITU-R709, SMPTE274M	P'_R	P'_B	0.6349 (.5/.7875)	0.5389 (.5/.9279)
SMPTE240M	E'_{PR}	E'_{PB}	0.6345 (.5/.788)	0.5476 (.5/.913)

*Normalized frequency deviations for FM modulation.

†Includes all SDTV systems when luminance and chrominance components are digitized. See MPEG standards Rec. ITU-T H262.

red-cyan range $\pm(1 - T_R)$. In transmission, the chrominance signals $M' = R' - Y'$ and $N' = B' - Y'$ are multiplied by scale (gain) factors K_R and K_B . Scale factors of digitized chrominance signals are $K_R = (1 - T_R)/2$ and $K_B = (1 - T_B)/2$ to yield scaled chrominance signal ranges of ± 0.5 , equal the unity range of the luminance signal Y' . Standard chrominance scale factors are shown in Table 21.1.6.

In NTSC and PAL the chrominance signals can also be represented by a vector

$$C = [U, V] = [0.493(B' - Y'), 0.877(R' - Y')] = [C \cos(c), C \sin(c)] \tag{26}$$

$$C = (U^2 + V^2)^{1/2} \text{ amplitude} \quad \text{and} \quad c^\circ = \arctan(V/U) = \text{phase in degrees}$$

The chrominance vector C is shown in Fig. 21.1.15. The vertical V -axis is in a “reddish” direction and the horizontal U -axis, in a “bluish” direction, is the reference direction of zero phase. The chrominance vector is displayed in an instrument called a *vector scope* as illustrated at the bottom of Fig. 21.1.16. Table 21.1.7 shows Y', M', N', V, U, C , and c° for white and for the saturated colors yellow, cyan, green, magenta, red, and blue. These are the colors shown in the ubiquitous color bars. While the color bar signals are the same in NTSC, PAL, and SECAM standards, the colors vary from system to system as well as within each system depending on the chromaticities of the display and adjustments of primary levels (gains).

In PAL the chrominance signals $V = .877(R' - Y')$ and $U = .493(B' - Y')$ are both bandlimited to 1.3 MHz. Because of lack of available transmission bandwidth in NTSC the V and U signals are further matrixed in a rotational network (33°) yielding the transmitted signals $I = .839V - .545U$ and $Q = .545V + .839U$. The I and Q axes are shown in Figs. 21.1.15 and 21.1.16. The NTSC standards specify the maximum I -frequency to be 1.3 MHz and the maximum Q -frequency to be 0.6 MHz. The reason for this choice is that the HVS has better resolution for colors along the I -axis (red-cyan) than for colors along the Q -axis (blue-yellow). More often than not I and Q both roll off toward a max. frequency < 0.6 MHz.

Video Component Signals

While the primary signals R, G, B and the precorrected signals R', G', B' are video component signals, what is usually meant by *video component signals* is the set consisting of the luminance signal Y' and the chrominance signals $K_r(R' - Y')$ and $K_b(B' - Y')$. Figure 21.1.13 illustrates an NTSC transmission system of *video component*

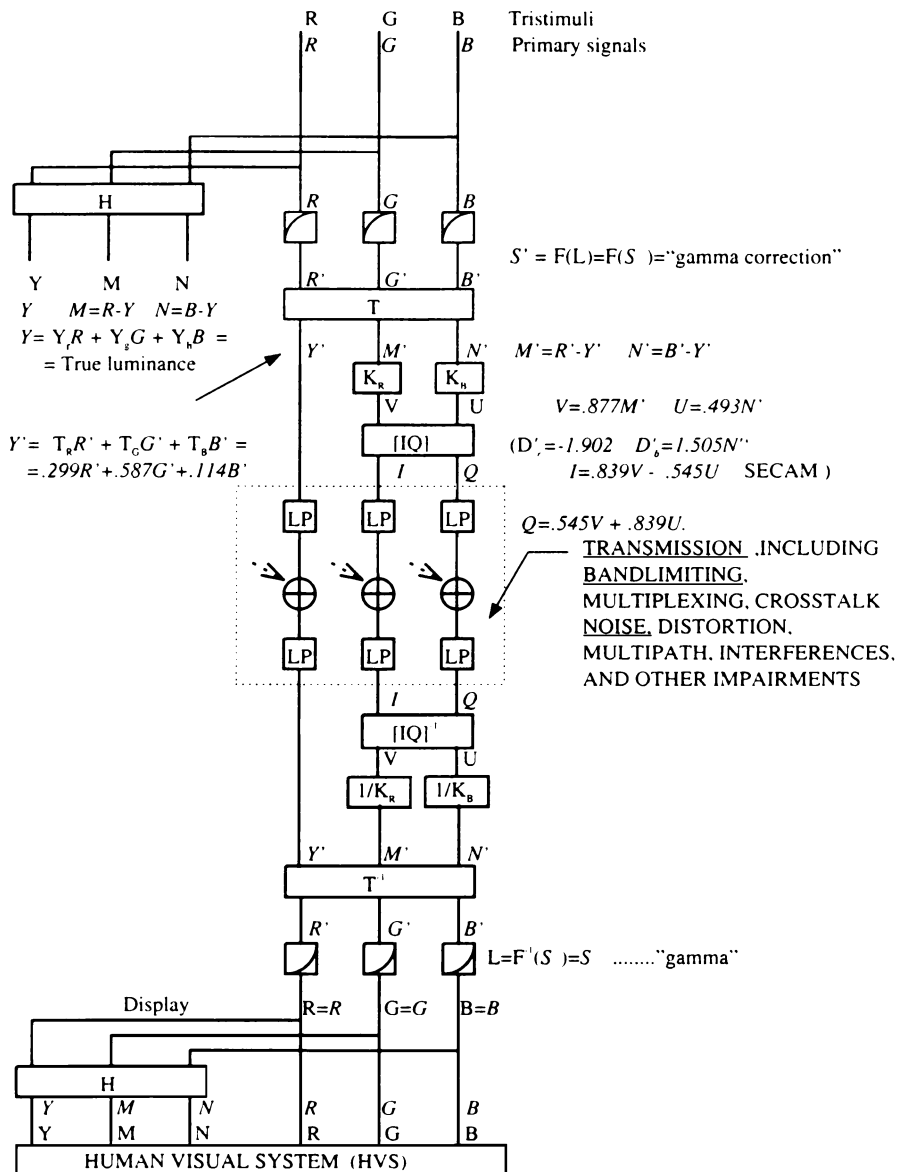

FIGURE 21.1.13 NTSC video transmission system. In PAL and SECAM drop the IQ matrices. In SECAM replace V by D'_r and U by D'_g . In digital systems, K_r and K_b are different. In HDTV the T matrices are different but, as in NTSC, the H and T matrices are identical.

signals. By dropping the IQ and IQ⁻¹ matrices and ignoring numerical illustrations of K_R, K_B, T_R, T_G, and T_B it is valid for all television systems. All SDTV systems use the same T-matrix (NTSC). The T and H matrices are identical in NTSC as well as in HDTV systems. The H matrices, which are not in the transmission path, only show conversion from R, G, B to true luminance and chrominance Y, M, N. The block with dotted borders shown in Figure 21.1.13 represents bandlimiting and impairments of the component signals in transmission. In digital television the block includes data compression. A/D and D/A conversions, contributing with quantization and compression errors, are usually also inside this block. If this block is bypassed, the transmission is perfect if the processes at the transmitter have corresponding inverse processes at the receivers. Many proposals have been made to “correct” for luminance lost in the narrowband chrominance channels. Since the early 1950s there have also been proposals to replace Y' [see Eq. (25)] with the compressed luminance signal F(Y) [see Eqs. (20) and (22)], thereby conveying all the luminance in the luminance channel. No such *constant luminance* standards have been adopted, partly because it would not be compatible with current receivers and production standards, and partly because of added receiver costs for nonlinear expansion.

The NTSC Composite Video Signal, the HBI, and the Color Bar Signal

In NTSC, PAL, and SECAM the video component signals are multiplexed to form a single signal. In NTSC and PAL the chrominance signals modulate a *color subcarrier* which is “inconspicuously” added to the luminance signal to form a *composite video signal*. SECAM uses two frequency modulated subcarriers. In NTSC there is only one *color subcarrier* at a frequency $f_c = 227.5 \times F_H = 315/88 \text{ MHz} \cong 3.58 \text{ MHz}$. It is amplitude modulated in-phase and in quadrature by the chrominance signals (QAM) and added to the luminance signal to form the *composite NTSC signal*:

$$\begin{aligned}
 S &= Y' + U\sin(\omega_c t) + V\cos(\omega_c t) = Y' + Q\sin(\omega_c t + 33^\circ) + I\cos(\omega_c t + 33^\circ) = Y' + C\sin(\omega_c t + c^\circ) \\
 V &= .877(R' - Y') \quad U = .493(B' - Y') \quad I = .839V - .545U \quad Q = .545V + .839U \\
 C &= (U^2 + V^2)^{1/2} = (Q^2 + I^2)^{1/2} \quad C^\circ = \arctan(V/U) = 33^\circ + \arctan(I/Q)
 \end{aligned} \tag{27}$$

The vector diagram in Fig. 21.1.15 illustrates the instantaneous level of the color subcarrier, given the chroma vector [U,V]. A reference phase ($c = 180^\circ$, “yellow”) for synchronous detection is transmitted during the horizontal blanking interval by a short *burst* (8 to 11 cycles) of the color subcarrier (see Figs. 21.1.14, 21.1.16, and 21.1.17). The subcarrier components are [0, V] when $\omega_c t = 0$, [U, 0] when $\omega_c t = 90^\circ$; and (-0.4, 0) for the burst at $\omega_c t = 270^\circ$. As time progresses the instantaneous NTSC color subcarrier amplitude progresses in the order V, U, -V, -U or I, Q, -I, -Q, as illustrated in Fig. 21.1.15.
